More recently, interest has been shown in using gas centrifuges for other kinds of separations like stable isotopes or the isotopes of spent reactor uranium. For the stable isotopes, demand is growing in medicine and fundamental physics research, and the use of the gas centrifuge process makes it possible to produce isotopes economically when large (kilograms) quantities are needed. This is the case for the isotopes of xenon, krypton, tungsten, molybdenum, iron, tin, tellurium, sulfur, silicon, germanium, chromium and many others. The separation of stable isotopes by gas centrifuge has been underway for more than three decades in Russia. Currently, cascades of thousands of centrifuges are producing tens of kilograms of various isotopes. In another application, some countries have considered gas centrifuge technology as part of the reprocessing cycle of the re-enrichment of the spent uranium from power reactors which contains five isotopes: U^{232} , U^{234} , U^{235} , U^{236} and U^{238} .

A centrifuge designed for binary separations with uranium hexafluoride cannot be efficiently used for nonuranium isotope separation with different chemical compounds. Therefore, centrifuges with specific characteristics must be designed for particular separation problems. For some isotopes, specially synthesized gaseous chemical compounds must be prepared for use as the process gas. The basic condition for the applicability of the process gas in these newly designed centrifuges is that the gas vapour pressure is not less than 5–10 mmHg under normal operating temperatures. In addition to the condition that this substance should not corrode the structural material of the centrifuge, it has to be sufficiently resistant to temperature dissociation, and preferably must possess the maximum possible content of the desired element in the molecule. The list of such substances includes fluorides and oxyfluorides of metals and nonmetals, metal-organic and complex compounds, phosphorus hydrides, boron hydrides, Freons and some others. Significant differences in the chemical and physical properties of process gases leads to the necessity to create a set of gas centrifuge designs for various ranges of molecular masses. The internal circulating flow must be optimized for each of these designs.

The synthesis of volatile compounds suitable for process gases was not the only scientific problem the researchers faced when separating nonuranium isotopes. In contrast to natural uranium, most chemical elements are polyisotopic. This property leads to additional difficulties in enriching the intermediate components of the isotope mixture.

As perhaps the greatest achievement in the development of centrifuge technology for enrichment of nonuranium isotopes, one may consider the complex isotope separation for iron, carbon and oxygen as a pentacarbonyl of iron – $Fe(CO)_5$. This separation has been realized on an industrial scale at the electrochemical plant in the Krasnoyarsk region of Russia. All chemical elements included in the molecule structure are polyisotopic: iron contains four, carbon two, and oxygen three isotopes. A natural isotope abundance of $Fe(CO)_5$ represents a mixture of 284 types of molecules with different isotope distributions. These types are distributed through 20 components with molecular masses from 194 up to 213. Almost every one of them contains several isotopes for each of the chemical elements. This isotopic overlapping of iron isotopes with intermediate masses and heavy isotopes of carbon and oxygen limits the direct enrichment by a centrifuge cascade. However, this limitation has been removed by introducing into the separation process the isotope exchange between the molecules of pentacarbonyl of iron in so-called photoreactors. The combination of isotope separation in gas centrifuges with isotope exchange has allowed the achievement in a single process of a complex mix of highly enriched isotopes: ^{57}Fe with concentration more than 99%, ^{13}C and ^{18}O with concentrations up to 80%.

Advantages

The accumulated experience in separating isotopes of both light (boron, carbon, nitrogen and oxygen) and heavier chemical elements has shown gas centrifuge technology to be extremely promising. At the moment, isotopes of more than 20 chemical elements have been separated by gas centrifuges. The centrifuge cascade used for the separation of nonuranium isotopes usually has very low energy consumption and tens of times higher productivity than that of the electromagnetic installation and with a comparable output (Figure 3). Nonuranium isotope separation has been transformed into an independent area for development of gas centrifuge technology. It includes solving problems in the design of different types of centrifuges, in the theory of multicomponent isotope mixture separation, in chemical synthesis of process gases, in transformation of process gases with enriched isotopes required for use in chemical compounds, etc.

In many applications of isotope enrichment, rigid requirements on the isotope purity must be met, and undesired gas impurities must be reduced to a specified level. Gas centrifugation has also been recommended as an excellent practical tool to clean small

Figure 3 Illustration to compare the separation of nonuranium isotopes by electromagnetic separation (1) and by gas centrifuge (2). Production, G (g day^{-1} : feed flow into the installation), versus molecular mass, M , of the separating chemical element. Reproduced with permission from Goldstein *et al.* (1993).

gas impurities. An extremely important benefit of gas centrifuges is the opening of an era of economical large scale production of many stable isotopes that have applications in medicine, industry and fundamental science. For example, experiments on neutrino physics with large detectors that require tens of kg of enriched isotope have been made possible by the cost reductions achieved through the large scale production by gas centrifugation.

Future

The gas centrifuge is now a mature technology, but nevertheless the development potential has not been

exhausted. The separation efficiency of existing gas centrifuges for separation of uranium and nonuranium isotopes can be further improved. Additionally, the technology can be applied in the near future to the re-enrichment of uranium from spent nuclear fuel as well as to enriching tails (depleted uranium of separating plants) to the natural isotopic concentration or higher. In yet another area, experiments have been performed which show promising results for the application of gas centrifuge technology to purification of process gas from aerosol particles that can be used, for example, in the semiconductor industry.

Introduction

The application of isotopes in science and especially in analytical chemistry is based on two rather contradictory assumptions. Tracer experiments require that

the isotopically modified and unmodified compounds behave in a very similar manner. A study of isotope effects must recognize, measure and interpret minute differences in the chemical and physical properties of compounds (isotopomers) that differ in their isotopic composition. These differences lead to different behaviour of isotopomers in all chromatographic processes, as has been demonstrated experimentally.

As early as 1938, Urey and coworkers published a paper on enrichment of ^6Li by ion exchange

chromatography and work in this field has been continuing to date. Gas–solid chromatography has been used for separation of the hydrogen isotopes, noble gases and some other gaseous elements and simple compounds. Low-molecular-mass volatile compounds labelled mainly with hydrogen isotopes have been separated by gas-liquid chromatography. During the late 1950s and the 1960s, papers were published concerning small but observable isotopic fractionation with liquid chromatography of isotopically labelled organic compounds. Over the last 20 years during which liquid chromatography (LC) has become a common analytical technique, many papers have been published dealing with separation of labelled compounds from their unlabelled counterparts. A review of these works, with a possible explanation of the mechanisms of the separation process, is presented.

Isotope Effects

Chromatography can be considered as a process in which the compounds to be separated interact with a stationary and a mobile phase. These mutual interactions differ in magnitude even for different isotopes of the same element. The magnitude of the interaction energy for an isotopic pair depends on many parameters that are discussed below.

It is possible to draw the following general conclusions from the experimental data on isotope effects on the physical properties of molecules.

1. The C–²H bond is shorter than the C–¹H bond (e.g. in ethane the C–H bond length is 111.2 pm; in hexadeuteroethane the C–²H bond length is 110.7 pm) and exhibits a higher electron density than the ¹H bond. The deuterium atom appears to be smaller than the hydrogen atom. There are small, but measurable differences in the dipole moments, e.g. $\mu(\text{CH}_3\text{--}^2\text{H}) = 3.7 \times 10^{-32}$ C m, $\mu(^1\text{HCl})\text{--}\mu(^2\text{HCl}) = 1.7 \times 10^{-32}$ C m.
2. The C–²H bond has a polarizability lower than that of the C–¹H bond.
3. The C–²H stretching vibrational frequency (around 2200 cm⁻¹) is lower than the corresponding C–¹H frequency (around 3000 cm⁻¹).
4. Heavier isotopes have smaller atomic volumes; deuterated compounds have smaller molar volumes than the corresponding unlabelled compounds. The molar volume differences between, e.g. deuterated and unlabelled benzene are due to a molecular size effect caused by differences in the zero-point intermolecular motion of the molecules.
5. Deuterium (²H) is more electropositive than protium (¹H) and thus some isotope effects can

Table 1 Isotope effect on dissociation constants^a

(C ² H ₃) ₃ ⁺ NH	0.207

^aWilli (1983), pp. 58–61.

^bOnly the isotope-modified compound is specified in the table.

be discussed in terms of inductive effects. This has been clearly demonstrated in the measurement of the secondary isotope effect on ionization equilibria of some deuterated carboxylic acids and protonated amines, as shown in **Table 1**.

6. Deuterated compounds are less lipophilic than the corresponding unlabelled compounds

All these experimentally demonstrated phenomena may influence chromatographic separation processes. Isotope effects on the chromatographic behaviour of compounds labelled with isotopes of heavier elements (carbon, nitrogen, oxygen, etc.) are so small that they can only be detected for simple compounds of low relative molecular mass. The following discussion is limited to deuterated and tritiated compounds and only a few examples are given of separations of heavier isotopes.

It should be pointed out that discussion of isotope effects in terms of inductive or other electronic effects is sometimes helpful but represents a gross simplification. A more exact description of the origin of the isotope effects uses the zero-point energy and the vibrational frequencies of the molecules in question.

Separation Processes

Two basic types of separation process can be distinguished. In systems with a polar stationary phase and nonpolar mobile phase (classical adsorption chromatography, normal-phase LC and chemically bonded polar stationary phase LC) the ‘ordinary’ (unlabelled) compounds are usually eluted first, i.e. the separation factor is less than unity ($\alpha = k_1/k_2 < 1$; subscripts 1, 2, 3 refer to protium, deuterium and tritium (³H), respectively). As mentioned above, deuterated or tritiated compounds are more polar and thus are more strongly bound to polar stationary phases.

Table 2 LC separation factors of some hydrocarbons versus their perdeuterated analogues

Compound	$\alpha = k_1/k_2$	Conditions ^{a,b}
[² H ₁₄]Hexane ^a	1.036	51
	1.049	40
[² H ₁₈]Octane ^a	1.054	51
[² H ₁₂]Cyclohexane ^a	1.044	33
[² H ₆]Benzene ^a	1.043	23
	1.048	18
[² H ₆]Benzene ^b	1.049	30
[² H ₈]Toluene ^a	1.046	33
	1.057	23
[² H ₈]Toluene ^b	1.052	40
[² H ₁₀]Phenanthrene ^b	1.067	70
[² H ₁₄]Durene ^b	1.071	70
[² H ₁₀]Biphenyl ^b	1.062	55

^a μ -Bondapak C₁₈ column; methanol in water (mol%); Tanaka (1977).

^bUltrasphere C₁₈ column; acetonitrile in water (v/v); Baweja (1987).

Partition chromatography and reversed-phase LC usually lead to the opposite result, i.e. a heavier isotopomer is eluted first ($\alpha > 1$). It has been suggested that a major contribution to the isotope effect is then a hydrophobic interaction. The fact that the separation factors are higher (see Table 2) when the mobile phase contains more water demonstrates that they are affected by more restricted motion of the C–H bonds (in solute), caused by a tighter solvation of the C–H bonds within the aqueous mobile phase relative to the hydrophobic stationary phase. On the other hand a less restricted motion of the C–H bonds in the stationary phase would tend to favour protium over deuterium, and this could contribute to the observed isotope effect.

Another important factor is the position of the label in a molecule. As these effects are essentially primary isotope effects, the best situation occurs when an isotopic atom is pushed out from the rest of a molecule, so that it is readily accessible for interaction. When the atom in question is in the shadow of a bulky group (e.g. *ortho* hydrogen in benzoic acid) or in an inconvenient configuration, hydrophobic interactions and adsorption can not take place or are greatly suppressed and no separation is attained. The other contributions, such as differences in solubility, molar volume and adsorption on the residual nonderivatized sites on the silica particles, seem to be of a far less importance for the magnitude of the isotope effect.

The above discussion deals with a direct interaction of an isotopic atom or bond with the stationary and mobile phases (primary isotope effect). However, there also exist chromatographic separations

based on secondary isotope effects. In molecules deuterated or tritiated in the position adjacent to an ionizable functional group, the magnitude of the isotope effect is often greatly enhanced. As follows from Table 1 α -deuterated amines are stronger bases than unlabelled amines, and α -deuterated acids are weaker acids than their protiated counterparts. In an elution system with a pH value near the pK_a values of the deuterated/unlabelled amine pair, this isotope-induced base strengthening would alter the ratio of protonated and unprotonated forms, leading to differences in the chromatographic mobility. However, at a pH much higher or much lower than the pK_a value where both labelled and unlabelled amines are completely protonated or unprotonated, the pK_a effect of isotopic substitution on the chromatographic separation is greatly suppressed. A similar effect was observed for labelled carboxylic acids.

Survey of Separations

Hydrocarbons and their Simple Derivatives

A separation of perdeuterated aliphatic and aromatic hydrocarbons has been performed on reversed-phase columns with similar results (Figure 1). A higher content of water in the mobile phase leads to higher separation factors (Table 2).

Chromatography of various isotopomers of benzoic acid shows a moderate effect of the number of deuterium atoms on the separation factor; however, an important effect is exerted by the position of the label (Table 3). Isotopomers containing deuterium in the *ortho* positions display lower isotopic separation than isotopomers with deuterium in

Figure 1 Reversed-phase LC separation of [²H₈]toluene and unlabelled toluene. Mobile phase: water–acetonitrile 60 : 40 (v/v). (From Baweja, 1987).

the *meta* or *para* positions. The isotope effects associated with the *ortho* positions are minimal, probably because interactions between the *ortho* C-¹H or C-²H bonds and the stationary phase are minimized by steric shielding of the carboxyl group. [9, 10, 12, 13-³H]Linoleic acid methyl ester and [9, 10, 12, 13-³H]oleic acid methyl ester were chromatographed on silica impregnated with silver nitrate, attaining partial separation from the appropriate [1-¹⁴C]methyl esters. The tritium atom bound on the olefinic carbon atoms affects the equilibrium constant of the formation of the silver-olefin complex.

Natural Substances

Tritium-labelled steroids have often been used for the elucidation of biochemical and physiological trans-

formations. During the chromatographic purification of such compounds, isotopic fractionation has often been observed. Good, sometimes baseline, separations of tritiated aldosterone, cortisone, oestrone, testosterone, prednisolone and oestradiol from their unlabelled or ¹⁴C-labelled analogues were obtained in reversed-phase LC, tritiated compounds being eluted first. Other techniques such as column partition chromatography and paper chromatography have also been successful.

Vitamin D₃ (cholecalciferol, [I]) is hydroxylated in living organisms to the 1,25-dihydroxy- or 24,25-

[I]

dihydroxy-derivatives. A significant chromatographic isotope effect was observed with both the derivatives labelled with tritium in positions 26 and 27, whereas labelling in positions 23 and 24 causes a substantially smaller effect. A similar behaviour was found in chromatography of the corresponding trimethylsilyl ethers (Table 4). As indicated in the table, the heavier isotopomers were eluted first on the reversed phase, and later than lighter isotopomers on the normal phase.

(III)

(III) X = ¹H, ²H or ³H

possessing antibiotic and antifungal properties, leads to the corresponding tetrahydroderivatives [III]. The isotope effect on the reversed-phase LC mobility was surprisingly large: $\alpha_2 = k_1/k_2 = 1.0190$ for the deuterated compound; $\alpha_3 = k_1/k_3 = 1.0233$ for the

tritiated compound. A Partisil 5 C₁₈ column and a mixture of 0.1% phosphoric acid (45%) with CH₃CN/THF/H₃PO₄ (90 : 20 : 0.1, v/v/v) (55%) as the eluent were used. Even though the chromatographic conditions described do not allow resolution of labelled and unlabelled species, such a possibility exists, e.g. when a column recycling system is used.

Reversed-phase LC of deuterated chlorophylls [III] obtained from green algae *Rhodospirillum rubrum* and *Rhodospirillum spheroides* grown in media containing 50%, 80%, 90% and 99.7% ²H₂O, exhibited baseline separation from isotopically unmodified chlorophyll. As usual, the labelled species were eluted first and the greater is the percentage of deuterium in the compound the faster it moved along the column (Figure 2, Table 5).

Drugs

[²H₁₀]Diphenylhydantoin (phenytoin [IV]) and [²H₁₀]-5H-dibenz[*b,f*]azepine-5-carboxamide (carbamazepine [V]) were separated from their unlabelled parent compounds by reversed-phase chromatography on a C₁₈ column with H₂O/CH₃CN/THF (80 : 16 : 4, v/v/v) as the eluent.

Table 5 LC separation factors of chlorophylls versus deuterated chlorophylls^a

Baseline separation was attained even when using extracted serum samples. The calculated resolution for the isotopomer pairs was 1.3. (Resolution $R_s = (t_2 - t_1)/[0.5(w_1 + w_2)]$.)

[CH₃-³H]Chlorpromazine [VI] and its metabolite [CH₃-³H]-7-hydroxychlorpromazine were separated on a chemically-bonded stationary phase (Spherisorb CN) from their unlabelled counterparts. Although the specific activity of tritiated compound was about 40 Ci mmol⁻¹ indicating approximately 1.5 tritium atoms per methyl group, the measured separation factors were rather high (Table 6). The separation factors depend strongly on the pH of the mobile phase, so that the isotope effect on the basicity of the dimethylamino group is probably significant. The labelled species was eluted later.

An almost complete resolution was attained between unlabelled and di-, tri- or tetra-deuterated drugs active on the central nervous system - 1,2,3,4,10,14b-hexahydro-2-methyldibenzo[*c,f*]pyrazino[1,2-*a*]azepine (mianserin [VII]) and 1,3,4,14b-tetrahydro-2,7-dimethyl-2H-dibenzo[*b,f*] pyrazino[1,2-*a*]-1,4-oxazepine (Org GC 94 [VIII]). [3,3,4,4-²H₄]Org GC 94 was chromatographed on a μ -Porasil column and n-hexane-2-propanol (90 : 10, v/v) to which 4% of ethanol and 0.1% of ammonia solution were added as the mobile phase. Various isotopomers of deuterated mianserin were chromatographed on LiChrosorb Si 60 and Spherisorb C₁₈ columns (Table 7). The deuterated compounds were always moving more slowly than the unlabelled ones. The greatest isotope effects have been found for compounds labelled on the piperazine ring (with the exception of position 14b) and on the methyl group,

indicating that the basicity change plays the most important role.

2-(N-Propyl-N-2-thienylethyl)-5-hydroxytetralinamine (N-0437 [IX]), an effective drug against Parkinson's disease and glaucoma, can be separated from its counterparts deuterated and tritiated at the propyl group. The corresponding diastereoisomeric glucuronides were prepared by enzymatic synthesis and separated in a reversed-phase LC system (Nova-Pak C₁₈). The separation factors were pH-dependent and relatively large, considering the remote positions of the labels from the nitrogen atom, e.g. $\alpha_2 = 1.033$; $\alpha_3 = 1.037$.

The above-mentioned effect of isotope substitution on the basicity of amines was demonstrated by thin-layer chromatography (TLC) of the popular antidepressant imipramine [X]. [²H₁₀]Imipramine labelled in both methyl groups and in aromatic rings and its parent compound were resolved on silica plates using different eluents, in which the pres-

ence of ammonia was necessary; e.g. benzene-acetone-NH₃ (300 : 60 : 1, v/v/v); R_F [¹H] = 0.24; R_F [²H] = 0.18. Labelling on the benzene ring exerted no effect on the chromatographic mobility.

Similar TLC behaviour has been observed with (R,S)-6-[CH₃-²H₆]dimethylamino-4,4-diphenyl-heptan-3-one.HCl ([²H₆]methadone [XI]) (silica gel Merck; benzene-methanol-NH₃; 85 : 15 : 0.65, v/v/v); R_F [²H] = 0.58; R_F [¹H] = 0.79. Reversed-phase LC showed baseline resolution, whereas gas-liquid chromatography afforded no separation.

Isotopes of Heavier Elements

Liquid chromatographic separations of the isotopes of elements other than hydrogen have been rather rare. A high-efficiency liquid-liquid chromatography system consisting of porous silica microspheres covered with 25% (w/w) bis(2-ethylhexyl)phosphoric acid in dodecane as the stationary phase and nitric acid as the mobile phase obtained a certain enrichment of heavier isotopes of calcium in the front of the elution curve. Separation factors calculated by Glueckauf (1961) for ⁴²C, ⁴⁵Ca, ⁴⁸Ca versus ⁴⁰Ca were 1.0012–1.0029.

Better resolution was obtained when isotopic pairs of ¹⁴⁴Sm–¹⁵⁴Sm, ¹⁴⁰Ce–¹⁴²Ce, and ¹⁵¹Eu–¹⁵³Eu were chromatographed on LiChrosorb 60 with di-2-propylether-THF-65% HNO₃ (100 : 20 : 5, v/v/v). Heavier isotopes were always eluted first, the separation factors being two orders of magnitude higher than in ion exchange chromatography (1.030–1.085).

Figure 3 Separation of benzoic acid (I) isotopomers by recycle chromatography. Column: Cosmosil 5-C₁₈-P × 4, 15 cm × 4.6 mm i.d. Mobile phase: methanol-0.05 mol L⁻¹ acetate buffer (pH 4.83) 20 : 80 (v/v). Cycles: (A) 1, (B) 5, (C) and (D) 17. (From Tanaka, 1986.)

There are very few references in the literature to liquid chromatographic separations of organic compounds labelled with isotopes heavier than hydrogen. For example, Tanaka *et al.* (1986) demonstrated the oxygen isotope effect on the reversed-phase LC separation of ¹⁸O-labelled benzoic acid (Figure 3). They demonstrated that successful separation was due to differences in the dissociation constants between the labelled and parent compounds. The isotope effect was pH-dependent and attained a maximal value around pH 5 (Table 8). An equation was derived to determine the ¹⁸O isotope effect on the dissociation constants from LC data. This isotope effect was calculated to be $^{16}K_a/^{18}K_a = 1.020 \pm 0.002$. A very good, nearly baseline, resolution was attained in a recycle system for the pair benzoic acid - [¹⁸O₂] benzoic acid after five cycles, and for the mixture benzoic acid - [¹⁸O]benzoic acid - [¹⁸O₂]benzoic acid after 17 cycles. Similar results were obtained in chromatography of [¹⁸O₂]4-chlorobenzoic acid and [OH-¹⁸O]4-nitrophenol with their unlabelled counterparts. The ¹⁸O-H bond is stronger than the ¹⁶O-H bond so that ¹⁸O-labelled acids are weaker acids than unlabelled ones. Therefore, a longer retention time in reversed-phase LC was expected and found for the labelled carboxylic acid compared to the unlabelled acid.

The same procedure as above was successfully applied to the separation of aniline and [¹⁵N]aniline on the same column with 0.05 mol L⁻¹ acetate buffer containing 5% methanol and 0.01% triethylamine as the eluent. At pH 4.24 the separation factor was found to be $\alpha = k_{14}/k_{15} = 1.010$. The complete separation was accomplished after 20 cycles.

LEAD AND ZINC ORES: FLOTATION

M. Barbaro, Istituto Trattamento Minerali CNR,
Rome, Italy

Copyright © 2000 Academic Press

Outline of the Problem

Today, owing to the limitation of sources and supplies of mineral raw materials and the need to treat ores of increasingly lower grades, as well as those which are fine, complex mineralogically, and refractory, new flotation technology must be developed.

Flotation is in fact the most common process in metallic mineral separation and is the main way for recovering such valuable metals as lead (Pb) and zinc (Zn), or copper (Cu) from ores.

It is known that separation by flotation of useful minerals from gangue in an aqueous pulp happens when particles with polar, hydrophilic or wettable surfaces remain in the liquid phase, whilst particles with apolar hydrophobic or not wettable surfaces adhere to air bubbles. Collectors or depressing/activating reagents modify surface characteristics of minerals thus influencing affinity towards water. Thus, research into new separation technologies is mainly concerned with the search for new flotation reagents.

In fact the value of a flotation concentrate containing a given mineral, from which a desired metal is extracted by a metallurgical process, decreases with an increase in the presence of minerals containing metals other than the one of prime interest. It is thus necessary to design new specific collectors to separate the desired mineral from the gangue. Collectors generally employed in flotation are surfactants that form, for instance, electrostatic bonds with the solids (Leja 1982). Difficulty therefore arises when a particular metallic mineral, such as Pb or Zn mineral, has to be separated from an ore of complex composition or low grade (complex sulfide ores) or when the surface properties of the mineral (oxidized Pb and Zn ores) make the response to flotation extremely poor. To overcome this basic drawback in metal ore flotation, the possibility of using new compounds endowed with a strong affinity for metals themselves has been investigated. The search for new reagents for mineral flotation therefore aims to discover collectors (or depressants) capable of linking more selectively with a given element present in the ore.

The present work deals with the recovery of Pb and Zn by flotation and reviews the main problems faced by research engineers in this field.

Complex Pb-Zn Sulfide Ores

Complex sulfide ores have been defined as those ores for which it is difficult to recover one or more selective product of acceptable quality and economic value with minimal losses and at reasonable costs. Complex sulfide ores are fine-grained, intimate associations of chalcopyrite (CuFeS_2), sphalerite (ZnS) and galena (PbS), disseminated in dominant pyrite, and containing valuable amounts of minor elements.

Generally, collectors employed for sulfide recovery are of the thiol type, and the most commonly used are xanthates. A great number of studies have been carried out on xanthates, examining their adsorption mechanism by spectroscopic techniques such as infrared spectroscopy (Giesekke 1983, Kongolo *et al.* 1984, Little *et al.* 1961, Marabini *et al.* 1983), IR-ATR techniques (Mielczarski *et al.* 1987, Mielczarski *et al.* 1981), X-ray photoelectron spectroscopy (XPS) (Laajalehto *et al.* 1988, Page *et al.* 1989), and also by calorimetric techniques (Partyka *et al.* 1987, Arnaud *et al.* 1989).

However xanthates are active towards the whole class of sulfide minerals, rather than towards one individual mineral. Thus, in order to float a given mineral from a mixture of minerals belonging to the same sulfide class, modifiers are used in order to render the action of the collector more specific, and to improve separation efficiency (Finkelstein *et al.*, 1976).

However, there are many problems in this procedure and the desired results are not always obtained, especially in the case of minerals of a complex composition as in the case treated.

Hence the importance of seeking out collectors capable of linking selectively with one single given mineral rather than with the whole class. Selective linkage is possible if the collector structure incorporates active groups having specific affinity for certain cation characteristic of the mineral surface.

Thus, the search for new, more selective reagents for sulfide mineral flotation is mainly concerned with chelate-forming reagents. In fact, chelating reagents are particular complexing reagents consisting of large organic molecules capable of linking to the metal ion via two or more functional groups, with the formation of one or more rings, thus forming a very stable bond. The stability of metal chelates is influenced by many factors which govern the selectivity and specificity of the chelation reaction.

Examples of the use of chelating reagents in flotation were known from studies on traditional thiol collectors. In fact, both dixanthogen and thionocar-

bamate act as chelating reagents (Ackerman *et al.*, 1987).

There are many studies on chelating agents as collectors more selective than xanthates (Marabini *et al.*, Rinelli *et al.*, Usoni *et al.*, Barbaro *et al.*, Somasundaran) and a review on this topic has been published by Pradip (Pradip 1988). Use of reagents of chelate type offers the possibility of improving selectivity in the flotation separation of complex sulfide minerals (Marabini *et al.* 1990 and 1991).

Oxidized Zn and Pb Minerals

It is well known that there is a difference between sulfurized and oxidized minerals as regards their separation by flotation. It is easy to recover Zn from sphalerite and Pb from galena even using xanthate collectors but it is not the same for Zn from smithsonite (ZnCO_3) and Pb from cerussite (PbCO_3).

Flotation of Zn and Pb oxidized minerals is difficult because there are no known direct-acting collectors capable of producing single metal concentrates. The need for new specific collectors is felt particularly in the case of oxidized lead and zinc minerals because their surface – unlike that of the sulfide variety – is not easily rendered hydrophobic by the collectors generally used, to achieve efficient flotation. Furthermore, the solubility of these oxide minerals is high. Consequently the collector also interacts with metal cations which have gone into solution, thus greatly increasing the amount of reagent required for flotation. It is therefore common practice to sulfurize such minerals prior to flotation so as to prepare their surface to receive xanthates, the collectors generally adopted for concentrating sulfides. Generally the collectors normally used in beneficiation plants act only if the ore has been subjected to a preliminary sulfidization phase which is extremely delicate and critical. In fact, sulfurization calls for careful dosage to avoid rendering the mineral surface inert.

Thus classical collectors have an affinity towards given mineralogical classes, whilst chelating reagents – when chemically adsorbed on the mineral surface – have specificity towards given cations, independently from the mineralogical form of the solid.

However this approach also has two main disadvantages, firstly, excessive consumption (Marabini 1973, Marabini *et al.* 1983), and secondly, lack of an aliphatic chain which renders the mineral surface hydrophobic.

In fact the chelating reagents commercially available are almost all aromatic molecules without a long hydrocarbon chain; thus, although the chelated min-

Figure 1 Structure of MBT-Pb chelate.

eral particle is fairly hydrophobic, it is not sufficiently aerophilic to ensure flotation. Studies on oxidized minerals (Usoni *et al.* 1971, Rinelli *et al.* 1973, Marabini 1975, Rinelli *et al.* 1976) were performed rendering particles hydrophobic by making contemporary available long-chain organic groups (as fuel-oil or oily frother) and chelating agents.

The first application of this concept is from 1973. A chelating reagent, namely 8-hydroxyquinoline (Figure 1) with fuel oil was used to float mixed oxide-sulfide minerals of Zn and Pb (Rinelli *et al.* 1973). Good recoveries have been attained on an ore containing 7.3% Zn with 1.4% as sphalerite, and 0.9% Pb with 1.4% as galena.

On the basis of the points made so far it is apparent that known chelating compounds form a class of reagents which can be used for the flotation of metallic ores, providing artificially the long chain organic portion by introducing a neutral oil (fuel oil). But the introduction of a new liquid phase into flotation pulp is damaging to the system as a whole and is not available on an industrial scale.

Studies, therefore, have been oriented towards the synthesis of new organic molecules containing both selective functional aromatic chelating groups and hydrophobic long alkyl chain portions. This is done by modifying known chelating collectors.

Indeed, much research was performed on the design of selective chelating collectors; this resulted in numerous structures being proposed and synthesized for laboratory-scale testing on lead/zinc ores prior to the performance of pilot-scale and plant-scale trials.

On the basis of a thermodynamic calculations for the selection of complexing collectors theoretically selective towards a cation (Marabini *et al.* 1983), two classes of reagents have been proposed by Marabini *et al.* (Marabini *et al.* 1988 and 1989, Nowak *et al.* 1991) for the flotation of oxidized Zn and Pb in a pilot plant. Much has been written on the role of the aliphatic chain in conventional collectors (Cases 1968, Predali 1968, Somasundaran 1964) but the work concerns new chelate-type reagents, of the mercaptobenzothiazole (MBT) and aminothiophenol (ATP) types having a mixed aromatic-aliphatic structure. The aromatic part contains specific functional

chelating groups that are selective towards the zinc or the lead of oxidized minerals (MBT is selective towards lead and ATP towards zinc) while the aliphatic part consists of a hydrocarbon chain which renders the surface-complex hydrophobic.

The collecting action of MBT is thus attributable to the formation of a surface film selectively chemisorbed on the mineral surface rendered hydrophobic by the aliphatic chain.

In fact in the case of hydrophilic oxidized minerals, the aromatic-heterocyclic portion of the MBT alone does not suffice to render the surface sufficiently hydrophobic to ensure flotation. Hence an aliphatic chain has to be introduced in the molecular structure. The aliphatic chain is necessary to ensure a hydrophobic condition and hence collecting power for the aromatic chelating (MBT or ATP) reagent.

It has been demonstrated that three carbon atoms is the minimum chain length needed to ensure collecting power that improves with aliphatic chain length. Performance is enhanced slightly by the presence of an ether oxygen atom.

Where reagents of the ATP type are concerned, these (as the Schiff bases derived therefrom) exert chelating action towards Zn (Barbaro *et al.* 1997). Chelation occurs through weak bonds with nitrogen and -SH as shown (Figure 2).

The formation of a chemisorbed surface film is sufficiently stable to account for the collecting action. The selectivity of molecules containing ATP and different aliphatic chains has been studied by flotation tests.

In this case the role of the aliphatic chain and of the ether oxygen is of more decisive importance than for MBT in assuring the stability of the adsorbed phase and thus floatability. The selectivity increases with the number of carbon atoms in the chain.

In particular, the presence of the oxygen in the chain enhances selectivity, whilst in MBT class reagents only chain length is effective. This difference can be explained by the different chemical structure of the two reagents. In the case of MBT, the effect of the aliphatic substituent is due mainly to its hydrophobicizing effect, and thus to its

Figure 2 Structure of ATP-Zn chelate.

length which favours reciprocal attraction of the chains of the adsorbed layer.

By contrast, in the case of ATP, the effect of the aliphatic substituent is due not only to its hydrophobicizing effect, but also to its effect on reactivity of the aromatic polar head of the molecule. In fact the ATP chelating functional group has a weaker reactivity in comparison with MBT, and therefore is more sensitive to the effect of the substituent on its unique benzenic ring (whilst MBT has two aromatic structures). For this reason, in the case of ATP it is possible to observe that the presence of the oxygen in the chain greatly enhances selectivity. The positive effect of the R-O group in the para position *vis-à-vis* the nitrogen of ATP can be explained with the electron-releasing effect due to resonance of the oxygen with the benzene ring, which increases reactivity with the nitrogen group (Morrison 1973).

In the case of ATP, which forms a less stable bond with the mineral cation and which consists of a single benzene ring, the conjugative effect of the ether oxygen and the hyperconjugative effect of the alkyl groups are more evident than for MBT. Selectivity is improved by the insertion of oxygen in the chain and also by an increase in chain length. Here the effect of the alkyl chain on the aromatic functional group is more marked, permitting modulation of selectivity.

This research based on the design and synthesis of new flotation reagents opens new possibilities in the field of metallic Pb and Zn mineral recovery by flotation.

LIPIDS

Gas Chromatography

A. Kuksis, University of Toronto, Charles H Best Institute, Toronto, Canada

Copyright © 2000 Academic Press

Introduction

Natural lipids consist of complex mixtures of molecular species, which are found in association with cell membranes, lipoproteins and other subcellular structures. The composition differs among different cell and tissue types, reflecting the function of lipids in these body structures. Industrial and food products may be of plant, animal or synthetic origin. The gas chromatography (GC) of fatty acids by James and Martin in 1956 provided the first success in dealing with the complexity of the hydrolysis products of fats and oils. A few years later Kuksis and McCarthy developed methods for the resolution of intact triacylglycerols by high temperature GC.

Improved design of GC equipment, culminating in the development of reliable capillary columns, together with enzymic and chemical derivatization of samples now permits the separation of molecular species of all lipids on a routine basis. In modern analyses, conventional or high temperature GC serves as the final step in the multi-method resolution and quantification of individual components of a total lipid extract. The high molecular weight and low volatility, however, require constant vigilance in quantitative GC analysis of natural lipids.

Nonpolar Capillary Columns

Nonpolar capillary columns provide resolution based on the overall molecular weight of the lipid molecules. The nonpolar phases are typically polymethylsiloxane polymers with 5% phenyl groups. They are

stable to 350°C or higher temperatures. Other nonpolar phases for GC are provided by certain hydrocarbons, which are limited to much lower temperatures and are operated isothermally.

Polarizable Capillary Columns

The methylsiloxane liquid phases containing 50–65% phenyl groups become polar as the temperature increases above 290°C, as indicated by the longer retention of the unsaturated compared to saturated triacylglycerols. Below this temperature the liquid phase is nonpolar, as indicated by the earlier elution of the unsaturated compared to saturated fatty acid trimethylsilyl (TMS) esters. The polarizable liquid phases are stable up to 360°C. Since these liquid phases possess high temperature stability, they are well suited for the resolution of molecular species of seed oil and milk fat triacylglycerols.

However, columns at least 25 m long are needed to provide sufficient resolving power for the separation of the saturated and unsaturated species of natural diacyl and triacylglycerols, and ceramides.

Polar Capillary Columns

Capillary columns containing polar and very polar liquid phases are utilized mainly for the separation of saturated and unsaturated fatty acids as the methyl esters. The more stable polar capillary columns can be programmed to 280°C and used for the separation of the TMS ethers of diacylglycerols and ceramides as well as low molecular weight triacylglycerols.

Detection and Quantification of GC Peaks

The principal detector for the GC of lipids is the flame ionization detector (FID), but electron-capture detectors are also used (e.g. for pentafluorobenzyl esters). A number of authors have evaluated the quantitative GC analysis of fatty acids and triacylglycerols. GC with online electron impact (EI) mass

spectrometry (GC-EI-MS) yields largely qualitative information from which the structure of unknown molecules can nevertheless be deduced. However, both total ion current and single ion monitoring have been utilized for quantitative analyses using appropriate calibration curves.

Resolution of Neutral Lipids

Neutral lipids, including common triacylglycerols, are readily resolved according to their molecular weight or number of carbon atoms by high temperature GC. Mixtures of high and low molecular weight neutral lipids are best dealt with by temperature programming. These methods are also suitable for the GC of certain polar lipids provided the polar head groups have been removed or masked. The neutral lipid separations are usually performed on nonpolar liquid phases, but polarizable liquid phases of high temperature stability have also been employed for the separation of intact neutral lipids. In both instances some prefractionation of the lipid mixture is necessary for optimum analysis.

Isolation and Preparation of Derivatives

Usually this includes the removal of the polar lipids from the neutral compounds by thin-layer chromatography (TLC), high performance liquid chromatography (HPLC) or simple adsorbent cartridges. Before GC, the free functional groups of the lipids must be protected in order to avoid dehydration and to increase volatility, as well as to improve other GC properties. This is readily accomplished by preparing TMS derivatives; in special instances other derivatives may be prepared. Free carboxyl groups may be methylated with diazomethane and alcohol groups may be acetylated with acetic anhydride in the presence of other ester bonds. **Table 1** lists the more common reagents for derivatization of neutral lipids along with the reaction conditions. Polar lipids, such as glycerophospholipids, can be converted into neutral lipids by dephosphorylation. This can be readily accomplished by hydrolysis with phospholipase C (*Bacillus cereus*), which releases the phosphocholine moiety from phosphatidylcholine, lysophosphatidylcholine and sphingomyelin, and the phosphoethanolamine moiety of both diacyl and alkenylacylglycerophosphoethanolamines. The *B. cereus* enzyme also attacks the plasma inositol phosphatides to yield diacylglycerol moieties. Alternatively, the plasma phospholipids may be dephosphorylated by pyrolysis, acetolysis and silolysis, but the latter procedures lead to isomerization of the acylglycerols, incomplete conversion and partial destruction of the lipid samples.

Table 1 Preparation of derivatives for GC analysis of neutral lipids, fatty acids and prostanoids^a

Reagent	Ratio	Temperature	Time	Application
<i>Neutral lipids</i>				
Pyridine/HMDS/TMCS	12/5/2	Ambient	0.5–1 h	Trimethylsilyl ethers of acylglycerols and sterols
<i>t</i> -BDMCS/imidazole/dimethylformamide	1 : 2.5 in DMF	80°C	20 min	<i>tert</i> -Butyldimethylsilyl ethers of acylglycerols and sterols
Ac ₂ O/pyridine	1 : 10	80°C	1 h	Acetates of acylglycerols and sterols
PFB ₂ O/pyridine	1 : 10	80°C	1–2 h	Pentafluorobenzoates of acylglycerols and sterols
<i>Fatty acids</i>				
BF ₃ /MeOH	15%	Ambient	20 min	Methyl esters of free fatty acids
BF ₃ /MeOH	6–15%	60°C/reflux	2–10 min	Methyl esters of fats and oils
H ₂ SO ₄ /MeOH	6%	80°C/reflux	2 h	Methyl esters and dimethylacetals of fatty acids
HCl/MeOH	5%	60°C	0.5–2 h	Methyl esters of free and bound fatty acids
CH ₂ N ₂ /ether	Dilute	Ambient	5 min	Methyl esters of free fatty acids
KOH/MeOH/benzene	0.2–2 N	Ambient	0.5 min	Methyl esters of glyceryl esters
NaOH/MeOH	0.5–2 N	Refluxing	0.5–1 h	Methyl esters of steryl esters
2-NH ₂ -2-MePr (DMOX)		170°C	18 h	4,4-Dimethyloxazolines of unsaturated fatty acids
DEADMS/3-pyridyl carbinol		60°C	10 min, 10 min	Picolinyldimethylsilyl (PICSI) esters
(TFA) ₂ O/3-pyridyl carbinol	2 steps	50°C	1 h	Picolinyl esters of fatty acids
Oxalyl Cl/pyrrolidide	2 steps	Ambient	30 min	<i>N</i> -acyl pyrrolidides of fatty acids
<i>Prostanoids</i>				
PFBBr/ <i>N,N</i> -DIPETn/ Meoxamine/BSTFA/pyridine	3 steps	Ambient, 60°C, and 60°C, resp.	10 min, 16 h, 15 min	PFB/MO/TMS derivatives of prostanoids, thromboxanes, hepxoilins

^aAbbreviations and experimental details are found in the text, in legends to figures and in references cited.

The dephosphorylated lipids are recovered by TLC or adsorbent cartridges and the exposed hydroxyl groups masked by acetylation or preparation of TMS derivatives. The diacyl, alkylacyl and alkenylacyl subclasses released from glycerophospholipids by phospholipase C can be readily resolved by normal-phase HPLC or TLC prior to the GC resolution of the molecular species of the *sn*-1,2-diradylglycerol moieties. Likewise, the method is suitable for the resolution of the molecular species of TMS ethers of the *sn*-1,2- and *sn*-2,3-diacylglycerol moieties of triacylglycerols derived by Grignard degradation, chiral-phase HPLC resolution as the dinitrophenylurethanes, and silylation.

Total Neutral Lipid Profiling

Total neutral lipids are easily resolved into component lipid classes by GC on short (8–15 m) nonpolar capillary columns. Longer (25 m) polarizable capillary columns provide separations of molecular species. The components ranging from free fatty acids to triacylglycerols can be effectively quantified by tridecanoylglycerol added as an internal standard to the mixture prior to the GC analysis. **Table 2** lists the more common liquid phases for GC of neutral lipids along with the column conditions and selected applications.

Nonpolar capillary GLC **Figure 1** shows a GC separation of total lipids in plasma, following dephos-

phorylation and preparation of TMS derivatives, on a nonpolar capillary column along with that of a mixture of ceramides and monoacylglycerols released from the combined sphingomyelin and lysophosphatidylcholine fraction isolated by preliminary TLC. The separations on the nonpolar capillary column are limited to resolution by carbon number, although the unsaturated species are eluted slightly ahead of the saturates of the same carbon number. The ceramides (peaks 32–42) are eluted over the same temperature range as the diacylglycerols (peaks 34–40). GC separations similar to those obtained for the total plasma lipids are readily obtained for individual plasma lipoproteins and lymph chylomicrons, as well as for other total lipid extracts from natural sources that can be converted to neutral lipids. GC-MS of plasma total lipids provides confirmation of the peak identity. Mass chromatograms of characteristic fragment ions, retrieved from the total ion current by a computer, permit identification and quantification of overlapping molecular species of free fatty acids, their esters and amides, as well as free sterols and steryl esters.

Partial separation of saturated and unsaturated plasma cholesteryl esters has been reported on a nonpolar capillary column and identification confirmed by negative ammonia ionization mass spectrometry. GC-MS analysis of synthetic steryl esters by nonpolar capillary GLC and EI and chemical ionization has been reported. The GC separation of C₂₇ sterols has

Table 2 Commonly used liquid phases and columns for GC of neutral lipids^a

Figure 1 GC of total lipids of normal human plasma on a nonpolar capillary column. A, Total neutral lipids as obtained by dephosphorylation with phospholipase C; B, ceramides and monoacylglycerols released from sphingomyelin and lysophosphatidylcholine. Simplified peak identification: 16 and 18, free fatty acids; 22–24, monoacylglycerols; 27, free cholesterol; 30, tridecanoylglycerol (internal standard); 32–42, diacylglycerols and ceramides; 43–47, cholesteryl esters; 48–56, triacylglycerols. GC conditions: column, 5 m × 0.25 mm i.d., 100% dimethylsilicone (SP-2100, Supelco); temperature, programmed, 170–350°C at 8°C min⁻¹ with hydrogen as carrier gas. (Reproduced with permission from Myher JJ and Kuksis A (1984) Determination of plasma total lipid profiles by capillary gas liquid chromatography. *Journal of Biochemical and Biophysical Methods* 10: 13–23.)

been reviewed and the retention times tabulated on DB-5 and CP-WAX columns for a large number of compounds as the TMS derivatives in relation to 5 α -cholestane.

Polarizable capillary GLC Figure 2 compares the plasma total lipid profiles as obtained by GC on (A) nonpolar and (B) polarizable capillary columns. The nonpolar column yields prominent peaks for free cholesterol, diacylglycerols and ceramides, cholesteryl esters and triacylglycerols. The lipid ester classes are resolved according to the total number of carbons. The polarizable column permits a separation of the glycerolipids and cholesteryl esters on the basis of both total carbon and double bond number. There is an extensive overlap among the molecular species of the diacylglycerols and ceramides but the cholesteryl esters are well resolved from each other and from the triacylglycerols of both higher and lower molecular weight. Characteristic lipid profiles are also obtained for the individual plasma lipoprotein classes. Cholesteryl arachidonate suffered some degradation and is incompletely recovered. The plasma triacylglycerols appear to be fully recovered, except for the more highly unsaturated long chain (56:4–66:18) species, which are only partially recovered.

Molecular Species of Diacylglycerols and Ceramides

The early GC analyses of molecular species of diacylglycerols were performed on nonpolar packed or capillary columns following a preliminary resolution based on unsaturation by argentation TLC. Polarizable capillary columns provide an improved resolution of the molecular species of diacylglycerols and especially of ceramides. Figure 3 compares the order of peak elution of diacylglycerols (partial Grignard deacylation products of lard triacylglycerols) and the ceramide moieties of plasma sphingomyelin. The diacylglycerol and ceramide peaks are eluted in order of increasing number of double bonds within a carbon number of each lipid class. Thus, the diacylglycerol 16:0–18:1 is eluted ahead of 16:0–18:2 and 18:0–18:1 is eluted ahead of 18:0–18:2, but 18:0–18:2 tends to overlap with 16:0–20:4. The ceramide d18:1–16:0 elutes earlier than the diacylglycerol 16:0/16:0 on the polarizable column, whereas on nonpolar columns they overlap.

The molecular species of diacylglycerols are best resolved by GC on polar capillary columns similar to those used for separation of fatty acid methyl esters. These columns provide especially detailed analyses of

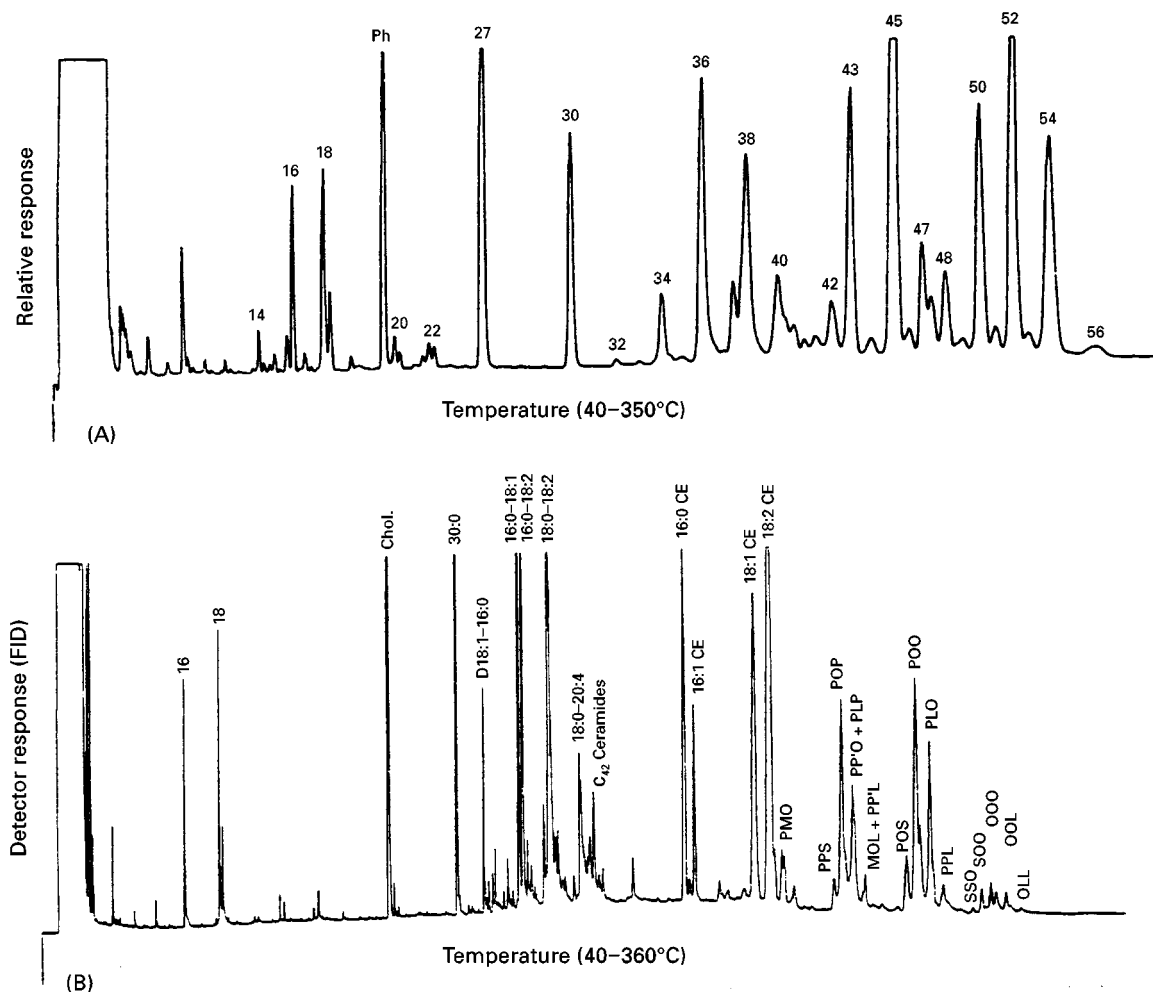

Figure 2 GC profiles of plasma total lipids on (A) nonpolar and (B) polarizable capillary columns. Peak identification: (A) as given in Figure 1; Ph, TMS ester of phthalic acid; (B) as given in the figure; L, linoleic; M, myristic; O, oleic; P, palmitic; S, stearic acids. GC conditions: (A) column, 5 m \times 0.25 mm i.d., dimethylsilicone (SP-2100, Supelco); temperature, programmed, 40–350°C at 8°C min⁻¹ with hydrogen as carrier; (B) column, 25 m \times 0.25 mm i.d., 65% phenylmethylsilicone (OV-22, Quadrex); temperature, programmed, 40–360°C at 50°C min⁻¹ to 150°C, then 10°C min⁻¹ to 310°C, and 2°C min⁻¹ to 360°C with hydrogen as carrier gas. (Reproduced with permission from Kuksis A, Myher JJ and Geher K (1993) Quantitation of plasma lipids by gas liquid chromatography on high temperature polarizable capillary columns. *Journal of Lipid Research* 34: 1029–1038.)

the TMS ethers of the diradylglycerol moieties of glycerophospholipids and triacylglycerols. **Figure 4** shows the resolution of the molecular species of the diacyl, alkylacyl and alkenylacyl subclasses of human plasma ethanolamine glycerophospholipids as obtained by polar capillary GC of the TMS ethers of the derived diradylglycerols. There are marked differences in the distribution of the chain length and unsaturation among the three subclasses of the plasma ethanolamine glycerophospholipids as anticipated from the fatty acid and diradylglycerol carbon number distribution. Polar capillary GC resolution of molecular species of the *sn*-1,2- and *sn*-2,3-diacylglycerols has been extensively utilized in structural

analyses of triacylglycerols. Tables have been compiled of GC retention factors of diradylglycerol TMS ethers on polar capillary columns.

Molecular Species of Triacylglycerols

GC is well suited for the separation of the molecular species of triacylglycerols. Nonpolar columns provided essentially carbon number or molecular weight resolution, while the polarizable liquid phases give effective separations of molecular species of saturated and unsaturated triacylglycerols. Polar capillary columns also provide separations based on both carbon and double bond number, but are limited to low molecular weight triacylglycerol mixtures.

Figure 3 GC profiles of (A) common diacylglycerols and (B) the ceramides of plasma sphingomyelin as obtained on a polarizable capillary column. Peak identification is as given in figure. GC conditions are as given in Figure 2B. (Reproduced with permission from Kuksis A, Myher JJ and Geher K (1993) Quantitation of plasma lipids by gas liquid chromatography on high temperature polarizable capillary columns. *Journal of Lipid Research* 34: 1029-1038.)

Nonpolar liquid phases The first GC resolutions of molecular species of triacylglycerols were obtained on nonpolar packed columns of short length. **Figure 5** compares the separation of butteroil triacylglycerols obtained on a nonpolar packed column and on a capillary column. Both columns yield essentially carbon number resolution, although the capillary column shows some peak splitting due to separation of saturated and unsaturated species within a carbon number. A combination argentation TLC or HPLC with nonpolar GC separation is required for a more extensive separation of molecular species.

Nonpolar capillary GC columns have been effectively utilized for resolution of the reduction products of ozonized lard, rapeseed and palm oil triacylglycerols, as well as the reduction products of ozonized partially hydrogenated soybean oil. **Figure 6** shows the elution profile on a nonpolar column of the triacylglycerols of soyabean oil after reductive ozonolysis. The peaks are identified by the triplets of the fatty acids: palmitic (P), stearic (S) and the C₉ aldehyde (U) of the unsaturated fatty acid.

Polarizable liquid phases The usefulness of the polarizable liquid phases for the separation of saturated and unsaturated triacylglycerols was discovered by

Geeraert and Sandra in 1984. **Figure 7** shows the resolution of the molecular species of butteroil triacylglycerols. Peak identification presents a problem because of extensive resolution of isobaric species. However, preliminary resolution by argentation TLC in combination with GC-MS enabled the pattern of elution to be established. At the present time, the polarizable capillary column provides the most complete GC resolution of the molecular species of triacylglycerols.

The resolution of triacylglycerols seen in the GC-MS profiles is somewhat reduced in comparison to GC-FID. The reduced resolution complicates post-column processing of the GC-MS data due to lack of discrete peaks in parts of the total ion chromatogram. GC-MS quantification of milk fat triacylglycerols is improved by employing the Biller-Biemann enhancement technique to produce mass-resolved total ion chromatograms. The Biller-Biemann enhancement algorithm examines each mass that appears in successive scans in the TLC to detect masses that are rising and falling in intensity.

Polar liquid phases The polar capillary columns commonly employed for fatty acid methyl ester separation can resolve low molecular weight

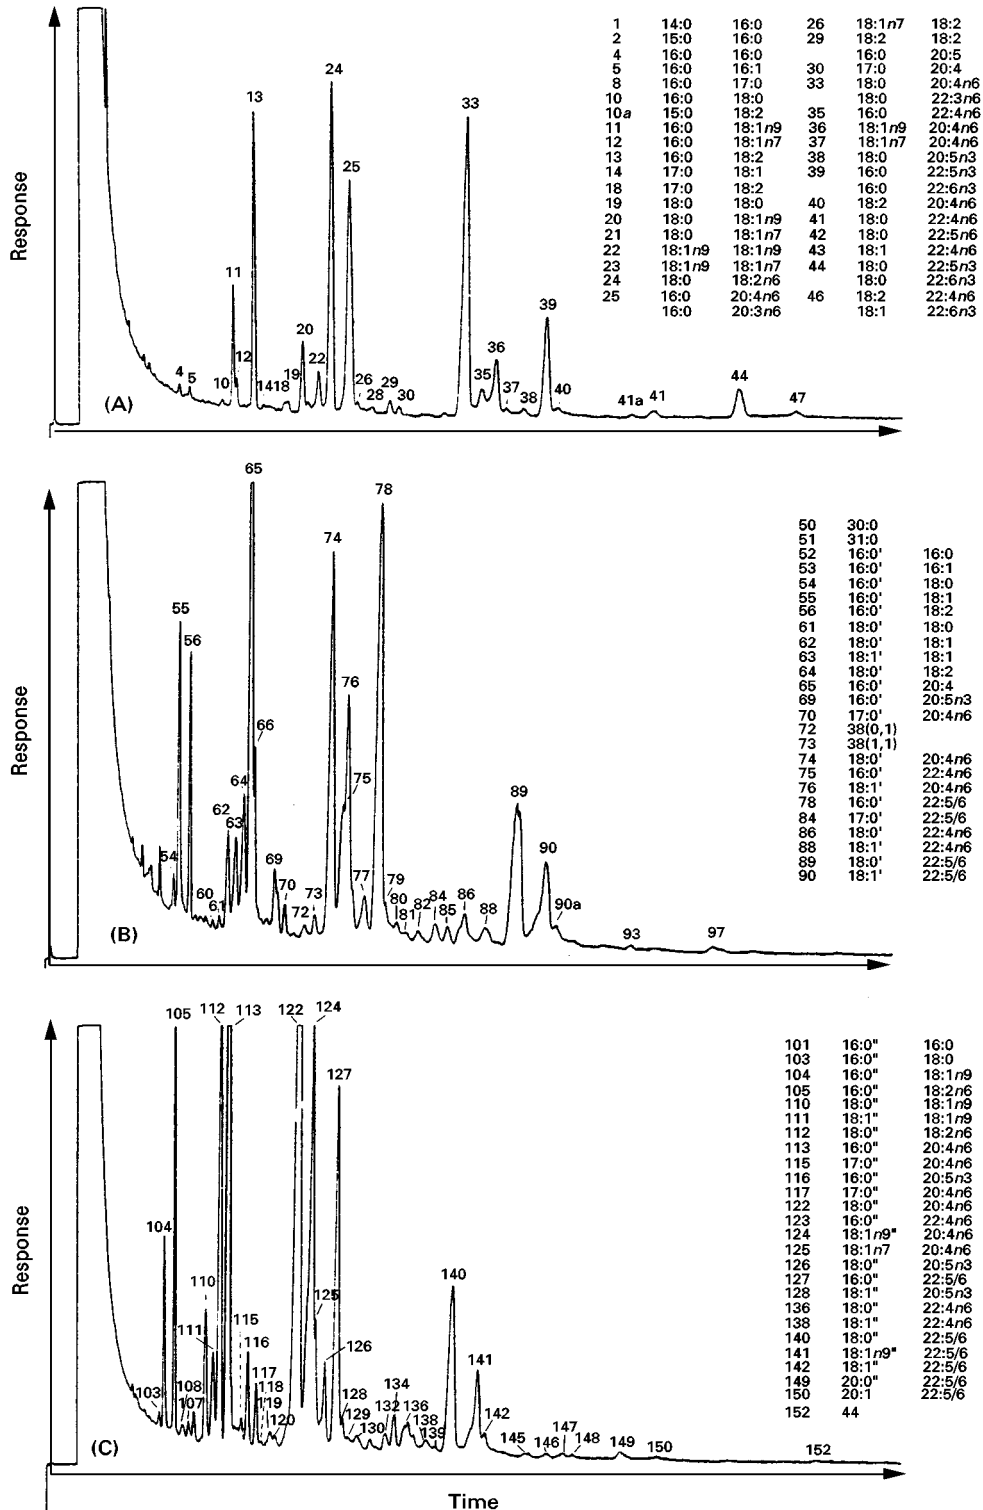

Figure 4 GC profiles of the TMS ethers diradylglycerol moieties of human plasma diradylglycerophosphoethanolamines (GPE). Peaks are identified in the figures. (A) Alkylacyl GPE; (B) alkenylacyl GPE; (C) diacyl GPE. Peak identification is given in the figures. GC conditions: column, 15 m × 0.32 mm, i.d. 68% cyanopropyl/32% dimethylsiloxane (RTx 2330, Restek); temperature, isothermal, 25°C with hydrogen as carrier gas. (Reproduced with permission from Myher JJ, Kuksis A and Pind S (1989) Molecular species of glycerophospholipids and sphingomyelins of human plasma: comparison to red blood cells. *Lipids* 24: 408–418).

Figure 5 GC profiles of butteroil triacylglycerols as obtained on nonpolar columns. (A) Packed column; (B) capillary column. Peaks are identified by total acyl carbon as shown in the figures. GC conditions: (A) packed column, 50 × 0.25 cm, i.d. 2.5% SE-30, Applied Science; temperature, linearly programmed from 200 to 325°C with nitrogen as a carrier gas (Reproduced with permission from Kuksis A and McCarthy MJ (1962) *Canadian Journal of Biochemistry and Physiology* 40: 679–685.) (B) Capillary column, 25 m × 0.25 mm i.d., methyl silicone (OV-1, Ohio Valley); temperature, programmed from 210 to 370°C in 20 min with hydrogen as a carrier gas. (Reproduced with permission from Geeraert, 1987.)

triacylglycerols and the diacetates of monoacylglycerols containing saturated and unsaturated fatty acids. Conventional polar capillary columns are not sufficiently stable at the high temperatures needed to elute long chain triacylglycerols.

Resolution of Fatty Acids

Fatty acids constitute the most extensively investigated class of lipids for GC separation, identification and quantification. Although the routines for the common fatty acids are well established, determination of minor fatty acids, including branched-chain and positional and configurational isomers, requires specialized approaches. Other problems arise from the presence of oxygenated functional groups in the fatty chains. Many of these fatty acids have been successfully identified by preparing nitrogenous derivatives in combination with GC-MS.

Isolation and Preparation of Derivatives

Proper isolation and preparation of derivatives are essential for both identification and quantification of fatty acids. The common procedures for isolating fatty acids consist of extracting lipids from biological materials, saponification and esterification of the recovered acids. Underivatized volatile fatty acids are difficult to quantify by GC because these highly polar compounds form hydrogen bonds that interact with the active sites on the column coatings and cause peak tailing and ghosting due to dimerization. These undesirable effects are avoided by converting the fatty acids into methyl esters or other volatile derivatives. Specially developed columns, however, may avoid both tailing and ghosting.

Preparation of methyl esters Table 1 also lists the more popular methods of derivatization of the common fatty acids for GC analysis. Formation of fatty

Figure 6 Non-polar capillary GC profile of the triacylglycerols of soybean oil after reductive ozonolysis. Peak identification is as given in figure: P, palmitic; S, stearic; U_n, unsaturated fatty acid residues. GC conditions: column 15 m × 0.32 mm i.d. 100% methylsilicone (OV-1, Ohio Valley); temperature, 200°C (0.15 min) isothermal then 20°C min⁻¹ to 360°C with hydrogen as carrier gas. (Reproduced with permission from Geeraert E (1985) In: Sandra P (ed.) *Sample Introduction in Capillary Gas Chromatography*, vol. 1, pp. 133–158. Heidelberg: Alfred Hüetig Verlag.

acid methyl esters is usually accomplished in the presence of acid or alkaline catalysts. Acidic catalysts transesterify glycerolipids and other complex lipids as well as esterify any free fatty acids in the presence of

methanol. Inclusion of butylated hydroxytoluene as an antioxidant in the transesterification solution results in the formation of methoxy butylated hydroxytoluene, which emerges in the 14:0–16:0 fatty

Figure 7 Polarizable capillary GC profile of butteroil triacylglycerols. Peak identification is as given in figure: P, palmitic; O, oleic; S, stearic; M, myristic acids; 28–54, total acyl carbon numbers; short chain triacylglycerols are shown as combinations with major long chain acids (x) of different degrees of unsaturation ($\Delta 0 - \Delta 1 + 1$) as identified elsewhere (Myher JJ, Kuksis A, Marai L and Sandra P (1988) *Journal of Chromatography* 452: 93–118.) GC conditions: column, 25 m × 0.25 mm i.d., 50% phenylmethylsilicone (RSL-300, supplied by Sandra P); temperature, linearly programmed from 280 to 355°C over 30 min with hydrogen as the carrier gas. *Major acetate peaks. (Reproduced with permission from Geeraert E and Sandra P (1987) *Capillary GC of triglycerides in fats and oils using a high temperature phenylmethylsilicone stationary phase. Part II. The analysis of chocolate fats. Journal of the American Oil Chemist's Society* 64: 100–105.)

acid elution region. Phthalate esters have also been detected among plasma lipids, even when prepared in the absence of external contamination. The precise point of elution relative to fatty acid derivatives is dependent on the nature of the phthalate ester and the stationary phase, but typically it is in the same range as the C₁₈–C₂₂ fatty acids. In many instances it is convenient to perform the acid transmethylation *in situ*, e.g. in the presence of silica gel scrapings from a TLC plate.

Acid-catalysed transmethylation also leads to significant dehydration of the sterol moiety and degradation of conjugated fatty acids. The peaks formed during acid-catalysed methylation were identified as positional allylic methoxy isomers of 18:1 by GC-MS. Re-evaluation of the H₂SO₄-isopropanol reaction showed just as extensive isomerization of conjugated dienes as the HCl-MeOH method.

Alkaline catalysts transesterify neutral lipid esters in anhydrous methanol much faster (a few seconds to a few minutes), but they are unable to esterify free fatty acids, which constitutes a serious shortcoming. Furthermore, *N*-acyl lipids are not methylated. The presence of water leads to saponification. Alkaline reagents dissolve silica gel and cannot be employed with gel scrapings from TLC plates. Diazomethane can be prepared in ether solution by the action of alkali on a nitrosamide (e.g. *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide) in the presence of alcohol. This reagent is commercially available as Diazald (Aldrich Chemical Co). Diazomethane is used for preparation of fatty acid methyl esters from lipids that have been first saponified. It has the disadvantages that it is highly toxic, explosive and likely to cause specific sensitivity.

Preparation of other derivatives Table 1 also lists a selection of reagents for derivatization of oxygenated fatty acids and prostanoids. Monohydroperoxy fatty acids are reduced to hydroxy acids after reaction for 1 h at room temperature with triphenylphosphine in diethyl ether prior to GC analysis of the methyl ester TMS ethers. The monohydroxy fatty acid methyl esters are hydrogenated for 5 min at room temperature in the presence of rhodium on alumina in methanol. They are converted to their TMS ether derivatives by reaction with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide for 30 min at room temperature. *tert*-Butyldimethylsilyl ethers of secondary hydroxy fatty acid methyl esters are prepared by dissolving the sample in a mixture of dry toluene, dimethylformamide and pyridine, and adding *N*-*tert*-butyldimethylsilylimidazole and *N*-methyl-*tert*-butyldimethylsilyltrifluoroacetamide containing 1% *tert*-butyldimethylsilylchloride (TBDMS).

Of the many different derivatives described in the literature for GC analysis of prostaglandins, the pentafluorobenzoate-methoxime-TMS (PFB-MO-TMS) derivatives yield the most satisfactory results in terms of GC properties, electron-capture detection and MS response and stability. These derivatives show single well-shaped peaks for each compound, except for prostaglandin E₂-PFB-MO-TMS, whose *syn-anti* isomers can be seen as well-separated peaks.

Normal oxygenated and nonoxygenated fatty acids have been converted into nitrogenous derivatives for structural analyses by GC-MS. The picolinyl esters are prepared from the fatty acids by first converting them into acid chlorides by dissolving in thionyl chloride. The acid chlorides are then treated with a dilute solution of 3-pyridylcarbinol in acetonitrile. The picolinyl dimethylsilyl derivatives of fatty alcohols are prepared by dissolving the alcohol in dry pyridine, adding diethylaminodimethylsilyl-3-pyridylcarbinol and heating at 60°C for 10 min. The picolinyl esters of the epoxides are prepared by dissolving the epoxide in dry methylene chloride and adding a freshly prepared solution of 1,1'-carbonyldiimidazole followed by 3-pyridylcarbinol solution of triethylamine. The preparation of picolinyl esters via fatty acid chlorides cannot be used for derivatization of the epoxides because of their instability in acidic solutions.

The pyrrolidides are prepared from the lipid ester. The sample is heated with an excess of pyrrolidine in the presence of acetic acid for 30 min at 100°C. 4,4-Dimethylloxazoline derivatives also have useful properties for locating functional groups by MS, but quantitative preparation requires heating the methyl esters with 2-amino-2-methylpropanol at 180°C overnight.

Separation of Saturated and Unsaturated Fatty Acids

Table 3 lists the more popular liquid phases for the separation of saturated and unsaturated fatty acids and prostanoids. The Carbowax phases based on polyethylene glycol appear to provide the best general-purpose columns.

Normal chain fatty acids and dimethylacetals For equivalent chain length (ECL) measurements, the separations of saturated and unsaturated fatty acids are performed isothermally. Isothermal analyses give good ECL values and these are remarkably consistent for the bonded polyglycol columns. Extensive tables of ECL values have been compiled for the methyl ester derivatives of natural fatty acids on silicone,

Table 3 Common liquid phases for capillary GC of fatty acids and their oxygenated derivatives^a

Chemical composition	Commercial names	Column dimensions	Type of separation (temperature programme)	Applications
90% bis-Cyanopropyl/ 10% cyanopropylphenylsilicone	SP-2380 (OV-275/CP-Sil-88)	15 m × 0.32 mm i.d.	Carbon and double bond number (260–270°C)	Short chain triacylglycerols of butteroil distillates
Cross-bonded polyethylene glycol	Supelcowax-10 (Carbowax)	30 m × 0.25 mm i.d.	Saturates and polyunsaturates (185–220°C)	Fish oil fatty acids
Cross-bonded polyethylene glycol	Stabilwax (Carbowax CP 51)	60 m × 0.25 mm i.d.	Saturated and unsaturated esters (212°C, isothermal)	Seed oils and fats, marine oils
90% bis-cyanopropyl/10% cyanopropylphenyl	Rtx-2330 (CP-Sil-88, BPX-70) ^b	100 m × 0.25 mm i.d.	Δ^5 - Δ^{16} -isomers of <i>trans</i> -18:1 (160°C, isothermal)	<i>Trans</i> -18:1 of beef tallow and human milk
Biscyanopropyl, 68%/ dimethylsilicone, 32%	SP-2380 (BPX-70/CP-Sil-84)	50 m × 0.25 mm	Cyclic fatty acid methyl esters (180°C, isothermal)	Hydrogenated cyclic fatty acid monomers from vegetable oils
14% Cyanopropylphenyl/ 86% polysiloxane	CP Sil 19 (DB-1701)	25 m × 0.25 mm	Methyl ethers of isomeric hydroxy fatty acids (100–250°C)	Hydrogenated hydroperoxides of plasma lipids
2% Dimethylsilicone	OV-101	0.4 m × 3 mm, packed	Carbon number (315–330°C, isothermal)	TMS ethers of mycolic acids
95% Dimethyl/5% phenyl silicone	SE-54 (HP-5/ DB5/CP-Sil-8)	18 m × 0.28 mm	Double bond location (70–240°C)	Oxazoline derivatives of fish oil fatty acids
Dimethylpolysiloxane	DB-1 (SE-30/OV-1)	30 m × 0.25 mm	Epoxide location (200–250°C)	3-Pyridinylmethyl esters of epoxides
Dimethylpolysiloxane	DB-1 (SE-30/OV-1)	20 m × 0.25 mm	Methoxy PFB esters (100–310°C)	Urinary prostanoids
86% Dimethyl/14% cyano propylphenyl polysiloxane	DB-1701 (DB-5, CP-Sil 19CB)	15 m × 0.2 mm	F ₂ -isoprostane TMS ethers and PFB esters (190–300°C)	Arachidonic acid peroxidation products
86% Dimethyl/14% cyano propylphenyl polysiloxane	DB-1701 (DB-5, CP-Sil 19CB)	30 m × 0.25 mm	Methoxy PFB esters (18–300°C)	Eicosanoids in blood

^aAbbreviations and details of applications are given in the text, in legends to figures and in references cited.

^bComparable liquid phases are given in brackets.

(Modified with permission from Restek Corporation (1998) *Chromatography Products*, International Version, pp. 544–545).

Carbowax, Silar 5CP and CP-Sil 84 columns. **Figure 8** shows the resolution of the fatty acid methyl esters of menhaden oil on a 30 m polyethylene glycol (Famewax, Restek) column using temperature programming (190–225°C). This liquid phase is stable to 250°C. The elution order of the complex polyunsaturated fatty acid methyl esters is comparable to that obtained on other Carbowax columns.

Acid-catalysed transmethylation leads to conversion of vinyl ethers (when present) into dimethylacetals, which are eluted ahead of the fatty acids of corresponding carbon number. **Figure 9** shows the resolution of the fatty acid methyl esters and dimethylacetals derived from human erythrocyte membranes on a deactivated cyanopropylsiloxane column. Although the separation of many of the dimethylacetals and the methyl esters is incomplete, it is still possible to obtain a good indication of the

relative amounts of plasmalogens that may be present in the sample. Resolution of the major dimethylacetals and methyl esters on cyanopropylsiloxane columns has been obtained of one-third the length used by earlier workers. Prior to GC, the fatty acid methyl esters and dimethylacetals are resolved by normal-phase HPLC.

Identification of very long chain fatty acids An extensive series of long chain polyunsaturated fatty acids has been shown to occur in phosphatidylcholines of the vertebrate retina, where they make up a homologous series of even carbon polyenes having up to 36 carbon atoms. A detailed study has been made of these acids in bovine retina, where they were shown to belong to the same families as well-known fatty acids of the *n*-6 and *n*-3 series like arachidonate (20:4*n*-6), docosapentaenoate (22:5*n*-3) and docosa-

Figure 8 Polar capillary GC of fatty acid methyl ethers of menhaden oil. Peaks are identified in the figure. GC conditions: column, 30 m \times 0.25 mm i.d., 0.25 μ m cross-bonded polyethylene glycol (Famewax, Restek); temperature, 190°C (hold 4 min) then 4°C min⁻¹ to 225°C; carrier gas, helium; split injection 1 : 50 (Reproduced with permission from Restek Corporation (1998) *Chromatography Products*, International Version, p. 447).

hexaenoate (22:6n-3). The fatty acids were analysed by temperature-programmed GC using glass columns packed with 15% OV-225. The position of the double bonds in the long chain polyenes was determined by means of oxidative ozonolysis.

Separation of short chain fatty acids Because of their high volatility, the short chain fatty acids create difficulties in GC separation and quantification when present in mixtures with long chain acids. The volatility can be effectively reduced by preparing higher molecular weight esters (propionyl or butyl esters) which also provide a more comparable response in the FID. It also permits a clear resolution of the short chain fatty acids from the solvent front and identification and quantification of the short chain acids in the presence of long chain acids. Recently developed high speed capillary columns (20 m \times 0.10 mm i.d., 0.10 μ m film thickness DB-WAX or DB-225, Restek) have been found to give an effective separation and quantification of both short and long chain fatty acids as methyl esters. A total of 37 fatty acids can be analysed in less than 15 min.

Separation of Oxygenated Fatty Acids and Prostanoids

Oxygenated fatty acids occur in nature as a result of enzymatic and nonenzymatic oxidation, and because

of their physiological activity there is much interest in their analysis.

Fatty acid hydroperoxides are labile key intermediates in plant and mammalian lipid metabolism, acting as precursors of a variety of lipid-derived mediators such as prostaglandins and leukotrienes. Until recently, these analyses were usually done by GC, but now reversed-phase HPLC has been shown to have advantages for the analysis of the thermo-labile oxygenated derivatives of the fatty acids.

Hydroxides, epoxides, hydroperoxides and isoprostanes A 30 m nonpolar methylsiloxane column was used to measure the ECLs of hydrogenated derivatives of isomeric hydroxydocosahexaenoates. Mass spectra of hydrogenated compounds indicated the presence of hydroxyl groups at carbons 20, 16, 17, 13, 14, 10, 11, 7, 8 and 4. The isomers were apparently racemic mixtures.

GC-MS was used to identify the arachidonate epoxides/diols. The epoxide regioisomers of arachidonic acid as the methyl esters overlapped on nonpolar capillary columns. The isomeric epoxides were identified as their hydrolysis products, the dihydroxyeicosatrienoic (DHET) acids, in the form of the PFB ester derivatives. The four regioisomers were not resolved by GC as PFB, TMS, TBDMS or Me esters. However, after being hydrolysed to the dihydroxyeicosatrienoic acids, three of the four regio-

Figure 9 Polar capillary GC of fatty acid methyl esters and dimethylacetals of human erythrocyte membranes. Peaks are identified by short-hand notation as indicated in figure. GC conditions: column, 100 m \times 0.25 mm i.d., 0.2 μ m deactivated cyanopropylsiloxane (SP 2560, Supelco); temperature, 80°C (hold 2 min) then 8°C min⁻¹ to 220°C and hold for 32 min; carrier gas, helium; split injection 1 : 30. (Reproduced with permission from Alexander LR, Justice JB and Madden J (1985) Fatty acid composition of human erythrocyte membranes by capillary gas chromatography mass spectrometry. *Journal of Chromatography and Biochemical Applications* 342: 1–12.)

isomers were resolved as TMS ethers, PFB esters. The fourth regioisomer, 5,6-DHET, was resolved after being converted to a δ -lactone. The regioisomers of DHET were resolved as the (bis)-TBDMS, PFB esters on a 60 m nonpolar column operated isothermally at 300°C. The 8,9-DHET was followed by 11, 12-DHET, which was followed by 14,15-DHET.

TBDMS ethers have been used for GC-MS separation and identification of synthetic secondary hydroxy fatty acid isomers with carbon chain lengths of 16–20. With the exception of the spontaneous formation of γ - and δ -lactones of C₄-OH and C₅-OH fatty acids, the TBDMS ethers of all hydroxy fatty acid methyl esters in a mixture are readily identified by GC-MS, yielding information on chain length, location of the hydroxyl group and degree of unsaturation. The method has been applied to the identification of a complex mixture of bovine skim milk hydroxy fatty acids, of which 19 were newly identified. The separations were performed on a 30 m column coated with 100% methylsilicone. Hydroperox-

ides are not sufficiently stable for GC analysis. Therefore, the fatty acid ester hydroperoxides are reduced to the corresponding alcohols with triphenylphosphine and transmethylated with sodium methoxide before GC analysis. A 20 m \times 0.32 mm i.d. DB-1 column has been used for GC-MS analysis of linoleate and arachidonate peroxidation products. The hydroxy fatty acid methyl esters were isolated by TLC and converted into TMS ethers. By a combination of normal-phase HPLC and GC-MS, the linoleate oxidation products were identified as 9- and 13-OH derivatives and those arising from arachidonate oxidation as the 5-, 8-, 9-, 12- and 15-hydroxyicosatetraenoates.

Among the free radical catalysed peroxidation products of arachidonic acid, prostaglandin-like compounds named isoprostanes have been recognized which arise independent of the cyclooxygenase enzyme. The evidence has been reviewed for the natural occurrence of these compounds, their mechanism of formation and methods of determination. They have

GC properties similar to those of prostaglandin $F_{2\alpha}$, with which they may be confused. GC-MS has been recently employed for the measurement of plasma isoprostanes.

Prostaglandins The prostaglandins and thromboxanes are cyclo-oxygenase metabolites of arachidonic acid, which are involved in numerous pathophysiological pathways. High resolution GC in combination with mass spectrometry is generally recognized as the most specific and reliable method for qualitative and quantitative analysis of prostanoids. In fact, the use of high resolution GC is mandatory when the stable cyclo-oxygenase metabolites of arachidonic acid have to be analysed as a group. The application of GC-MS techniques to the analysis of prostaglandins and related substances has been reviewed, as well as the application of GC-MS to the analysis of other oxygenated fatty acids. Electron capture GC-MS analysis of the PFB-TMS derivatives has provided the most sensitive method for molecular mass determination. This method, however, does not provide structural information and even low energy collision-induced dissociation (CID) of the carboxylate anions from these derivatives does not yield structurally significant ions.

Figure 10A shows by means of authentic standards that a complete separation of all major metabolites of arachidonic acid via the cyclo-oxygenase pathway can be obtained in a relatively short time (30 min)

using a 30 m capillary column of OV-101-OV-17 (8:2). The selected ion monitoring profiles of the prostaglandins and thromboxanes were obtained with the PFB-MO-TMS derivatives at 220°C with helium as carrier gas. Figure 10B shows a chromatogram of the same substances detected by electron capture. A critical aspect of the application of high resolution GC in routine analyses of prostaglandins is that it requires greater purification of biological material.

Structural Identification

The location of double bonds and other modifications of the fatty chains is required for a complete characterization of the structure of the fatty acids. GC-MS techniques approach this problem by chemical modification prior to analysis.

Double-bond isomers Derivatization at the double bond to oxygenated compounds (carbonyl compounds and vicinal diols) leads to distinctive fragmentation patterns that allow determination of the points of unsaturation or epoxidation but this method leads to the formation of highly polar derivatives and an increase in molecular weight, which makes it unsuitable for the analysis of polyunsaturated fatty acids.

An alternative technique is based on derivatization of the terminal carboxylic group (remote site modification), whereby fatty acids are converted to *N*-acyl

Figure 10 Polar capillary GC and selected ion monitoring (SIM) of authentic prostaglandins and major metabolites of arachidonic acid as PFB-MO-TMS derivatives. (A) SIM; (B) high resolution GC with electron capture detection. Peak identification is given in the figure. GC conditions: column, 30 m × 0.3 mm i.d., dimethylsiloxane/50% phenylmethylsiloxane 8:2 (OV-1/OV-17, Ohio Valley); temperature, 220°C isothermal; carrier gas, helium. (Reproduced with permission from Chiabrando C, Nosedà A and Fanelli R (1982) Separation of prostaglandins and thromboxane B_2 by high resolution gas chromatography coupled to mass spectrometry or electron-capture detection. *Journal of Chromatography* 250: 100–108.)

pyrrolidides or picolinyl (3-hydroxymethylpyridinyl) esters that easily stabilize the ions containing the double bonds or substituents of the fatty chain. The pyrrolidides have been studied most often for the analysis of natural samples, but recently have been overtaken by the picolinyl esters or 4,4-dimethyloxazoline (DMOX) derivatives. Although distinctive modes of fragmentation can be obtained, the interpretation of spectra becomes substantially more difficult if the number of double bonds is greater than four. The picolinyl esters of isomeric unsaturated fatty acids give more abundant diagnostic ions than the pyrrolidides. **Figure 11** shows the capillary GC separations obtained with the picolinyl and pyrrolidide derivatives of pig testis fatty acids on OV-101 and BP-20 liquid phases, respectively. On the nonpolar methylsilicone (OV-101) column, the more unsaturated picolinyl esters emerge ahead of the less unsaturated and saturated fatty acids of the same acyl carbon number. On the polar BP 20, the pyrrolidide derivatives emerge in order of increasing unsaturation. The picolinyl esters require column temperatures about 50°C higher than methyl esters. The picolinyl esters are resolved according to number of double bonds on polar phases of high temperature stability, such as BPX-70 or Supelcowax 10, but

fatty acids of more than 20 acyl carbons may cause difficulty.

It has been shown that the DMOX derivatives of fatty acids are only slightly less volatile than the corresponding methyl esters and that they can be subjected to GC analysis on polar capillary columns to give resolutions based on degree of unsaturation. The GC separation has been carried out with the DMOX derivatives of fatty acids of rat testis and fish oil on a nonpolar methylsilicone (SE-54) column, from which the more unsaturated derivatives emerged ahead of the less unsaturated ones of the same acyl carbon number.

The picolinyl esters and DMOX derivatives can be separated by reversed-phase or argentation HPLC before GC-MS analysis, which is important for the detection of minor components in natural samples. These derivatives have high volatility and their mass spectra show easily recognizable diagnostic peaks for determination of the position of unsaturation. Tables have been prepared of characteristic ions in EI mass spectra of DMOX derivatives of 22 unsaturated fatty acids. The DMOX derivatives have been employed for successful identification of Δ^5 -unsaturated polymethylene-interrupted fatty acids from conifer seed oils. Most analysts now prefer either picolinyl esters

Figure 11 Capillary GC of (A) picolinyl and (B) pyrrolidide derivatives of pig testis fatty acids on nonpolar and polar phases. Peak identification is given in the figure. GC conditions: (A) column, 50 m \times 0.22 mm i.d., methylsilicone (OV-101, Ohio Valley); temperature, programmed from 195°C (hold 3 min) then 1°C min⁻¹ to 235°C; carrier gas, helium; (B) column, 12 m \times 0.22 mm i.d., polyethylene glycol (BP 20, SGE); temperature, programmed from 190°C (hold 3 min) then 1°C min⁻¹ to 230°C; carrier gas, helium. (Reproduced with permission from Christie WW, Brechany EY, Johnson SB and Holman RT (1986) A comparison of pyrrolidide and picolinyl ester derivatives for the identification of fatty acids in natural samples by gas chromatography-mass spectrometry. *Lipids* 21: 657-661.)

or DMOX derivatives for structural studies on fatty acids, but the pyrrolidides also provide informative mass spectra in many instances.

***cis/trans*-Isomers and conjugated acids** Identification of *cis/trans* isomers of unsaturated fatty acids cannot usually be achieved by GC-MS without reference substances. Satisfactory separations of the geometric isomers from margarine fatty acids and 44 synthetic C₁₈ unsaturated fatty acids have been obtained by GC on a 60 m capillary column coated with 100% cyanoethylsilicone (SP-2340). Overlaps occur between different double-bond systems and between some mono- and diethylenic, as well as between di- and triethylenic fatty acids. Because of these overlaps, the isomers cannot be determined by GC alone on the SP-2340 or on any other cyanosilicone phase. Prefractionation by silver ion TLC or HPLC is necessary. The GC separation of the *cis*- and *trans*-acids has been reported in milk samples using a 100 m capillary column coated with bis-cyanopropyl-32% dimethylsiloxane (SP-2560). The authors were able to calculate the total *trans* acid content by adding the relative percentage of all *trans* monounsaturated fatty acids and *cis/trans* linoleate and total conjugate dienes in the milk chromatograms. SP-2560 capillary columns were used to conduct an extensive investigation of the effect of various methods of methylation upon the estimation of the conjugated fatty acid content of bovine milk. Acid-catalysed methods caused extensive isomerization of conjugated dienes and formed allylic methoxy artefacts and are therefore not recommended for this purpose. Base-catalysed methods caused no isomerization of conjugated dienes and the formation of artefacts. GC-Fourier transform infrared-MS (GC/FTIR/MS) has been used to identify fatty acid methyl esters and differentiate between *cis/trans* isomers. In the FTIR spectra *cis/trans* isomers are identified by analysis of bands arising from C-H out-of-plane bending: for both fatty acid methyl esters and DMOX derivatives *cis*-1,2-disubstituted double bonds give a strong band near 720 cm⁻¹ and the corresponding *trans* isomers near 967 cm⁻¹. A greatly improved resolution of individual *trans*-18:1 isomers has been reported by capillary GC on a 100 m cyanopropyl polysiloxane (CP-Sil 88) column.

Epoxides The picolinyl esters are also adequate for the location of epoxide functions in linoleic, arachidonic and docosahexaenoic acids. The electron impact (EI) mass spectra of these derivatives show a molecular ion and a sequence of peaks, with two characteristic abundant ions that result from formal

cleavage of the carbon-carbon bonds at the oxirane ring. Both these ions retain the ester group. This fragmentation pattern allows the unequivocal identification of the separate epoxide isomers. The picolinyl esters of the epoxides are resolved on a 30 m methylsiloxane (DB-1) column, temperature-programmed from 220 to 300°C. These picolinyl esters provide characteristic GC-MS profiles that allow differentiation of the isomeric epoxides at nanogram levels.

Branched-chain and cyclic acids The methyl esters of branched and cyclic fatty acids are usually eluted ahead of their normal-chain counterparts. The methyl branched acids may be confused with straight-chain odd-carbon number isomers. Long (50 m) capillary columns with nonpolar (5% phenylmethylsilicone) stationary phases are preferred and cyclopropane acids are resolved from their monounsaturated counterparts. The position of the methyl branching and cyclopropane ring is not readily determined by GC-MS with EI even after preparation of pyrrolidide and picolinyl derivatives, although exceptions are known. Only small differences are seen among the DMOX derivatives, but they may be sufficient for distinction between close isomers.

It has been shown that low-energy CID of the molecular ions of fatty acid methyl esters obtained by electron ionization (70 eV) in the tandem quadrupole mass spectrometer yield a regular homologous series of carbomethoxy ions. This method can be used to determine methyl (or alkyl) branching positions, as shown by enhanced radical site cleavage at the alkyl branching positions of several methyl esters, including phytanic acid, isomethyl and anteiso-methyl branched acids and tuberculostearic acid. Analyses of various stable isotope variants support the hypothesis of alkyl radical migration to the carboxy carbonyl oxygen atom, with subsequent radical site directed cleavage, either with or without a cyclization event.

GC-MS Analyses of Stable Isotope-Labelled Lipids

In addition to identification of structures, GC-MS also provides the distribution and content of the stable isotope, both natural and enriched. Highly sensitive and reproducible estimates have been obtained for the isotopomer distribution by GC combined with isotope ratio mass spectrometry (isotopomer analysis). Furthermore, the utilization of appropriately labelled isotopic homologues as internal standards for the solute to be measured has greatly improved quantification by GC.

Isotopomer Analyses

Mass isotopomer distribution analysis (MIDA) uses stable isotopes with quantitative mass spectrometry. It is based on the principle that the isotope distribution or labelling pattern of a fatty acid (e.g. palmitic acid) synthesized from an isotopically perturbed monomeric precursor pool conforms to a binominal expansion. The proportion of unlabelled, single-labelled, double-labelled, and so on, molecular species of a fatty acid is a function of the probability that each precursor subunit is isotopically labelled in the fraction of newly synthesized fatty acid present. The advantages and disadvantages of this approach in studies of lipid metabolism have been discussed in the literature. Analogous combinatorial probability methods have long been used to measure endogenous synthesis of fatty acids. The analytical data for the biosynthesis of palmitic acid from [^2H -ethanol], [$^2\text{H}_2\text{O}$] or [^{13}C -acetate], for example, are provided by GC-MS analysis of the palmitic acid methyl ester and the methyl esters of any other fatty acids of interest. In this method every newly synthesized molecule is counted and the total synthesis calculated by summation of the newly formed molecules.

Definitive Methods

One of the major applications of GC-MS is in quantitative analysis with stable isotope dilution and selected ion monitoring. A known amount of a stable isotope-labelled variant of the molecule to be measured is added to the biological sample as an internal standard, followed by extraction, purification and chemical derivatization. The ions specific for the substance and the internal standard are then monitored. The ratio of the two ion abundances provides the quantitative measurement, which is independent of absolute sensitivity. The superiority of this approach has been demonstrated in the quantitative GC-MS analysis of prostaglandin $F_{2\alpha}$ in a biological extract using a deuterated derivative. Examples of this approach are provided by the highly sensitive measurement of thromboxane B_2 (TXB $_2$). Another group based their method on the use of low-blank ($^1\text{H} < 0.2\%$) tetradeuterated 18,18,19,19- $^2\text{H}_4$ TXB $_2$, which they synthesized as the internal standard. After purification and HPLC, the samples were derivatized to give an open chain derivative of TXB $_2$, a PFB-MO-TMS ether derivative, most suitable for negative ion chemical ionization mass spectrometry. In the selected ion monitoring mode, the detection limits per injection for pure standards and biological samples were 10 and 30 pg, respectively. GC was carried out on a 50 m \times 0.25 mm i.d. bonded SE-30 column. An antibody-mediated extraction method

for GC-MS analysis of thromboxane A_2 (TXA $_2$) urinary metabolites has been reported. An antibody (Ab) raised against TXB $_2$ (35% cross-reacting with 2,3-dinor-TXB $_2$) was coupled to CNBr-activated Sepharose 4B (Se) and used as a stationary phase for simultaneous extraction of both compounds from urine. Quantification was performed by GC-negative chemical ionization-MS, monitoring the carboxylate ion. The GC was performed on a 26 m cyanopropyl siloxane (CP-Sil 5CB) column.

The vasoconstrictor and platelet activator TXA $_2$, the predominant product of arachidonic acid in the platelet, is a very reactive substance. It is rapidly converted by nonenzymatic hydrolysis to the stable TXB $_2$. Detailed GC-MS analyses of the PFB-MO-TMS ether derivatives of the thromboxanes and their major metabolites have been described.

GC-MS with selected ion monitoring has been used to demonstrate the global changes in the prostaglandins and thromboxanes in rat circulation after administration of arachidonic acid. **Figure 12** illustrates the measurements of the prostaglandins with multiple deuterium isotope dilution involving separation of pentafluorobenzyl esters, *O*-methyl oximes and TMS ether derivatives by high resolution GC and specific detection by NICI-MS in the selected ion mode. The selected ion monitoring profiles show the detection of reference prostaglandins (d_0 and d_4) and their 15 K and 15 KD metabolites: top chromatogram, total ion current; other chromatograms, selected ion mass chromatograms.

GC-MS-MS analyses

In GC-MS-MS, a specific ion is selected from the initial mass spectrum. The selected parent ion is allowed to enter a field-free reaction region, where it may undergo unimolecular or CID. The resulting fragments are analysed by a second mass spectrometer, which provides the MS-MS spectrum. Although commonly referred to as MS-MS, tandem mass spectrometric analysis is usually MS-CID-MS. The application of GC-MS-MS for the analysis of long chain carboxylic acids and their esters has proved enormously successful.

Conclusion

The complex nature and large number of molecular species with similar physicochemical properties make GC the preferred method of lipid analysis. GC provides the highest resolution and the shortest analysis time compared to other chromatographic techniques. GC with FID is highly sensitive and readily automated. Its applicability is limited by high temperature

Figure 12 GC-negative chemical ionization-MS with selected ion monitoring of reference prostaglandins (D₀ and D₄) and their 15 K and 15 KD metabolites. Peak identification is given in the figure. GC conditions: column, 60 m \times 0.2 i.d., 0.25 μ m methyl silicone (DB-1, J & W); temperature, programmed from 100°C (hold for 2 min) to 280°C at 30°C min⁻¹; carrier gas, hydrogen. (Reproduced with permission from Pace-Asciak, 1987.)

stability and low volatility of the analytes, which may be overcome by enzymic and chemical modification of the samples. With appropriate strategy, automated GC provides a precise tool for the resolution and quantification of lipids ranging from fatty acids to triacylglycerols. Although appropriate GC strategy also provides identification of unknowns in relation

to standards, this must remain tentative unless combined with mass spectrometry. GC-MS of appropriate derivatives of fatty acids provides details of the molecular structure of the fatty acids and their esters. With continued development of liquid phases of increased thermal stability and lipid derivatives of increased volatility and informative mass spectra, GC

and GC-MS is likely to remain the method of choice for analyses of molecular species of most lipid classes for the immediate future.

Introduction

Natural lipids consist of complex mixtures of molecular species, which are found in association with cell membranes, lipoproteins and other subcellular structures. The composition differs among different cell and tissue types, reflecting the function of lipids in these body structures. Much experimental effort and imagination has been expended in determining the exact composition of lipid species during dietary alterations and physiological activity.

The complex nature of natural lipids and their high solubility in organic solvents makes the separation and isolation of individual lipid classes and molecular species by most physical methods difficult or impossible. Only chromatographic methods have proven suitable for this. The earlier thin-layer and gas chromatographic routines have been complemented in recent years by high performance liquid chromatography (HPLC), which has proven to have nearly universal applicability.

Principles of Liquid Chromatography

Normal-phase Columns and Solvents

Normal-phase HPLC provides resolution based on the overall polarity of the lipid molecules. The

stationary phase is typically silica gel. The best column and mobile phase for a specific application are selected by trial and error or based on previous experience using thin-layer chromatography (TLC). More refined solvent selection is based on chemometric methods. The solvents selected for the mobile phase in either isocratic or gradient separations should be excellent lipid solubilizers and should not degrade the stationary phase. Therefore, the addition of buffering salts should be minimized and strong acids should be avoided. Other restrictions on the selection of the mobile phase may be imposed by the choice or availability of the detection system, e.g. ultraviolet (UV) and refractive index (RI) detectors.

Silver ion HPLC provides resolutions based on the number, position and configuration of the double bonds present in the lipid molecule. It complements other methods of separation. For this purpose silica gel columns are impregnated with silver nitrate or silver ions are immobilized on columns containing benzenesulfonic acid groups. Chlorinated solvents as the mobile phase, with acetone or acetonitrile as a polar modifier, afford especially good separations.

Reversed-phase Columns and Solvents

Reversed-phase HPLC is believed to separate lipid molecules based on their partition properties in a biphasic liquid-liquid system, although the exact mechanism is unknown. The most widely used and most important reversed phases for lipid analysis are silicas with relatively long hydrocarbon chains chemically bonded to the surface. Octyl- and octadecyl-bonded chains have been found to provide the best resolution of fatty acids and triacylglycerols.

Chiral-phase Columns and Solvents

HPLC on columns containing a stationary phase with chiral moieties bonded chemically to a silica matrix has proven well suited for the resolution of chiral glycerolipids. The approach has been to prepare 3,5-dinitrophenyl urethane (DNPU) derivatives of mono- and diacyl-*sn*-glycerols and related compounds, where the hydrogen atom on nitrogen in the urethane group is available for hydrogen bonding with the stationary phase. The 3,5-dinitrophenyl moieties of the urethanes contribute to charge-transfer interactions with functional groups having π electrons on the stationary phase; they are also advantageous for detection by UV absorption. A column with a polymer of (*R*)-(+)-1-(1-naphthyl)ethylamine moieties chemically bonded to silica gel (YMC-Pack A-KO3TM) has been applied to the resolution of diacyl-*sn*-glycerol

derivatives in a similar manner. The best solvents so far have been the hexane/dichloromethane/ethanol mixtures, which, for the purpose of online mass spectrometry, have been replaced by mixtures of hexane/dichloroethane/acetonitrile or isooctane/*tert*-butyl methyl ether/acetonitrile/isopropanol.

There are no foolproof recommendations for the selection of solvents. Previous success appears to be the best guide. However, the polarity of the solvents must be chosen so as not to destroy the hydrogen bonding responsible for the differential affinity between the enantiomers and the stationary phase.

Detectors and Quantification of Solutes

In early work, RI detectors were used in normal-phase HPLC. However, this detector is only applicable to isocratic elution, because RI detection is very sensitive to change in solvent composition. Short wavelength UV (205–210 nm) is also frequently employed for lipid detection but again suffers from sensitivity towards changes in solvent composition. However, UV absorption at longer wavelengths can be effectively used for the specific detection of UV-absorbing solutes. Furthermore, lipids with functional groups can be converted into UV-absorbing or fluorescing derivatives (e.g. free fatty acids, aminophospholipids), which have been widely exploited in reversed-phase HPLC. Many of these derivatives are sufficiently sensitive to permit detection of femtomole levels of the solute (see below).

In HPLC with flame ionization detection (FID), the analyte after solvent removal is burned in a flame and the ions formed are collected by applying an electric field. This nearly universal detector yields a linear relationship between the mass of the solute and peak area over a wide concentration range. More recently, the evaporative light-scattering detector (ELSD) has become the detector of choice in most analytical lipid separations. Like the FID, it is destructive, and must be employed with a stream splitter for peak collection.

It is generally agreed that all detectors require preliminary calibration with reference species to examine the response-structure relationship, and to determine the character of the calibration graph constructed in response-quantity dimensions to be able to work in the linear range. In principle, the quantification is based on measurements of peak area, normalization of the values and calculation of the relative percentage of each component.

Another detector for HPLC of universal application is provided by the mass spectrometer using a variety of ionization techniques to generate total or single ion current response. The use of this detector is

discussed along with the use of online mass spectrometry for peak identification (see below).

Liquid Chromatography–Mass Spectrometry/(LC-MS)

LC-MS

Online mass spectrometry allows one to obtain direct evidence about the nature of chromatographic peak, e.g. purity, molecular weight and characteristic fragment ions. This information, together with the knowledge of the relative retention time, is usually sufficient for peak identification. More complete identification may be obtained by MS-MS, which is based on the specific mass spectrometric fragmentation of primary ions. Recent reviews of LC-MS applications to lipid analyses are available (see Kuksis and Myher, 1995 and Kuksis, 1997 in Further Reading, below).

The online LC-MS analysis of lipids is accomplished using interfaces which eliminate the HPLC solvent and effect a reliable and efficient transfer of the solute to the ion source. An early method of interfacing HPLC and a mass spectrometer utilized a direct liquid inlet. Several successful applications to lipid analyses with chemical ionization mode were reported. In the positive ion mode, this method produced mass spectra similar to those recorded in electron impact mass spectrometry. Thus, for a triacylglycerol species, a pseudomolecular ion along with characteristic diacylglycerol-like ions were obtained. These ions are frequently sufficient to identify the molecular weight and degree of unsaturation of the component fatty acids. Furthermore, the regiodistribution of the fatty acids in acylglycerols can also be obtained by this ionization method. More recently, the softer ionization techniques, thermospray (TS), electrospray (ES) and atmospheric pressure chemical ionization (APCI) have been utilized for online monitoring of triacylglycerols resolved by HPLC. The latter techniques also allow direct LC-MS of the molecular species of intact glycerophospholipids, which yield largely or exclusively the pseudomolecular ions $[M + 1]^+$ and $[M - 1]^-$ respectively in the positive and negative ionization modes. This information is sufficient for tentative identification of molecular species when combined with knowledge of HPLC retention times and the overall composition of the fatty acids.

LC-MS-MS

Simple LC-MS is not sufficient to establish the exact composition of all molecular species, which requires the identification of the component fatty acids

in each parent acylglycerol molecule. The fast atom bombardment (FAB) and especially the ES ionization techniques are compatible with LC-MS-MS approaches and have been extensively utilized in polar lipid analysis. In many instances, flow ES-MS-MS has also proven adequate for identification of molecular species.

Pseudo MS-MS

LC-ES-MS ionization can be used to produce collision-induced dissociation (CID) spectra of singly charged species with greater sensitivity than can be achieved with flow ES-MS-MS systems. The HPLC effluent is carried into the ES source via a stainless-steel or fixed silica needle at flow rates of 1–40 $\mu\text{L min}^{-1}$. When analytes are present in the sprayed solution, molecular adduct ions from these analytes, typically protonated ions $[M + H]^+$, are formed. If a low voltage of 50–120 V is applied to the capillary exit, the molecular ion remains intact and the molecular weight of the analyte is obtained. If higher voltages are applied (e.g. 200–300 V) to the capillary exit, extensive and reproducible fragmentation of the molecular adduct ion is realized (pseudo MS-MS).

Isolation of Natural Lipids

In order to determine the composition of the lipid phase associated with a particular function it is necessary to isolate the appropriate subcellular structure and to determine the component lipid classes and molecular species. For the purpose of discussion the analyses are considered separately as those of neutral lipids, glycerophospholipids and sphingolipids, including glycosphingolipids.

Preparation of Lipid Extracts

The neutral lipids can be extracted from natural sources by means of benzene, chloroform and other non-polar solvents. More complete lipid isolation is obtained by extraction with more polar solvents, such as mixtures of chloroform and methanol. However, use of chloroform/methanol results in low recoveries of acidic phospholipids, lysophospholipids and non-esterified fatty acids, while acidified solvents generate lysophospholipid artefacts from tissues containing plasmalogens.

Purification and Preliminary Separation

Recently, organic solvent extraction has been replaced by solid-phase extraction. It is a simple, rapid technique and can be up to 12 times faster than liquid extraction when executed with commercially

Table 1 Separation scheme for fractionation of lipid classes from wheat flour using combined silica and aminopropyl solid-phase extraction columns

prepared cartridges. These cartridges have proven adequate for rapid removal of nonlipid components from total lipid extracts and for preliminary separation of both neutral and polar lipid classes. For this purpose, the cartridges are eluted by passing through them measured volumes of solvents of appropriate polarity. **Table 1** summarizes a separation scheme successfully applied to the fractionation of lipid classes from wheat flour that is also applicable to the resolution of most lipid classes from animal tissues. A major disadvantage of the solid-phase method is the difficulty of monitoring the separations, so that TLC must be frequently used to assess the results of such isolations.

The currently available techniques concerning extraction and characterization of the different lipids from biological specimens are designed for particular families and do not address consecutive isolation of lipid constituents in their totality. It must be pointed out that conventional TLC remains a convenient, rapid and reliable technique for lipid class isolation which permits efficient extraction of lipid components including gangliosides, without preferential loss of any one group and without the

uncertainty of working blindly. The protocol is applicable to biological samples of limited availability.

Derivatization

In order to improve resolution, detection and recovery, natural lipids may be subjected to derivatization prior to HPLC. Since neutral lipids are more readily resolved than polar lipids, the polar functional groups of natural lipids may be removed or masked prior to separation. Thus, the phospholipids may be subjected to dephosphorylation by phospholipase C and the resulting diradylglycerols silylated, acetylated or benzoated before normal-phase or reversed-phase HPLC. This procedure allows improved resolution of the diradylglycerol classes by normal-phase HPLC and of molecular species by reversed-phase HPLC. The preparation of the benzoates also improves the UV detection of the molecular species by reversed-phase HPLC. The preparation of the benzoates also improves the UV detection of the molecular species, while a preparation of the pentafluorobenzoates improves the sensitivity of mass spectrometric detection of the lipid classes and molecular species. The diacylglycerols generated randomly from natural triacyl-

glycerols by Grignard degradation may be converted into the naphthylethyl urethane derivatives by an enantiomeric reagent prior to normal-phase separation of the resulting diastereomers. Using another approach to stereospecific analysis of triacylglycerols, the racemic diacylglycerols resulting from the Grignard degradation are converted into the dinitrophenyl urethanes of the diacylglycerols prior to separation of the enantiomers. In other instances, free fatty acids, free acylglycerols and aminophospholipids may be converted into UV-absorbing or fluorescent derivatives prior to reversed-phase HPLC. The total lipid extracts or any fraction of them may be hydrogenated, reduced with borohydride, peroxidized or ozonized prior to HPLC to provide reference materials or to improve the chromatographic behaviour of the solutes.

Separation of Neutral Lipids and Free Fatty Acids

Neutral lipids and free fatty acids are made up of monoacylglycerols, diacylglycerols, triacylglycerols, unesterified and esterified sterols, unesterified fatty acids and various other minor components of natural lipids, which migrate with neutral lipids just listed, e.g. tocopherols, alcohols, hydrocarbons, ketones, aldehydes and simple esters. This definition also includes neutral lipids derived from polar lipids by enzymic or chemical transformation (e.g. acylglycerols and ceramides), as well as the peroxidation products of lipids and prostanoids. These lipids possess excellent chromatographic properties.

Normal-phase Separations

Total lipid profiling on adsorption columns was practised in various forms long before the existence of any other comparable method. Reproducibility and quantification were the major problems which have now been resolved by the combination of HPLC and light scattering or mass spectrometric detection. **Figure 1** shows the separation of selected neutral and polar lipid standards and rat liver lipids by automated normal-phase HPLC using a light-scattering detector. Both neutral and phospholipid classes are well separated and this approach is suitable for use with ES-MS. Normal-phase HPLC is also well suited for the separation of natural and peroxidized fatty acid esters. **Figure 2** shows the separation of a mixture of standard oxosterols along with various other mixtures of oxosterols. The peaks were detected by UV at 205 nm.

Normal-phase HPLC can be employed for separation of the diastereomeric diacylglycerol naph-

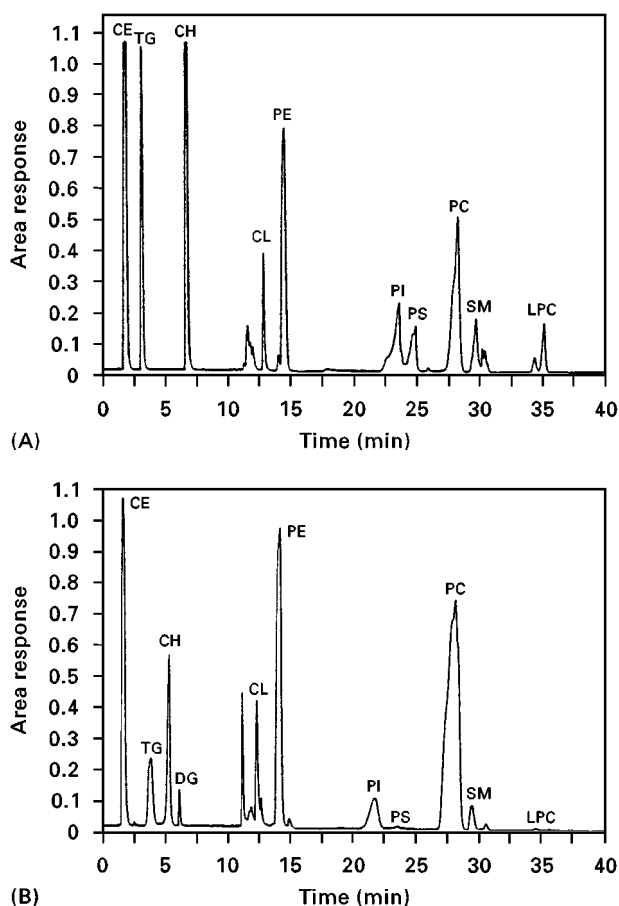

Figure 1 Separation of (A) standard and (B) rat liver lipids by automated normal-phase HPLC with light-scattering detection. Peak identification: CE, cholesteryl esters; TG, triacylglycerols; CH, unesterified cholesterol; DG, diacylglycerols; CL, cardiolipin; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PS, phosphatidylserine; PC, phosphatidylcholine; SM, sphingomyelin; LPC, lysophosphatidyl choline. HPLC conditions: column, 5 μ m Ultrasphere Si (25 cm \times 4.5 mm); solvent, a binary gradient of three different solvent mixtures made up of hexane/tetrahydrofuran (99 : 1, v/v), isopropanol/chloroform (4 : 1, v/v) and isopropanol/water (1 : 1, v/v). (Reprinted with permission from Redden and Huang, 1991.)

thylethyl urethanes for the purpose of stereospecific analysis of the positional distribution of the fatty acids in natural triacylglycerols. **Figure 3** shows the separation of the diastereomeric diacylglycerols as the naphthylethyl urethanes. The *sn*-1,2- and *sn*-2,3-enantiomers are resolved with the elution order depending on the *S*- or *R*-configuration of the reagent. The diastereomeric naphthylethyl urethanes are prepared by reacting the free *sn*-1,2(2,3)-diacylglycerols with either the *S*- or *R*-isocyanate. The partial overlap between molecular species of enantiomeric diacylglycerols from natural sources does not compromise the identification and quantification of the species by ES-LC-MS.

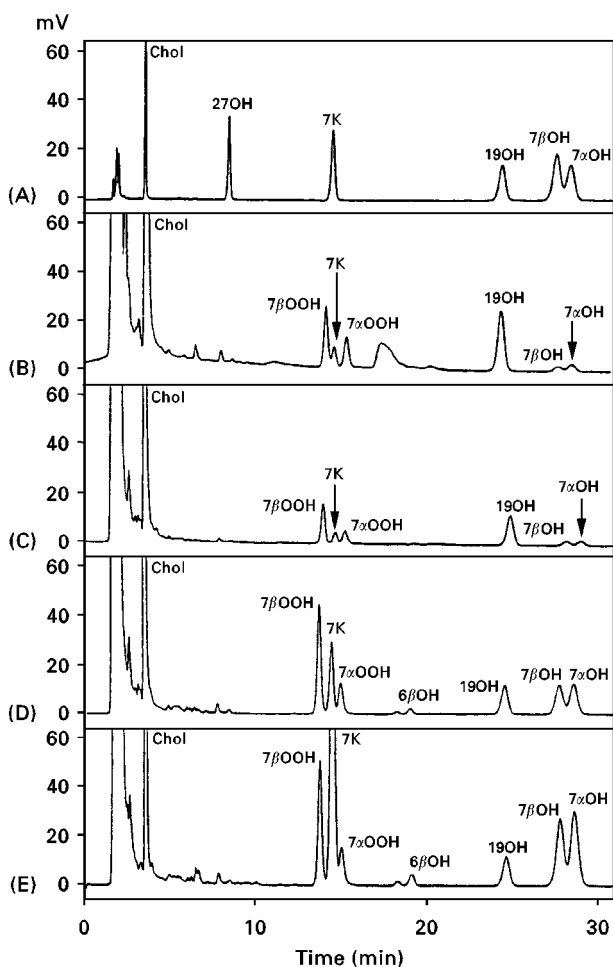

Figure 2 Normal-phase HPLC of (A) standard oxosterols and (B–E) oxidation products of cholesterol. B, Liposomal cholesterol oxidized with azoamidopropane at 37°C for 20 h; C–E, LDL cholesterol oxidized with Cu^{2+} for 4 h, 8 h and 24 h, respectively. Peak identification: Chol, cholesterol; 27OH, 27-hydroxycholesterol; 7K, 7-ketocholesterol; 19OH, 19-hydroxycholesterol (internal standard); 7βOH, 7β-hydroxycholesterol; 7αOH, 7α-hydroxycholesterol; 7βOOH, 7β-hydroperoxycholesterol; 7αOOH, 7α-hydroperoxycholesterol; 6βOH, 6β-hydroxycholesterol. HPLC conditions: two columns, 3 μm Ultramex (10 × 0.46 cm) in series with a 3 cm guard column; solvent, hexane/isopropanol/acetonitrile (95.8 : 3.90 : 0.30, by vol) at 1.5 mL min⁻¹. (Reprinted with permission from Brown AJ, Leong S-L, Dean RT and Jessup W (1997) 7-Hydroperoxycholesterol and its products in oxidized low density lipoprotein and human atherosclerotic plaque. *Journal of Lipid Research* 38: 1730–1745.)

Normal-phase HPLC is used for the separation of the leukotriene B₄ (LTB₄) metabolites, with a mobile phase consisting of hexane/isopropanol/acetic acid (96 : 4 : 0.1 by vol; **Figure 4**). The retention times of these compounds are closely related to their polarities, with LTB₄ having the longest and 10,11-dihydro-12-oxo-LTB₄ the shortest time. The 12-oxo-LTB₄ and 10,11-dihydro-LTB₄ have similar retention

times but can be distinguished from each other by their UV spectra. Normal-phase HPLC also separates the hydroxyeicosatetraenes (HETEs) and oxo-eicosatetraenes (oxo-ETEs) with a mobile phase of hexane/isopropanol/acetic acid (90.05 : 0.45 : 0.5 by vol), as shown in the same figure. As expected from its polarity, 15-oxo-ETE had a retention time considerably shorter than that of 15-HETE. The retention time of 12-oxo-ETE is also shorter than that of 12-HETE, but only marginally so.

Normal-phase HPLC on columns containing immobilized silver ions has been used for the fractionation of simple fatty acid esters and triacylglycerols according to the number and configuration of double bonds. **Figure 5** shows an Ag^+ -HPLC separation of a commercial mixture of conjugated linoleic acids (CLA). Using 0.1% acetonitrile in hexane, 12 peaks were obtained, which emerged into three groups of four peaks each. Evidence for the identity of the individual isomers was obtained by comparison with standards and by complementary chromatographic and MS techniques.

Reversed-phase Separations

Figure 6 shows the separation of the molecular species of randomized butterfat by reversed-phase HPLC with light-scattering detection. Butterfat constitutes one of the most difficult mixtures for any chromatographic separation. The analysis of a randomized sample has the advantage that all the

Figure 3 Normal-phase HPLC separation of 1,2- and 2,3-diacyl-*sn*-glycerols in the form of 1-(1-naphthyl)ethyl urethane derivatives. S: (S)-(+)-1-(1-naphthyl)ethyl urethanes; R: (R)-(1)-1-(1-naphthyl)ethyl urethanes. HPLC conditions: two columns, 3 μm Hypersil™ (250 × 4.6 mm i.d.) in series; solvents: hexane/isopropanol (99.5 : 0.5, v/v) at 0.8 mL min⁻¹ and UV detection at 280 nm. Figure 4 Normal-phase HPLC resolution of (A) LTB_4 , 12-oxo- LTB_4 (12o- B_4), 6-*trans*-12-oxo- LTB_4 (6t-12o), 10,11-dihydro- LTB_4 (dh- B_4), 12-oxo-10,11-dihydro- LTB_4 (12o-dh- B_4) and 12-epi-10,11-dihydro- LTB_4 (12e-dh- B_4) with hexane/isopropanol/acetic acid (96:4:0.1, v/v) and (B) HETEs and oxo-ETEs with hexane/isopropanol/acetic acid (99.05/0.45/0.5, v/v) as the mobile phase. The inset shows the normal-phase HPLC separation of 5-oxo-EETe and 5-HETE using a stronger mobile phase (hexane/isopropanol/acetic acid, 97.2:2:0.1, v/v). (Reproduced with permission from Powell *et al.* (1997) High-pressure liquid chromatography of oxo-eicosanoids derived from arachidonic acid. *Journal of Biochemistry* 247: 17–24.)

molecular species can be calculated on the basis of random distribution and sorted by number of acyl carbons and double bonds. Although there is nearly complete separation of the various triacylglycerol subclasses, numerous molecular species overlap. It is therefore necessary to employ MS to distinguish among the molecular species within each chromatographic peak. There is no resolution of enantiomers or regio-isomers.

Reversed-phase HPLC provides impressive separation of the complex fish oil triacylglycerols using either light-scattering or MS detection. Figure 7 shows the separation of a triacylglycerol mixture containing 43% docosahexaenoic acid by LC-ESI-MS. Some 33 major components are detected. An examination of the ions generated from each triacylglycerol peak revealed the presence of both

molecular and diacylglycerol-like fragment ions from which the triacylglycerol composition of each peak was determined. Figure 7B and 7C illustrates the identification of peaks 20 and 26 in the chromatographic profile. This extremely powerful method allows identification of species that have the same elution times but different elution times.

The triacylglycerol structures in the HPLC effluent can be determined by atmospheric pressure chemical ionization (APCI) using a corona discharge to ionize vaporized molecules to form both molecular and diacylglycerol-like fragment ions. Figure 8 compares the elution patterns recorded for a mixture of 35 triacylglycerols by reversed-phase HPLC with FID or APCI detection. Although different gradients of acetonitrile and dichloromethane were used in the two systems, the chromatographic patterns are similar.

Figure 9 relates the retention times of various synthetic oxotriacylglycerols to their theoretical carbon numbers used to aid identification of peroxidized

Figure 5 Silver ion HPLC of a commercial conjugated linoleic acid standard. Peak identification is as given in figure: CLA, conjugated linoleic acid. Figure 6 Reversed-phase HPLC elution profile of randomized butterfat triacylglycerols as monitored by light-scattering detection. Peak identification is given in the figure on the basis of total acyl carbon:double bond number. HPLC conditions: column, 5 μ m Supelcosil C₁₈ (250 \times 4.6 mm i.d.) solvent gradient: 10–90% isopropanol in acetonitrile in 90 min. (Reproduced with permission from Marai *et al.*, 1994.)

natural triacylglycerols by reversed-phase HPLC with ES-MS. The theoretical carbon numbers and correction factors for the oxidized and unsaturated triacylglycerols were calculated using the curve for the saturated triacylglycerols as a reference.

Tocopherols exist in nature as a complex mixture of 2-methyl-6-chromanol homologues and aromatic ring position isomers, each having a three-terpene-unit side chain at the C-2-position. These components of closely related structures can be separated by normal-phase HPLC on silica-based columns. However, the most extensive separations have been obtained by reversed-phase HPLC on a column of octadecyl polyvinyl alcohol sorbent. **Figure 10** shows the separation obtained for the α -, β -, γ -, δ - and ϵ_2 -tocopherols on such a column with acetonitrile/water or methanol/water as the mobile phase.

Cholesterol, sitosterol and their metabolic precursors are also separated by reversed-phase HPLC. Conversion to UV-absorbing derivatives greatly facilitates their detection and quantification. Likewise, reversed-phase HPLC is suitable for the separation of cholesteryl esters. **Figure 11** demonstrates the separation of the cholesteryl esters in a lipid extract from cholesterol-loaded J774 macrophages showing esters ranging from eicosapentaenoate (docosahexaenoate) of cholesterol to stearate in order of their partition number. There are several minor peak overlaps. Normally, the cholesteryl esters in a total lipid extract would overlap with the triacylglycerols

also present in the mixture. This problem can be solved by a mild alkaline hydrolysis, which destroys the triacylglycerols without affecting the cholesteryl esters.

Similarly, reversed-phase HPLC can be employed for the separation of retinyl esters. **Figure 12** illustrates the separation of 15 synthetic retinyl esters with minimal overlap, except for retinyl linolenate, laurate and arachidonate, which are unlikely to occur together in a natural mixture.

Reversed-phase HPLC has been most extensively employed for the separation of the molecular species of diacylglycerols derived from glycerophospholipids by hydrolysis with phospholipase C and from triacylglycerols by hydrolysis with lipase or Grignard degradation. Both UV-absorbing and fluorescent derivatives are prepared to facilitate detection and quantification (**Table 2**). Reversed-phase HPLC is also excellent for the separation of the molecular species of the diacylglycerol DNPU derivatives recovered from chiral HPLC.

Finally, reversed-phase HPLC is suitable for the separation of fatty acids as UV-absorbing or fluorescent derivatives (**Table 3**) and may rival gas chromatography for specific applications. Thus, excellent separation and sensitive detection of the 9-anthrylmethyl esters and the 1-pyrenyldiazomethane derivatives of free fatty acids has been obtained (**Figure 13**). The method has been applied to the determination of endogenous fatty acids released from a cell culture upon stimulation.

Figure 7 Reversed-phase HPLC of docosahexaenoic acid-rich oil with online ESI/MS. (A) Total positive ion current profile; (B) ESI-CID-MS of peak 20 (14 : 0/16 : 0/22 : 6): m/z 868, $[M + 18]^+$; m/z 873, $[M + 23]^+$; m/z 523, $[M\text{-RCOO}]^+$ (30 : 0 DG); m/z 595, $[M\text{-RCOO}]^+$ (36 : 6); m/z 623, $[M\text{-RCOO}]^+$ (38 : 6 DG); (C) ESI-CID-MS of peak 26 (14 : 0/14 : 0/18 : 1; 14 : 0/16 : 0/16 : 1): m/z 794, $[M + 18]^+$; m/z 799, $[M + 23]^+$; m/z 495, $[M\text{-RCOO}]^+$ (28 : 0 DG); m/z 521, $[M\text{-RCOO}]^+$ (30 : 1 DG); m/z 549, $[M\text{-RCOO}]^+$ (32 : 1 DG); m/z 577, $[M\text{-RCOO}]^+$ (34 : 1 DG). HPLC conditions: column, 5 μm Supelcosil LC-18 (250 \times 4.6 mm i.d.); solvent, linear gradient of 20–80% isopropanol in acetonitrile in 30 min; ESI-CID-MS conditions, capillary exit voltage 215 V. (Reproduced with permission from Myher *et al.*, 1997.)

Chiral-phase HPLC

Chiral HPLC permits the separation of enantiomeric diacylglycerols derived from Grignard degradation or lipase hydrolysis. **Figure 14** shows the separation of the *sn*-1,2(2,3)-diacylglycerols derived from Grignard degradation of a complex triacylglycerol mixture containing 43% docosahexaenoic acid; there is excellent separation of the enantiomers. With this chiral phase, the *sn*-2,3-enantiomers emerge last. There is considerable resolution of molecular species, especially within the longer-retained *sn*-2,3-enantiomers. The X-1,3-isomers not removed by borate TLC

emerge just ahead of, or overlap with, the *sn*-1,2-enantiomers. A chiral-phase LC-MS analysis of the 3,5-DNPU derivatives of the *sn*-1,2- and *sn*-2,3-diacylglycerols revealed the presence of a high proportion of species containing two long chain fatty acids per acylglycerol molecule, including 20 : 2–20 : 4 and 22 : 6–22 : 6.

Separation of Glycerophospholipids and Sphingomyelins

HPLC analysis of glycerophospholipids and sphingomyelins is usually performed with the total phos-

Figure 8 Reversed-phase HPLC separation of synthetic mixture of 36 triacylglycerols containing five randomly distributed fatty acids. Peaks are identified by component fatty acids: Ln, linolenic; L, linoleic; O, oleic; P, palmitic; S, stearic. HPLC conditions: column, 5 μ m Adsorbosphere C₁₈ (250 \times 4.6 mm, i.d.) in series with 10 μ m Adsorbosphere UHS C₁₈ (250 \times 4.6 mm); solvent, linear gradient of acetonitrile/dichloromethane 70 : 30 to 40 : 60, by vol, over 120 min; detector, FID. APCI conditions: initial acetonitrile/dichloromethane 65 : 35, v/v, followed by a 20–25 min linear gradient acetonitrile/dichloromethane 60 : 40, v/v, and held until 85 min. (Reproduced with permission from Byrdwell WC, Emken EA, Neff WE and Adlof RO (1996) Quantitative analysis of triglycerides using atmospheric pressure chemical ionization-mass-spectrometry. *Lipids* 31: 919–935.)

pholipid fraction recovered from the preliminary isolation of the lipid classes, unless it already involved the separation of the individual phospholipid classes. The purified phospholipid classes can be separated further into molecular species by HPLC using the original molecules or their enzymatic or chemical transformation products.

Normal-phase HPLC

Normal-phase HPLC is well suited for the separation of the phospholipids. Various silica gel columns yield excellent separations of the major phospholipid classes which, in many instances, also provide a readily discernible separation of the minor components.

Figure 9 Plot of theoretical carbon numbers (TCN) versus retention times of reference oxo-triacylglycerols along with a series of saturated monoacid triacylglycerols. TCN and correction factors were calculated for oxotriacylglycerols and unsaturated triacylglycerols using the saturated triacylglycerols as a reference curve. (Reproduced with permission from Sjovald O *et al.*, 1997.)

Figure 15 shows the separation obtained with a silica gel column for the ethanolamine, choline, inositol and glycerol glycerophospholipids and sphingomyelin isolated from a subfraction of human high density lipoprotein preparation with online MS detection. In the positive ion mode only the choline-containing phospholipids are readily detected, although the ethanolamine glycerophospholipids can also be seen at low intensity. The acidic glycerol, inositol and serine phosphatides, along with any ethanolamine phospholipids, are best detected in the negative ion mode. The negative ion mode also registers the choline phospholipids as the chloride adducts. There is a complete baseline separation for all phospholipids without significant resolution of molecular species, except for SM, which is separated into long chain and short chain species.

Normal-phase HPLC with online MS can be used to assess the molecular species present in

the individual phospholipid classes. It is possible to obtain single ion chromatograms retrieved from the total positive ion current spectra for the major molecular species of the choline and ethanolamine phosphatides. In this normal-phase system the newly identified glycosylated diradylglycerophosphoethanolamine migrates with the front of the phosphatidylcholine peak. The single ion chromatograms retrieved by the computer from the total negative ion current permit accurate quantification of the major molecular species of the acidic glycerophospholipids.

Normal-phase HPLC can be used for the separation of the alkylacyl, alkenylacyl and diacyl subclasses of the ethanolamine glycerophospholipids as the trinitrophenyl derivatives. The diradyl subclasses of the choline glycerophospholipids cannot be separated by chromatography of the intact parent molecules. For this purpose, diradylglycerophosphocholines must be dephosphorylated and the re-

Figure 10 Reversed-phase HPLC separation of tocopherols. HPLC conditions: columns (A and B), 5 μm Asahipak containing octadecyl polyvinyl alcohol phase; column C, 5 μm Phenomenex Curosil-PFP phase (250 \times 4.6 mm i.d.); solvents: (A) acetonitrile/water (85 : 15, v/v); (B and C) methanol/water (87.5 : 12.5, by vol). (Reproduced with permission from Abidi and Mounts, 1997.)

sulting diradylglycerols converted into UV-absorbing or fluorescent derivatives (Table 2) prior to HPLC separation unless an ELSD system is used. The molecular species separation of the diradylglycerols is carried out by reversed-phase HPLC, as described for the diacylglycerols derived from triacylglycerols by Grignard degradation.

Reversed-phase HPLC

The total phospholipid mixture can also be separated on a reversed-phase column. Although this leads to extensive separation of the molecular species, there is little overlap among the different phospholipid classes. Both phospholipid classes and molecular species are readily identified and quantitated by online MS with ES ionization. Using 0.5% ammonium hydroxide in a water/methanol/hexane mixture on a C_{18} column, complex mixtures of phospholipid

classes and molecular species were identified mainly as protonated or natriated molecules.

The molecular species of the underivatized phospholipids can be separated by reversed-phase HPLC with a mixture of organic solvents and a counterion. The molecular species of intact aminophospholipids have previously been resolved as the UV-absorbing trinitrophenyl derivatives. The reversed-phase systems are also capable of separating the hydroxylated and hydroperoxidized glycerophospholipids from their unoxidized parent species.

Chiral-phase HPLC

The stereochemical configuration of phosphatidylglycerols has been assessed with chiral phases. Although natural phosphatidylglycerols possess two chiral carbons and are diastereoisomers, they are not readily separable by normal-phase columns. However, the bis-3,5-dinitrophenylurethanes can be separated by chiral-phase HPLC (Figure 16). The molecular species of all synthetic phosphatidylglycerol derivatives examined can be separated into diastereomeric peaks in a short time using a mobile phase of hexane/dichloromethane/methanol containing a small amount of trifluoroacetic acid.

Separation of Sphingolipids and Gangliosides

The neutral glycosphingolipids or cerebrosides are ceramide monohexosides, lactosides and higher sugar glycosides. The great complexity and number of new glycosphingolipid components being reported challenge the best contemporary methods of characterization. These lipids have been frequently investigated by FAB, chemical ionization and electron ionization MS with prior chromatographic separation. Likewise, the sulfatides and the sialic acid-containing glycosphingolipids (gangliosides) have been separated by HPLC prior to MS.

Normal-phase HPLC

A highly sensitive analytical method that allows the separation of ganglioside mixtures and quantification of individual nonderivatized gangliosides has been reported using Spherisorb- NH_2 . Gangliosides in the 2 pmol to 1 nmol range are separated on a 1 mm i.d. column with a gradient of acetonitrile/phosphate buffer. Figure 17 shows the resolution of standard gangliosides and gangliosides from the serum of a healthy human female and from human oligodendroglioma. Complete separations are obtained for GM3, GM2, GM1, GD3, GD1a, GD1b, GT1b and GQ1b. The

Figure 11 Reversed-phase HPLC of cholesteryl esters isolated from macrophages by lipid extraction and treatment of the extract with a dilute solution of ethanolic potassium hydroxide. Peak identification is given in the figure. HPLC conditions: column, 3 μm Spherisorb ODS2 (250 \times 4 mm, i.d.); isocratic solvent, isopropanol/heptane/acetonitrile (35/12/52, by volume) and detected by UV absorption at 206 nm. (Reproduced with permission from Cullen P, Fobker M, Teglkamp K *et al.* (1997). An improved method for quantification of cholesterol and cholesteryl esters in human monocyte-derived macrophages by high performance liquid chromatography with identification of unassigned cholesteryl ester species by means of secondary ion mass spectrometry. *Journal of Lipid Research* 38: 401–409.)

new method of separation bypasses the earlier difficulties regarding baseline stability of the 195 nm absorption by using a high purity phosphate buffer.

Other workers have employed both FAB-MS and ES-MS to characterize monosialogangliosides of human myelogenous leukaemia HL60 cells and normal human leukocytes. The gangliosides were extracted and subjected to extensive segregation and examina-

tion of the selectin-binding ability of each fraction. Fractions were resolved on an Iatrobed column pre-equilibrated with isopropyl alcohol/hexane/water (55:40:5) and subjected to a linear gradient of isopropyl alcohol/hexane/water 55:40:5 to 55:25:20 with a flow rate of 1 mL min⁻¹. They were also reanalysed on a semipreparative Iatrobed column with a linear gradient of isopropyl alcohol/hexane/water 55:40:5 to 55:25:20 over

Figure 12 Reversed-phase HPLC of retinyl esters. Peak identification: 1, acetate; 2, caprate; 3, linolenate; 4, laurate; 5, arachidonate; 6/7, palmitoleate/linoleate; 8, myristate; 9, pentadecanoate; 10, oleate; 11, palmitate; 12, heptadecanoate; 13, stearate; 14, arachidate; 15, behenate. HPLC conditions: column, 5 μm Suplex pKb 100 (250 \times 4.6 mm) with a 20 mm guard column; solvent, isocratic elution (14 min) with solvent A (acetonitrile/methanol/dichloromethane/hexane, 88 : 4 : 4 : 4, by volume) at 1 mL min^{-1} followed by a linear gradient of 100% B (acetonitrile/methanol/dichloromethane/hexane, 70 : 10 : 10 : 10, by volume) over a 2 min period; isocratic elution with the final solvent composition continued for 14 min at 1.5 mL min^{-1} . Detection was at 325 nm. (Reproduced with permission from Wingerath T, Kirsch D, Spengler B *et al.* (1997) High performance liquid chromatography and laser desorption/ionization mass spectrometry of retinyl esters. *Analytical Chemistry* 69: 3855–3860.)

200 min with a flow rate of 0.5 mL min^{-1} . The final fractions from the normal-phase HPLC were analysed by TLC and the pure components subjected to negative and positive ion FAB-MS.

Reversed-phase HPLC

Of the sphingolipids, the ceramides, cerebrosides and sphingomyelins have been most extensively studied by reversed-phase HPLC. Sphingomyelins obtained from bovine brain, chicken egg yolk and bovine milk fat were separated using a binary solvent system consisting of *n*-butanol/water isopropanol/isooctane on a C_{18} column. The positive ion mass spectra exhibit prominent ions related to the amine base structure and fragments which can be utilized for identification of molecular species.

Introduction

Thin-layer chromatography (TLC) is widely used for the separation and identification of lipid classes with silica gel as the most frequently used stationary phase. Numerous mobile phases (solvent systems) are avail-

able for the separation of lipids and there are many nonspecific and specific detection reagents (visualization reagents) that are useful for detection.

There is no consensus as to the definition of a lipid. Kates considers lipids as compounds generally insoluble in water but soluble in a variety of organic solvents. He recognized the following classes of lipids: hydrocarbons, alcohols, aldehydes, fatty acids and derivatives such as glycerides, wax esters, phospholipids, glycolipids and sulfolipids. Gunstone and

Table 1 Lipids frequently separated by TLC

<i>Neutral lipids</i>	<i>Phospholipids</i>	<i>Glycolipids</i>
Diacylglycerols	Diphosphatidylglycerol	Gangliosides, e.g. monosialogangliosides; disialogangliosides; trisialogangliosides; tetrasialogangliosides
Free fatty acids Free sterols	Lysophosphatidylcholine Lysophosphatidylethanolamine	Plant and bacterial glycolipids, e.g. mono- and digalactosyldiacylglycerols
Monoacylglycerols Triacylglycerols	Phosphatidic acid Phosphatidylcholine	Sphingolipids, e.g. ceramides; sphingomyelin; cerebrosides; globosides; sulfatides
Wax esters	Phosphatidylethanolamine Phosphatidylglycerol Phosphatidylinositol Phosphatidylserine Phosphonolipids	

Hersl f consider that lipids are compounds based on fatty acids or closely related compounds such as the corresponding alcohols or sphingosine bases. Christie noted that a variety of diverse compounds usually soluble in organic solvents are classified as lipids and set up a convenient system of lipid classification that is followed here. His system considers the simple lipids (compounds that upon hydrolysis yield no more than two types of primary products per mole), also referred to as neutral or apolar lipids. According to Christie, the polar or complex lipids (compounds that upon hydrolysis yield three or more primary products per mole) are the glycerophospholipids (or simply phospholipids) and the glycolipids (also termed glyceroglycolipids or glycosphingolipids), including gangliosides. **Table 1** lists the major neutral lipids, phospholipids and glycolipids of interest in studies on the TLC of lipids.

Functions

Lipids are involved in many functions of animals, plants and microorganisms and these functions are often studied using TLC. Lipids are important as storage depots for energy reserve. In mammals the storage depot is usually in the form of adipose tissue and TLC analysis shows that the major storage lipids are triacylglycerols, free fatty acids and mixed glycerides. Less information is available on lipid storage in invertebrates but TLC studies have shown that storage sites exist in invertebrates, including chlorogagen tissue in earthworms, the digestive glands in snails and specialized organs called trophosomes in some nematodes. As shown by TLC, triacylglycerols are major storage components in invertebrates. Lipids

(mainly sterols, phosphoglycerides, glycolipids and sphingolipids) are important in the structural integrity of cells and comprise the major components of membranes. Phosphoglycerides in the membranes of nervous tissue are involved in the transmission of electrical signals. Phosphoinositides are involved in cellular communication. Neutral lipids serve as pheromones or carrier of pheromones in both invertebrates and vertebrates. TLC has been used extensively for at least tentative identification of these pheromones.

Christie has documented numerous lipid functions, including their role in abnormal lipid metabolism associated with various disorders; accumulation of lipids associated with coronary blood vessel and cardiac diseases; the importance of lipids in human welfare, including nutrition and disease; the role of lipids as important dietary factors and suppliers of calories for humans and animals; and the importance of lipids to the palatability of foods.

Glycolipids play an important role in cellular metabolism and TLC has helped to elucidate this role. Glycolipids occur at the external surfaces of cell membranes and help regulate cell growth; they also serve as receptors for toxins and hormones and modulate immune responses.

Sample Preparation

Lipid analysis should be done as soon as possible after samples have been obtained from plants and animals. If this is not possible, samples should be maintained at 4 C overnight or at -20 C for longer periods. Tissues that have been fixed in formalin, alcohol or other preservatives should not be used. Glass vessels

Table 2 Frequently used methods for sample preparation of lipids

<i>Lipid extraction technique</i>	<i>Comments</i>
<i>Vertebrate and invertebrate organ and tissue samples</i>	
Chloroform-methanol (2 : 1); typically 1 part of tissue or fluid to 20 parts of the solvent	Most widely used method of lipid extraction; useful for TLC of neutral and complex lipids
Chloroform-methanol-H ₂ O (1 : 2 : 0.8); following extraction, dilute the sample with 1 vol of chloroform and 1 vol of water to get a biphasic system	Particularly useful for extraction of more polar lipids such as gangliosides
Pre-extraction of brain tissue with 0.25% acetic acid followed by chloroform-methanol (2 : 1)	Nonlipid material first removed with the acetic acid; relatively pure lipid fraction then obtained by treatment with chloroform-methanol
Chloroform-methanol (1 : 2); typically 1 part of tissue to 3 parts of solvent mixture	Good for large amounts of tissue where complete recovery of lipid is not needed; does not use as much solvent as the previous extraction techniques
<i>Blood and amniotic fluids</i>	
Chloroform-isopropanol-water (7 : 11 : 2)	Extracts lipids but not pigments; lipids are not contaminated with blood pigments; neutral and complex lipids are quantitatively extracted
Amniotic fluid or blood plasma (about 1 mL) is added directly to a Spice C ₁₈ solid-phase extraction cartridge (Analtech, Newark, DE); the analyte is eluted with chloroform-methanol	Good separation of phospholipids achieved, since most extraneous material is removed; technique also useful for separating neutral lipids from steryl esters and phospholipids
<i>Plant tissues</i>	
Tissues first treated with isopropanol and then chloroform-isopropanol (1 : 1) prior to usual chloroform-methanol (2 : 1) extraction procedure	Isopropanol inhibits the action of plant lipases

are recommended for lipid analysis, along with aluminium foil or Teflon-lined lids. Plastic vessels should be avoided because they may dissolve in the organic solvents used during the TLC process. Most samples are extracted in mixtures of chloroform-methanol (Table 2) to remove quantitatively the lipids prior to subsequent chromatographic techniques. The first procedure listed in Table 2, usually referred to as the Folch extraction procedure, is the one most frequently used. In brief, this procedure generally uses a 20 : 1 ratio of chloroform-methanol (2 : 1) to sample so that, for example, if 100 mg of tissue is being extracted, 2 mL of chloroform-methanol is suitable for total lipid extraction. The tissue is usually extracted in a glass homogenizer and the extract passed through a glass wool filter; the lipid-containing filtrate is collected and used for TLC following concentration of the sample under nitrogen gas. Many variants of this extraction procedure are available.

Chromatographic Systems

The chromatographic system consists of the sample mixture (the analyte), the stationary phase (the sorbent) and the mobile phase (the development solvent). Along with the sample mixture, lipid standards (usually obtained from a commercial supplier) are

run at the same time. Development of the plate in a suitable mobile phase, from the origin to the solvent front, constitutes the essential part of the chromatographic process. Following development, the plate is allowed to dry and the analytes are detected (see detection, next section) and compared to the standards on the plate.

Numerous stationary phases are available for TLC, but the one of choice for lipid work is silica gel. There are many different types of silica gel plates and sheets and most workers use commercially prepared plates. Silica gel plates can be modified for particular purposes. For example, silver nitrate plates can be prepared and used to separate *cis*-enoic compounds based on unsaturation. Other examples exist that show how commercial and home-made silica gel plates can be altered for specialized lipid applications. The 1990s have seen considerable use of high performance thin-layer chromatography (HPTLC) for lipid analysis. HPTLC plates are made of fine silica particles of narrow size distribution, and have excellent resolving power. The quantity of sample applied to such plates can be reduced markedly from that applied to conventional TLC layers. Many samples can be analysed on the same plate with minimal amounts of mobile phase. HPTLC plates are now being used frequently in densitometric studies on lipids.

Table 3 R_F values of common neutral lipids separated in five frequently used solvent systems on silica gel

Compound	$R_F \times 100$				
	S_1	S_2	S_3	S_4	S_5
Cholesteryl esters	97	97	85	94	90
Triacylglycerols	63	79	70	60	82
Free fatty acids	42	21	62	39	50
Cholesterol	28	42	38	19	30
1,3-Diacylglycerols	24	66	46	21	40
1,2-Diacylglycerols	21	53	41	15	25
Monoacylglycerols	8	11	10	2	5

S_1 , hexane–diethyl ether–formic acid (80 : 20 : 2). S_2 , toluene–diethyl ether–ethyl acetate–acetic acid (80 : 10 : 10 : 0.2). S_3 , isopropyl ether–acetic acid (96 : 4) followed by petroleum ether–diethyl ether–acetic acid (90 : 10 : 1) in the same direction. S_4 , petroleum ether–diethyl ether–acetic acid (80 : 20 : 1). S_5 , heptane–isopropyl ether–acetic acid (60 : 40 : 4).

Numerous mobile phases are available for lipid TLC and most are used with a single development in the ascending mode. However, some systems have been designed for two or more developments in the same direction. A good example of this is the classical Skipski system (Table 3) that uses two developments

Figure 1 Separation of a hen's egg yolk–saline extract on a silica gel sheet. Lipids were developed 10 cm from the origin in petroleum ether–diethyl ether–acetic acid (80 : 20 : 1) and detected by spraying with 5% phosphomolybdic acid in ethanol. Lane 1 contains a neutral lipid mix consisting of equal parts of cholesterol (c), oleic acid (o), triolein (t), methyl oleate (m) and cholesteryl oleate (co). Lane 2 shows the presence of triacylglycerols and free sterols as the predominant neutral lipids in the yolk–saline extract. Lane 3 contains saline alone that is neutral lipid–negative. (Reproduced with permission from Fried and Sherma (1999).)

Figure 2 Separation of a snail liver extract on a silica gel sheet using the dual solvent system of Skipski (see text). Lane 1 contains a neutral lipid mix as described in Figure 1. Lane 2 shows the separation of snail neutral lipids; note the abundance of free sterols and cholesteryl esters in this tissue. Lane 3 contains a neutral lipid mix with equal parts of monoolein (mn), dioleoin (d), triolein (t), and methyl oleate (mm). (Reproduced with permission from Fried and Sherma (1999).)

in the same direction. Some mobile phases have been designed with two-dimensional TLC in mind, in which the second development is done after the plate is turned through a 90° angle.

Of the many unidimensional solvent systems available to resolve neutral lipids, the Mangold system and its modifications are most frequently used (Figure 1). This system consists of different combinations of petroleum ether (or hexanes), diethyl ether and acetic acid with a typical ratio of 80 : 20 : 1 v/v (petroleum ether–diethyl ether–acetic acid; Table 3). Changes in the ratios will affect R_F values of the neutral lipids being separated. Double development in the same direction as in the Skipski system is used to ensure good separation of glycerols from free fatty acids and free sterols (Figure 2). Although two-dimensional systems are infrequently used to separate neutral lipids, an example of such use is shown in

Figure 3(A) Chromatogram of the neutral lipids from an extract of the digestive gland-gonad (DGG) complex of the medically important snail *Biomphalaria glabrata*. The silica gel G plate was developed in the first direction in hexane-diethyl ether (80 : 20) and in the second direction in hexane-diethyl ether-methanol (70 : 20 : 10). Lipids were detected by spraying the plate with H_2SO_4 . (Reproduced with permission from Thompson SN (1987) *Comparative Biochemistry and Physiology* 87B: 357-361.) **(B)** Chromatogram of phospholipids from a similar extract as in Figure 3(A). The silica gel plate was developed in the first direction in chloroform-methanol- NH_4OH (65 : 35 : 5) and in the second direction in chloroform-methanol-water-acetic acid (65 : 25 : 4 : 1). Phospholipids were detected using various specific phospholipid detection reagents. (Reproduced with permission from Thompson SN (1987) *Comparative Biochemistry and Physiology* 87B: 357-361.)

Figure 3A, where a neutral lipid map is obtained. Two-dimensional development is used more frequently to resolve complex lipid mixtures and **Figure 3B** shows such a chromatogram resolving phospholipids in the medically important snail *Biom-*

phalaria glabrata. **Table 4** shows the most widely used solvent systems for two-dimensional separations of complex lipids in animal and plant tissues.

Numerous one-dimensional systems for phospholipids are available. The commonly used ones for

Table 4 Four recommended solvent systems for two-dimensional separations of phospholipids and glycolipids on silica gel

System	Direction	Solvent composition and ratio	Comments
A	First	Chloroform-methanol-water (65 : 25 : 4)	Systems A and B are good for separating polar lipids of animal tissue on silica gel H; 10-15 complex lipids are separated
	Second	<i>n</i> -Butanol-acetic acid-water (60 : 20 : 20)	
B	First	Chloroform-methanol-28% aq. NH_3 (65 : 35 : 5)	Good for separating bacterial polar lipids on silica gel G; 10-15 polar lipids are separated
	Second	Chloroform-acetone-methanol-acetic acid-water (10 : 4 : 2 : 2 : 1)	
C	First	Chloroform-methanol-7 mol L^{-1} NH_4OH (65 : 30 : 4)	Good for separating a wide variety of ganglioside species on HPTLC plates
	Second	Chloroform-methanol-acetic acid-water (170 : 25 : 25 : 6)	
D	First	Chloroform-methanol-0.2% aq. CaCl_2 (60 : 35 : 8)	Good for separating a wide variety of ganglioside species on HPTLC plates
	Second	<i>n</i> -Propanol-water-28% aq. NH_3 (75 : 25 : 5)	

separating phospholipids on silica gel are shown in Table 5. The most widely used system is that of Wagner (see S_5 in Table 5), consisting of chloroform-methanol-water (65 : 25 : 4 v/v). In this system, the neutral lipids are moved as one or several bands near the solvent front and the common phospholipids of plant and animal tissues are clearly resolved. Figure 4 shows a chromatogram of such a separation.

Glycolipid separation by unidimensional chromatography can be achieved in mobile phases consisting of various combinations of chloroform-methanol-water or chloroform-acetone-methanol-acetic acid-water. However, unidimensional separation of glycolipids is best done in the absence of phospholipids. Because glycolipids are difficult to separate completely by one-dimensional TLC, various two-dimensional procedures have been designed. A recommended two-dimensional system for glycolipids is chloroform-methanol-7 mol L⁻¹ ammonium hydroxide (65 : 30 : 4 v/v) in the first direction and chloroform-methanol-acetic acid-water (170 : 25 : 25 : 6 v/v) in the second direction.

One-dimensional TLC can be used to separate gangliosides with various combinations of chloroform-methanol-water or *n*-propanol-water as solvent systems. As noted for glycolipids, because of the diversity of oligosaccharides associated with gangliosides, it is difficult to achieve complete separation of these lipids using one-dimensional TLC. Thus, various maps have been prepared in which ganglioside species have been separated in two-dimensional systems. These maps follow the nomenclature of Svennerholm and use esoteric designations

Table 5 R_F values of common phospholipids separated in five frequently used solvent systems on silica gel

Compound	$R_F \times 100$				
	S_1	S_2	S_3	S_4	S_5
Diphosphatidyl-glycerol	91	94	-	-	-
Phosphatidylglycerol	-	-	90	78	-
Phosphatidyl-ethanolamine	65	56	81	59	40
Phosphatidylserine	-	47	51	47	13
Phosphatidylinositol	-	34	34	52	13
Phosphatidylcholine	24	21	90	30	20
Lysophosphatidyl-choline	6	6	-	-	6

S_1 , chloroform-methanol-water (25 : 10 : 1). S_2 , chloroform-methanol-acetic acid-water (25 : 15 : 4 : 2). S_3 , chloroform-light petroleum-methanol-acetic acid (50 : 3 : 16 : 1). S_4 , chloroform-ethanol-triethylamine-water (30 : 34 : 30 : 8). S_5 , chloroform-methanol-water (65 : 25 : 4).

Figure 4 Separation of phospholipids extracted from snail-conditioned water (SCW) on a silica gel plate in the Wagner solvent system (see text). Lane 1 contains a standard with equal amounts of lysophosphatidylcholine (l), phosphatidylcholine (pc), phosphatidylethanolamine (pe) and cholesterol (ch). Lane 2 is a water blank without snails and is lipid-negative. Lane 3 contains SCW and shows that snails release significant amounts of phosphatidylcholine (pc) and phosphatidylethanolamine (pe), along with an unidentified component that migrates ahead of the pe. The bands near the solvent front are neutral lipids. Note the origin (o) and the solvent front (s). (Reproduced with permission from Fried and Sherma (1999).)

to indicate the nature of the gangliosides being separated. Details of this work are beyond the scope of this article. Experience, patience, and trial and error are needed to effect good separations of glycolipids and gangliosides with one- and two-dimensional TLC.

Detection

Following development, lipids are usually detected by a wide variety of detection (visualizing) agents either sprayed or dipped on to the plate. Detection reagents may be nondestructive and reversible such as iodine or destructive and nonreversible such as sulfuric acid. The afore-mentioned agents are considered general because they react with numerous different compound types. Table 6 provides a list of such general detection reagents frequently used to localize lipids on TLC plates. More or less specific detection reagents are used widely in TLC lipid studies and they generally indicate a particular compound or functional group, e.g. ninhydrin is used to localize amine groups associated with phospholipids such as phosphatidylserine or phosphoethanolamine. A list of spe-

Table 6 Five nonspecific reagents useful for the detection of lipids on TLC plates

Reagents	Procedure	Results
Iodine	Spray as 1% alcoholic solution or place a few crystals in the bottom of a closed tank	Dark-brown spots on a pale yellow or tan background in a few minutes
2',7'-Dichlorofluorescein	Spray with a 0.2% solution in 95% ethanol. Observe in UV light	Saturated and unsaturated polar lipids give green spots on purple background
Phosphomolybdic acid	Spray with a 5% solution in ethanol; heat at 100°C for 5–10 min	Blue-black spots on yellow background
Sulfuric acid	Spray with 50% aq. H ₂ SO ₄ ; heat as above	Black spots on a colourless background
Cupric acetate–phosphoric acid	Dissolve 3 g of cupric acetate in 100 ml of an 8% aq. phosphoric acid solution. Heat at 130–180°C for up to 30 min	Black spots on a colourless background

cific detection reagents frequently used in lipid TLC is shown in Table 7.

Quantification

There are many methods available for quantifying lipids using TLC. Some involve scraping and eluting lipids from the plate followed by spectrophotometric, gravimetric or chromatographic determination. The 1990s saw widespread use of direct *in situ* quantification, usually by densitometric methods, and an extensive literature is now available. Densitometry is performed in the reflection or transmittance mode with a specific brand of commercial densitometer. Any lipid that can be detected by ultraviolet or visible light is subject to densitometric analysis. Suitable standards, usually purchased from a commercial supplier, are needed and should match closely the compounds of interest. Quantification involves

bracketing the analyte between two standards, one of slightly lower concentration, and the second of slightly higher concentration. Standards can be used to construct a calibration curve.

A list of recent TLC lipid applications by densitometry for the quantification of lipids is shown in Table 8.

Concluding Remarks and Future Developments

The most extensive use of TLC is for the analysis of pharmaceuticals, followed by all aspects of lipid analysis. Silica gel TLC is an excellent tool for the separation and identification of neutral and complex lipid classes. Densitometry allows for the quantification of these compounds at least at the class level. Numerous specific detection reagents are helpful for identifying lipids. Moreover, techniques in which

Table 7 Specific chemical detection reagents for various lipids

Compound class	Reagent	Results
Cholesterol and cholesteryl esters	Ferric chloride	Cholesterol and cholesteryl esters appear as red-violet spots
Free fatty acids	2',7'-Dichlorofluorescein–aluminium chloride–ferric chloride	Free fatty acids give a rose colour
Lipids containing phosphorus	Molybdic oxide–molybdenum Zinzadze reagent	Phospholipids appear as blue spots on a white background within 10 min of spraying the plate
Choline-containing phospholipids (phosphatidylcholine and lysophosphatidylcholine)	Potassium iodide–bismuth subnitrate Dragendorff reagent	Choline-containing lipids appear in a few minutes as orange-red spots
Free amino groups (phosphatidyl-ethanolamine and phosphatidylserine)	Ninhydrin	Lipids with free amino groups show as red-violet spots
Glycolipids	α-Naphthol–sulfuric acid	Glycolipids (cerebrosides, sulfatides, gangliosides, and others) appear as yellow spots
Gangliosides	Resorcinol	Gangliosides appear as a violet-blue colour; other glycolipids appear as yellow spots

Table 8 Selected applications of densitometric TLC to the quantitative analysis of lipids

Material	Comments
Neutral lipids in egg yolk	HPTLC silica gel; Mangold solvent system of petroleum ether–diethyl ether–acetic acid (80 : 20 : 2) for determination of cholesterol, triacylglycerols, and free fatty acids, and <i>n</i> -hexane–petroleum ether–diethyl ether–acetic acid (50 : 20 : 5 : 1) for cholesteryl esters. Lipid detection and quantification as described for neutral lipids in <i>Biomphalaria glabrata</i> snails in this table
Neutral lipids in <i>Biomphalaria glabrata</i> snails	HPTLC silica gel plates; petroleum ether–diethyl ether–acetic acid (80 : 20 : 2) mobile phase; detection by spraying with 5% ethanolic phosphomolybdic acid; lipid zones measured by scanning at 700 nm with a Shimadzu CS 930 TL densitometer operated in the single-beam reflectance mode
Phospholipids in <i>Biomphalaria glabrata</i> snails	HPTLC silica gel plates; multiple developments in a chloroform–methanol–isopropanol–0.25% and KCl–ethyl acetate (30 : 9 : 25 : 6 : 18) mobile phase; detection by spraying with 10% cupric sulfate–8% phosphoric acid solution; phospholipids measured by reflectance scanning at 400 nm with a Shimadzu CS-930 densitometer in the single-lane/single-beam mode
Lecithin and sphingomyelin from amniotic fluid	Silica gel plates developed in chloroform–methanol–water (75 : 25 : 4); sprayed with phosphomolybdic acid; scanned in a densitometer at 450 nm in double-beam transmission mode; detection of each lipid at 0.2 µg level
Sphingolipids in the parasitic protozoan, <i>Blastocystis hominis</i>	Sphingolipids along with neutral lipids and phospholipids were quantified on HPTLC plates; sphingolipids resolved on plates with chloroform–methanol–water (70 : 22 : 3) and detected with the orcinol reagent; plates scanned with a Shimadzu Flying Spot densitometer operated in the reflectance mode at 580 nm
Brain gangliosides	Complex sample preparation; use of HPTLC plates; chloroform–methanol–0.22% CaCl ₂ (55 : 45 : 10) solvent system; detection by spraying with resorcinol–hydrochloric acid reagent; chromatogram scanned at 580 nm in transmission mode; separation and quantification of 4–8 brain gangliosides

plates can be impregnated with special agents have allowed for the separation and identification of molecular species within classes, e.g. molecular species of triacylglycerols.

A new area of work has used multiphase TLC, in which components are separated in two directions according to different parameters, e.g. conventional silica gel in one direction and reversed-phase in the other. This technique has proved useful in the analysis of triacylglycerols. The use of HPTLC-densitometry has revolutionized our ability to quantify lipids by relatively simple procedures. There are attempts underway to automate various aspects of the TLC process. Certainly with more automated methodology, TLC will be used more widely in the future by both chemists and biologists interested in lipid separations.

Introduction

High resolution gas chromatography (HRGC) is the most suitable technique for the analysis of volatile compounds. If the sample is a complex matrix, such as natural products, food products or environmental pollutants, direct gas chromatographic (GC) analysis is not advisable for several reasons, and a sample pretreatment is necessary. In fact, peaks of different classes of compounds may overlap, rendering the

qualitative and quantitative analysis of some compounds difficult. Moreover, if the compounds of interest are present only as trace amount, a preconcentration step is necessary before the GC analysis.

If the mixture is subjected to a preliminary separation by liquid chromatography (LC), the fraction so obtained can be analysed by GC. Offline coupling of LC and GC is laborious, involving numerous steps with the risk of contamination and possible greater loss of part of the sample than if online techniques were used. The online coupling of LC and GC offers a number of advantages compared to offline coupling: the amount of sample required is much lower; no sample work-up, evaporation or dilution is necessary and complex automated sample pretreatment is possible.

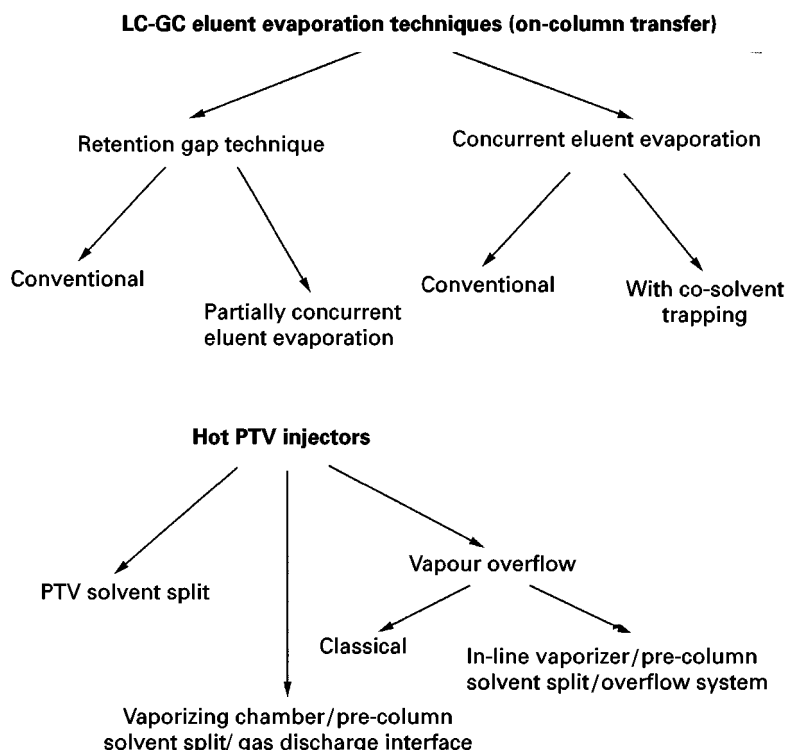

Figure 1 LC-GC transfer techniques. Possible mechanisms for LC-GC eluent evaporation.

The introduction of large amounts of solvent into a GC column requires the use of special techniques to separate the solvent from the sample selectively. At present, the principal techniques of eluent evaporation that allow transfer of large LC fraction into GC are based on the use of a modified on-column injector or on the use of a programmed temperature vaporizing (PTV) injector. Figure 1 summarizes the transfer techniques used for online LC-GC coupling.

Concurrent Eluent Evaporation

Concurrent eluent evaporation is the most used technique, because of its simplicity and the possibility of transferring large amounts of solvent (up to 10 mL!). The technique involves complete evaporation of the eluent during its introduction into the GC system. This technique is suitable for the analysis of solutes with intermediate to high elution temperature, depending on the volatility of the eluent and on the volume of the LC fraction transferred.

When the sample solvent evaporates at the front end of the liquid, volatile compounds co-evaporate with the solvent and immediately start passing into the analytical column. The consequence is that, if the solvent vapours are vented through an early vapour exit, the volatile compounds are lost with the solvent vapour while, if venting is delayed, the most volatile compounds reach the detector even before the end of solvent evaporation. This causes a broadening of the initial band of solutes, which will give peaks that start with the solvent peak and spread out, masking some of the volatile peaks. Only high boiling substances, which migrate slowly during the transfer, will elute after the oven temperature increase, and will give sharp peaks. In practice, the first properly shaped peaks are eluted some 40–120°C above the transfer temperature.

The fraction to be analysed is contained in a loop, connected to a switching valve. The opening of the valve allows the sample in the loop to be driven by the carrier gas into the GC. Usually an early vapour exit is located after a few metres of deactivated precolumn and 3–4 m of retaining column (cut from the analytical column). The retaining pre-column provides a short zone where the solute can be focused in the stationary phase, so that volatile components will be trapped, avoiding their loss through the vapour exit. This is opened during solvent evaporation to reduce the amount of solvent that would reach the detector, and at the same time to increase the solvent evaporation rate.

Figure 2 shows the scheme of the loop-type interface.

Figure 3 shows an example of tocopherols, free sterols and esterified sterols determined in a single analytical run after acetylation. These compounds were pre-separated from the triacylglycerols by normal-phase LC.

Retention Gap

The retention gap method represents the best approach in the case of qualitative and quantitative analysis of samples containing highly volatile compounds. In fact, the retention gap technique allows the analysis of substances eluting immediately after the solvent peak, due to the reconcentration of these components by the so-called solvent effects (primarily solvent trapping). Figure 4 shows the scheme of the retention gap transfer technique.

The term retention gap means a column inlet of a retention power lower than that of the analytical column. In the retention gap technique, the sample is introduced into the GC at a temperature below the boiling point of the LC eluent (corrected for the current inlet pressure). In this way, the solvent

Sandra and AJ Rackstraw.)

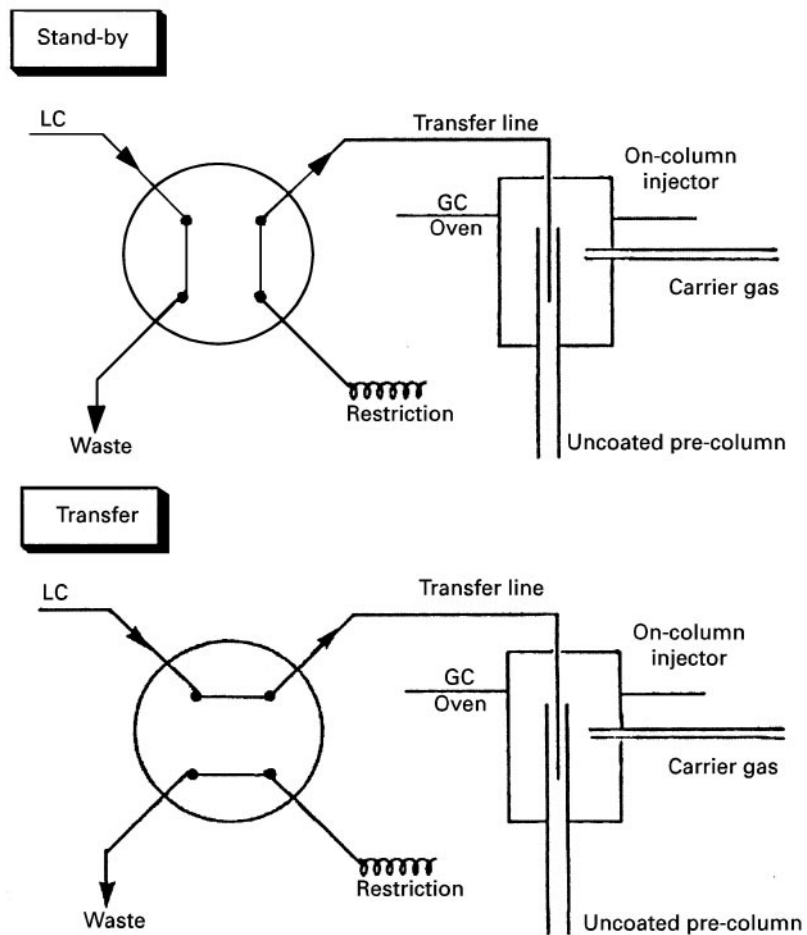

Figure 4 Retention gap scheme.

Figure 5 Solvent evaporation in a retention gap. The evaporation occurs from the rear part of the solvent.

vapours replace only part of the carrier gas, which continues to flow through the column. In the carrier stream, solvent evaporates from the rear towards the front of the sample layer (Figure 5). Under these conditions, the volatile compounds that are liberated from the solvent envelope start moving, but they are immediately trapped again by the solvent present ahead of the evaporation site (solvent-trapping effect). In this way, the volatile components can start moving in the carrier gas only when the process of solvent evaporation is complete.

A second effect, called phase soaking, occurs in the retention gap technique. This effect is obtained because the carrier gas is saturated by solvent vapours, so it swells the stationary phase with this amount of solvent. The consequence is that the column shows an increased retention power that can be used to trap the volatile compounds.

During the evaporation process, band broadening in space spreads the high boiling compounds. Two retention gap effects can reconcentrate these solute bands. First, compounds migrate more rapidly through the retention gap zone than through the main column; reconcentration depends on the ratio between the retention power in the pre-column and in the main column (phase-ratio focusing). Second, the compounds arrive at the entrance of the main column at a temperature at which they are practically unable to migrate, so they accumulate until the temperature

is increased, and concentrate. The limitation of the method is that, due to the poor capacity of uncoated pre-columns to retain liquid, only modest volumes can be transferred (100–150 μL of eluent) and long uncoated pre-columns are needed.

Two additional techniques have been developed to overcome the drawbacks of the techniques described above, with the aim of obtaining sharp peaks at elution temperatures below 120–150°C, for concurrent eluent evaporation, and to transfer large LC fractions, for the retention gap technique: partially concurrent solvent evaporation and co-solvent trapping.

Partially Concurrent Solvent Evaporation

Partially concurrent solvent evaporation allows working under conditions that still produce a zone flooded by the eluent (retention gap), providing solvent trapping. This causes a large amount of eluent to evaporate during its introduction (concurrently), so that shorter uncoated pre-columns or larger volumes of transferred fraction can be handled. In practice, an early vapour vent may be placed between the uncoated pre-column and the analytical column, but this makes closure of the vent critical for partial losses of early eluted peaks. A section of the analytical column may be installed after the uncoated pre-column but before the solvent vapour exit.

Figure 6 shows GC chromatograms obtained after pre-separation by normal-phase LC, applying the partially concurrent solvent evaporation. This application consists of the measurement of the enantiomeric ratio of linalol contained in sweet and bitter orange essential oil. This ratio characterizes each oil, differentiating them, so that the presence of the less valuable sweet orange oil can be detected in the more valuable bitter orange oil.

Co-solvent Trapping

Co-solvent trapping is used to obtain sharp solute peaks of correct size even for volatile compounds, with concurrent evaporation technique. A small amount of a higher boiling co-solvent is added to the main solvent (for example, *n*-heptane added to pentane), to prevent co-evaporation of the volatile compounds with the main solvent (Figure 7).

It is necessary to adjust the concentration of co-solvent so that some co-solvent is left behind as a liquid, while some is evaporated with the main solvent. In this way, the co-solvent remaining forms a layer of liquid film that evaporates from the rear to the front, as in the retention gap technique. The solutes are trapped by the solvent-trapping effect, and

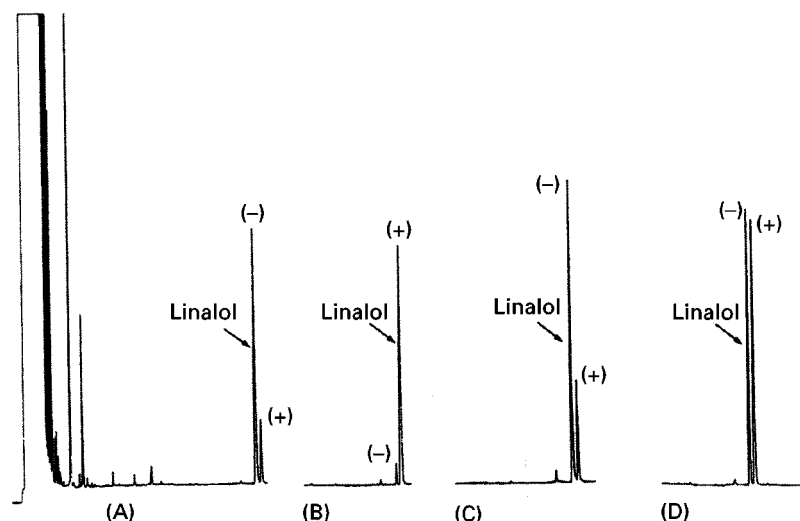

Figure 6 GC chiral separation of linalol from sweet orange, bitter orange and mixtures of the two essential oils, showing the different enantiomeric ratios. Linalol fraction was transferred from the LC system using the partially concurrent solvent evaporation technique. (A) Bitter orange; (B) sweet orange; (C) bitter orange 90%, sweet orange 10%; (D) bitter orange 70%, sweet orange 30%. are released after the co-solvent has been evaporated. As can be seen, this technique shows some similarity to partially concurrent solvent evaporation. The main difference is that it is designed for the loop-type interface, while partially concurrent solvent evaporation works with an on-column interface. The optimization of the transfer conditions is not easy, so this technique has never been routinely applied to the transfer of normal-phase eluents, because the partially concurrent solvent evaporation technique is

easier to use. It can be the technique of choice for the transfer of water-containing solvents, because in contrast to retention gap techniques, concurrent eluent evaporation does not need wettability, and co-solvent trapping retains the volatile solute. Under these conditions, transfer occurs at 110–120°C, so the first compounds should elute at this temperature. Unfortunately, the problem is the lack of an uncoated pre-column resistant to condensed water. Studies on improving pre-column deactivation have been carried out, but the scant interest in reversed-phase LC coupled to GC prevented re-evaluation of this promising technique with improved methods of deactivation.

Vaporization with Hot Injectors

Together with the techniques described above, other techniques using hot injectors for the transfer from LC to GC, have been developed. PTV with solvent trapping in packed beds can be used successfully to transfer large volume fractions into the GC instead of into a capillary pre-column (uncoated, deactivated silica tubing). This technique shows some advantages compared to the techniques that use on-column sample introduction:

1. Packed beds retain more liquid per unit internal volume.
2. Wettability is no longer critical.
3. Packing material is more stable than deactivated silica tubing.
4. PTV is more easily heated than capillary column.

Figure 7 Concurrent eluent evaporation with co-solvent trapping effect. The volatile components are retained by the solvent film.

Because of the high retention power, the packed chambers have to be heated above the column temperature to release the solutes. This is a drawback in the analysis of thermally labile compounds, and high boiling compounds. In the PTV solvent split mode, the injection is made into a cool injector, and the solvent is largely removed via the split valve. Volatile compounds can evaporate with the solvent; many studies have been carried out to minimize the loss of volatiles, for example, reducing the temperature of the injector. On the other hand, high boiling compounds are difficult to release, due to the high retention power of the packing material. Introduction of large volumes in the PTV solvent-split mode was introduced in the 1970s and, since its introduction, many different approaches have been described.

The first configuration was a glass tube with a packed bed with a cool injector. The solvent vapours are discharged through the split valve. After solvent evaporation the split valve is closed and the injection chamber is heated to transfer the solutes into the column. Liners are usually packed with Tenax TA and Thermotrap TA. To increase trapping efficiency, liners with sintered porous glass beads were introduced.

Recently a new, fully automated online LC-GC coupling has been introduced. This interface consists

of a flow cell, where the fraction is sampled by a large volume autosampler, and automatically injected into a PTV device using the solvent vent mode. This technique was successfully applied to determine pesticide residues in complex natural matrices such as essential oils (Figure 8).

Vapour Overflow

The vapour overflow technique is intended for introducing samples into large volumes of solvent by syringe injection of dilute samples or by coupled LC-GC. The liquid is introduced into a packed (generally with Tenax) vaporizing chamber maintained above the solvent boiling point at a pressure which is near or below ambient. This technique is performed in the absence of carrier gas and vapours are discharged by expansion during evaporation (overflow). The vaporizing chamber is filled with packing material of a GC retention power for the volatile components. The carrier gas supply line is equipped with a switching valve, allowing the gas supply to be stopped during sample introduction. The sample is released by a syringe or a transfer line from the LC near the bottom of the vaporizing chamber. Vapours expand and, driven by the expansion, leave the system through the septum purge (Figure 9).

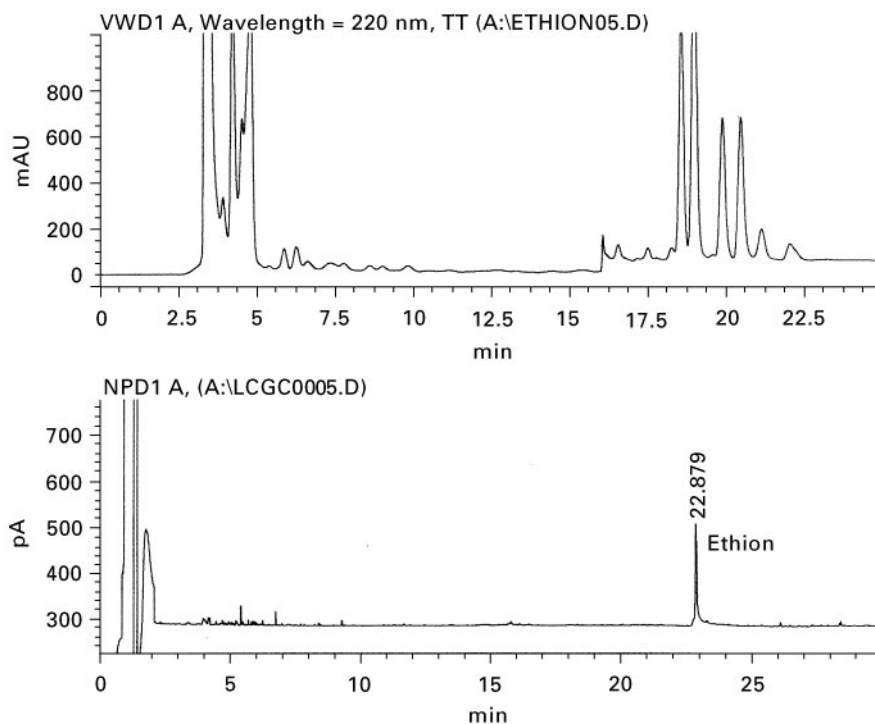

Figure 8 LC separation of (A) orange essential oil and (B) GC/NPD chromatogram of the fraction containing the pesticide ethion, transferred from the LC system, using the PTV interface type in the solvent vent mode. NPD, nitrogen-phosphorous detector. (Reproduced with permission from David F, Correa RC and Sandra P (1998) *20th International Symposium on Capillary Chromatography*, Riva del Garda, Italy. Copyright P. Sandra and AJ Rackshaw.)

Figure 9 Vapour overflow interface. The solvent vapours are eliminated through the septum purge of the PTV injector.

After solvent evaporation is completed, the septum purge is closed, the injector is warmed up (PTV) and the trapped analytes are released into the column. More recently, this system has been modified for use with a conventional hot injector.

In-line Vaporizer/Pre-column Solvent-split/Overflow System

The in-line vaporizer/pre-column solvent-split/overflow system was developed by Grob for large volume liquid injection and for online LC-GC. This system is an overflow-based technique, but with an improvement for the retention of more volatile compounds. As can be seen from Figure 10, the vaporizer consisted of a transfer line (from the LC) of fused silica. Inside the vaporizer a 5 cm length of steel wire (untreated or deactivated) or of fused silica is inserted for complete evaporation of the liquid (250–350°C). Moreover the system is equipped with a retaining pre-column and an early vapour exit. The oven in this case is maintained at a low temperature (lower than with a loop interface) to improve retention of sample components by phase soaking. The improvement in the arrangement corresponds to about four extra carbon atoms retained (undecane instead of pentadecane).

Vaporizing Chamber/Pre-column Solvent-split/Gas Discharge Interface

The sample is injected by an autosampler or by online transfer from a high performance liquid chromatography (HPLC) into a heated device. The vaporizer is packed and maintained at a temperature suitable for solute evaporation. Compounds that are sensitive to high temperatures are injected into a PTV injector in

Figure 10 In line vaporizer/pre-column solvent-split/overflow system. The more volatile components are retained by the retention gap, letting the solvent out from the early vapour exit.

Figure 11 Vaporizing chamber/pre-column solvent-split/gas discharge interface. The vaporizer is packed and heated at a suitable temperature for solvent evaporation. The vapour exit can be positioned at the end of the retention gap.

order to evaporate the solvent first and then the solutes. As shown in **Figure 11**, the vapours are discharged through a pre-column and an early vapour exit. If solvent trapping is needed, an uncoated pre-column is installed after the injector and before the solvent vapour exit. Moreover, the use of a retaining pre-column is possible depending on how critical is the solvent vapour exit closure.

Conclusions

Coupled LC-GC is an excellent online method for sample preparation and clean-up. For the analysis of nonaqueous media the transfer technique of choice is certainly concurrent eluent evaporation using a loop-type interface. The main drawback of this technique is the loss of volatile solutes due to the solute co-evaporation with the solvent. If volatile compounds are present, transfer from LC to GC is best achieved by a retention gap technique. This on-column method yields sharp peaks starting from the programming of the GC oven temperature during eluent transfer. However, due to the limited capacity of uncoated pre-columns for liquid retention, the technique is only suited for the transfer of relatively small fractions. Larger fractions can be transferred by partially concurrent eluent evaporation since this includes the retention gap procedure. Presently, PTV solvent-split injection is considered as the method of choice for

large volume injection of 'dirty' or water-containing samples. Finally, vaporizing chamber/pre-column solvent-split/gas discharge interface and in-line vaporizer/pre-column solvent-split/overflow systems seem to be promising techniques for LC-GC coupling in a wide range of applications.

MARINE TOXINS: CHROMATOGRAPHY

A. Gago-Martínez and J. A. Rodríguez-Vázquez,
Universidad de Vigo, Vigo, Spain

Copyright © 2000 Academic Press

Introduction

The marine environment may be seriously affected by contamination due to the massive proliferation of toxic phytoplanktonic species for example toxic algae or 'algal blooms', which appear at certain times of the year under the influence of various environmental factors. These phytoplanktonic microorganisms are essential food for filter-feeding bivalve shellfish as well as other types of marine seafood. This phenomenon is commonly known as a 'red tide'.

These toxic algal blooms cause important socio-economic damage to those regions that depend on aquaculture or fisheries industry, owing to their environmental and human health impacts.

It is believed that the first reference to a harmful algal bloom appears in the Bible: '... all the waters in the river turned to blood, the fish died' (Exodus 7:20–21). One of the first recorded fatal cases of

human poisoning happened in 1793 in Poison Cove (British Columbia), caused by a group of alkaloids now called 'paralytic shellfish poisoning' toxins (PSP). Since this toxic event, a number of different toxic episodes have been reported in several places worldwide.

There are different type of shellfish poisoning: the main causative organisms and important toxicological effects are summarized in Table 1. In this article we will focus on the paralytic, diarrhoeic and amnesic shellfish poisoning toxing (PSP, DSP and ASP) because they are responsible for most of the toxic events on the European Atlantic Coast and are also of general occurrence in many other places worldwide.

These toxins cause important cause important human contamination and their impact has increased considerably over the last few years. For this reason, strict control of these toxins is necessary to prevent serious damage to health. The conventional mouse bioassay (still considered as official and routine methodology in most countries) is useful for determining most of the implicated toxins, but alternative analytical methods are desired, especially for research

Table 1 Main types of harmful algal blooms

Type of poisoning	Causative organism	Symptoms
Paralytic shellfish poisoning (PSP)	<i>Alexandrium catenella</i> <i>A. minutam</i> <i>A. tamarense</i> <i>Gymnodinium catenatum</i> <i>Pyrodinium bahamense</i>	Typical neurological symptoms. The severity of these symptoms is related to the ingested dose. Also symptoms like dizziness, nausea, vomiting, diarrhoea, muscular paralysis, respiratory difficulties, death through respiratory paralysis (in extreme cases).
Diarrhoeic shellfish poisoning (DSP)	<i>Dinophysis acuminata</i> <i>D. acuta</i> <i>D. fortii</i> <i>D. norvegica</i> <i>Prorocentrum lima</i>	Vomiting and diarrhoea typical of gastrointestinal disorders. Chronic exposure may cause tumour promotion, especially in the digestive system (stomach intestine and colon).
Amnesic shellfish poisoning (ASP)	<i>Pseudo-nitzschia multiseriis</i> <i>Pseudo-nitzschia</i> <i>Pseudo-nitzschia australis</i>	Typical gastrointestinal disorders (nausea, vomiting, diarrhoea). Neurological symptoms, especially in older people and people with chronic illnesses – confusion, short-term memory loss.
Neurotoxic shellfish poisoning (NSP)	<i>Gymnodinium breve</i>	Headache, diarrhoea, muscle weakness, nausea and vomiting. Paraesthesia, respiratory difficulties, vision alterations, speech difficulties.
Ciguatera poisoning	<i>Gambierdiscus toxicus</i> <i>Prorocentrum lima</i>	Gastrointestinal disorders (diarrhoea, abdominal pain, nausea, vomiting), difficulty in balance, heart problems (low heart rate and blood pressure), death through respiratory failure (in extreme cases).

purposes where high sensitivity and specificity are required.

Owing to the complexity of the sample matrix, separation techniques are required to remove interferences and to increase the selectivity in the analytical response. During the 1990s considerable research has been focused on the development of chromatographic approaches for the analysis of PSP, DSP and ASP toxins. Liquid chromatography (LC) has been shown to be one of the most successful alternatives for the sensitive determination of these compounds using different detection modes. Capillary electrophoresis (CE) is another analytical alternative that has been recently developed for the analysis of PSP and ASP toxins and, as we will discuss later, this is a promising technique for the analysis of such compounds.

Separation Techniques for the Analysis of Marine Biotoxins

PSP Toxins

Paralytic shellfish poisoning (PSP) is a worldwide problem caused by consumption of shellfish that have accumulated potent neurotoxins produced by toxicogenic dinoflagellates. The PSP toxins include saxitoxin (STX) and several of its derivatives formed by addition of sulfo, hydrosulfate and *N*-1-hydroxyl groups (Figure 1).

The most common chemical method used for the analysis of PSP toxins is the combination of LC with online post-column oxidation and fluorescence detection, using two different isocratic and gradient

elution modes. This evolved from earlier work, which showed that STX could be easily oxidized to a fluorescence derivative by hydrogen peroxide under alkaline conditions. Hydrogen peroxide is not able to oxidize the *N*-1-hydroxylated derivatives, which are better oxidized by using periodate. This reagent is therefore commonly used in post-column oxidation systems in order to detect all PSP toxins. LC combined with post-column oxidation has resulted in a successful approach but unfortunately is not without difficulties, especially concerning the operation of the equipment. This has made it necessary to optimize parameters such as stationary phase, mobile phase, etc. An alternative LC method employing pre-chromatographic oxidation has been reported. This method results in improved separation and quantitation of most PSP analogues. Modification of the periodate oxidation reaction for the *N*-hydroxy-containing toxins has led to improved sensitivity and stability of the products, enabling overnight analysis.

All the high performance liquid chromatography (HPLC) methods mentioned have resulted in valid approach for the control of these toxic compounds, but although these methods offer good sensitivity and dynamic range, the sensitivity is dependent on parameters such as reagent concentration, reaction times, pH and temperature of the oxidation reaction. In addition to the elaborate procedure required to achieve reliable and reproducible results, the main drawback of the alkaline oxidation reaction is the reliance on fluorescence response factors for the different PSP toxins based on the only commercially available standard. Figure 2 shows an example of the

application of the LC technique with fluorescence detection for the analysis of PSP toxins in contaminated extracts of mussels for Galicia (northwest Spain). The conditions used to carry out this isocratic HPLC analysis with post-column oxidation are described in Table 2. Under these conditions good resolution was achieved for most of PSP toxins, with the exception of the gonyautoxin (GTX) group, owing to the presence of other GTX components with similar

retention times (this was confirmed using mass spectrometric detection).

The successful separation of these toxins by both ion exchange chromatography and cellulose acetate electrophoresis prompted investigations of the application of CE to their analysis. With the exception of the Ciguatera (C) toxins, which have neutral overall charge, all PSP toxins have positive charge under acidic conditions, and can be separated by elec-

trophoresis. Capillary electrophoresis should provide an efficient separation of most PSP components; however, some of the inherent difficulties in analysing these compounds are the lack of a chromophore absorbing in the usual UV range as well as the lack of standards to confirm the electrophoretic peak identity.

To overcome situations where the electrophoretic peak identity presents some uncertainties, or standards are not available to correlate with the peaks of interest, it is necessary to use a complementary technique, such as mass spectrometric detection using

electrospray ionization. This technique has shown excellent sensitivity for PSP as well as for other marine toxins. Mass spectrometric detection coupled with CE has been used for the rapid and efficient determination of PSP toxins. This technique has also been applied for the analysis of real mussel samples and an efficient separation for most of PSP toxins was achieved.

An example of the application of CE to the analysis of PSP toxins in mussels is shown in **Figure 3**. Under the conditions described in **Table 3**, several contaminated Galician mussel samples were analysed by this technique. Clean-up of the samples was required to remove interferences, but after this clean-up good resolution was obtained for most PSP toxins with the exception of the C toxins, which are not ionized in acidic media. The potential of this technique in terms of sensitivity was clearly increased by using isotachopheresis. Resolution in terms of efficiency, by means of theoretical plates, was clearly higher than that achieved by using HPLC.

DSP Toxins

Since PSP toxins are potent neurotoxins, the term '*diarrhoeic shellfish poisoning*' (DSP) has been associated with a number of different groups of toxic compounds; these include polyether compounds such as okadaic acid (OA), dinophysistoxins (DTX1, DTX2, DTX3), pectenotoxins and the fused polyether yessotoxin. Toxicological studies have shown that okadaic acid and dinophysis compounds are potent phosphatase inhibitors; their common symptomatology is related with the occurrence of diarrhoea. The mechanism of action of the other compounds has not been fully established, but it seems that they do not cause diarrhoea; instead they are described as hepatotoxins. The main reason for including these toxins in the DSP group is probably their polyether structure (**Figure 4**).

DSP toxins are also produced by certain toxic dinoflagellates; the chemical structure of these toxins emerged following the isolation of new polyether toxin named okadaic acid, from the sponge *Hali-*

UVD detection	Time, 90 s Wavelength 200 nm

Figure 4 Chemical structure of DSP toxins.

chondria okadai. The similarities between okadaic acid and DTXs were quickly recognized. Several places worldwide have been affected by such toxic outbreaks since the first toxic event, which took place in the Netherlands in 1960. Although the toxic effects of okadaic acid are related to gastrointestinal disorders, these toxins have been shown to have the potential to bind to protein phosphatases. Consequently the toxicological activity of DSP toxins is also associated with the promotion of tumours, especially in the stomach, intestine and colon.

As for PSP toxins, mouse bioassay is the method commonly used for the analysis of DSP compounds, but the problems associated with this bioassay, such as long assay time, poor reproducibility and false positives, have instigated the search for alternative techniques. Since DSP toxins are lipid-soluble, organic solvents are required for their extraction. However, such lipid-soluble extracts are considerably more complex than aqueous extracts of the same organism and for this reason additional clean-up steps are required before analysis. DSP toxins can be detected by thin-layer chromatography (TLC), although the presence of interferences causes difficulties when using this technique.

DSP toxins may be separated by reversed-phase HPLC using an octadecylsilica (ODS) stationary phase and an acidified aqueous acetonitrile or methanol mobile phase. Detection can be accomplished with UV absorbance at 205–215 nm or with a refractive index detector, to give a detection level of about $10 \mu\text{g mL}^{-1}$ in solution, but the low selectivity of these detectors requires a high degree of clean-up prior to analysis. DSP toxins have a carboxyl group that is easily converted into a fluorescent ester derivative, which allows HPLC analysis with fluorescence detection. Pioneering work using this fluorescence

detection method uses 9-anthryldiazomethane (ADAM) as the derivatization reagent. Several other reagents have also been used for derivatization to try to overcome the problems of instability of ADAM; however, none has proven as selective and sensitive as ADAM. An HPLC method has been developed with fluorescence detection, using ADAM as derivatization reagent, which was synthesized *in situ* and used immediately. This method offers a reformulation of the previous *in situ* method. The ADAM method is very sensitive for DSP toxins, being able to detect 10 pg of the okadaic acid (OA) derivative injected on-column; the practical quantitation limit is about 10 ng g^{-1} tissue. **Figure 5** shows an example of the application of the *in situ* ADAM-HPLC analysis of standards and a real Galician mussel sample under the chromatographic conditions described in **Table 4**. This ADAM method is not suitable for the analysis of DTX-3 compounds owing to their high molecular weight and lipophilicity. They must first be converted back to OA, DTX-1 or DTX-2 via alkaline hydrolysis; nevertheless, these compounds can be directly analysed by mass spectrometric techniques.

Mass spectrometry is a powerful tool for the analysis of marine toxins. This technique can provide structural information, as well as offering high sensitivity and selectivity; this structural information is useful not only for the confirmation of toxin identity, but also for the identification of new toxins. The combination of HPLC with electrospray mass spectrometry (LC-ESMS) appears to be one of the most sensitive and rapid methods of analysis for DSP toxins. The detection limit found for this technique is about 1 ng g^{-1} in whole edible shellfish tissue. This mass spectrometric detection has been also applied for the analysis of Galician samples, allowing the first confirmation of DTX-2 in these mussels.

Figure 5 Chromatogram obtained for the DSP toxin profile by using ADAM-HPLC-FLD.

ASP Toxins

This new type of seafood toxicity was first described after a contamination that took place in Prince Edward Island, Canada, in 1987. None of the known shellfish toxins was implicated in this incident and eventually domoic acid was identified as the toxic agent. Amnesic shellfish poisoning was originally isolated from a red macroalga, *Chondria armata*, by Japanese researchers studying insecticidal properties of algal extracts. Most of the people affected by this intoxication experience gastroenteritis but many older people develop neurological symptoms including memory loss. Intraperitoneal injections of acidic aqueous extracts of mussels contaminated with domoic acid into mice cause death with unusual neurotoxic symptoms very different from those of paralytic shellfish poison and other known toxins.

Domoic acid (DA) is a known neurotoxin that is absorbed through the gastrointestinal system, causing damage in the central nervous system. The source of this toxin is a diatom, *Nitzschia pungens multiseriata*, which is ingested by shellfish such as mussels during normal filter feeding. The chemical structure of domoic acid is shown in **Figure 6**. This rare naturally occurring amino acid is a member of a group of potent neurotoxic amino acids that act as an agonist to glutamate, a neurotransmitter in the central nervous system. A number of DA isomers that show

varying degrees of toxicity have also been identified. Isomerization of DA can occur photochemically or thermally, the latter being significant in cooked seafood.

Like the toxins previously described, reliable methods for the analysis of DA and isomers in seafood products are extremely important for protection of public health. Domoic acid can be analysed semiquantitatively by TLC, but instrumental methods of analysis are most commonly used. HPLC or ion exchange chromatography using ultraviolet absorbance detection are the methods of choice. HPLC has been used since 1987 by Canadian regulatory agencies to prevent other incidents of shellfish poisoning, and is also the official method of analysis for domoic acid in most countries. Domoic acid may be extracted from shellfish tissues by boiling with water or by blending with aqueous methanol. The latter is most commonly used because it is better suited for trace analysis and combines well with a highly selective clean-up based on strong anion exchange. The detection of domoic acid is facilitated by its strong absorbance at 242 nm. The main problem of using this technique is associated with the presence of interferences, which can give false positives with crude extracts. This is the case of tryptophan and some of its derivatives. Since these compounds are often present in shellfish and elute close to domoic acid, SAX-SPE clean-up prior to HPLC-UV analysis avoids the problem caused by these

interferences. An example of the application of the HPLC-UV technique for the analysis of domoic acid in standards, mussel tissue reference material and real contaminated bivalves under the chromatographic conditions described in Table 5 is shown in Figure 7.

A very sensitive alternative HPLC method using fluorescent detection has been proposed. This method uses 9-fluoronylmethyl chloroformate (FMOC) as derivatization reagent and the FMOC derivative is analysed with fluorescence detection.

Capillary electrophoresis offers the potential of fast high resolution separation of DA and its isomers and the possibility of trace analysis with very small amounts of sample. This method is also attractive in terms of being inexpensive and complementary to HPLC.

Extraction and clean-up procedures are priority steps in order to achieve the best chromatographic and electrophoretic resolution; when combined with a selective extraction and clean-up procedure, CE with UV detection is an excellent method for the separation and quantitative analysis of domoic acid and its isomers in shellfish tissues. Figure 8 shows the

application of CE to the analysis of standard solution of domoic acid, mussel tissue reference material (MUS-1) and Galician mussel samples. The conditions for this CE analysis are summarized in **Table 6**.

The use of cyclodextrins allows an increase on the separation efficiency when compared with LC-UVD. The better mass detection limit provided by this CE technique could be very useful for situations where limited sample size is available.

Future Trends

The techniques of HPLC and CE for the analysis of marine toxins provide the separation efficiency required for complicated matrices such as marine samples as well as the high resolution required to determine the toxins present in contaminated samples with very low detection limits. Extraction and clean-up steps prior to the chromatographic analysis are essential in order to obtain accurate quantitative results and also to prevent interferences that can cause false positives. New, fast and on-line automated procedure could give shorter and more accurate analyses. The possibility to combine this automation with simple methods is also desirable, especially for routine control purposes.

Taking into account the lack of standards for all toxins and also the appearance of new, unknown toxic compounds, the development of confirmatory techniques for their detection is an important research field. The development and optimization of coupling techniques, such as LC-MS or CE-MS, and the development of adequate interfaces as well as efficient ionization modes is a high priority.

MECHANICAL TECHNIQUES: PARTICLE SIZE SEPARATION

Introduction

Particles of many kinds and various sizes have played an important role in man's interaction with his physical environment. They abound in the soil and earth below; they are also present in water, air, chemical products, and many other sources. If particles were spherical or cubical, it would be easy to characterize them. Unfortunately, most of the particles present in our environment are of irregular size and shape. Therefore, it is desirable to try to develop methodologies and techniques to characterize particles of irregular size and shape, and this is the main objective of particle size analysis. Moreover, particle size analysis is important in studying particle behaviour in a medium as in many analytical sciences and industrial applications.

Particle size analysis in physical, chemical, and biological processes involves many concepts and techniques; however, this article focuses on the methods of particle size analysis utilizing mechanical techniques.

This article will first introduce some basic principles used in particle size analysis. This will be followed by a summary of the applicable particle size ranges for the different methods and the size ranges of most common particles found in industrial, chemical, environmental, and clinical applications. The most common mechanical techniques and methods used in particle size analysis will be briefly presented.

Particle Properties

Particle size analysis plays an important role in many analytical sciences and industrial applications. To assist in developing useful methodologies and tech-

niques it is essential to identify the main factors that control the behaviour of particles in a medium. Such factors include particle density, shape, size, size distribution, concentration, and surface characteristics, and the carrier medium dynamics (Figure 1). This article focuses on particle size analysis using mechanical techniques in relation to clinical, industrial, and environmental applications: therefore, the particles under consideration could be solid or liquid and the medium could be liquid or gas. In aerosol systems the medium is gas (air).

Density

Particles originating from a solid will have the same density as that of the parent material. However, if the material undergoes hydration or surface oxidization or if it agglomerates in clusters, its specific gravity will change. The particle density plays an important role in the separation of solids as in centrifugal and gravitational sedimentation, for example.

Particle Shape

Shape factors The method of formation influences the resultant particle shape. In comminution, attrition or disintegration, the generated particle resembles the parent material. On the other hand, if the method of formation is condensation from vapour, the smallest unitary particle may be spherical or cubical. In many cases condensation is followed immediately by solidi-

Figure 1 Main factors affecting particle behaviour in a medium.

fication and formation of chain-like aggregate (e.g. iron oxide fumes, carbon black).

Based on experimental data it has been found that for a collection of groups of particles having an average diameter D_{pi} for group i , the total surface area can be expressed as:

$$A_p = \alpha_s (\sum n_i D_{pi}^2) \quad [1]$$

where α_s is defined as the surface shape factor. The total volume can be expressed as:

$$V_p = \alpha_v (\sum n_i D_{pi}^3) \quad [2]$$

where α_v is defined as the volume shape factor. The surface and volume shape factors may be related to a combined shape factor k_p as:

$$k_p = \frac{\alpha_s}{\alpha_v} \quad [3]$$

In the case of spherical or cubical particles it can be shown that the shape factor is 6. For irregular particles, values vary from 6 to 10. Some other relationships can be obtained by using eqns [1]–[3]:

$$A_v = \frac{A_p}{V_p} = \frac{k_p}{D_p^*} \quad [4]$$

$$D_p^* = \frac{\sum n_i D_{pi}^3}{\sum n_i D_{pi}^2} \quad [5]$$

$$A_m = \frac{k_p}{\rho_p D_p^*} \quad [6]$$

where A_v = specific surface area (surface area per unit volume); D_p^* = specific surface diameter; A_m = surface area per unit mass; ρ_p = density of the particle material. The surface and volume information are used in estimating the equivalent spherical particle diameter which is used in studying particle behaviour in a medium.

Fractal geometry Mandelbrot introduced the basic concepts and theories of a new type of geometry called fractal geometry, in order to describe rugged structures. The main idea put forward by Mandelbrot is that the boundary of a rugged system can be described in its embedding space by a fractal dimension which describes its space filling effect. In the case of a fractal surface the estimate of surface area (A_λ) tends to increase without limit as the step size (resolution) λ of an elemental square decreases. This can be expressed as:

$$A_\lambda = k_a \lambda^{-(\delta-2)} \quad [7]$$

where k_a is a constant and the fractal dimension δ is greater than 2. Hence a plot of $\ln(A_\lambda)$ versus $\ln(\lambda)$ will have a slope of $[-(\delta-2)]$, where 'ln' designates a natural logarithm.

Kaye applied fractal geometry in his studies of the profiles of carbon black agglomerates. In subsequent studies he demonstrated the usefulness of fractal geometry in studying boundary and mass fractal dimensions of aerosol systems, fractal structures of fine particle systems, fragmentation, description of porous bodies and gas adsorption.

Surface Characteristics and Interfacial Phenomena

The surface characteristics of small particles include surface area, rate of evaporation and condensation, electrostatic charge, adsorption, adhesion and light scatter. In certain circumstances, changes in the environment of a particle during sampling and particle size analysis may change its size or state of aggregation or its surface characteristics. Such changes must be considered in the selection of a suitable sampling device or method for particle size analysis.

Surface area One of the important characteristics of small particles is the rapid increase in exposed surface area per unit mass as size decreases, which leads to increased chemical reaction rate. Fine powders of organic and inorganic oxidable materials (such as coal, iron, flour, sugar, and starch) burn vigorously or explode violently when in the form of an aerosol. Moreover, an increase in surface area increases the toxicity of some granular materials.

Evaporation and condensation Evaporation and condensation are diffusion mass transfer processes which proceed at rates proportional to the surface area exposed. The temperature and partial pressure in the vicinity of the surface control the time required for small particles (e.g. water) to evaporate into still air. The evaporation time is given by:

$$\tau = \frac{RT \rho_p D_p^2}{8M D \Delta_p} \quad [8]$$

where τ = evaporation time (s); ρ_p = density of particle material (kg m^{-3}); D_p = particle diameter (m); D = diffusion coefficient of vapour from particle ($\text{m}^2 \text{s}^{-1}$); Δ_p = difference between the particle pressure at the particle surface and in the surrounding fluid (N m^{-2}); R = gas constant ($8.3144 \text{ J mol}^{-1} \text{ K}^{-1}$); T = absolute temperature (K); M = molecular weight of evaporating particulate material. Finer particles can act as centres for

Figure 2 Mechanisms producing natural charge on particles.

condensation of moisture, leading to an increase in their size.

Electrostatic charge Electrostatic charge represents an excess or deficiency of electrons on the particle surface. This charge may be assumed to reside on the particle surface in an absorbed gas or moisture film. Mechanisms which produce natural charge on particle surfaces are shown in **Figure 2**. The electrostatic charge generated on a particle is proportional to the particle surface area, which is the principle used in the design of electrostatic classifiers and precipitators. Furthermore, the presence of electrostatic charge on particle surfaces controls the behaviour of particles in an electric field (see II/PARTICLE SIZE SEPARATION/Electrostatic Precipitation).

Scattering properties Scattering of radiation arises from inhomogeneities, such as dispersed dust or water drops, in the fluid medium. Scattering is often accompanied by absorption, and both scattering and absorption remove energy from the incident beams. The quantitative response of the intensity of transmitted and/or scattered beams can be used to characterize the size of a particle.

Kinetic Behaviour of Particles

The equivalent spherical particle diameter of an aggregate of irregularly-shaped particles can be determined by studying the inertial motion of particles in a medium. Such inertial motion can be found in many applications such as pulmonary deposition, design of industrial ventilation, particle collectors, and electrostatic precipitation. The various processes that affect particle motion in a field are shown in **Figure 3**.

Figure 3 Processes affecting particle motion in a medium.

Medium Resistance

For a small spherical particle moving in a medium at low velocities (i.e. laminar flow), the drag (medium resistance) force acting on the particle is given by Stokes' Law as:

$$F_R = 3\pi\mu_m D_p V_{pm} = C_D \frac{\rho_m A V_{pm}^2}{2} \tag{9}$$

where F_R = medium resistance (N); D_p = particle diameter (m); ρ_m = medium density (kg m^{-3}); μ_m = medium viscosity ($\text{kg m}^{-1} \text{s}^{-1}$); V_{pm} = relative velocity between particle and medium (m s^{-1}); A = projected area of particle normal to its motion (m^2).

It is useful to relate the magnitudes of the inertial and viscous forces in the form of a dimensionless Reynolds' Number as:

$$Re_p = \frac{\rho_m D_p V_{pm}}{\mu_m} \tag{10}$$

The relationship between the drag coefficient C_D and the Reynolds' Number can be found in any fluid mechanics textbook. However, for spheres with $Re_p < 1, C_D = 24/Re_p$.

In finite containers a particle experiences an increase in the drag force due to two effects. First the fluid streamlines around the particle impinge on the container walls and are reflected back causing increased drag on the particle. The second effect occurs because the fluid is stationary at a finite distance from the particle, and there is a distortion of the flow pattern which reacts back on the particle. Taking into consideration these two effects, the drag force may be modified as:

$$F_R = 3\pi\mu_m D_p V_{pm} \left(1 + \frac{kD_p}{L} \right) \tag{11}$$

where L represents the distance from centre of particle to the container walls and $k = 0.563$ for a single wall or container bottom and $k = 2.104$ for a cylindrical container.

Particle Motion

Particle motion in a gravitational/drag field The linear motion of a particle in a direction X relative to time t and under the influence of the drag, gravitational, and buoyancy forces is governed by:

$$\frac{\pi}{6}\rho_p D_p^3 \left(\frac{d^2 X}{dt^2} \right) = \frac{\pi}{6}(\rho_p - \rho_m) D_p^3 g - 3\pi\mu_m D_p \frac{dX}{dt} \tag{12}$$

where g denotes gravitational acceleration. If the particle starts from zero velocity it will accelerate until it reaches a terminal velocity given by:

$$\left(\frac{dX}{dt}\right)_{t \rightarrow \infty} = V_{gt} = \left[\frac{D_p^2(\rho_p - \rho_m)}{18\mu_m}\right] \cdot g \quad [13]$$

from which the particle diameter can be expressed as:

$$D_p = \left[\frac{18\mu_m}{(\rho_p - \rho_m)g} \cdot V_{gt}\right]^{1/2} \quad [14]$$

Note that eqns [12] to [14] are applicable for $Re_p < 1$.

For a particle settling in air, it is usual to neglect the buoyancy correction, since ρ_p is of the order of unity, the air density is of the order of $10^{-3} \text{ g cm}^{-3}$, and viscosity of ambient air is $1.8 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$. Equation [13] reduces to:

$$V_{gt} = 3.03 \times 10^4 \rho_p D_p^2 \quad [15]$$

where V_{gt} , ρ_p , and D_p are expressed in m s^{-1} , kg m^{-3} , and m , respectively.

Particles with diameters less than or close to the mean free path of the fluid molecules begin to slip between molecules and settle at a higher velocity than that predicted by eqn [13] for settling velocity. Cunningham considered this so-called slip effect and introduced a correction term to the terminal settling velocity as:

$$V_{gtc} = C_c V_{gt} \quad [16]$$

$$C_c = \left(1 + \frac{2\alpha\lambda}{D_p}\right) \quad [17]$$

where C_c denotes the Cunningham slip correction factor, λ is the mean free path of medium molecules, and α is a constant of approximately one.

Particle motion in a rotational (centrifugal) field In a centrifugal field the radial motion of a particle at a distance R from the centre of rotation is governed by:

$$\frac{\pi}{6}\rho_p D_p^3 \left(\frac{d^2 R}{dt^2}\right) = \frac{\pi}{6}(\rho_p - \rho_m) D_p^3 \omega^2 R - 3\pi\mu_m D_p \frac{dR}{dt} \quad [18]$$

where ω is the angular velocity of the particle. Assuming that the particle movement outward is resisted by viscous drag, Stokes' law provides a reasonable approximation for the drag. Therefore, the terminal radial velocity at equilibrium is given by:

$$\left(\frac{dR}{dt}\right)_{t \rightarrow \infty} = V_{rt} = \left[\frac{D_p^2(\rho_p - \rho_m)}{18\mu_m}\right] \cdot \omega^2 R \quad [19]$$

which is equivalent to eqn [13].

To evaluate the performance of a centrifugal separation process, a separation factor ' SF ', defined as the ratio of centrifugal acceleration to gravitational acceleration:

$$SF \text{ or } g\text{-force} = \frac{\omega^2 R}{g} \quad [20]$$

is used. For dust-collecting cyclones (particles $> 100 \mu\text{m}$), $SF = 200$, while conventional centrifuges used in precipitation of submicron particles and large molecules in liquid suspension have $SF = 5000$. See II/PARTICLE SIZE SEPARATION/Hydrocyclones for Particle Size Separation.

Particle motion in an electrostatic field When particles larger than $1 \mu\text{m}$ are passed through a corona discharge as the result of bombardment charging, they acquire charges from electrons and adsorbed gas ions proportional to the surface area of the particle. The saturation charge acquired is given by:

$$Q_{pb} = ne = \pi\epsilon_0\epsilon_1\kappa D_p^2 E \quad [21]$$

$$\kappa = \frac{3\epsilon_2}{\epsilon_2 + 2\epsilon_1} \quad [22]$$

where Q_{pb} = saturation bombardment charge acquired (C); n = number of electron charges acquired; e = electron charge ($1.6022 \times 10^{-19} \text{ C}$); ϵ_0 = permittivity of vacuum ($8.8542 \times 10^{-12} \text{ F m}^{-1}$); ϵ_1 = relative permittivity of medium (gas); ϵ_2 = relative permittivity of particle material; E = external electric field strength (V m^{-1}). For particles less than $0.2 \mu\text{m}$, diffusion charging predominates and the charges acquired at time t are given approximately by:

$$Q_{pd} = ne = \frac{D_p k T}{2e} \ln \left(1 + \frac{\pi D_p V_i N_0 e^2}{2kT} t\right) \quad [23]$$

where Q_{pd} = diffusion charge acquired (C); k = Boltzmann constant ($1.3807 \times 10^{-23} \text{ J K}^{-1}$); T = absolute temperature (K); N_0 = ion density (ions m^{-3}); V_i = ion velocity (root mean square, m s^{-1}). Based on the acquired charge on the particle and assuming that air resistance is approximated by Stokes' Law, the particle terminal velocity in an electric field is given by:

$$V_{et} = C_c \left(\frac{EQ_p}{3\pi\mu_m D_p}\right) \quad [24]$$

where C_c = Cunningham slip correction factor; μ_m = medium (gas) viscosity; Q_p = acquired (bombardment or diffusion) charge on the particle.

Particle motion in a thermal gradient field It has been observed that particles in suspension move from hotter to colder regions. Later it has been shown that in a thermal gradient field and at atmospheric pressure, the thermal force acting on a particle is given by:

$$F_t = (-9\pi) \left(\frac{D_p}{2}\right) \left(\frac{\mu_m^2}{\rho_m T}\right) \left(2 + \frac{\kappa_p}{\kappa_m}\right)^{-1} \left(\frac{dT}{dx}\right) \quad [25]$$

where κ_p = thermal conductivity of the particle material ($J m^{-1} s^{-1} K^{-1}$); κ_m = thermal conductivity of the air ($J m^{-1} s^{-1} K^{-1}$); T = absolute temperature (K); dT/dx = temperature gradient in the air ($K m^{-1}$). The negative sign in the equation indicates that the force is in the direction of negative thermal gradient. By setting the thermal force equal to the resistive force of the medium, the terminal velocity of a particle is given as:

$$V_t = (-1.5) \left(\frac{C_c \mu_m}{\rho_m T}\right) \left(2 + \frac{\kappa_p}{\kappa_m}\right)^{-1} \left(\frac{dT}{dx}\right) \quad [26]$$

The particle velocity and the flow velocity and geometrical configuration are used in the design of thermal precipitators.

Common Methods of Particle Size Analysis and Particle Size Ranges

To assist in covering the scope of the different techniques used in particle size analysis, an attempt was made to survey the current literature on particle

size analysis techniques. The results of this investigation are summarized in **Figure 4**. It should be emphasized that this summary is not exhaustive. There are other sophisticated techniques which are outside the scope of this article. Of more importance is the identification of the size ranges of most common particles found in industrial, environmental, chemical and clinical applications (**Figure 5**). From an industrial point of view, the different types of gas particulate collecting equipment are summarized in **Figure 6**. Some basic definitions of particle size ranges of gas and atmospheric dispersoids and soil are included in **Figure 7**.

Mechanical Techniques for Particle Size Analysis

Based on the information given in Figures 4–7, it can be seen that the most common mechanical techniques for particle size analysis relevant to analytical sciences and industrial applications are: sieving, sedimentation (gravitational or centrifugal), elutriation, electrostatic precipitation, thermal precipitation, hydrodynamic chromatography and impaction. Each technique will be briefly presented; the details of each technique can be found in the references listed in the bibliography.

Sieving

Sieving is an obvious and most widely used technique for particle size analysis. The particles are classified based on their size, independent of any other particle characteristics such as density and surface properties.

Medium flow around particle	Brownian motion		Transition zone	Laminar flow		Transition zone	Turbulent flow	
Electromagnetic waves	X-rays	Ultraviolet	Visible	Near-infrared	Far-infrared		Microwave	
Particle diameter (μm)	0.0001	0.001	0.01	0.1	1	10	100 (1 mm)	1000 (1 cm)

			Confocal microscopy					

Figure 4 Common methods of particle size analysis. *Average particle diameter but not size distribution. **Size distribution may be obtained by special calibration.

Figure 5 Typical particles and gas dispersoids.

Micromesh sieves are used to classify particles of size range 5–20 μm, while particles of size range 20–125 μm are classified in the standard woven wire sieves. Coarse particles (> 125 μm) are classified in

punched plate sieves. Punched plate sieves are commonly used in industrial applications where the openings are circular or rectangular; the sieves can take different configurations.

Figure 6 Different types of gas particulates collecting equipment (φ, diameter).

Figure 7 Some size range definitions.

The sieving test is conducted using up to 11 sieves stacked with progressively larger aperture openings towards the top, and placing the powder on the top sieve. A closed pan (receiver) is placed at the bottom. There are several schemes for shaking the sieves by mechanical or ultrasonic means. The residues in each sieve are recorded and expressed in percentage as cumulative values against the nominal sieve aperture values.

The common methods for fine sieving are machine, wet, hand and air-jet sieving. Wet-sieving is recommended for material originally suspended in a liquid and is necessary for powders which form aggregates when dry-sieved. In such tests the stack of sieves is filled with liquid and the sample is fed to the top sieve. Sieving is accomplished by rinsing, vibration, reciprocating action, vacuum, ultrasonication or a combination of these.

Table 1 presents the different international sieve standards and the corresponding sieve types. There are several sieve aperture progression ratios commonly available depending on the different international standards. In the USA, a progression ratio of $2^{1/2}$ is used. This ratio corresponds to successive particle groups of 2 : 1 particle surface ratio. The progression rate of $2^{1/3}$ ($10^{0.1}$) which has been adopted by the French corresponds to successive particle groups of 2 : 1 particle volume ratio. The progression ratios of $10^{0.1}$ and $10^{0.05}$ are recommended for narrow size distributions.

Table 1 International sieve standards

Country	Standard	Sieve type
Great Britain	BS 410	Woven wire
USA	ASTM E11	Woven wire
	ASTM E161-607	Micromesh (electroformed)
Germany	DIN 4188	Woven wire
	DIN 4187	Perforated plate
France	AFNOR NFX 11-501	Woven wire
International	ISO R565 1972(E)	Woven wire
		Perforated plate

The probability of a particle passing through sieve apertures depends on the particles size distribution, the number of particles on the sieve (sieve loading), the method of sieve shaking, the dimension and shape of the particle, and the ratio of open area of sieve to total area. In addition, the sieving operation can be affected by the friability and cohesiveness of the powder.

Sedimentation

Sedimentation of fine powders in a suspension is an important tool in the determination of particle size distribution. Table 2 presents a classification of the methods and techniques used in sedimentation (gravitational or centrifugal). To conduct particle size analysis using sedimentation, the suspension can be prepared using the line start (two-layer) or the homogeneous suspension techniques. In the two-layer technique, the powder is introduced at the top of a column of clear liquid. In the homogeneous suspension technique, the powder is uniformly dispersed in the liquid. As the particles start to settle the change in solids concentration at a particular fixed height with time or the sedimentation time rate is measured. The solids concentration or density measurements is used in the incremental methods, while the settling rate measurement is used in the cumulative methods. Incremental methods may be divided as fixed time and fixed depth methods, the latter being more popular, although a combination is sometimes used.

A powder is made up of three types of particles: primary particles, aggregates and agglomerates. The

primary particles are crystalline or organic structures bound together by molecular bonding, while the aggregates are primary particles tightly bound together at their point of contact by atomic or molecular bonding. The force required to break these bonds is considerable. In case of agglomerates, the primary particles are loosely bound together with weak van der Waals forces. It is often necessary to disperse the powder in a liquid prior to analysis. Dispersion is affected by the use of wetting agents which break down the agglomerates to their constituent parts. This process is facilitated by mechanical or ultrasonic agitation.

Gravitational sedimentation In gravitational sedimentation there are four main techniques: volume sample, mass sample, manometry and sedimentation vessel-wall pressure sensing as shown schematically in Figure 8.

Incremental methods Based on the results of motion of a particle in a gravitational/drag field, it can be shown that the solids concentration of settling suspension at depth h can be related to the cumulative undersize mass distribution as:

$$\frac{C(h, t)}{C(h, 0)} = \frac{\int_{D_{\min}}^{D_t} f(D) dD}{\int_{D_{\min}}^{D_{\max}} f(D) dD} = \Psi \quad [27]$$

$$D_t = \left[\frac{18\mu_m}{(\rho_p - \rho_m)g} \cdot \frac{h}{t} \right]^{1/2} \quad [28]$$

Figure 8 Main gravitational sedimentation techniques.

where $dm(D) = f(D)dD$ represents the mass fraction having particle size between D and $D + dD$. In eqns [27] and [28], it is assumed that the volume of particles (powder) in suspension is very small compared with the total volume of suspension. By plotting 100Ψ against the free-falling particle diameter D_t the resulting curve shows the cumulative undersize percentage curve by mass.

Similarly, it can be shown that:

$$\frac{C(h, t)}{C(h, 0)} = \frac{\phi(h, t) - \rho_m}{\phi(h, 0) - \rho_m} = \Phi \quad [29]$$

where $\phi(h, 0)$ and $\phi(h, t)$ are the suspension density at a height h at $t = 0$ and $t = t$, respectively. By plotting 100Φ against D_t , the resulting curve shows the cumulative undersize percentage size curve.

The pipette method In this method, the changes in concentration occurring within a settling suspension are determined by drawing off definite volumes at a set of discrete intervals of time by means of a pipette. The solids concentration in the suspension is required to be between 0.2 and 1.0 vol%. If the concentration exceeds 1% the hindered settling adversely affects the results of the analysis. Initially the powder is made into a paste; this is followed by slow addition of the dispersing liquid, using a spatula plus mixing, to form a slurry. Further dispersion may be carried out in an ultrasonic bath. The suspension is washed into a sedimentation vessel. The analysis starts with violent agitation of the vessel avoiding the use of a stirrer. It is recommended that the container be continually inverted by hand for 1 min. Since initially the particles are not at rest, it is advisable to wait 1 min before withdrawing samples. The use of a time scale progression of 2 : 1 which produces a $2^{1/2}$ particle size progression is recommended. The collected samples are prepared to determine the solids concentration for particle size cumulative mass determination.

Hydrometers and divers The variation in density of settling suspension may be monitored with hydrometers, a method used widely in the cement industry. The method starts with a fully dispersed suspension and the densities at known depths are recorded as the solid phase settles out. The hydrometer technique is useful for quality control but not as an absolute method.

Divers are an extension of the hydrometer technique. They act as miniature hydrometers where each diver is calibrated to a particular density. Several divers of different densities are added to the fully dispersed suspension and each will settle at a height where its density is equal to the suspension around it.

Sealed in each diver is a copper ring which enables an external search coil to monitor and determine the location of the diver using high-frequency alternating current.

The specific gravity balance The specific gravity balance may be used to monitor the change within a settling suspension. Such a balance comprises two bobs, one in clear fluid and the other in the suspension being studied. The bobs are connected to the two arms of a beam balance. The depth of immersion of the bobs is adjustable. The change in buoyancy is counterbalanced by means of solenoids which are connected to a pen recorder. From the trace of the pen recorder, the particle size distribution can be calculated.

Cumulative methods Cumulative methods have an advantage over incremental methods in that the amount of sample required is small (about 0.5 g), which reduces the interaction between particles. This is a useful feature when only a small quantity of powder is available or when dealing with toxic materials.

Line start method In this case the size distribution may be directly determined by plotting the fractional weight settled against the free-falling diameter of particles. Special care needs to be exercised to eliminate the streaming problem, especially when the suspension at the top has higher density than the liquid.

Homogeneous suspension method Let us consider a powder with a mass distribution such that $dM = f(D)dD$, where dM represents the fractional mass of particles having a diameter between D and $D + dD$. Let us assume that the powder is completely dispersed in a liquid, and consider a suspension chamber of height h . It can be reasoned that mass per cent P which has settled out at time t is made up of two parts:

- (1) all the particles with a free-falling speed greater than that of D_t as given by Stokes' Law or some related law, where D_t is the size of particle which has a velocity of fall h/t ;
- (2) particles smaller than D_t which started off at some intermediate position in the chamber. The falling velocity of one of these smaller particles is v , the fraction of particles of this size that have fallen out at time t is (vt/h) .

This mechanism can be represented mathematically as:

$$P = \int_{D_t}^{D_{\max}} f(D) dD + \int_{D_{\min}}^{D_t} \frac{vt}{h} f(D) dD \quad [30]$$

which after some manipulation can be rewritten as:

$$P = M + t \frac{dP}{dt} \quad [31]$$

eqn [31] may be written in a different form as:

$$M = P - \frac{dP}{d \ln(t)} \quad [32]$$

Both eqns [31] and [32] can be used to determine M . The most obvious way is to tabulate t and P , and hence derive dP/dt , and finally M (cumulative percentage oversize) versus D_t . Equation [32] is recommended in cases of wide size distribution.

Centrifugal sedimentation Gravitational sedimentation for particle size analysis has limited flexibility. Firstly, the only means of varying the particle velocity is by selecting a medium with different density or viscosity. Secondly, gravitational sedimentation cannot handle particles smaller than $5 \mu\text{m}$. Thirdly, most sedimentation devices suffer from the effects of convection, diffusion and Brownian motion. These difficulties can be reduced by speeding up the settling process by centrifuging the suspension. Furthermore, by the use of a centrifugal field, a substantially lower size limit and reduced analysis time can be achieved. As with gravitational methods the data may be cumulative or incremental and the sample may be homogeneous or two-layer.

Calculations of size distribution from centrifugal data are more difficult than calculations from gravitational data, since particle velocities increase as they move away from the axis of rotation (i.e. the particle velocity depends on its radial position). One way to overcome this difficulty is to use a relatively small settling radial zone at a far distance from the centre of rotation (i.e. the centrifugal force acting on all particles is approximately the same). Another solution is to use the line start technique. The most common techniques used in centrifugal sedimentation are schematically presented in **Figure 9** where S and D designate source and detector, respectively.

Line start method Rewriting eqn [19] as:

$$V_{rt} = \frac{dR}{dt} = \left[\frac{D_t^2(\rho_p - \rho_m)}{18\mu_m} \right] \cdot \omega^2 R \quad [33]$$

together with separation of variables and integration of eqn [33], yields:

$$D_t = \left[\frac{18\mu_m}{(\rho_p - \rho_m)\omega^2 t} \cdot \ln\left(\frac{R}{S}\right) \right]^{1/2} \quad [34]$$

Figure 9 Main centrifugal sedimentation techniques.

where t is the time for a particle of size D_t to settle from the surface of the fill (at distance S from the centre of rotation) to a radial distance R . Hence, at time t , all particles at R will be of size D_t . Monitoring the per cent solids or density of the suspension at specified intervals of time will produce the particle size distribution which can be represented using cumulative values at different values of D_t .

Homogeneous suspension method Equation [34] still applies: however, at time t , all particles of size greater than D_t will have settled out radially to a distance R . Conversion of the sedimentation curve into a cumulative curve is not as simple in this case as for that of gravitational sedimentation. Difficulties involved in evaluating the sedimentation curve may be overcome in the case of a centrifugal field by assuming a constant centrifugal field, i.e. for $(R - S)$ interval is small enough to allow the approximation:

$$\ln\left(\frac{R}{S}\right) \approx \frac{(R - S)}{R} \quad [35]$$

when the value $(R - S)$ is one twentieth of R , the cumulative curve can be obtained directly by the pipette technique with an error of 1%.

Elutriation

In fluid classification, the effects of different forces on the movement of suspended particles control the separation of dispersed particles. As discussed in the kinetic behaviour of particles, the field forces are gravitation, as with elutriators, or centrifugal or Coriolis force in classifiers. The medium is usually water or air. In general all fluid classifiers can be divided into two classes, counterflow equilibrium (elutriation) and inverse flow separation. The elutriation is presented briefly below.

In the elutriation technique, the field and the drag forces act in opposite directions and particles leave the separation zone in one of two directions, depending on their size. Particles of a certain size stay in equilibrium in the separation zone. The grading is carried out in a series of vessels (cylindro-conical form) of successively increasing diameter. Hence, the fluid velocity decreases in each stage, the coarse particles being retained in the smallest vessel and the relatively finer particles in the following vessels. For air elutriation, the analysis is considered complete if the rate of change of weight in residues is less than 0.2% of the initial weight in half an hour, and for water elutriation the analysis ends when there is no sign of further classification.

Using Stokes' Law, the particle size retained in an intermediate vessel can be predicted approximately as

$$D_p = \left[\frac{18\mu_m}{(\rho_p - \rho_m)g} \cdot V_{\max} \right]^{1/2} \quad [36]$$

$$V_{\max} = 2V = 2\frac{Q}{A} \quad [37]$$

where Q = volumetric flow rate, A = vessel cross-sectional area at the equilibrium zone. In eqn [37] it is assumed that the flow profile in the vessel is parabolic. It is clear that elutriation is only suitable for rough dispersions. With small particles, sedimentation may be speeded up by using a centrifuge. This technique is utilized when classifying aerosols using a stream of air which flows in the direction opposite to the centrifugal force.

Electrostatic Precipitation

The electrostatic precipitator consists of an ionizing cathode at high potential surrounded by a collecting anode; typically, these anodes consist of concentric cylinders, the inner one often being a single wire. The gas suspension passes between the cylinders, picks up the charge, and travels to the anode where the charge is deposited. The transfer of electrons from one anode to the other constitutes an electric current. The mag-

nitude of this current is proportional to the number of particles deposited. Particle sizes can be determined by varying the flow rate or applied potential.

Classification in an electrostatic field by differences in charge is related explicitly to particle size. This type of instrument has been used for collecting aerosol bacteria. The instrument consists of a glass cylinder with a central electrode. The inner surface of the cylindrical glass is coated with a suitable material to act as the other electrode and to collect samples. The principal advantages of this type of instrument are high collection efficiency over a wide size range, low resistance and high flow-rate capacity.

Thermal Precipitation

Particles in a thermal gradient medium move in the direction of negative gradient, i.e. from hotter to colder regions. Based on this principle, the instrument typically consists of two parallel round microscopic plates and a heated wire in between as shown in Figure 10. The sample is drawn between the plates and the particles deposit on the glass plates and are collected for further analysis.

Normally a sample flow of $1-2 \text{ cm}^3 \text{ s}^{-1}$ is recommended and the collection efficiency is high for particles smaller than $5 \mu\text{m}$. The collecting device may be modified so that the sample is collected directly on an electron microscope grid. Modifications of the basic design include means of centering the wire in position, substitution of the wire by a ribbon to give more uniform deposits, and using inlet elutriators to exclude coarse particles. The practical application of thermal precipitation in gas cleaning plants has only rarely been attempted.

Figure 10 Thermal precipitation.

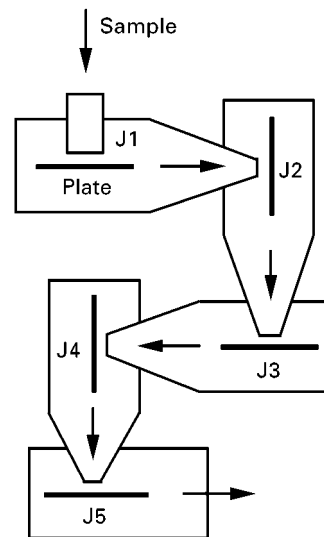

Figure 11 Cascade impactor.

Impaction

Impactor Inertial impaction devices cause an air sample to be drawn into a round or rectangular nozzle where the gas velocity is substantially increased. The jet from the nozzle is discharged against an adjacent flat surface, causing the air to diverge sharply. Particles in the air have more inertia than the air, and tend to continue forward as the air passes off to the sides, causing some of the particles to impact onto the surface. To prevent the particles from re-entrainment, a viscous material such as silicone fluid (or substrate) is used to coat the plate. The efficiency of impaction may be defined in terms of the dimensionless impaction factor as:

$$I = \left(\frac{C_c \rho_p D_{pa}^2 V_j}{18 \mu_m D_j} \right)^{1/2} \quad [38]$$

where D_{pa} = particle aerodynamic diameter; D_j = jet diameter or width; V_j = average air velocity at the jet outlet.

Classification of a particle cloud into discrete sizes using cascade impaction may be interpreted as measuring aerodynamic (equivalent spherical particle) diameter. Several impaction stages (cascade impactor) are used in the classification of a polydisperse cloud (see Figure 11). The stages are arranged to permit jet velocity to increase with each succeeding stage (by successive reduction in jet diameter or width), and to therefore cause particles of progressively smaller sizes to be impacted. In effect, the cascade impactor classifies particles according to their aerodynamic size. The aerodynamic diameter can be expressed in terms of Stokes'

diameter as:

$$D_{pa} = D_{Stokes} \rho_p^{1/2} \quad [39]$$

where D_{Stokes} is the measured diameter. The aerodynamic size is important because it controls the motion of a particle in an air stream. Therefore, it is significant for studies concerning lung inhalation, spray effectiveness, and gaseous cleaning devices. A special duty impactor (five-stage cascade impactor) has been developed for sampling and grading acid mists in the size range 0.3–3 μm .

Impinger Another sampling instrument, referred to as an impinger, also utilizes inertial impaction: however, deposition occurs at the bottom of a liquid-containing vessel. The downward-directed air-jet displaces the liquid and uncovers the bottom of the vessel. The particles that impinge against the wet surface are subsequently washed off by the liquid. The undeposited particles may be caught as air bubbles rise through the liquid. The particles are usually examined in the liquid suspension. Water is the most commonly used liquid.

Hydrodynamic Chromatography

Size information about colloidally suspended particles (0.01–1 μm) can be obtained by employing hydrodynamic chromatography (HDC). A medium (an aqueous solution) is pumped through a column packed with impermeable spheres. A pulse of colloidal suspension (0.2 cm^3) containing about 0.01 wt% polymer is injected into the flowing stream of the column entrance. The mobile phase from the column effluent is passed through a suitable detection system, such as a flow through spectrophotometer of the type used in liquid chromatography, and the detector response of the colloid is determined as a function of elution time. An extra step is needed to determine the concentration of solids in the eluted solution.

It has been observed that the larger particles elute faster than the small ones. It has also been found that the smaller the packing diameter the better the separation. Other factors which affect the rate of transportation through the bed are the size of bed particles, the ionic strength, and flow velocities, as well as the particle size of eluting particles.

In general, HDC has been successfully applied to the size characterization of a number of polymer lattices. The method is applicable to the size separation of particles between 0.02 and 1 μm , if they are rigid. Moreover, it is expected that HDC has wide applicability to sub- μm particles such as in lattices, carbon black, colloidal silica, paint, and photo-

graphic pigments, dyes, food colours, natural and artificial blood, and metallic fumes.

Another extension of HDC is to replace the packed bed with a long capillary. Capillary particle chromatography (CPC) requires 30 kPa pressure and has a separating range of 0.2–200 μm . In such techniques the particle transit time is a logarithmic function of particle size.

Liquid Particle Size Measurement Techniques

In the areas of combustion and chemical processes and in the pharmaceutical and agriculture industries, measurement of droplet size and velocity distributions is important. In one respect the measurement of droplets is easier than that of solid particles because droplets are usually spherical and smooth. In another respect the measurement of droplets is more difficult because they are not easy to collect and stabilize, and they may be volatile. Thus, an *in situ* measurement is usually preferable. The applications commonly used can be grouped as spray diagnostics (using ensemble scattering techniques and optical single-particle analysis) and spray measurement.

MEDICINAL HERB COMPOUNDS: HIGH-SPEED COUNTERCURRENT CHROMATOGRAPHY

T. Zhang, Beijing Institute of New Technology
Application, Beijing, China

Copyright © 2000 Academic Press

Introduction

Medicinal herbs are an important source of natural products for medicine. They include various chemical components ranging from fat-soluble to water-soluble compounds. The isolation of the biologically active components is the starting point of further research in chemistry and pharmacology as well as in the utilization of these compounds.

Traditional Chinese medicine is an extremely rich source of the experience acquired over a long period of time. In order to make greater use of traditional Chinese medicine, modern scientific methods are used to find the bioactive compounds in the traditional drugs and to use them as leading compounds for new drug design. New drugs developed in this way include anisodamine and the antimalarial agent Qinghaosu (artemisinin).

For separating and purifying bioactive compounds from medicinal herbs, modern chromatographic techniques, such as gas chromatography, high performance liquid chromatography, thin-layer chromatography and electrophoresis have significantly raised the technical level and have shortened the time required for research projects.

High speed countercurrent chromatography (HSCCC) has been recognized as an effective means for separation and purification of a wide variety of bioactive components. It is a liquid-liquid partition chromatography system based on a coil planet centrifuge system without the use of any solid support. This technique has developed rapidly during the past dec-

ade. It has been demonstrated to have preparative capabilities and unique properties for fractionating a variety of natural products and medicinal herbs.

Here some applications of the separation of bioactive compounds, such as alkaloids and flavonoids, in medicinal herbs by HSCCC are described.

Separations of Alkaloids

Separations of Alkaloids Extracted from *Stephania tetrandra* S. Moore

Dried roots of *Stephania tetrandra* S. Moor (Menispermaceae) or Fenfangji in Chinese is a traditional Chinese drug used for rheumatism and arthritis. The total active alkaloid content in the natural products is 2.3%. Three major alkaloids have been identified as tetrandrine (I, 1%), fangchinoline (II, 0.5%) and cyclanoline (III, 0.2%). I and II are inseparable by conventional methods, while III is well separated from the other two. As illustrated in Figure 1, I and II are both bisbenzylisoquinoline alkaloids, whereas III is a water-soluble quaternary protoberberine-type alkaloid.

A sample solution was prepared as a mixture of I and II with purified III to obtain a 10 : 5 : 2 weight ratio to simulate their composition in the natural drug. 3 mg of this sample was dissolved in 0.5 mL of the upper stationary phase of the selected solvent system. The solvent system was composed of n-hexane/ethyl acetate/methanol/water at two different volume ratios of 3 : 7 : 5 : 5 in the first experiment and 1 : 1 : 1 : 1 in the second. In both cases the lower phase was used as the mobile phase at a flow rate of 60 mL h⁻¹ in the normal elution mode. The apparatus used in these experiments was a Pharmatech Model CCC-2000 analytical countercurrent

Figure 1 The chemical structures of tetrandrine(I), fangchinoline(II) and cyclanoline(III).

chromatograph made by Pharma-Tech Research Corp. It is equipped with a column holder at a 6.4 cm revolution radius. A multilayer coil prepared from a 70 m length of heavy wall 0.85 mm i.d. PTFE tubing is coaxially mounted on the holder. The total capacity of the column is 43 mL. The maximum speed of this centrifuge is 2000 rpm. The apparatus is equipped with a metering pump, a speed controller with a digital rpm display, and a pressure gauge.

Figure 2 shows the chromatogram obtained from the first experiment. In the normal elution mode,

Figure 2 Chromatogram of the sample mixture of tetrandrine (1)–fangchinoline (2)–cyclanoline (3) (10 : 5 : 2). Solvent system n-hexane–ethyl acetate–methanol–water (3 : 7 : 5 : 5).

peaks 1 and 2 were completely resolved and collected in 70 min. This was followed by a reversed elution mode without interrupting the centrifuge run to collect the third peak in an additional 30 min. As shown in the chromatogram, a very small amount of impurity present between peaks 1 and 2 was also resolved.

The chromatogram obtained from the second experiment is shown in Figure 3. It demonstrates an alternative approach where the solvent composition was adjusted to modify the partition coefficients of the compounds to shorten the separation time without the use of a reversed elution mode.

A Finnigan MAT mass spectrometer was used to analyse the peak fractions to identify the compounds in peaks 2 and 3 in Figure 3 as purified fangchinoline and cyclanoline respectively.

Semipreparative Separation of Alkaloids from *Cephalotaxus fortunei* Hook f.

The alkaloids, isoharringtonine (I), homoharringtonine (II) and harringtonine (III) isolated from *Cephalotaxus fortunei* Hook f., possess anticancer potency. Among those compounds, (I) and (III) are isomers, and (II) and (III) differ only by a $-\text{CH}_2$ group (Figure 4).

A crude alkaloid powder was prepared from the leaves and branches of *C. fortunei* Hook f. 20 mg of the crude powder was dissolved in 1 mL of the solvent mixture (upper phase and lower phase) as the sample solution for each separation. The two-phase solvent system was composed of chloroform/0.07 M sodium phosphate buffer solution at the volume ratio of 1 : 1 (pH 5.0).

The apparatus used in these experiments was a GS-10A HSCCC made by Beijing Institute of New Technology Application. A pair of column holders

Figure 3 Chromatogram of the sample mixture of tetrandrine (1)–fangchinoline (2)–cyclanoline (3) (10 : 5 : 2). Solvent system n-hexane–ethyl acetate–methanol–water (1 : 1 : 1 : 1).

are held symmetrically on the rotary frame at a distance of 8 cm from the central axis of the centrifuge. The multilayer coil separation column was prepared by winding a 130 m length of 1.5 mm i.d. PTFE tubing directly on to the holder hub. The total capacity of the 14 layer column was 230 mL. The speed of this machine was regulated with a speed controller in a range between 0 and 1000 rpm, while 800 rpm was used as the optimum speed for the conventional two-phase solvent system.

In each separation, the column was first entirely filled with the stationary aqueous phase followed by injection of the sample solution. The apparatus was rotated at 800 rpm while the nonaqueous mobile phase was pumped into the column at a flow rate of

2 mL min⁻¹. Effluent from the outlet of the column was continuously monitored with a UV monitor at 254 nm and collected with a fraction collector at 2 min intervals. After a group of nonpolar compounds was eluted, the centrifuge was stopped while pumping was resumed to collect a polar compound still retained on the column. **Figure 5** shows the chromatogram obtained. Each fraction was analysed by TLC and the fractions corresponding to peaks 2, 4 and 6 were identified as isoharringtonine, homoharringtonine and harringtonine.

In order to increase the yield of the component homoharringtonine, 300 mg of crude extract was applied to produce 70 mg of the pure product. The method is useful for semipreparative separation of alkaloids and other natural products with similar polarity.

Separation of Flavonoids

Separation of Flavonoids in Crude Extract from Sea Buckthorn

The results of separations of a crude ethanol extract from dried fruits of sea buckthorn (*Hippophae rhamnoides*) are described. Five flavonoid constituents were successfully separated by P.C. Inc. A two-phase solvent system composed of chloroform–methanol–water at a 4 : 3 : 2 volume ratio was used. The sample solution was prepared by dissolving the crude ethanol extract in the solvent mixture of upper and lower phases at a concentration of 2.2 g %.

Separation was performed as follows: The coiled column was first entirely filled with the upper phase as the stationary phase followed by injection of sample solution containing 100 mg crude mixture through the sample port. The apparatus was rotated at the optimum speed of 800 rpm while the lower phase was pumped into the head end of the column as the mobile phase at 200 mL h⁻¹ flow rate. Effluent from the outlet end of the column was continuously monitored at 278 nm and fractionated into test tubes. An aliquot of each fraction was diluted with methanol and the absorbance was determined at 260 nm with a spectrophotometer. **Figure 6** shows the chromatogram obtained. Five flavonoid components were completely resolved from each other as symmetrical peaks and eluted in 2.5 h. Partition efficiencies computed from the equation $N = (4R/W)^2$ (where N is the efficiency expressed in terms of theoretical plates (TP), R is retention time of the peak maximum, W is the peak width expressed in the same unit as R) range from 800 TP (2nd peak) to 530 TP (5th peak). By calculating the partition coefficients of each peak and comparing the values

Figure 4 Chemical structures of harringtonine, isoharringtonine and homoharringtonine.

obtained with those of the pure compounds, quercetin and isorhamnetin peaks were identified as labeled in the chromatogram.

The same crude sample of ethanol extract from dried fruits of sea buckthorn can be separated with an analytical HSCCC for a series of rapid separations. The apparatus was a Pharma-Tech Model CCC-2000 made by Pharma-Tech Research Corp. The multilayer coiled column was prepared from a single piece of 0.85 mm i.d. heavy wall PTFE tubing. The total capacity of the column is 43 mL including 3 mL in the flow tubes. The revolution speed of the centrifuge can be continuously adjusted up to 2000 rpm. A LDC/Milton Roy Pump, a speed controller with digital rpm display and a pressure gauge are also included.

In these separations, 3 mg of sample of the flavonoid mixture were dissolved in 0.5 mL of solvent

Figure 5 High speed CCC separation of harringtonine, isoharringtonine and homoharringtonine from a crude extract of *Cephalotaxus fortunei* Hook f. Peak 2, isoharringtonine; 4, homoharringtonine and 6, harringtonine.

mixture and loaded for each experiment. The centrifuge was rotated at the optimum speed of 1800 rpm. The effluent from the outlet of the column was continuously monitored with an LKB Uvicord S at 278 nm and then collected as 1 mL fractions with an LKB fraction collector. Each fraction was diluted with 2 mL of methanol and the absorbance was determined at 260 nm with a Zeiss spectrophotometer Model PM6.

Figure 7 shows the result of separation obtained at a flow rate of 60 mL h⁻¹. The high efficiency of the separation is evidenced by a minor peak present between the first and the second major peaks, which

Figure 6 Counter-current chromatogram of flavonoids in crude extract from dried fruits of sea buckthorn by a multilayer coil planet centrifuge. Conditions for CCC: sample size, 100 mg; solvent system, chloroform-methanol-water (4:3:2); mobile phase, lower phase; flow rate, 200 mL h⁻¹; speed, 800 rpm; fraction volume, 6 mL.

Figure 7 Chromatogram obtained from 3 mg extract by analytical countercurrent chromatography, flow rate of 60 mL min^{-1} .

was not detected in the semipreparative separation shown in Figure 6. Flow rates as high as 300 mL h^{-1} can be used to give a separation time of only 15 min, which is quite comparable with that of analytical HPLC.

The analytical HSCCC can be used to interface with MS to provide a new analytical methodology HSCCC-MS, combining the versatility and high resolution of HSCCC with the identification capability and low detection limit of mass spectrometry.

Preparative Separation of Kaempferol, Isorhamnetin and Quercetin from Extracts of *Ginkgo biloba* L.

Extracts of the leaves of *Ginkgo biloba* L. are used to increase peripheral and cerebral blood flow. *Ginkgo* extracts contain active compounds such as flavonoids and terpene lactones (ginkgolides and bilobalide).

They show effects on vascular and cerebral metabolic processes and inhibit platelet-activating factor. The standard compounds used to control the quality of *Ginkgo* extracts and its preparations, such as isorhamnetin, kaempferol and quercetin, the three major flavone aglycones in the leaves of *Ginkgo biloba* L., are expensive and difficult to obtain. Some commercial quercetin standards, usually used in quantitative analysis of total flavonoids, are not pure and contain isorhamnetin, kaempferol and impurities. The preparative separation and purification of flavonoids from plant materials by classical methods are tedious and usually require multiple chromatographic steps. HSCCC as a form of liquid-liquid partition chromatography without using a solid support matrix is very suitable for the separation of flavonoids.

HSCCC was performed using a Model GS-10A multilayer coil planet centrifuge made by the Beijing Institute of New Technology Application. A NS1007 constant-flow pump, a model 8823A UV monitor operating at 254 nm and a manual sample injection valve with a 35 mL loop, were used in the experiment. A Rainin Model SD-200 HPLC was used for analysis.

In these studies, a two-phase solvent system composed of chloroform-methanol-water at a volume ratio of 4 : 3 : 2 was used. The crude *Ginkgo* flavone aglycones were prepared by several steps, from the extract of *Ginkgo* leaves. A second sample was a commercial quercetin standard. The sample solutions were prepared by dissolving these two samples in equal volumes of upper and lower phases.

In each separation, the column was first entirely filled with the upper aqueous phase as stationary phase, and then the apparatus was rotated at 800 rpm, while the lower chloroform phase was pumped into the column at a flow rate of 2 mL min^{-1} . After the mobile phase front emerged and the two phases had established hydrodynamic equilibrium in the coil column, the sample solution containing 200 mg of crude *Ginkgo* flavone aglycones or commercial quercetin standard was introduced through the injection valve. HPLC analysis of the crude *Ginkgo* flavone aglycones is shown in Figure 8A. According to MS analysis, quercetin, kaempferol, isorhamnetin and some impurities were present. HPLC analysis of the commercial quercetin standard is shown in Figure 8B indicating that a larger amount of unknown impurity was present.

After repurification of the isorhamnetin peak by HSCCC, the purities of the three flavone aglycones were more than 99% according to the results of HPLC analysis. The identities of the three flavone aglycones were confirmed by MS analysis.

Figure 8 Chromatograms of the HPLC analyses of the crude *Ginkgo* flavone aglycones from the Ginkgo extracts (A) and the commercial quercetin standard (B). Mobile phase: methanol-0.04% H_3PO_4 (50:50, v/v); flow rate: 1.0 mL min^{-1} ; detection: 254 nm. Peak 1: quercetin; Peak 2: kaempferol; Peak 3: isorhamnetin.

Semipreparative Separation of Taxol Analogues

Taxol is a promising new anticancer drug. Currently, taxol intended for human consumption is mainly obtained from the bark of *Taxus*. Although taxol is the compound most commonly used in clinical treatment, numerous analogues have also been identified. Some of them are of similar biological activities to taxol, and some can be used as natural precursors to semisynthesize taxol by simply modifying the C13 side chains. Meanwhile, the study of these compounds may lead to the discovery of new alternatives with improved pharmaceutical properties or economic benefits. The separation and purification of taxol analogues by classical methods such as preparative TLC, open column chromatography and HPLC in general are complicated and have low recoveries. HSCCC can be used for the semipreparative separation of some taxol analogues such as cephalomannine and 7-epi-10-deacetyltaxol.

HSCCC was performed with a model GS-10A multilayer coil planet centrifuge made by the Beijing Institute of New Technology Application. The

chromatography system was the same as that described previously.

A crude extract containing 10% taxol from *Taxus yunnanensis* was pre-separated through a C_{18} column eluted by an acetonitrile–water gradient. After recovering the majority of the taxol and removing some other polar components, the fraction mainly containing cephalomannine, 7-epi-10-deacetyltaxol, residual taxol and an unknown compound was collected, concentrated and dried. The sample solution was prepared by dissolving the sample in the solvent mixture of upper and lower phases.

The two-phase solvent system, a quaternary system of n-hexane–ethyl acetate–ethanol–water was selected. In those studies a two-step separation was chosen. Firstly, the solvent system in 1:1:1:1 proportion was employed to separate the sample into two groups, A and B. Secondly, the system in 3:3:2:3 and 4:4:3:4 proportions was employed to separate the two compounds in A and B. In each separation, the coiled column was first entirely filled with the upper phase as the stationary phase. After the apparatus was rotated at 800 rpm, the lower phase was pumped into the column at a flow rate of 2 mL min^{-1} , while the sample solution was introduced via the injection valve. The effluent from the outlet of the column was continuously monitored at 254 nm. Twelve consecutive injections of 10–16 mg of sample mixture were performed without changing the stationary phase in the coiled column.

The four compounds were first separated into two groups as shown in Figure 9. Peak A contains mainly cephalomannine and taxol, while peak B contains mainly 7-epi-10-deacetyltaxol and the unknown compound. After 12 consecutive injections, 84.4 mg of A and 42.1 mg of B were obtained. Cephalomannine and taxol in peak A were well separated in the second step with the 3:3:2:3 solvent system

Figure 9 First step separation of taxol and its analogues by HSCCC with three consecutive injections. Solvent system: n-hexane–ethyl acetate–ethanol–water (1:1:1:1, v/v/v/v). A, cephalomannine + taxol; B, unknown + 7-epi-10-deacetyltaxol.

Figure 10 Second step separations of peak fractions (A) and (B) in Figure 9 by HSCCC with three consecutive injections. Solvent system: n-hexane–ethyl acetate–ethanol–water. (A) 3 : 3 : 2 : 3, (B) 4 : 4 : 3 : 4. 1, Cephalomannine; 2, taxol; 3, unknown; 4, 7-epi-10-deacetylaxol.

as shown in Figure 10. 49.3 mg of cephalomannine and 14.6 mg of taxol were obtained after six consecutive injections. The purities were about 99% and 87% respectively according to the results of HPLC analysis. Similarly with peak B, 7-epi-10-deacetylaxol and the unknown compound were separated

with the 4 : 4 : 3 : 4 solvent system as shown in Figure 10B: 12 mg of 7-epi-10-deacetylaxol and 10 mg of the unknown compound were obtained after three consecutive injections. The purities were about 85% according to the results of HPLC analysis.

Conclusions

Many applications of HSCCC such as the separation of alkaloids, flavonoids, hydroxyanthraquinone derivatives, etc., have been performed successfully. The main advantages of HSCCC are as follows:

1. Since no solid supports are used, all compounds in the sample solution are recovered. The crude sample can be injected directly into the column, which simplifies sample preparation.
2. Numerous two-phase solvent systems with a broad spectrum of polarity can be used with either the aqueous or organic phase as the mobile phase. Some examples are shown in Table 1.
3. The quantity of purified compound may range from milligrams to grams. Consecutive injection can be applied for large scale separation.
4. HSCCC will become widely used in the research and production of natural drugs, since the instrument is inexpensive, convenient to operate, solvent saving and has preparative capacity.

MEDIUM-PRESSURE LIQUID CHROMATOGRAPHY

K. Hostettmann and C. Terreaux,
University of Lausanne, Lausanne, Switzerland

Copyright © 2000 Academic Press

Introduction

Medium-pressure liquid chromatography (MPLC) is one of the various preparative column chromatography techniques. Separation under pressure renders the use of smaller particle size supports possible and increases the diversity of usable stationary phases. MPLC was introduced in the 1970s as an efficient technique for preparative separation of organic compounds. MPLC overcame one major drawback of low pressure liquid chromatography (LPLC), i.e. the limited sample loading. This separation method is now routinely used beside or in combination with the other common preparative tools: open-column chromatography, flash chromatography, LPLC or preparative high performance liquid chromatography

(HPLC). The distinction between low pressure, medium pressure and high pressure LC is based on the pressure ranges applied in these techniques and the overlap is often considerable. MPLC allows purification of large compound quantities and, unlike open-column chromatography and flash chromatography, faster and improved separations are obtained. Packing of material with lower particle size under pressure enhances separation quality and moreover the solid phase can be reused. Table 1 provides a comparative description of these different methods. Simplicity and availability of the instrumentation, together with recycling of packing materials and low maintenance costs, contribute to the attractiveness of this technique. More details about experimental conditions are given below.

Instrumentation

A schematic representation of a simple MPLC setup is shown in Figure 1. The instrumentation is made up of

Table 1 Comparative description of various preparative column chromatographic techniques

Technique	Stationary phase particle size (μm)	Pressure (bar)	Flow rate (mL min^{-1})	Sample amount (g)	Solvents	General
Open-column chromatography	63–200	Atmospheric	1–5	0.01–100	General solvent used	Frequent packing; RP not possible
Flash chromatography	40–63	1–2	2–10	0.01–100	General solvent used	Frequent packing
Low pressure LC	40–63	1–5	1–4	1–5	More solvent required	Prefilled Lobar columns
Medium pressure LC	15–40	5–20	3–16	0.05–100	More solvent required	Infrequent packing
Preparative HPLC	5–30	> 20	2–20	0.01–1	High purity solvent required	Higher resolution

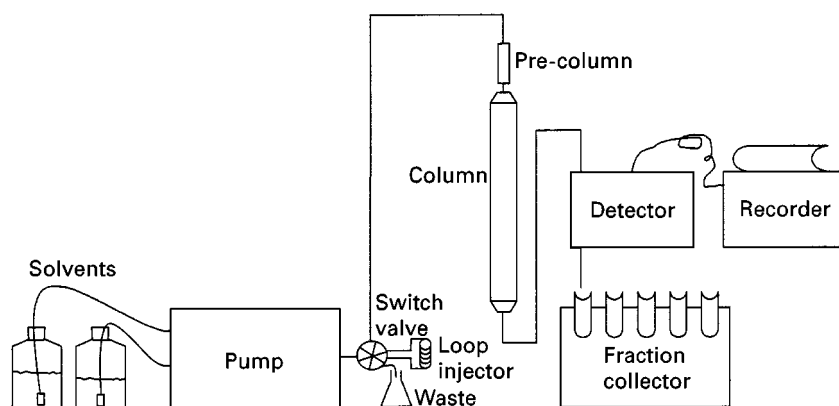

Figure 1 Typical MPLC instrumental setup.

a pump for solvent delivery, a sample injection system, and a self-packed column. Product separation can be followed either manually by monitoring with thin-layer chromatography (TLC) or automatically with a detector and a recorder connected to the column outlet. Separated compounds are collected by means of a fraction collector.

Pump

Chromatographic separation of 0.1–100 g sample within a few hours requires flow rates ranging from about 5 to 200 mL min⁻¹, with a maximal pressure of 40 bar. Several companies provide pumps suitable for MPLC. Criteria for selecting an MPLC pump include: flow rate range; presence or absence of a pulse-damper, which provides regular flow rates and pressures during separation and increases the reproducibility of the separation; presence of a pressure cut-off device; and presence of a gradient former. Some manufacturers provide pumps with exchangeable piston heads, thus allowing flow rates from 0.5 to 160 mL min⁻¹ with pressures up to 40 bar.

Column

The column is the central point when optimizing a preparative chromatographic separation and criteria such as amount of sample to be purified, amount of packing material and column length versus column diameter, have to be carefully considered. MPLC columns are generally made of thick glass coated with protective plastic and can withstand pressures up to 50 bar; however, some columns from some manufacturers cannot withstand pressures exceeding 20 bar. The columns vary in length as well as in internal diameter (i.d.) and sizes are expressed as filling volumes. Filling volumes range from 63 mL (9 mm i.d. × 100 mm) to 15 000 mL (105 mm i.d. ×

1760 mm) for the larger columns available. Selection of the column dimensions depends on the sample amount to be separated, ranging from 0.1 g with the smallest columns up to 100 g with large columns. Selectivity (α) and retention factor (k) are the prominent factors influencing resolution. Sample loading can greatly affect resolution. Therefore, when separations are 'easy' ($\alpha > 1.2$; high resolution between the eluted compounds), larger sample amounts can be loaded. Increasing the column diameter allows injection of a larger sample mass (higher throughput), but also makes use of smaller particle size material possible. On the other hand, increasing the column length results in higher resolution but has little or no effect on sample throughput. The back pressure increase with longer columns often implies the use of larger particle size material. The influence of column dimensions on resolution has been studied through the separation of standard mixtures. The correlation between resolution and amount of packing material was shown to be linear either when testing columns with identical internal diameter and different lengths or when varying the internal diameter in a set of columns of the same length. However, a lesser increase in resolution was observed with the use of larger internal diameter and a constant length. Consequently, longer columns are preferred in order to improve the separation of a given sample. The column system supplied by Büchi (Flawil, Switzerland) gives the possibility to couple columns together vary simply by means of a Teflon sealing joint, resulting in an increased resolving power.

Detector and Recorder

Monitoring of a MPLC separation can be performed by TLC of the collected fractions. Online detection is also routinely used with single-wavelength UV/Vis detectors. Most available UV detectors are designed for analytical purposes and are of little use for

preparative separations. Accommodation of high flow rates is a prerequisite for a preparative chromatographic detector. This results in a loss of sensitivity, which is compensated by the usual high concentration of the eluate. In fact, these concentrations are often so large when coming through the detection cell that the detector is overloaded. This problem can be solved by the use of detectors with a splitting system before the UV cell: one part of the sample goes directly from the column outlet to the fraction collector, while another part is diverted through the detector. Detectors with a pathlength < 0.1 mm are also very useful. Selection of a detection wavelength where absorption of the products is low can also be an alternative to avoid detection overload. The Gow-Mac 80-800 LC-UV detector is a specially designed detector for preparative separations: flow rates up to 500 mL min^{-1} are possible and the eluate arrives through a needle and passes as a thin film on a 6.5 cm wide quartz cell. Connection to a recorder allows visualization of the chromatographic separation.

Fraction Collector

Automatic collection of fractions can be performed by connecting a fraction collector to the column or detector outlet. The volume of the collected fractions is of course strongly dependent on the internal diameter of the column and the flow rate; it is in most cases time-monitored. Presence of a built-in peak detector or connection to an external one allows peak-monitored fraction collection. In its standard MPLC setup, the Büchi system provides a fraction collector with a total capacity of 240×20 mL tubes, 120×50 mL tubes or 48×250 mL tubes. This type of fraction collector has proved to be particularly suitable for MPLC.

Column Packing

Packing Material

Selection of the stationary phase is probably the most crucial parameter affecting separation quality. Several types of packing material are commonly used in MPLC and various factors have to be considered when choosing the packing material:

- particle size
- column length
- operating pressure
- type of sample
- cost.

With regard to cost-effectiveness, the most frequently utilized stationary phase is silica gel. Beside

its economic advantage, silica gel possesses other advantages such as a wide range of possible solvents as eluents, easy evaporation of the fractions and elution with high flow rates. The risk of irreversible adsorption is a possible major drawback of this support.

A wide range of particle sizes is commercially available. The smallest average particle size (5–10 μm) is used for analytical HPLC, while for preparative LC, stationary phases with sizes starting at 15 μm are the most convenient. Optimal separations are generally obtained with sizes around 20 μm . The influence of particle size on resolution has been investigated. A large decrease in resolution was observed when the average particle size changed from 15 μm to 30 μm . Using particle sizes of 52 μm or 130 μm resulted in a slower resolution decrease but the retention times increased significantly: 3 h more with an average particle size of 130 μm than with one of 15 μm .

The use of modified silica gel phase (bonded phases) has become more common. These inherent advantages, such as a lower risk of sample decomposition and less irreversible adsorption, allowing an easier recycling of the column sorbent. Reversed-phase (such as RP-18, RP-8 or RP-4) or dihydroxypropylene-bonded (Diol, Merck, Germany) silica gels are frequently used for MPLC separations. Moreover, it is possible to use other commercially available bonded phases for MPLC separations.

Column Packing Methods

Different filling methods are described for packing MPLC columns. Filled columns should possess an optimal homogeneity and a good density. Two methods are most frequently used: dry filling and the slurry method.

Dry filling Dry filling is generally applied for silica gel. This method usually gives a 20% better packing density than the slurry method. The 'tap-and full' technique can be used with particle sizes larger than 20–30 μm ; however, when applying eluent pressure up to 40 bar, the packing density obtained may not be sufficient. Packing under nitrogen pressure allows use of 15 μm particle size silica gel and provides a high packing density. Filling is carried out manually by connecting a reservoir to the top of the column, which is then filled with dry stationary phase until it contains approximately enough phase to fill another 10% of the column (Figure 2). The system is then connected to a nitrogen cylinder and a 10 bar pressure is applied (with the column outlet open) until the level of packing material remains constant. The nitrogen valve can be closed and the pressure slowly goes down to atmospheric. Vacuum at the column exit can

Figure 2 Dry filling of Büchi MPLC glass columns. (Reproduced with permission from Hostettmann *et al.*, 1997.)

be used as an alternative to nitrogen pressure. An automatic mechanism has been suggested to slowly and homogeneously fill the column ($3\text{--}4\text{ g min}^{-1}$). Passing mobile phase through the column induces compression of the stationary phase, which is compensated by the further addition of dry silica gel.

Slurry method The slurry method is an alternative method to pack silica gel, with the inconvenience of a lower packing density. However, slurry filling is the preferred method for packing bonded phases. The slurry is prepared by suspending homogeneously an appropriate amount of stationary phase in the eluent. The mixture is then poured into the column and the eluent is passed through the column until the stationary phase level is constant.

Column preparation and regeneration Before sample introduction, it is recommended that a separation test is performed with a standard mixture of compounds. A mixture of phthalic acid dimethyl-, diethyl- and dibutyl esters is convenient for testing silica gel columns, whereas the separation of benzene and naphthalene can be used for reversed-phase columns.

Usually, packing material is regenerated after each chromatographic separation. For silica gel supports, this can be performed by washing successively with methanol, ethyl acetate and *n*-hexane. However, after a certain time, the stationary phase should be

changed and the column repacked. Regular elution of a test mixture is a good method to determine column quality. Bonded-phase columns are generally easier to clean (for example with a mixture of methanol/tetrahydrofuran (1 : 1)) and thus have a longer working life. In order to prolong column lifetime, a pre-column can be used. Contaminating material remaining at the top of the column is thus eliminated after each MPLC separation.

Solvent Selection

Selection of the eluent system is also a crucial point in development and optimization of a MPLC separation. The ideal case would be successive direct testing of various solvent mixtures on the MPLC column. However, in routine practice such an approach is obviously impossible because of the waste of time due to column equilibration, together with loss of sample, etc. Two methods are mainly used for solvent selection: optimization by TLC or transposition of analytical HPLC conditions on MPLC.

Preliminary TLC allows rapid screening of numerous possible solvents and it is now well established how TLC results on silica gel plates can be transposed to silica gel columns. Solvent testing on silylated TLC plates can be used for reversed-phase columns. One important factor that has to be considered is that the surface areas of silica gel used in TLC is about twice that of the column packing material. Therefore, it is recommended that sample constituents display a retention factor (R_F) lower than 0.3 on the TLC plate. The major drawback of this method is the lower separation and resolution observed when reducing the solvent strength to obtain an $R_F \leq 0.3$. An alternative has been suggested to circumvent this problem: the use of overpressured-layer chromatography (OPLC) as a pilot method for MPLC. In a first step, a suitable multicomponent eluent with a good selectivity is searched for by means of TLC. Adjustment of the solvent strength and fine tuning are performed with OPLC. Unlike TLC, OPLC is a closed and equilibrated system and can be viewed as a 'planar column'. Because of these properties, direct transposition from OPLC to MPLC is an accurate and efficient method. Such an approach is also applicable to the other preparative pressure chromatography techniques using normal silica gel as stationary phase.

Because of the similarities of the phases used in analytical HPLC and preparative packing materials, separation optimization on an analytical HPLC column very often provides excellent results and transposition to MPLC is straightforward and direct. This is particularly evident for separations on

reversed-phase sorbents, where studies with TLC are more difficult. Due to the wider range of solvents available for normal-phase chromatography, preliminary tests on TLC are of major use prior to analytical HPLC optimization. Examples of transposition of analytical HPLC conditions to MPLC are given below.

Once the ideal conditions have been selected, a compromise has to be found between speed of separation and sample loading: decreasing the solvent strength (for example, by adding water to the solvent system in reversed-phase separations) will increase the separation between the different components and afford higher sample loading, but will require a considerable longer separation time. The influence of solvent strength on the resolution of a standard mixture has been studied and a linear decrease of resolution was observed when increasing the solvent strength. Running a gradient is also possible with MPLC, provided a suitable solvent delivery system is used. Peak sharpening can be obtained by a simple stepwise change of mobile phase composition.

Evaporation of large quantities of solvent takes place after fraction collection in order to concentrate the purified compounds. This procedure can cause the accumulation of considerable amounts of nonvolatile impurities from the solvent. As high purity solvents are very expensive, preliminary distillation of ordinary grade solvents to prepare the eluent can be a good compromise between solvent purity and quantity employed. Use of such lower grade solvents often implies an additional purification step by gel filtration, for example.

Sample Introduction

Several criteria have to be considered before sample injection on a MPLC column:

- sample preparation
- sample mass and volume
- solubility characteristics of the sample
- type of injection used.

If solubility is not a problem, the eluent should be chosen to dissolve the sample. However, even in such a case, care has to be taken to adjust the sample volume: a sample that is too dilute (injection of a large volume) results in decreased separation efficiency, while precipitation at the top of the column may be observed by injection of samples that are too concentrated. High concentrations of the sample may alter the viscosity of the solution, which is then very different from that of the mobile phase. High viscosity leads to severe tailing, while fronting may result from lower sample viscosity compared to the

mobile phase. Despite these inconveniences, injection of a small volume of a concentrated solution is usually preferred. Sample solubilization in a solvent different from the mobile phase is also possible, but special care has to be taken with such an approach: solubility after mixing the sample solution with mobile phase has to be checked in order to avoid sample precipitation on the top of the column. Samples can be injected either directly on the column through a septum, or by means of a sample loop. In both cases, injection success depends on the quality of the column packing to ensure a homogeneous distribution of the sample at the top of the column.

The various problems mentioned above are more frequently encountered with separations on reversed-phase columns. The mobile phase usually contains a large proportion of water and organic compounds are often encountered that are insoluble in water. Solid injection or solid introduction is an alternative to circumvent low sample solubility. The introduction mixture is prepared by mixing dry powdered sample with a suitable amount of column packing material. The sample can also be preadsorbed on stationary phase by removing the volatile solvent (e.g. dichloromethane, ethyl acetate, acetone, etc.) in which it was solubilized from the suspension containing the stationary phase. Homogeneity of the injection powder is a prerequisite for efficient separations. The proportions of the introduction mixture are generally one part sample mixed with two to five parts stationary phase. The prepared sample is then placed directly onto the column inside a small pre-column and the eluent is passed through the system for separation.

Applications: MPLC in Natural Product Isolation

MPLC has recently become widely used in the pharmaceutical, chemical and food industries, and many applications are found in natural product isolation. Both applications given below have been selected as examples of the transposition of analytical HPLC conditions to MPLC.

The methanol extract of *Halenia corniculata*, a Gentianaceae plant from Mongolia, was first passed through a Sephadex LH-20 gel column and the glycoside-rich fraction (300 mg) was then purified by MPLC on a reversed-phase RP-18 column, yielding six xanthone glycosides (1–6). The search for optimal conditions was performed by analytical HPLC (Figure 3A) and was followed by direct transposition to MPLC separation (Figure 3B).

The dichloromethane extract from the roots of *Tinospora crispa* (Menispermaceae) was first

Figure 3 Transposition of conditions for the MPLC separation of xanthone glycosides from *Halenia corniculata* (Gentianaceae). (A) Analytical HPLC on a Lichrosorb 7 μm RP-18 (250 mm \times 4 mm) column with MeOH/H₂O 40 : 60 (v/v); flow rate 1 mL min⁻¹; (B) MPLC on Lichrosorb RP-18 (15–25 μm) with MeOH/H₂O 40 : 60 (v/v); flow rate 3 mL min⁻¹; column dimensions 460 mm \times 12 mm. (Reproduced with permission from Hostettmann *et al.*, 1997.)

fractionated by centrifugal partition chromatography and one fraction was submitted to analytical HPLC with an acetonitrile gradient (Figure 4A). Owing to the lower convenience of acetonitrile for preparative purposes (cost, toxicity), conditions were found with methanol on analytical HPLC (Figure 4B). The selected isocratic eluent system was transposed directly to MPLC and 6-h separation led to the isolation of three phenylpropane derivatives (7–9) (Figure 4C).

Conclusion

Since the early 1980s MPLC has been confirmed as an excellent preparative chromatographic tool that is

now routinely used in many laboratories. The extended use of various bonded phases in MPLC no longer restricts the use of this technique to the isolation of lipophilic substances with silica gel. For reasons of economy, recycling the stationary phase by simple washing or repacking of the column is of great interest in MPLC. Furthermore, a working experimental setup can be easily and rapidly assembled. The wide range of sample amounts that can be separated with this technique, together with the use of TLC and analytical HPLC in the search for optimal conditions, are also major benefits of this chromatographic method. However, good column packing and adequate sample preparation are prerequisites for successful separations. Further developments in MPLC

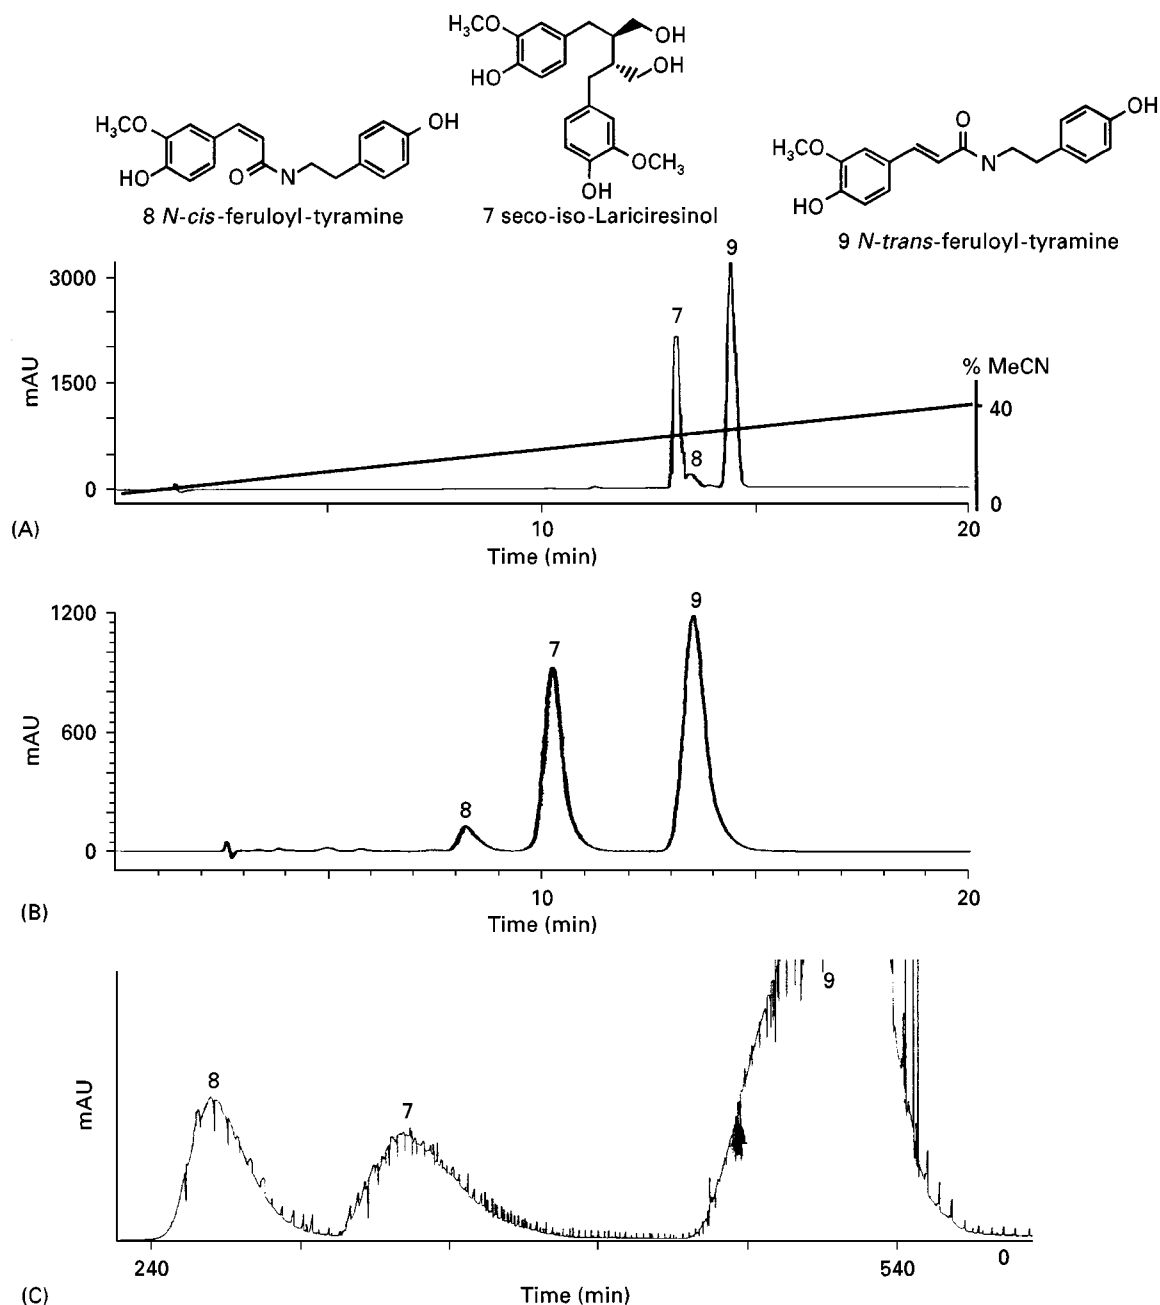

Figure 4 Transposition of analytical HPLC conditions for MPLC separation of phenylpropane derivatives from *Tinospora crispa* (Menispermaceae). (A) Analytical HPLC on a Lichrosorb 7 μ m RP-18 (250 mm \times 4 mm) column with a MeCN/water gradient 0 : 100 to 40 : 60 (v/v) in 20 min; flow rate 1 mL min⁻¹; (B) analytical HPLC on a Lichrosorb 7 μ m RP-18 (250 mm \times 4 mm) column with MeOH/water 40 : 60 in 20 min; flow rate 1 mL min⁻¹; (C) MPLC on Lichrosorb RP-18 (15–25 μ m) with MeOH/water 30 : 70; flow rate 4 mL min⁻¹; column dimensions 460 mm \times 12 mm.

will mainly concern detection problems with the optimization of detectors that can accommodate high sample loads.

MEMBRANE CONTACTORS: MEMBRANE SEPARATIONS

Membrane-based processes are receiving recognition for their flexibility and efficiency. Processes like reverse osmosis, ultrafiltration and dialysis are already well developed and recently, membrane application to other separation processes, such as absorption and liquid–liquid extraction, have been gaining considerable attention.

In these latter processes, the porous membrane acts as contacting media for gas–liquid or liquid–liquid phases with comparable advantages to the traditional continuous contact equipment. While in conventional two-phase processes, dispersion of one phase into another immiscible phase is used in order to promote an efficient contact and increase the transport rate, membrane extraction is accomplished without dispersion of the two phases.

Consider a liquid–liquid extraction process and a microporous hydrophobic membrane with the aqueous–organic interface stabilized inside the membrane pores (Figure 1). Since the membrane is hydrophobic, the organic phase spontaneously wets the membrane and may permeate through the pores to the aqueous phase. This breakthrough problem can be controlled by applying a higher pressure on the phase that does not wet the pores. This higher pressure must not exceed a critical value, Δp_{cr} , otherwise the nonwetting fluid will

penetrate the pores and contaminate the other fluid phase.

If a hydrophilic membrane is used, the procedure is analogous, but in this case it is necessary to impose an organic phase pressure which is higher than that of the aqueous phase.

Although extraction can be conducted using a number of different membrane configurations, including flat-sheet, spiral-wound, rotating annular and hollow fibres, hollow fibres have received the most attention due to their high packing density: typical interfacial areas of contact per unit volume range from 1500 to 7000 m² m⁻³.

Figure 1 Organic–aqueous interface immobilized in a microporous hydrophobic membrane. P_{aq} , aqueous-phase pressure; P_{org} , organic-phase pressure.

The associated advantages of this configuration, which will be discussed in detail in the next section, have led to the development of an enormous range of processes, either with liquid-liquid phases or with gas-liquid phases.

Comparison between Membrane Contactors and Conventional Equipment

Advantages of Membrane Contactors

High contact area per unit volume Using a suitable module configuration such as a hollow fibre, membrane contactors can provide a contact area per unit volume which is 20–100 times higher than conventional equipment. The higher the interfacial area provided, the more efficient the contactor becomes and the smaller its size required for a given separation.

No loading and flooding constraints As the fluids to be contacted flow on the opposite sides of the membrane, both flow rates can be set independently. The available contact area remains constant even at very low or very high flow rates. This feature is particularly useful in applications where the required solvent/feed ratio is very low or very high, in contrast to conventional equipment, which is subjected to flooding at high flow rates and unloading at low ones.

Reduction of phase back-mixing When using membrane contactors, the mass transfer between the two phases occurs at the fluid-fluid interface immobilized at the mouth of the pores. This nondispersive contact minimizes emulsion formation and the occurrence of back-mixing is also reduced. By reducing back-mixing, a higher number of transfer units (NTU) can be achieved.

No need for density between the phases Unlike conventional dispersed-phase contactors, no density difference is required between fluids in liquid-liquid extraction because coalescence and separation of the dispersed phase are not necessary when using membrane contactors.

Reduced solvent hold-up Solvent hold-up is rather low when using membrane contactors; this may be important when using expensive solvents.

Modular design – direct scale-up The modular character of this equipment allows an easy straightforward scale-up procedure. Membrane operations

usually scale linearly and thus, when an application requires several contactors in series or parallel, this modular design allows a given process to be easily tested on a reduced scale.

Easy process integration As membrane contactors do not involve the dispersion of the two fluid streams, it is easy to combine them with other operation units. These hybrid processes can be highly advantageous from a technical and economic point of view. For example, a combined extraction/stripping process can be designed by coupling two membrane contactors in series, without the need for an intermediate coalescence step.

Limitations of Membrane Contactors

Additional membrane resistance Besides the mass transfer resistances associated with the boundary layers of the two fluid phases, the membrane provides a third resistance. While this additional resistance is often negligible it may, under some conditions, contribute significantly to the overall mass transfer resistance. It will be discussed later in this chapter a few heuristic rules to minimize this effect.

Fluid distribution in the shell side In hollow-fibre contactors the spatial distribution of the fibres is not perfectly uniform. This uneven distribution can induce fluid flow maldistribution in the shell side and, eventually, bypassing, especially when high flow rates are used. This problem may become particularly important when large scale modules are used.

Transmembrane pressure constraints The transmembrane pressure can become quite important in porous membrane contactors, because it may induce flow across the membrane (breakthrough), causing unwanted froth, foam and dispersion between the two phases. For this reason, the option between operation with co- or counter-current mode and the setting of the fluid flow velocity has to take into consideration the pressure drop profile developed along the module. This explains why laminar flow conditions are usually used.

Construction materials Membrane contactors employ polymeric membranes and potting adhesive resins to bond the fibre bundle to the module casing. These materials may have a limited compatibility with certain organic solvents, especially with aromatic compounds.

Linear up-scaling factor It was mentioned as an advantage that the scaling-up of membrane contac-

tors is rather simple and linear. On the other hand, this linearity is a serious drawback when comparing with traditional contacting equipment where the factor for scale-up cost is typically 0.6. This means that, if we want to double the capacity of a membrane contactor, the cost will be twice the original one, while for conventional equipment the cost will be $2^{0.6}$ of the original cost.

Membranes and Modules

Membrane Selection

Unlike most membrane operations, in membrane contactors the chemistry of the membrane is relatively unimportant, as it imparts no selectivity to the separation. The goal is to choose a membrane whose effect is not negative, i.e. that has no influence on mass transfer. Thus, the success of membrane contactors greatly depends on minimizing the membrane resistance to mass transfer. As a general rule, choose the membrane that is wet by the fluid to which the solute has more affinity (higher partition): if the solute partitions favourably to the solvent (organic), a hydrophobic membrane should be used; if it partitions favourably to the aqueous phase, then a hydrophilic membrane would be the best choice.

For gas-liquid contact two modes of operation are possible: wetted mode and dry mode. The wetted mode occurs when the pores are filled with liquid and the dry is when the pores are filled with gas: a hydrophilic membrane operates in wetted mode if the liquid phase is aqueous and in dry mode if it is organic, whilst a hydrophobic fibre will operate the inverse way. The dry mode is usually preferred to take advantage of the higher diffusivity of the solute in the gas phase, except in systems with an instantaneous interfacial reaction where the gas-phase resistance controls.

Still concerning the maximization of mass transfer, microporous membranes, typically with pore sizes between 0.05 and 1.0 μm and 20–100 μm thick have been used, in order to hinder solute diffusions as little as possible.

Hydrophobic membranes present the following advantages:

1. Higher pH and chemical stability
2. Reduced fouling with whole cells
3. Easier sterilizability

On the other hand, hydrophilic membranes are advantageous in the following conditions:

1. Systems with lysed cells or proteins, as they are likely to foul the membrane's surface to a lesser extent

2. Systems with very low interfacial tension. As hydrophilic membranes are commercially available with smaller pore sizes than the hydrophobic ones it can be easier to stabilize the interface (higher Δp_{cr}).

Module and Operating Mode Selection

Due to its high packing density (providing interfacial areas of contact up to 7000 $\text{m}^2 \text{m}^{-3}$), the hollow-fibre modules are the most attractive configuration.

Any design should be preceded by some preliminary considerations regarding the operating mode:

1. Should the feed stream flow in the tube or in the shell side of the module?
2. Should the extraction be carried out co- or counter-currently?
3. Should the operation be carried out in unsteady-state batch mode or in continuous mode?

As a general rule, the feed stream should circulate in the tube side whilst the extract should flow in the shell side. This observation stems from the fact that commercially available hollow-fibre modules still present deficient mass transfer in the shell side due to uneven distribution of the fibres, that can produce effects of channelling, bypassing and back-mixing on the shell side. With the aim of minimizing these problems, new modules have recently been marketed with baffles and better distribution of the fibres.

However, exception may be considered when dealing with feeds containing solids or a high degree of particles. Although cost considerations should be taken into consideration, a prior filtration is suggested.

Regarding co- or counter-current operation mode, although an attractive higher driving force could be attained with the latter, the stability of interface must be taken into consideration: when operating counter-currently, the transmembrane pressure difference along the module presents a higher variation which can interfere with the interface stability and even lead to breakthrough. The breakthrough pressure, Δp_{cr} , is determined by the pore size of the membrane, the interfacial tension between the two fluids and the contact angle, according to the Laplace equation:

$$\Delta p_{cr} = \frac{2\gamma \cos \theta}{r_p} \quad [1]$$

As to operating in batch recirculation or continuous contact mode, attention must be paid mainly towards the degree of extraction needed: the batch mode cannot achieve an extraction beyond the final equilibrium concentrations of both phases, while the

single-pass continuous counter-current operation can reach further extraction, depending on the fibre length and flow rates. For not such a high degree of extraction, the design equations must be looked at so as to choose the mode that minimizes the costs inherent in the desired extraction.

Commercially Available Membrane Contactors

The best known module is the Liqui-Cel® Extra-Flow, marketed by Celgard LLC (Figure 2). This module uses Celgard microporous polypropylene fibres, up to 22 500, that are woven into a fabric and wrapped around a central tube feeder that supplies the shell side fluid. It also contains a central shell side baffle that improves efficiency by minimizing shell side bypassing and provides a component of normal velocity to the membrane surface, which results in higher mass transfer coefficients than those achieved with strictly parallel flow. The larger modules can operate with liquid flow rates up to several thousand litres per minute.

Also, commercial hollow-fibre microfiltration and ultrafiltration modules with hydrophilic membranes, generally with parallel flow, can also be used as membrane contactors.

For bubble-free gas-liquid mass transfer applications, Membrane Corporation and W.L. Gore market modules with different nonporous membrane arrangements: the first with the fibres potted at one end only and individually sealed at the other end, so that all entering gas permeates the membrane; the second has the fibres arranged as a helix, offering higher shell side mass transfer coefficients than the parallel configuration.

Equipment Design

A hollow-fibre membrane contactor is a continuous contact equipment and so the well-known concept of mass transfer unit is also applied here:

$$L = HTU \cdot NTU \quad [2]$$

Figure 2 Schematic representation of a Liqui-Cel Extra-Flow membrane contactor.

where HTU is the height of the transfer unit and NTU is the number of transfer units necessary for a given separation. This equation allows the evaluation of the height or length of the contactor necessary to obtain the required extent of mass transfer.

The mathematical description of this design equation can be illustrated for an extraction process where the aqueous phase circulates in the tube side. In this case, a differential mass balance to the hollow-fibre module can be used to determine the change in solute concentration during a single pass:

$$-Q_{aq} \cdot dC_t = K_t \cdot dA_m \cdot (C_t - C_t^*) \quad [3]$$

where K_t is the overall mass transfer coefficient, Q_{aq} represents the aqueous-phase flow rate, A_m the membrane transfer area, equal to $\pi \cdot d_f \cdot L \cdot n_f$, where n_f is the number of fibres, and C_t is the solute concentration in the tube side phase. The superscript * refers to the solute concentration in the tube side (aqueous phase) in equilibrium with the solute concentration in the shell side (organic phase).

Eqn [3] can be integrated for the fibre length. For the module inlet ($z = 0$) $C_t = C_t^{in}$ and for the outlet ($z = L$) $C_t = C_t^{out}$, where C_t^{in} and C_t^{out} are the solute concentrations entering and exiting the module, respectively:

$$L = HTU \cdot NTU = \frac{v_{aq}}{K_t a_i} \int_{C_t^{in}}^{C_t^{out}} \frac{dC_t}{C_t^* - C_t} \quad [4]$$

where v_{aq} is the fluid velocity circulating in the tube side, K_t is the module-averaged overall mass transfer coefficient and a_i is the interfacial area per unit module volume.

If a constant partition coefficient, P , can be assumed during the extraction process, integration of eqn [4] using $C_t^* = C_s/P$ where C_s , the solute concentration in the shell side phase, is obtained by mass balance, yields an analytical expression for the contactor length. The NTU expressions for a hydrophobic membrane with aqueous phase in fibre lumen and organic phase in the shell side, respectively for co-current flow and counter-current flow are the following:

$$NTU = \frac{1}{1 + \frac{Q_{aq}}{Q_{org}P}} \ln \frac{C_t^{out} - C_s^{out}/P}{C_t^{in} - C_s^{in}/P} \quad [5]$$

$$NTU = \frac{1}{1 - \frac{Q_{aq}}{Q_{org}P}} \ln \frac{C_t^{in} - C_s^{out}/P}{C_t^{out} - C_s^{in}/P} \quad [6]$$

For gas-liquid separations the partition coefficient may be replaced by H , Henry's law constant, and the aqueous and organic flow rates replaced by liquid and gas flow rates.

For systems with a variable partition coefficient it is necessary to introduce the equilibrium relation between C_t^* and C_s and a numerical integration is required.

Evaluation of Mass Transfer Coefficients

Three individual mass transfer resistances may be considered in membrane contactor extraction processes:

1. the inside tube boundary layer resistance
2. the membrane resistance to the solute diffusion through the pores
3. the shell side boundary layer resistance

The resistances are inversely proportional to the local mass transfer coefficients and a function of the system's geometry. Thus, for a hollow-fibre system when the membrane is wetted by the shell side phase, we obtain:

$$\frac{1}{K_t \cdot A_i} = \frac{1}{k_t \cdot A_i} + \frac{1}{P \cdot k_m \cdot A_{lm}} + \frac{1}{P \cdot k_s \cdot A_o} \quad [7]$$

where K_t represents the overall mass transfer coefficient (based on the tube side phase), k_t , k_m and k_s are

the local mass transfer coefficients on the tube side, membrane and shell side, respectively, and A_i , A_o and A_{lm} are the fibres' internal, external and logarithmic mean areas, respectively.

As the membrane may be hydrophobic or hydrophilic and the aqueous phase may circulate either in the fibre lumen or in the shell side, four different expressions for the overall mass transfer resistance for liquid-liquid extraction can be determined. Figure 3 shows the concentration profiles and the overall mass transfer resistances.

The tube side and the shell side mass transfer coefficients can be obtained experimentally and several correlations may be found in the literature.

Mass Transfer Correlations

Since laminar flux is predominant in hollow-fibre membrane contactors, a Lévêque type equation can be used to correlate both the tube side and the shell side mass transfer coefficients:

$$Sh_t = \alpha \cdot Sc_t^{bt} \cdot Re_t^{ct} \cdot \left(\frac{d_i}{1}\right)^{1/3} \quad [8]$$

$$Sh_s = \beta \cdot Sc_s^{bs} \cdot Re_s^{cs} \cdot \left(\frac{d_h}{1}\right) \quad [9]$$

where the subscripts t and s refer to the tube and shell sides, respectively, and α and β are constants. The

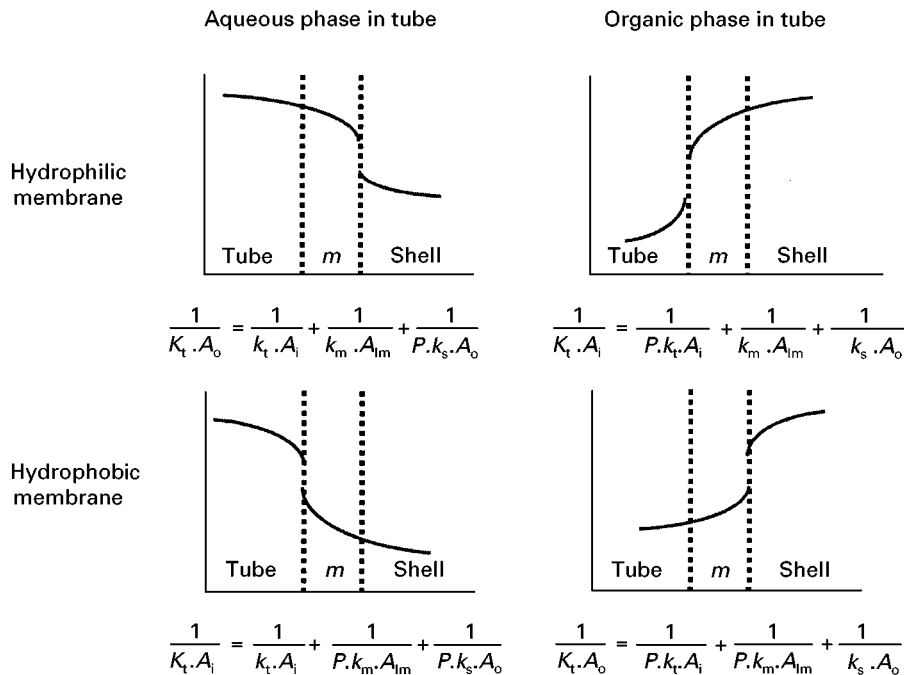

Figure 3 Concentration profiles and overall mass transfer resistance expressions for a chemical system with a solute partition coefficient favourable to the aqueous phase ($P < 1$).

d_e , external fibre diameter; d_s shell diameter; d_h hydraulic diameter; ϕ packing factor = $n_i d_e^2/d_s^2$.

Concerning the tube side, in most published works an exponent of $c_t = 1/3$ is usually obtained for a higher tube side Reynolds numbers range. However, using tube side Reynolds numbers in a low range ($Re < 50$ and $Gz < 100$), values of $c_t = 1$ were reported.

For the shell side, the values of the exponent of the Reynolds number are $0.5 < c_s < 1$. Values of 0.5 for laminar flow and 0.6 for turbulent flow on the shell side of a shell and tube heat exchanger are reported. Deviation from these values may be due to the nonuniform distribution of the fibres and their deformation by action of organic solvents, both inducing an irregular flow due to the formation of stagnant zones, preferential pathways and deficient mixing.

Applications

Liquid-Liquid Extraction

Liquid-liquid extraction cover quite a broad range of applications, including metal extraction, wastewater treatment and extraction of pharmaceutical and other products of biotechnological interest, such as organic acids and proteins.

Recovery of metals from industrial process wastewater is important, not only because metals are valuable, but also because of environmental legislation restrictions. Several examples of metal extraction (Cu, Zn, Ni, Cr(VI), Cd) using membrane contactors, have been reported. Reactive extraction is usually employed and extractants such as organophosphorous compounds (TOPO, D₂EHPA), tertiary amines (tri-*n*-octylamine) and liquid ion exchangers (Aliquat 336) are used.

Extraction of pollutants from wastewater such as phenol, toluene and volatile organic compounds (VOCs) using methyl isobutyl ketone (MIBK), hexane and kerosene as solvents and also reactive extraction with several extractants were reported. A pilot-scale plant for extraction of chlorinated and aromatic compounds from industrial wastewaters in the Netherlands was in operation for periods up to 3 months, reducing contaminant levels to $10 \mu\text{g L}^{-1}$.

Reactive extraction of organic acids produced by fermentation, such as acetic, citric, lactic and succinic acid, were also reported. Extraction of amino acids using reversed micelles was also studied.

Protein extraction can be accomplished either by two-phase aqueous extraction or by reversed micelles. Problems of interface stabilization caused by emulsions due to the adsorption of surfactant to the membrane surface, thus lowering the interfacial tension, were reported. Careful control of the pressure difference across the membrane was required for a stable operation.

Gas-Liquid Contactors

In gas-liquid extraction with membrane contactors, most efforts have been conducted in the areas of gas absorption/stripping and of wastewater treatment. Other fields like dense gas extraction and semiconductor cleaning water have been the object of study more recently.

Commercial applications include the Pepsi bottling plant in West Virginia that has been operating a bubble-free membrane-based carbonation line since 1993, showing reduced foaming, improved yield, lower CO₂ pressures and increased filling speed at high temperatures. Also, several beer production plants are using this technology for CO₂ removal to obtain a dense foam head, while others remove oxygen from beer to preserve its flavour; the stripping of oxygen from water, which is then used to dilute beer, is also being applied. Other commercial applications include the treatment of boiler feedwater, stripping of CO₂ from anion exchange feed streams and ultrapure water production for semiconductor manufacture.

In wastewater treatment, air stripping of VOC has been studied using polypropylene hollow fibres to remove chloroform, tetrachloroethylene, carbon tetrachloride, 1,1,2-trichloroethane and trichloroethylene from aqueous streams. Also, several studies have reported the use of membrane contactors for bubble-free aeration in wastewater treatment. Advantages include the absence of foaming, higher aeration rates, lower power input and ability to handle solids.

A list of applications is summarized in Table 3.

Membrane Distillation

In membrane distillation a nonwetted hydrophobic microporous membrane separates two phases of different water chemical potential. The difference in the water chemical potential may be induced by a temperature difference of the aqueous

Separation of saturated/unsaturated (ethane/ethylene)

Figure 4 Schematic representation of water transport in osmotic distillation.

solutions corresponding to a difference in vapour pressure at both ends of the membrane. It may also be due to the different nature and concentration of the solute components of both phases, thus causing a different osmotic pressure of the two liquids. Since the osmotic pressure of an electrolyte solution is about 10 times higher than an equimolar solution of electrically uncharged particles, salt solutions (NaCl , CaCl_2 , KH_2PO_4) are efficient and relatively cheap systems to create high osmotic pressure differences. In both cases, water evaporates in the solution of higher chemical potential and the water vapour formed is transported across the membrane pores before being condensed in the solution of the lower water potential (Figure 4).

Solutions whose vapour pressure is relatively unaffected by the presence of the solute are ideal candidates for concentration using osmotic distillation. This includes solutions consisting primarily of sugars, such as fruit juices.

Two pilot-plant facilities located in Melbourne and Mildura (Australia) are successfully operating for concentration of fruit juices. Colour, flavour and aroma retention is good due to the lower operating temperature and stresses.

Grape juice concentrates used for production of high quality wines may also be concentrated by membrane distillation. Since these concentrates are stable for long periods of storage they can be shipped over long distances and high priced wines can be produced in regions where these grapes are not available or are too expensive.

Opportunities also exist for the concentration of pharmaceutical products, which are susceptible to thermal degradation.

Biphasic Membrane Bioreactors

Multilayer membrane bioreactors can readily be constructed from several membrane films to which different biocatalysts have been attached or from

combinations of permselective and catalytic membranes.

The use of permselective membranes in conjunction with catalytic films (or catalytic compartments) makes possible a high degree of control over the fluxes of the reaction participants, and hence over the course of reaction, that is impossible to achieve with catalyst particles. By using an adequate permselective membrane the fluids on either side of a membrane can be segregated, thus providing an additional degree of freedom in reactor design.

Most research work has been oriented to the development of biphasic membrane bioreactors where a microporous (hydrophobic or hydrophilic) membrane is used to separate an aqueous from an organic compartment. In this way, two immiscible liquid phases can be contacted across a membrane without one of the phases having to be dispersed in the other, as is required in most conventional multiphase reaction systems. In this type of reactor the biocatalyst may be linked to the membrane (Figure 5) or dispersed in one of the bulk phases.

The opportunity for development of biphasic membrane bioreactors is quite clear: the demand for selective removal of defined pollutants and the need for enantioselective transport and reaction for chiral synthesis in the pharmaceutical and food industries require new approaches in this field. Special attention has been devoted to the development of biphasic membrane bioreactors for enzymatic esterification and hydrolysis reactions.

Future Developments

Membrane contactors are unique equipment for promoting mass transfer while avoiding the dispersion of the fluid phases involved. This article has briefly reviewed the potential of membrane contactors in different areas of application and the problems which are still to be solved.

The industrial future of membrane contactors for liquid-liquid extraction processes, and in some defined situations for gas absorption, will depend very strongly on the ability to synthesize specific carriers or receptors with the potential to achieve recognition of individual solutes. Therefore, the trend will be the development of very selective carriers, in some cases with the ability for chiral recognition.

Membrane stability, in the sense of avoiding contamination between the two contacting fluids, is of major importance for the penetration of membrane contactors in some industrial markets. In particular, in the food and the pharmaceutical industries, trace contamination between the two fluid phases is a sufficiently strong reason to reject this type of process.

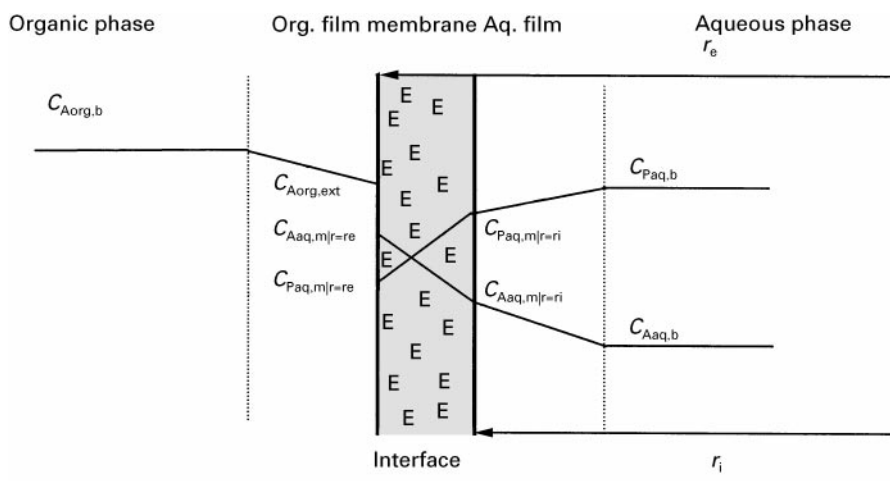

Figure 5 Representation of the enzymatic conversion of a substrate (subscript A) soluble in the organic phase to a product (subscript P) soluble in the aqueous phase. The enzyme is entrapped inside the porous structure of a hydrophilic membrane.

Development of organic solvents which are insoluble in water, nonvolatile and without the tendency to form emulsion would be highly desirable. Recently, the development of ionic liquids has been reported in the literature. These are entirely comprised of ions (complete absence of water), and are nonvolatile and insoluble in water. This type of solvent opens a world of new opportunities for liquid-liquid extraction and gas absorption using membrane contactors, without the risk of fluid cross-contamination. Also the use of dense gases and supercritical fluids has been suggested in membrane contactors. Again, the problem of contamination with the solvent phase could be eliminated.

Finally, new module design and new manufacturing materials will be welcome for certain type of applications, especially when viscous fluids and aggressive solvents are used. Further increases in membrane contactor performance are expected with the use of hollow-fibre fabrics and baffled modules.

MEMBRANE PREPARATION

Hollow-Fibre Membranes

M. van Bruijnsvoort and P. J. Schoenmakers,
University of Amsterdam, Amsterdam,
The Netherlands

Introduction

Hollow-fibre membranes are an attractive alternative to conventional flat membranes in a growing number of important applications. Arguably, they have proliferated most in the biomedical and biochemical fields, thanks to their simple geometry and small dimensions in combination with their inherently high surface-to-volume ratio. Dialysis is the technique in which hollow-fibre membranes are most commonly employed.

There exist a number of extensive reviews on the technology, application and fabrication of membranes. A true classic is the book by Mulder, which contains a detailed overview of developments in the preparation of membranes and their use in purification. McKinney has provided a useful review of the preparation of organic hollow-fibre membranes. Tsapatsis has reviewed the preparation of inorganic membranes.

We have a particular interest in hollow fibres for polymer separations, with hollow-fibre flow field-flow fractionation (HF₅) as the analytical principle. Inorganic fibres are of great interest for polymers that require (strong) organic solvents. This article is biased due to this specific interest, our limited personal experience with different types of fibres and their preparation, and by our background as analytical chemists. The latter also provides us with an original perspective. To us there is an obvious analogy between the preparation of hollow-fibre membranes and open-tubular columns for chromatography. Both areas may benefit from such a comparison, presented in Table 1.

Types of Membranes

Basically, three types of membranes are distinguished:

- porous membranes;
- nonporous membranes; and
- liquid membranes.

All three types can be used in the hollow-fibre geometry. Porous membranes allow the passage of relatively large molecules. Depending on the size of the pores, one speaks of microfiltration (pore size > 100 nm), ultrafiltration (pore size < 100 nm), or nanofiltration (molecular weight cut-off > ca. 1000 Da). Nonporous membranes are permeable to very small molecules (gases). Liquid membranes are of interest because of the selectivity and flexibility they provide. A broad review of liquid membranes has been provided by Sastre and co-workers.

Hollow-fibre membranes are often the preferred geometry, offering distinct advantages over flat or tubular (diameter larger than 1 mm) membranes, for a number of reasons:

- high surface-to-volume ratio;
- conceptual simplicity;
- easy incorporation in flow streams;
- broad availability.

In preparing hollow-fibre membranes, we must try and capitalize on these advantages. For example, if the surface-to-volume ratio is a key parameter, then narrow-bore fibres are most interesting.

Membranes are used in many different ways in analytical chemistry. Most of their applications are in the areas of sampling and sample preparation, thanks to the fundamental ability of semipermeable

Table 1 Analogy between the properties of membranes and chromatographic columns

<i>Type of membrane selectivity</i>	<i>Chromatographic equivalent(s)</i>
Preferential interaction and adsorption from a gas, liquid or supercritical fluid	Gas chromatography with solid or polymeric stationary phases (GC) Normal-phase and reversed-phase liquid chromatography (LC) Supercritical-fluid chromatography (SFC)
Size selectivity (sieving effect)	Molar sieve columns (GC) Size exclusion chromatography (LC)
Charge selectivity	Ion exchange chromatography Ion exclusion chromatography
Affinity membranes	Affinity chromatography

membranes to differentiate between different materials (viz. matrix and analytes). This selectivity of the membrane can be based on molecular size, affinity, charge, or a combination of these properties. There are only a limited number of situations in which the actual analysis relies on the application of hollow-fibre membrane interfaces. These include the following:

- *Affinity chromatography.* Porous membranes combine a large surface area with a high permeability. By bonding specific groups to the surface, targeted species can be bound very strongly to the membrane. After the entire sample has been passed through the membrane, the analyte(s) can be removed. Affinity chromatography is of particular interest in the biochemical and biomedical areas. Since the membranes have a high permeability, the danger of degradation of vulnerable proteins is reduced. Moreover, the high fluxes possible allow more mass to be purified within the same period of time. Two extensive reviews (Roper and Josic) have been dedicated to this important field.
- *Extractions.* The intrinsic ability of hollow-fibre membranes to separate two distinct phases has found multiple applications in the field of extractions. Recently, Gabelman and Hwang published an extensive review on the subject of membrane contactors, i.e. membranes used to separate two immiscible phases.
- *Chiral separations.* The field of preparative chiral separations using hollow-fibre membranes is too interesting to remain unmentioned. In particular, in the pharmaceutical industry there is a great demand for the separation of racemic mixtures on a preparative scale. For example, a hollow-fibre supported liquid membrane can be used to separate two phases, with a chiral selector present in one of these. Alternatively, a chiral selector can be chemically bonded to the membrane surface, prepared in a manner similar to the membrane used for affinity chromatography.
- *Hollow-fibre flow field-flow fractionation (HF₅).* A technique in which the simplicity of hollow-fibre membranes is very advantageous is flow field-flow fractionation (flow FFF). The concept of flow FFF was brilliantly conceived by Giddings. In flow FFF, macromolecules or particles are injected into a channel with a porous wall and displaced by a flow perpendicular to its direction of movement. Based on the difference in average velocity lines that are occupied by particles with different diffusion characteristics (related to particle size or molecular mass), a fractionation is obtained. Ideally (i.e. for spherical particles), the re-

tention time is directly related to the diffusion coefficient of the analyte.

HF₅ was introduced by Carlshaf and Jönsson in 1988 as an instrumentally simple and cost-effective alternative to flow FFF channels with a flat configuration. However, during the 1990s only a limited number of papers have been dedicated to this promising technique. Flow FFF poses very high demands on the quality of the hollow-fibre membrane and, especially, on the fibre-to-fibre repeatability. This is definitely the most important reason for slow progress on the subject. Recently, Lee *et al.* showed an impressive fractionation of latex particles (Figure 1). For this type of fractionation their HF₅ system performed at least as good as alternative techniques, such as the more-established flat-channel flow FFF.

- *Isoelectric focusing.* In 1998, Korlach published an original article on pH-regulated electro-retention chromatography (ERC). This technique is quite similar to (electrical) FFF. A voltage is applied

Figure 1 Hollow-fibre flow FFF fractogram showing the separation of polystyrene latex beads. (Reprinted with permission from Lee WJ, Min BR and Moon MH (1999) Improvement in particle separation by hollow fiber flow field-flow fractionation and the potential use in obtaining particle size distribution. *Analytical Chemistry* 81: 3446–3452.)

across the diameter of a hollow-fibre membrane. Subsequently, a pH gradient is applied in a fluid reservoir which surrounds the fibre. The gradient gradually diffuses into the hollow-fibre membrane. At some point (when the pH crosses the isoelectric point or pI value), the charge on the analyte reverses and the ions will start to migrate to the middle of the fibre, from where they will be rapidly eluted owing to the higher axial flow velocity. The bottleneck in the development of this technique, which is mainly applied to the separation of proteins, is adsorption of the analytes on the membrane.

Semipermeable membranes allow us to manipulate processes that take place at the interface between two (miscible or nonmiscible) phases. They can be used in the gas phase for sampling purposes (e.g. membrane-assisted headspace injection in GC, membrane inlet mass spectrometry, MIMS) or in the liquid phase for sample preparation (e.g. dialysis) or sample concentration. Membranes used for gas sampling usually consist of simple fibres made of polymeric materials, such as polysiloxanes. More sophisticated separations, such as affinity chromatography, require more sophisticated membranes with dedicated selectivities. Also when in contact with liquid phases, most of the fibres used in analytical chemistry are based on organic (polymeric) materials.

The most important characteristic of a membrane is its separation selectivity. Differences in permeability for different materials can be based on a sieving effect (size selectivity) or on the chemical structure of the membrane. Hydrophobic membranes are more permeable to (nonpolar) organic molecules, while hydrophilic membranes are more permeable to water. Membranes will also show adsorption effects. Certain materials (analytes or matrix components) may be preferentially contained in and on the membrane. In some cases this is a desired effect (affinity membranes are the obvious example). Where fibres are used for sampling or sample clean-up in analytical chemistry, adsorption effects are often undesirable.

Preparation of Hollow-Fibre Membranes

The art of hollow-fibre-membrane preparation has taken a high flight in recent years. Nowadays, hollow-fibre membranes are attainable in a fantastic variety of membrane and support materials, pore sizes, diameters, thicknesses, etc. An overview of the techniques involved in the preparation of hollow-fibre membranes is given below.

The various processes for preparing fibres tend to be rather complex, and certainly are laborious and time-consuming. The most difficult step is the optimization of the process, viz. ensuring repeatable (in-house) and ultimately reproducible (transferable) results. Hence, for small-scale applications of hollow-fibre membranes, including all practical applications within analytical chemistry, the most sensible approach to the technology is to obtain suitable fibres from a commercial source.

Preparing Fibres

Most commonly, polymer tubing is prepared by a process referred to as spinning. This can be seen as an extrusion process. A viscous polymer solution (or melted polymer) is pressed through a small hole, while a fluid (bore liquid) is pumped through the centre. This construction is known as a spinneret. It allows precise control of the fibre dimension, thickness, etc. On exiting the spinneret, the fibre is drawn through a coagulation bath, after which additional treatment steps may take place.

The coagulation bath may merely be used to solidify the polymer and stabilize the fibre, but it may also be used to deposit a membrane (see next section). Many different polymers can be processed this way and the porosity of the resulting microfiltration membrane is affected by a large number of parameters. A summary is provided in Table 2. In the case of porous fibres, the type of material used is usually of little relevance to the properties of the membrane. The latter are almost totally determined by the parameters of the pores (size distribution, shape) and the membrane thickness. The material is selected based on other criteria, such as compatibility with the materials (fluids) encountered in the application, mechanical strength and cost. A typical example of a hollow-fibre membrane is shown in Figure 2.

Membrane Films

Polymeric membrane films are usually formed by transferring a polymer from the liquid phase (solution, melt or suspension) to the solid phase. Such a process is known as *phase inversion*. Alternatively, membranes can be formed by *in situ* polymerization. Several processes will be considered below in some detail.

Liquid membranes from a special class of membrane films. They are prepared simply by immersing a microporous hollow fibre in a liquid. The liquid membrane, supported by the hollow fibre, separates two phases; by adding a selective carrier to the membrane (carrier-mediated transport), an increased selectivity can be obtained.

Table 2 Summary of variables affecting fibre properties

Variable	Values	Effects
Consumption of casting solution	Suspension of polymer in non-solvent ('dry spinning') Melted polymer ('melt spinning') Polymer solution ('wet spinning')	Great effect on fibre porosity (and other properties)
Spinning parameters	Extrusion rate (mass flux of solution) Tearing rate (speed of drawing the fibre) Bore fluid rate Distance between spinneret and coagulation solution Composition of coagulation bath Temperature at the various stages	Determines fibre dimensions (internal and external diameters) Significant effect on fibre porosity
Fibre treatments	Washing Chemical modifications	Removes contamination Determines selectivity

Film deposition techniques In order to create a film of a polymeric material on the inside of the fibre, the complete fibre can be filled with a solution of a polymer. Upon evaporation of the solvent, a film will be formed (*static coating*). The critical step is the evaporation of the solvent. This must take place slowly and regularly, in order to obtain a membrane with constant properties throughout the fibre. After a film has been deposited, it may be stabilized by heat treatment or by *in situ* cross-linking.

Instead of an evaporation step, a solvent displacement step may be introduced. In this case, a nonviscous liquid is pumped through the column containing the (viscous) film of polymer solution. The newly introduced liquid may either be a solvent or a non-solvent for the polymer, but it must dissolve the initial solvent. The solvent is then either extracted from the

film, or replaced by a non-solvent. In either case, phase inversion will occur and a solid polymeric layer is obtained.

A second method for depositing a film is to press a plug of a polymer solution or a liquid polymer through the fibre. Behind this plug, a polymeric film will be left on the wall (*dynamic coating*).

Important parameters determining the properties of the membrane include the solution thermodynamics of the specific polymer-solvent combination, the concentration of the polymer in the solution, the temperatures at various stages of the process, the rate of solvent evaporation (or the rate of replacement of the solvent by a non-solvent) and the presence of additives in the solution.

***In situ* polymerization** Using the processes of static or dynamic coating described above, it is also possible to deposit a film of a solution containing monomers or polymer precursors (pre-polymers). This has the considerable advantage of a low solution viscosity, allowing the formation of relatively thick films without the need to apply high pressures. The residual solvent needs to be evaporated slowly and carefully after the polymerization to avoid cracks in the film or radial differences in film thickness.

Sol-gel deposition A promising class of membranes is that of the inorganic membranes, which are resistant to a wide variety of solvents, including potent organic solvents such as tetrahydrofuran or hexafluoro-isopropanol. The most common technique of preparation is sol-gel deposition on a ceramic support. This procedure was developed in the early 1980s by Burggraaf's group. A sol of nanometre-sized γ -alumina particles is deposited on the wall of the fibre from an aqueous solution containing a small percentage of polyvinyl alcohol. The deposited sol

Figure 2 Typical scanning electron micrograph of an asymmetrical composite hollow-fibre membrane. (Reprinted with permission from Chung TS, Teoh SK and Hu X (1999) Formation of ultra-thin high-performance polyethersulfone hollow-fibre membranes. *Journal of Membrane Science* 133: 161-175.)

can be converted to a defect-free membrane by sintering.

Okubo pointed out in 1991 that for the preparation of membranes inside a narrow-bore ceramic hollow fibre (1.4 mm inner and 2.0 mm outer diameter) dynamic coating procedures (see Film Deposition Techniques, above) are required. By forcing the sol through the hollow fibre, a stable and thick defect-free layer can be obtained. Reducing the diameter of hollow-fibre membranes is important, as it results in an increase of the surface-to-volume ratio, so that very small volumes can be separated or purified. Many applications in medicine, biology and analytical chemistry stand to benefit.

Chemical Modification of Membranes

Polymers or reactive groups can be chemically bonded to suitable groups on the solid surface inside membrane pores. A large number of surface modification reagents are readily available and specific functional groups, to create the desired membrane selectivity, can be readily attached to such molecules. The process of chemically modifying membrane surfaces may also involve several reaction steps, which, however, may result in a less well-defined product.

Polymers can be attached to the surface ('grafted') through reactive functional groups, or through a pre-deposition radiation treatment. This process allows the creation of a great variety of selective membranes, which can be tailored for specific separations. These tailor-made phases allow affinity-type separations to be performed, in which extremely selective interactions are realized between the membrane surface and a selected analyte. Such interactions can be very strong, but desorption is possible by an appropriate change of conditions (displacing solvent or buffer).

Polymeric films can also be modified by introducing ionic groups, which drastically alters the properties of the membrane. Highly inert, nonpolar

polymeric membranes, such as polyethylene or polytetrafluoroethylene (Teflon®), can be modified to yield highly polar, ionic interfaces.

Hollow Fibres in Analytical Chemistry

As stated earlier, in most applications of hollow-fibre membranes in analytical science commercially available fibres are used. In only a limited number of cases (i.e. liquid membranes and affinity membranes) have analytical scientists reverted to in-house preparation. A nonexhaustive list of major suppliers of hollow-fibre membranes is provided in Table 3. Also, two suppliers of ceramic tubular membranes are listed in this table. Ceramic tubular membranes are not yet commercially available in diameters small enough ($d < 1$ mm) to be called fibres.

In Table 4 we present a selection of recently developed applications of hollow-fibre membranes in analytical chemistry, with emphasis on the types of fibres used and their preparation or commercial availability. Here, we concentrate on the use of hollow-fibre membranes directly coupled with analytical techniques. The case in which the membrane solely determines the separation process has been covered above. Omitted from this table are instruments featuring on-line couplings of either dialysis or filtration units to standard high performance liquid chromatography (HPLC) instruments. These techniques are already well established and commercially available. A very useful review on the state of the art in the on-line coupling of dialysis to HPLC and capillary electrophoresis (CE) has been provided by van de Merbel.

In ion chromatography, hollow-fibre membranes can be used either before the analytical separation column (pre-column) for sample preparation, or post-column to suppress the conductivity of the effluent (mobile phase) prior to conductivity detection. In an interesting article, Kaufmann described the insertion of a hollow-fibre membrane between an HPLC

column and a detector for continuously exchanging buffer ions.

Following Davis, Haginaka's group has developed a hollow-fibre membrane-based post-column reactor. By immersing the fibre in, for example, an alkaline solution, the pH of the eluent can be altered to enable the detection of penicillins, amino acids, barbiturates, etc. However, since the process is diffusion-limited, a long fibre is usually required, leading to additional band broadening. Nonetheless, this is an elegant method to change the pH without the need to introduce an additional reagent stream and a post-column mixing coil.

Two important applications of hollow-fibre membranes are as sample preparation devices to extract specific analytes from a gaseous matrix. When the extracted components are directly fed into the ion source of a mass spectrometer, we speak of membrane-inlet mass spectrometry or MIMS. When the membrane serves as the inlet for a gas chromatograph various acronyms are used, of which MESI (membrane extraction with a sorbent interface) is the most common. The main objective of using membranes in these cases is to prevent large amounts of water (vapour) from entering the analytical instrument.

The membrane in MIMS can be used in different configurations. One of these involves a flat-disc membrane at the tip of a tubular probe, which is

inserted or immersed in the sample or sample stream. In most cases, however, a tubular membrane is used. Polysiloxane tubes (of surgical quality) are the most popular. The sample can either flow through this tube or be on the outside. In the first case, the membrane tube will be inside the mass spectrometer. In the second case, the membrane forms the interface between the mass spectrometer and the outside (chemical) world. A purge gas may pass through the inside of the tube, or it may just be connected to the mass spectrometer vacuum system.

The membrane tubes used for mass spectrometry are usually 1–2 mm in diameter. Using narrower tubes or fibres will not lead to lower detection limits, as the response of a mass spectrometric system increases with the amount (mass) of sample introduced per unit time. In principle, the mass flow of sample is proportional to the tube diameter, so that larger tube diameters are more favourable in this respect. A very large area can also be obtained by using flat, folded membranes. The use of hollow-fibre membranes for MIMS has the advantage that very small samples or sample streams suffice. An efficient parameter by which to affect the sensitivity of the system is the thickness of the membrane (tube wall). The selectivity of the system may be influenced by varying the tube materials. MIMS is most commonly applied to liquid samples, although the concept is

Figure 3 Principle of the MESI set-up. (With permission from the Web page <<http://sciborg.uwaterloo.ca/chemistry/pawliszyn/>>.)

equally valid for gaseous samples. The concept is very attractive for introducing components into the mass spectrometer from aqueous samples, such as those encountered in biotechnology (e.g. measuring the amounts of gases in fermentation broths) or in waste management, but can also be a practical tool in the laboratory. There are at this time relatively few known applications of MIMS for process monitoring, although this is one of the most promising areas.

The principle of MESI is illustrated in **Figure 3**. Analytes, following selective passage through the membrane, are trapped onto a sorbent interface. After a sufficient amount of the analytes has been accumulated, these components are desorbed. In GC this can be done by rapidly increasing the temperature (thermal desorption). Finally, the analytes are separated on the GC column. Most commonly, the membrane probe is used to sample a gaseous phase, either a gaseous sample or sample stream, or the

headspace of a liquid or solid sample. However, there is no fundamental reason why a liquid (e.g. aqueous) phase cannot be sampled directly. The technique can elegantly be used for the field analysis of air.

An interesting trend is the online coupling of hollow-fibre membranes to modern miniaturized separation techniques, where the intrinsic small volumes of hollow-fibre membranes come fully to their right. The hollow-fibre membrane introduces selectivity between analytes and matrix components (sample preparation), and can be used to concentrate the analytes prior to analysis. A liquid membrane device for sample preparation, developed by Mathiasson and Jönsson in 1996, is shown in **Figure 4**. The fibre is positioned in a small channel ($d < 1$ mm) that serves as the donor compartment. From the receptor compartment, i.e. the lumen of the fibre, small volumes can be manipulated towards the attached separation devices through narrow-bore capillaries. The device has been coupled to both μ -LC and CE, and has been

Figure 4 A liquid membrane device for sample preparation. Interfacial Composite Membranes

Introduction

The development of asymmetric cellulose acetate membranes in the 1960s was a breakthrough in membrane technology. These membranes consisted of a thin surface skin layer on a microporous support. The skin layer performed the separation required and because it was very thin fluxes were high. The microporous support provides the mechanical strength required. Following these developments Rozell *et al.* in 1967 described the preparation of the first interfacial (IFC) composite membranes. These membranes have since become the standard for reverse osmosis (RO) and nanofiltration (NF) applications.

IFC membranes have the same asymmetric status of the first-generation cellulose acetate membranes but are made by a very different procedure, shown schematically in Figure 1. In a first step a microporous polysulfone support membrane is impregnated with an aqueous solution containing a multifunctional amine. The impregnated membrane

is then contacted with a hexane solution containing a multifunctional acid chloride. Because the two solutions are immiscible the reactants can only combine at the membrane interface and so a thin polymer film layer forms at the surface. This layer performs the separation required.

Figure 1 Schematic of the interfacial polymerization procedure. (From Cadotte JE and Petersen RJ (1981) Thin-film composite reverse osmosis membranes: origin, development and recent advances. In Turbak AF (ed.) *ACS Symposium Series 153*, Washington, DC, pp. 305–326.

IFC membrane development can be divided into two time periods. The earlier development from 1967 to approximately 1980 was characterized by work funded through the US Department of the Interior, whereas the majority of the development since 1980 has been industry funded. The early membrane preparations experienced a transition from the use of polymeric to monomeric amine reactants resulting in more durable products. Today the state-of-the-art IFC membrane chemistry consists of cross-linked aromatic polyamides derived from monomeric reactants. A review by Cadotte of composite RO membranes gives an account of the evolution of developments leading up to the commercialization of high performance membranes.

The basic interfacial method of membrane preparation using porous support has changed little since its inception though improvements in reactant chemistry and processing conditions have been made. The laboratory-scale preparation method remains a valuable initiation step in the development of IFC membranes because of its efficiency and simplicity. This method will be given a detailed discussion in the sections which follow.

Interfacial Polycondensation

Early Thin Film Synthesis

The origins of interfacial polycondensation reactions can be traced to Morgan of Du Pont who studied the interfacial polymerization of numerous polyamides and polyesters. He found the Schotten-Bauman reaction of diamines with acid chlorides to be an effective laboratory process, which was termed interfacial polycondensation. In this process, the irreversible polymerization of two highly reactive monomers takes place near the interface of the two phases of nonmiscible liquids, as demonstrated by the model system hexamethylenediamine sodium hydroxide-water/sebacoyl chloride-hydrocarbon solvent to produce Nylon 610. This model system is the basis for the discussion which follows.

When the two liquid phases containing diamine and acid chloride are brought together and the hydrocarbon or halogenated solvent, etc.) solvent is a non-solvent for the final polymer, a thin film of the polymer will be formed rapidly at the liquid interface. Generally this polymer is found to be tough and of high relative molecular mass. In a very short time interval equivalent amounts of reactants combine nearly quantitatively, with elimination of hydrogen chloride, and produce a thin film. In Nylon 610 polymerization, the optimal molar ratio of diamine to diacid chloride was found to be about 6.5, indicating the rate-limiting

feature of diamine diffusion across the interface and through the growing polymer film. Also noteworthy is the observation that polymer film growth occurs exclusively in the organic solvent phase owing to the extremely low solubility of acid chloride reactants in the aqueous phase. In general it is found that the mass transfer of the diamine is the rate-controlling step at all concentrations of reactants. The variables affecting interfacial polycondensation determined from experimentation are listed in **Table 1**.

Mechanism of Interfacial Polycondensation

The mechanism of membrane formation has been studied using the reaction between diamines and diacid chloride and can be generalized in eqn [1]:

Normally in the interfacial polymerization, sodium hydroxide or other suitable base is added to the aqueous phase as an acid acceptor to neutralize the hydrogen chloride formed and drive the reaction to completion. In some systems excess diamine reactant can serve as the acid acceptor since amine hydrochlorides are highly water soluble and at the same time insoluble in hydrocarbon solvents. In addition to the simple difunctional reactants shown in eqn [1], trifunctional and combinations of di- and trifunctional reactants may be used to achieve the desired degree of polymer cross-linking.

Initially the polymer film grows rapidly; growth then slows and finally a constant film thickness is reached. This is due to the inability of the amine reactant to diffuse through the polymer film to react with the acyl halide. Enkelmann and Wegner

described this process in eqn [2]:

$$\frac{dx}{dt} = K\frac{c}{x} - k'x \quad [2]$$

where x is the membrane thickness; c is the concentration of diamine; K is the diffusion coefficient of diamine through the membrane; and k' is the rate constant of the inhibiting reaction (\propto acid chloride hydrolysis).

When the limiting thickness x_{∞} of the film is reached, $dx/dt = 0$ and eqn [2] simplifies to $x_{\infty} = \sqrt{Kc/k'}$. The limiting film thickness is therefore proportional to the square root of the diamine concentration. Subsequently, Enkelmann and Wegner established as a solution of eqn [2] the rate law of membrane growth:

$$x' = \frac{x}{x_{\infty}} = [1 - \exp(-2k't)]^{1/2} \quad [3]$$

where x' is the reduced membrane thickness. Solving in terms of t (seconds) gives:

$$t = \log \frac{(1 - x')^2}{-2k'} \quad [4]$$

From this equation one can obtain values for early film growth from a period of seconds to over 10 min for more complete growth. It was found from this work that the limiting film thickness depended on both the absolute concentration and concentration ratio of the diamine and diacyl chloride reactants. Enkelmann also showed by X-ray diffraction techniques that in Nylon 610 membranes the polymer chains are ordered perpendicular to the interface. It was also concluded that membrane properties could be regulated by selecting particular reactive monomer ratio and concentrations, solvents and reaction times.

Early IFC Membranes

The IFC Membrane Structure

The development of IFC membranes is a logical outcome following the earlier development of asymmetric cellulose acetate (CA) membranes, as well as the previously discussed interfacial polycondensation work. The CA membrane is comprised of a soluble polymer or blend of polymers of varied cross-sectional morphology with the uppermost surface (skin) forming a permselective barrier. The IFC membrane, which is now the state-of-the art product, contains

a microporous support layer of one polymer and a separate permselective skin or thin film of another polymer. The advantage of the IFC membrane is that the chemistry of the all-important permselective thin-film layer can be chosen independently from the underlying porous support material. Asymmetric membranes require polymers that are soluble in solvents necessary for the phase inversion process and this limits the number and type of polymers that can be utilized. Many useful crystalline, semicrystalline, and all cross-linked polymers are thus excluded from asymmetric membrane manufacture. The thin films of IFC membranes are in the range of 20–300 nm thick and when coupled with microporous supports of low hydrodynamic resistance provide membranes with unmatched productivity and solute retention.

NS-100 and PA-300 Membranes

In the discussions of IFC membranes that follow, technical milestones are highlighted with emphasis on commercially significant developments. The early period of membrane development shown in **Table 2** began in 1967 with the investigation of various aqueous diamine and hexane-diacyl chloride interfacial solutions upon polysulfone porous supports by Rozelle *et al.* at North Star Research Institute. These first IFC membranes had low salt rejections, probably due to lack of film integrity since the resultant polymers were not cross-linked. This pioneering work, however, is significant in that the essential elements for the preparation of IFC membranes were demonstrated. Shortly thereafter, in 1970, the first high salt-rejecting IFC membrane, NS-100, was also developed at North Star Research. This membrane was made from polyethylenimine (PEI) in the aqueous solution and toluene diisocyanate (TDI) in the hexane solution. The coated and drained polysulfone support was subsequently dried at 110°C to yield a dry composite membrane with greater than 99% salt rejection on a synthetic seawater feed at 1000 psig (6.9 MPa). A later related membrane, designated NS-101, substituted isophthaloyl chloride (IPC) for TDI as the cross-linker and provided similar results. The selective layers in these membranes consisted of cross-linked polyurea and polyamide films, respectively. The membranes demonstrated high permselectivity but were mechanically delicate and highly vulnerable to attack by chlorine disinfectant.

The sensitivity of early interfacial membranes to chlorine attack was a serious problem that has still not been completely solved. Chlorine is routinely added to water to prevent bacterial growth on the membrane surface. However, exposure to even p.p.m. levels of chlorine destroyed the permselective layer of IFC membranes within a few hours.

	NS-300 membrane
	<p> $\text{Piperazine} + \text{IPC} + \text{TMC}$ </p> <p> Piperazine IPC TMC </p>

Another early membrane developed from a polyamine reactant was the PA-300 membrane by Riley *et al.* at UOP Fluid Systems Division in 1975. The advantage of this polyamide membrane prepared from IPC cross-linker was the lack of residual amines or amide functional groups in the polymer backbone, which exhibited improved chlorine tolerance. The performance of the PA-300 membrane was similar to that of the NS-100 and was the first IFC membrane to be utilized in a large-scale commercial desalination facility located in Jeddah, Saudi Arabia.

NS-300 Membrane

The last example of the earlier generation IFC membranes – the NS-300 – differed from its predecessors in that it was prepared from a difunctional *monomeric* amine, piperazine, and a trifunctional acyl chloride, TMC. This cross-linked polyamide membrane, developed at North Star division of Midwest Research Institute in 1975 by Cadotte *et al.*, demonstrated improved tolerance to chlorine compared to its predecessors due to absence of the

vulnerable amidic hydrogen. Later variants of this membrane included addition of the difunctional IPC acyl chloride, which resulted in increased salt rejection and decreased flux. As might be expected, this is probably due to the decrease in residual carboxylic acid functionality resulting from decrease of the trifunctional TMC cross-linker. Another interesting structural aspect of this polyamide is the nearly 90° out-of-plane orientation of the piperazine ring relative to the aromatic ring. This rigid polymer structure containing a high volume geometry may in part account for the high permeability of this membrane.

Contemporary IFC Membranes

Performance Goals

The goal of further membrane development was to maximize solvent passage while at the same time minimizing solute passage. In a typical reverse osmosis desalination application, this means developing membranes with high water permeability yet low salt passage. This effort applies to nanofiltration membranes as well, except in this case passage of monovalent salts and organics of low relative molecular mass is preferred. Since the two performance properties of solvent flux and solute retention are competing, it is found in practice that one generally observes a trade-off in these values with membrane optimization. Both the thin film chemistry and morphology determine its transport properties. Additional goals of recent IFC membrane development include durability, chlorine and other oxidant stability, and fouling resistance.

MPD-Based Membranes

Table 3 lists recent significant IFC membrane developments. Beginning with the wholly aromatic polyamide FT-30 membrane developed by Cadotte at Film-Tec in 1978, it is seen that all of the subsequent membrane examples rely on the aromatic diamine monomer *m*-phenylene diamine (MPD). With the exception of the A-15 membrane, all of the MPD-based membranes provide very high salt rejection and similar water fluxes. Consistent with the general trade-off principle, the A-15 yields higher water flux with commensurately lower salt rejection, making it what is commonly called in the industry a 'loose RO' membrane. The cross-linked aromatic polyamide remains the-state-of-the-art in IFC membrane chemistry. Membranes of this kind are durable, hydrolytically stable, temperature stable, and exhibit high transport properties. A range of commercially successful membranes encompassing nanofiltration, brackish RO and seawater RO applications have

been achieved with the basic MPD/TMC reactants. These and other modern IFC membranes are made essentially by the same techniques of interfacial polymerization onto porous polysulfone substrates as were their predecessors.

IFC Membrane Preparation

This section provides general information on how IFC membranes have been prepared and discusses guidelines for others to follow in preparing their own such membranes. The laboratory-scale preparations are discussed in an ordered sequence below with emphasis on techniques commonly practised in the desalination membrane industry for flat-sheet IFC membranes. The basic principles of these interfacial techniques are also applicable to the less commercially significant hollow fibre IFC membranes or other composite membrane formats.

Porous Support Preparation

The preferred polymer for use in porous support preparation is polysulfone, a moderately priced material with many desirable chemical and mechanical properties. In addition to strength and temperature stability, it is resistant to hydrolysis and oxidative attack. Its disadvantages, though relatively minor, are its hydrophobicity and lack of solvent resistance. The former property necessitates inclusion of surfactants or wetting agents for some aqueous coating methods used in IFC membrane manufacture and the latter property limits its applications to ones which are predominantly aqueous or contain nonaggressive solvents such as alcohols and aliphatic hydrocarbons. Nevertheless, polysulfone has been and remains the polymer of choice for the porous support of RO and NF IFC membranes.

Preparation of the polysulfone microporous support may be carried out using laboratory, pilot, or full-scale production equipment. Regardless of scale, all of these procedures involve conversion of a polymer in solvent solution to a porous solid layer in what is called the phase inversion process. As the water in the gelation or solidification bath replaces the solvent, the clear polysulfone solution, or casting solution, is transformed to an opaque plastic layer on to the surface coated. With laboratory preparation this is normally carried out by applying a 14–18% polysulfone solution in *N,N*-dimethylformamide (DMF) onto a flat glass plate using a Gardner blade or other suitable device set with a blade gap of 0.13–0.26 mm, then immersing the plate into a small tank of water. For better strength and ease of later processing, it is advisable to do the solution coating onto a calendered polyester fabric or related material attached to the

glass plate. After several minutes, immersion time in the water bath to remove all solvent, the newly formed porous substrate is immersed again in a fresh water bath as a final rinse. This batchwise process can be scaled up and carried out as continuous processes employing pilot 1 foot (30 cm) wide or production 40-in wide (~ 100 cm) equipment. The advantages of utilizing the continuous process include not only the obvious efficiency but also better reproducibility in resultant porous support properties. However, it is sometimes necessary to pursue the laboratory batchwise process when experimenting with small quantities of costly new polymers or processing conditions that are not easily implemented on the larger-scale continuous equipment.

A typical polysulfone microporous support used in RO or NF IFC membrane fabrication is, by its pore size designation, an ultrafilter (UF) with surface pore sizes ranging from 0.005 to 0.05 μm . Since this size is an order of magnitude smaller than the interfacial film thickness, it easily supports the film even under operating pressures as high as 1000 psi (6.9 MPa). The thickness of the PS support must be sufficient to cover completely the carrier fabric surface plus irregularities caused by improper calendaring, debris and lack of flatness during the casting operation. In practice the net thickness of the PS layer ranges from 25 to 75 μm and that of the carrier fabric upon which it lies ranges between 75 and 150 μm . Scanning electron micrographs (SEM) of a typical PS porous support cross-section and top view are shown in Figure 2A and B, respectively. The anisotropic structure is plainly evident with the finest and most supportive pores residing in the upper surface of the support. The finished PS support is normally stored fully immersed in water or at least damp and protected from dust, debris and biological growth. In some cases it is necessary to include a biocide in the storage water, particularly if it is to be stored a long time. A simplified drawing of a continuous casting machine designed to manufacture PS porous supports in which a carrier fabric is used is given in Figure 3. A few additional comments regarding the porous support should be noted. In addition to polysulfone, other similar aromatic polyethers may be used such as polyether sulfone. However, these and other variants are significantly more expensive and, except for certain specialized applications, are generally not warranted. The final PS support should be rinsed free of the casting dope solvent otherwise this residual may fuse the porous structure when the IFC membrane is dried.

Aqueous Amine Reactant Application

The two basic formulations used in the RO IFC membrane industry contain the diamines piperazine

Figure 2 (A) SEM polysulfone porous support cross-section. (B) SEM polysulfone porous support (top view).

(Pip) or *m*-phenylenediamine (MPD). Because both the reactivity and solubility (partition coefficients) of these two monomers are different, it is necessary to utilize each at different absolute concentrations as well as different concentration ratios with the cross-linker. When using the Pip formulation it is usually necessary to include an acid acceptor such as sodium hydroxide (NaOH) to neutralize the hydrochloric acid by-product of the polyamidization reaction. This is not necessary when using MPD since it is a much weaker base than Pip and used in a higher excess concentration so that, excess MPD serves as its own acid acceptor. It is generally preferred also to include a surfactant in the aqueous amine formula to acid in the wetting and thus even coverage of the PS support. An anionic or neutral surfactant type is preferred.

There are many acceptable techniques for applying the aqueous amine solution to the PS support. Examples of these include dipping, pouring on, spraying, kiss coating, cloth coating, reverse roll coating, etc. A simple yet effective laboratory-scale method involves sandwiching a 6-in. (~ 15 cm) square piece of PS support between two plastic frames using metal clips to hold the two pieces together. An excess of amine solution is then poured onto the top surface of

Figure 3 Continuous casting machine for porous support.

the PS support and after a brief time interval is drained off leaving an even, wet layer. Depending on the particular formulation the excess amine may be further removed by rubber roller, squeegee, or air knife. It is important that some degree of wetness remains prior to the contact with the cross-linker solution, otherwise the amine cannot transfer effectively via the water-solvent interface.

Cross-Linker Reactant Application

The choice of solvent for the acyl chloride reactant is dictated by the following requirements:

1. It must completely dissolve the acyl chloride (or other cross-linker) but not react with it.
2. It must be insoluble or virtually insoluble in water.
3. It must not dissolve or swell porous support.
4. It must have a sufficient volatility such that membrane-degrading temperatures are not required for its evaporation.

In practice, the only solvents meeting all of the above requirements are aliphatic hydrocarbons and chlorofluorocarbons (CFCs). There may also be some examples of hydrogenated chlorofluorocarbons (HCFCs) that are acceptable and at the same time are more environmentally friendly than the CFCs. For manufacturing purposes, further restrictions may include preferences for flash point above 100°F and (37.8°C) and low level toxicity. As mentioned previously, the concentration of cross-linker required will be different for the two types of diamines. The concentration of acyl chloride needed for the Pip

formulation is approximately five times that needed for the MPD formulation.

The method of cross-link solution application is generally limited to those which do not disrupt the biphasic nature of the interfacial reaction. If excessive disturbance to this step occurs, the growing polymer may be disrupted, leading to thin film discontinuity and ultimately to high salt passage through the defect regions. Dipping, pouring on gently, kiss coating, etc., are effective methods. For the laboratory-scale techniques, excess acyl chloride cross-link solution is gently poured onto the amine solution-coated PS support contained in the frame and kept horizontal for a brief period. The cross-link solution is then drained off vertically, leaving behind the delicate IFC film residing between thin aqueous and solvent layers. The final step involves some form of evaporation of these two solvents as described below.

Drying the IFC Membrane

Since the freshly polymerized thin film resides on a thin layer of water, this layer must be removed for the film to strongly adhere to the PS support surface. It is also desirable to remove the cross-link solvent so that the finished IFC membrane can be safely and conveniently handled in a dry state.

Depending on the volatility of the cross-link solvent and amount of moisture present under the IFC film layer, a temperature range of from ambient to 150°C is required. The higher temperature is a practical upper limit owing to tendency for discoloration and degradation of the IFC membrane. Though many

forms of heating are possible forced air can be used with less heat because of the efficient mechanical effect it has on liquid evaporation. This can be an advantage for IFC membranes that are vulnerable to excessive dehydration. In general, it is found that lower boiling solvents combined with lower drying temperatures often result in membranes with higher fluxes and lower salt rejections than their higher boiling, higher drying temperature counterparts. Of course, longer time periods of drying can be employed in a similar manner with lower drying temperatures to achieve a similar effect, but the choice is ultimately dictated by mechanical and space requirements of the manufacturing equipment. For laboratory scale preparation, it is convenient to use forced hot air devices such as hair-dryers and/or laboratory convection ovens to dry the IFC membrane after the cross-link solution is drained off the frame. Because the thin film is not yet adhered to the PS support excessive air velocity is to be avoided.

The laboratory scale membrane preparation method described in previous sections is now recalled, combining the various steps together: Six inch (~ 15 -cm) square pieces of a polysulfone ultrafilter support are clamped between two Teflon[®] frames and coated on the upper surface with an aqueous solution of the amine monomer for several seconds; the excess solution is removed by any of the various methods previously mentioned. This freshly coated surface is immediately contacted with the cross-linker-solvent solution horizontally for a period of several seconds then drained vertically for several seconds and finally dried by either forced air and/or convection oven for several minutes. The precise conditions for each of the above steps will depend on the particular type of IFC membrane product that is desired, i.e. NF or RO application, and high productivity or high solute retention, etc., according to the development-performance relationships discussed in the previous sections. A listing of the major IFC membrane prepara-

**Figure 4** SEM piperazine IFC membrane (top view).

tion variables is given in Table 4. SEM pictures of Pip- and MPD-based membranes are given in Figures 4 and 5, in which difference in surface roughness is seen. Figure 6 gives a simplified diagram of the continuous IFC membrane manufacturing process.

Testing and Optimization

Test Criteria

The membrane performance throughout the optimization process is obtained by testing on various saline or other solute feeds as appropriate for the particular type of membrane being developed. Examples of test feeds commonly used for RO and NF membrane evaluation are shown in Table 5. Because these feeds are in some respects arbitrary, one can easily substitute other concentrations of solutes, types

**Figure 5** SEM *m*-phenylenediamine IFC membrane (top view).

Figure 6 Continuous coating machine for IFC membrane.

of solutes, or test pressures to suit the desired application for the membrane.

The permeate quantity and quality are measured for each membrane sample tested and utilized as performance criteria. In the desalination industry, the former is termed membrane flux, with units of gallons/foot²-day (gfd) ($\times 40.8$ L/m²-day) and the latter as salt rejection (%). Flux measurements are made by collecting a volume of permeate under a controlled temperature and time interval. Knowing the active area of the membrane sample and utilizing a temperature correction factor for the viscosity of water, one can calculate the flux normalized to 25°C. Salt rejection is calculated from electroconductivity measurements of the permeates with correction for specific conductance as a function of sodium chloride concen-

tration, or via specific ion probe measurement. Salt rejection is finally calculated as

$$\left(1 - \frac{\text{permeate p.p.m.}}{\text{feed p.p.m.}}\right) \times 100$$

In the case of organic solutes, measurements of permeate and feed are done with a total organic carbon (TOC) analyser with rejection calculated in the same manner as before.

During the membrane development process it is often necessary to rank membranes based upon an objective evaluation. This is difficult because membrane flux and rejection both change. For example, how can a 20 gfd (815 L/m²-day) 99.0% membrane be ranked against a 15 gfd (611 L/m²-day)

Table 5 Test feeds for IFC RO and NF membranes

RO membranes			
35 000 ppm NaCl 800 psig	1500 ppm NaCl 150–225 psig	1500 ppm NaCl 1000 ppm CaCl ₂ 150–225 psig	1500 ppm isopropanol 150–225 psig
NF membranes			
500 ppm NaCl 75 psig	500 ppm MgSO ₄ 75 psig	500 ppm NaCl 300 ppm MgSO ₄ 75 psig	500 ppm sucrose 75 psig

99.3% membrane, that is, one with a lower flux but higher rejection. A simple ranking method, if the salt rejection of the membrane is 75% or higher, is to take the ratio of flux/salt passage (F/SP) in which salt passage is simply $100 - \text{salt rejection}$. This value correlates well with the more sophisticated ranking calculation of A^2/B , in which A is the pure water permeability constant ($\text{g mol cm}^{-2} \text{s}^{-1} \text{atm}^{-1}$) and B is the salt transport coefficient (cm s^{-1}). In the discussion below, both a simple and a more sophisticated performance optimization example are presented for membrane development.

Simple Approach Optimization

If one has some development experience with a particular amine and cross-linker reactant system such that the workable range of reactant concentrations and processing conditions are at least roughly definable, or if highly optimized membrane performance is not essential, a simplified approach may be pursued. A listing of the recommended minimum number of optimization variables has been given in Table 4. The membrane optimization plan should be carried out in the order shown in this table since it is ordered from highest to the lowest criticality. This approach relies on selecting previously known conditions or educated estimates of some of the variables to be surveyed. The amine monomer concentration experiment would begin by comparing amine concentrations ranging, for example, from x to $3x$ with increments in-between while holding all other variables in Table 4 constant. This requires some discretion in selecting median values of the held constant variables based on prior knowledge. After determining the 'optimum' amine concentration one would proceed in order to the next variable and carry out the next experiment, holding all other variables constant except the acid acceptor concentration that is to be varied. This procedure continues until all the variables have been individually optimized. It is strongly recommended after a once-through optimization to reiterate this process at least once more since new values of many of the variables are likely to have been established. The second time through is likely to result in refinements of both the optimization variable values and the membrane performance.

It should be pointed out that this simple single-variable optimization approach can suffer errors due to interactive variables that can only be optimized in concert. For example, it is likely that, consistent with general principles of chemical reactants, when the amine concentration increases the need for cross-linker increases but so does that for the acid acceptor. In this example there is a three-variable interaction, not merely the two-variable one that the simple method exam-

ines. Thus it is often desirable to consider a more sophisticated approach to optimization in which the best combination of variables is found. A multivariable optimization process is offered below.

Self-Directing Optimization Approach (SDO)

In the SDO process, a regular simplex in K variables is constructed. The experiment can be initiated in K variables with $K + 1$ experiments and upon completion of the $K + 1$ experiments, the results are ranked from best to worst. In the case of IFC desalination membranes, ranking is performed using either F/SP or A^2/B calculations made from the flux and rejection results from a specified test feed type and operating pressure. An example of a Plackett-Burmann SDO plan containing 11 variables A-K in 12 experiments is presented in Table 6. Corresponding to the + and - symbols are high and low levels, respectively, to be selected for each variable A-K. The experiments 1-12 are carried out as one series in a random order. After completion of the first series of 12 experiments, the best eight cases, for example, will have the averages of each of the variables calculated. These average values are then multiplied by 2, then from these are subtracted each of the conditions of the four worst cases. The four new experiments created are then run and ranked against the previous eight best cases as before with subsequent elimination of the four worst cases. This process is repeated several times, each time eliminating the worst cases and creating new ones to be compared with the previous best. Eventually the variables will be found to converge such that the optimization is complete.

Future Developments

Within the polyamide family of chemistry used in IFC membrane preparation dramatic differences in transport properties can be obtained. It is believed that the thin film polymer chemistry and macrostructure play critical roles in determining these performance differences, thus it is expected that future development will rely heavily on the understanding of polymer structure-property relationships. Though there is relatively little such information available to date concerning membrane polymers, recent computer molecular modelling studies are beginning to show promise. Studies such as these and ones involving the mechanism of solvent/solute transport in permselective polymers will lead to future intelligent design of polymer membranes for specific separation processes. In addition to transport performance, there is still need for improvement in chlorine tolerance and fouling resistance by both RO and NF membranes.

There are performance gaps in presently available membrane products for the NF area of separations involving species with relative molecular masses ranging from 100 to 3000. It is foreseeable that markets will expand for NF membrane applications in high value separations for biotech, chemical, food, and pharmaceutical industries if well-defined relative molecular mass cutoffs can be achieved.

With respect to commercial IFC membrane manufacture, there is a need for improved uniformity and quality of carrier fabrics upon which the porous support is cast. Lack of control here can result in defects that are translated right through the completed composite membrane product. An additional future goal is the development of real-time membrane film integrity and/or performance measurement so that corrections to the process can be made during the course of the manufacture.

Phase Inversion Membranes

Introduction

Phase inversion is the most versatile technique with which to prepare polymeric membranes. A variety of morphologies can be obtained that are suitable for different applications, from microfiltration membranes with very porous structures, to more dense reverse osmosis membranes, to gas separation and pervaporation membranes, with a complete defect-free structure. **Table 1** gives an overview of the techniques that are commonly applied for the preparation of synthetic polymeric membranes.

Most commercially available membranes are prepared by phase inversion. This is a process by which a polymer is transformed from a liquid or soluble state to a solid state. The concept of phase inversion covers a range of different techniques such as immersion precipitation or 'diffusion-induced phase separation', thermal-induced phase separation, 'vapour-phase' precipitation and precipitation by controlled evaporation. The technique of phase inversion has been known for quite some time; the first paper on the preparation of porous nitrocellulose membranes by phase inversion appeared in 1907.

Table 1 Frequently used techniques for the preparation of synthetic polymeric membranes

Process	Techniques
Microfiltration	Phase inversion, stretching, track-etching
Ultrafiltration	Phase inversion

Reverse osmosis	Phase inversion, interfacial polymerization ^a
Pervaporation	Dipcoating ^a , plasma polymerization ^a
Gas separation	Phase inversion, dipcoating ^a , plasma polymerization ^a
Vapour permeation	Dipcoating ^a

^aSupport layer prepared by phase inversion.

After World War I the number of publications on membrane preparation and characterization increased significantly and led to the development of the first methods for producing porous nitrocellulose membranes in a reproducible way. The 'Membranfiltergesellschaft Sartorius-Werke' in Göttingen was the first company to produce microfiltration membranes on a commercial scale, based on the work of Zsigmondy. This early work on preparation and characterization was reviewed by Ferry in 1936.

Until World War II most membrane research was performed in Germany, but after the war the technology was transferred to USA. In 1960 Goetz developed a new method for the production of porous membranes. Some years later the Millipore Corporation was founded, which commercialized this production method. The membranes were typically microfiltration membranes and were still based on cellulosic materials. It was more than two decades before ultrafiltration membranes were developed. Alan Michaels, founder of the Amicon Corporation, promoted the development of ultrafiltration membranes. Until that time the research was still focused on cellulose as material but it became clear that due to the limited thermal and chemical stability other materials were required. This resulted in the development of various ultrafiltration membranes from polyacrylonitrile, polysulfone and polyvinylidene fluoride. Today polymeric materials are still the most commonly employed materials both in ultrafiltration and microfiltration. The early companies such as Sartorius and Schleicher and Schuell still exist and have expanded their membrane business to the technical market. Recently the market for the production of drinking water and industrial water from surface water has become important. Here both microfiltration/ultrafiltration and nanofiltration/reverse osmosis are either used as a single separation unit or in combination with each other or with another technique. The nanofiltration and reverse osmosis membranes are either thin film composites or, less commonly, asymmetric phase inversion membranes. In the case of composite membranes a phase inversion mem-

brane is usually used as support (see Table 1). For gas separation, vapour permeation and pervaporation composite membranes are generally applied with a porous support membrane prepared by phase inversion. Some gas separation membranes, such as polyphenylene oxide, are prepared by immersion precipitation, which results in completely defect-free asymmetric membrane.

Phase Inversion Membranes

Phase inversion is a process whereby a polymer is transformed in a controlled way from a solution state to a solid state. The concept of phase inversion covers a range of different techniques such as precipitation by controlled evaporation, thermal precipitation from the vapour phase and immersion precipitation. The majority of phase inversion membranes are prepared by immersion precipitation.

Precipitation from the Vapour Phase

This method was used as early as 1918 by Zsigmondy. A cast film, consisting of a polymer and a solvent, is placed in a vapour atmosphere where the vapour phase consists of a nonsolvent saturated with the solvent. The high solvent concentration in the vapour phase prevents the evaporation of solvent from the cast film. Membrane formation occurs because of the penetration (diffusion) of nonsolvent into the cast film. This results in a porous membrane without a top layer. With immersion precipitation an evaporation step in air is sometimes introduced and, if the solvent is miscible with water, precipitation from the vapour will start at this stage. An evaporation stage is often introduced in the case of hollow fibre preparation by immersion precipitation ('wet-dry spinning') exchange between the solvent and nonsolvent from the vapour phase, leading to precipitation.

Precipitation by Controlled Evaporation

In this method the polymer is dissolved in a mixture of solvent and nonsolvent where the solvent is more volatile than the nonsolvent. The composition shifts during evaporation to a higher nonsolvent and polymer content. This eventually leads to polymer precipitation, resulting in the formation of a skinned membrane.

Thermally Induced Phase Separation

A solution of polymer in a mixed or single solvent is cooled to enable phase separation to occur. Evaporation of the solvent often allows the formation of a skinned membrane. This method is frequently used to prepare microfiltration membranes, as will be discussed later.

Immersion Precipitation

Most commercially available membranes are prepared by immersion precipitation: a polymer solution (polymer plus solvent) is cast on a suitable support and immersed in a coagulation bath containing a nonsolvent. Precipitation occurs because of the exchange of solvent and nonsolvent. The membrane structure ultimately obtained results from a combination of mass transfer and phase separation.

All phase inversion processes are based on the same thermodynamic principles, as will be described in the next section.

Phase Separation

The change in Gibbs free enthalpy of mixing (dG) for a two-component system i and j , where the numbers of moles are n_i and n_j , respectively, is given by:

$$dG = V dP - S dT + \left(\frac{dG}{dn_i} \right)_{T,P,n_j} dn_i + \left(\frac{dG}{dn_j} \right)_{T,P,n_i} dn_j \quad [1]$$

Here V is the volume, S the entropy, P the pressure and T the temperature (K). The chemical potential of a component i , which is the partial molar free enthalpy, is defined as:

$$\mu_i = \left(\frac{\partial G}{\partial n_i} \right)_{P,T,n_j,n_k,\dots} \quad [2]$$

where μ_i is equal to the change in free enthalpy of a system containing n_i moles when the pressure, temperature and the number of moles of all the other components are held constant. For a multicomponent system eqn [1] becomes:

$$dG = V dP - S dT + \sum \mu_i dn_i \quad [3]$$

The chemical potential μ_i is defined at temperature T , pressure P , and composition x_i . For the pure component ($x_i = 1$), the chemical potential may be written as μ_i^0 .

The free enthalpy G_m of a mixture consisting of two components is given by the sum of the chemical potentials (the partial free enthalpy). If G_m is expressed per mole, then:

$$G_m = x_1 \mu_1 + x_2 \mu_2 \quad [4]$$

The dependence of the free enthalpy on the composition of the mixture is shown schematically in Figure 1. The value of the G_m at the y -axis represent

Figure 1 Schematic drawing of the free enthalpy of a mixture at temperature T as a function of the composition.

the chemical potential of the pure components. μ_1^0 and μ_2^0 , respectively.

For ideal solutions the free enthalpy of mixing per mole is given by:

$$\Delta G_m = RT(x_1 \ln x_1 + x_2 \ln x_2) \quad [5]$$

The solubility behaviour of polymer solutions differs completely from that of a solution containing components of low relative molecular mass because the entropy of mixing of the long polymeric chains is much lower. Flory and Huggins used a lattice model to describe the entropy of mixing of polymer solutions. In general for a binary system ΔG_m is given by:

$$\Delta G_m = RT(n_1 \ln \phi_1 + n_2 \ln \phi_2 + n_1 \phi_2 \chi) \quad [6]$$

where an additional term has been added that was originally derived as an enthalpic contribution and which contains the Flory-Huggins interaction param-

eter χ . In the original Flory theory χ was considered to be constant but for many systems it has been proven that this is not the case. In addition, χ is considered to be an excess free energy parameter containing all nonideality (including excess entropy). Differentiation of eqn [6] with respect to n_1 and n_2 , respectively, gives the partial molar free enthalpy difference of component 1 ($\Delta\mu_1$) and ($\Delta\mu_2$) upon mixing:

$$\begin{aligned} \Delta\mu_1 &= \mu_1 - \mu_1^0 = \left(\frac{\partial \Delta G_m}{\partial n_1} \right)_{P,T,n_2} \\ &= RT \left(\ln \phi_1 - \left(1 - \frac{V_1}{V_2} \right) \phi_2 + \chi \phi_2^2 \right) \quad [7] \end{aligned}$$

and:

$$\begin{aligned} \Delta\mu_2 &= \mu_2 - \mu_2^0 = \left(\frac{\partial \Delta G_m}{\partial n_2} \right)_{P,T,n_1} \\ &= RT \left(\ln \phi_2 - \left(1 - \frac{V_2}{V_1} \right) \phi_1 + \chi \frac{V_2}{V_1} \phi_1^2 \right) \quad [8] \end{aligned}$$

In the case of polymer solutions the entropy term is very small and a positive enthalpy of mixing will cause demixing. Decreasing the temperature often causes an increase in the enthalpy of mixing.

Figure 2 shows two plots of ΔG_m versus ϕ for two different temperatures. At temperature T_1 (Figure 2A), the system is completely miscible over the whole composition range. This is indicated by the tangent to the ΔG_m curve, which can be drawn at any composition. For example, at composition a the intercept at $\phi_2 = 0$ gives $\mu_1(a)$ (the chemical potential of component 1 in the mixture of composition a) and the intercept at $\phi_2 = 1$ gives $\mu_2(a)$. This means that the chemical potentials of both components 1 and 2 de-

Figure 2 Free energy of mixing as a function of composition for a binary mixture. $T_2 < T_1$ ($H_m > 0$).

crease (or $\Delta\mu_i < 0$). At temperature T_2 (Figure 2B), the curve of ΔG_m exhibits an upward bend between ϕ^I and ϕ^{II} . These two points lie on the same tangent and are thus in equilibrium with each other. All the points on the tangent have the same derivative ($= \partial\Delta G_m / \partial n_i = \Delta\mu_i$), i.e. the chemical potentials are the same. In general, increasing the temperature leads to an increase in miscibility, which means that the enthalpy term becomes smaller. The two points on the tangent will approach each other and eventually they will coincide at the so-called critical point. This critical point is characterized by $(\partial^2\Delta G_m / \partial\phi_i^2) = 0$ and $(\partial^3\Delta G_m / \partial\phi_i^3) = 0$. Two points of inflection are also observed in Figure 2B, i.e. ϕ^1 and ϕ^2 . A point of inflection is the point at which a curve changes from being concave to convex, or vice versa. These points are characterized by $(\partial^2\Delta G_m / \partial\phi_i^2) = 0$. Plotting the locus of the minima in a ΔG_m versus ϕ diagram leads to the binodal curve. The locus of the inflection points is called the spinodal. A typical temperature–composition diagram is depicted in Figure 3.

The location of the miscibility gap for a given binary polymer–solvent system depends principally on the chain length of the polymer (see Figure 4). As the chain length increases the miscibility gap shifts towards the solvent axis as well as to higher temperatures. The critical point shifts towards the solvent

Figure 3 Temperature–composition phase diagram for a binary polymer–solvent system.

Figure 4 Schematic drawing of a binary mixture with a region of immiscibility. Binodal (A): mixture of two components of low relative molecular mass; binodals (B), (C), (D): mixtures of a solvent with low relative molecular mass and a polymer with increasing relative molecular mass.

axis, while the asymmetry of the binodal curve increases. The interaction between polymer and solvent is another important parameter, and this is expressed by the Flory–Huggins interaction parameter.

The location of the phase diagram in a binary or ternary system can be determined experimentally, e.g. by cloud point measurements, or theoretically by applying Flory–Huggins thermodynamics with suitable values for the interaction parameters.

Demixing Processes

Liquid–Liquid Demixing (Binary Systems)

To understand the mechanism of liquid–liquid demixing more easily, a binary system consisting of a polymer and a solvent will be considered. The starting point for preparing phase inversion membranes is a thermodynamically stable solution (see Figure 5), for example one with the composition A at a temperature T_1 (with $T_1 > T_c$). All compositions with a temperature $T > T_c$ are thermodynamically stable. As the temperature decreases demixing of the solution will occur when the binodal is reached. The solution demixes into two liquid phases and this is referred to as liquid–liquid demixing.

Suppose that the temperature is decreased from T_1 to T_2 . The composition A at temperature T_2 lies inside the demixing gap and is not stable thermodynamically. The curve of ΔG_m at temperature T_2 is also given in Figure 5. At temperature T_2 all compositions between ϕ^I and ϕ^{II} can reduce their free enthalpies of mixing by demixing into two phases with compositions ϕ^I and ϕ^{II} , respectively (see Figure 3). These two phases are in equilibrium with each other since they lie on the same tangent to the ΔG_m curve, i.e. the

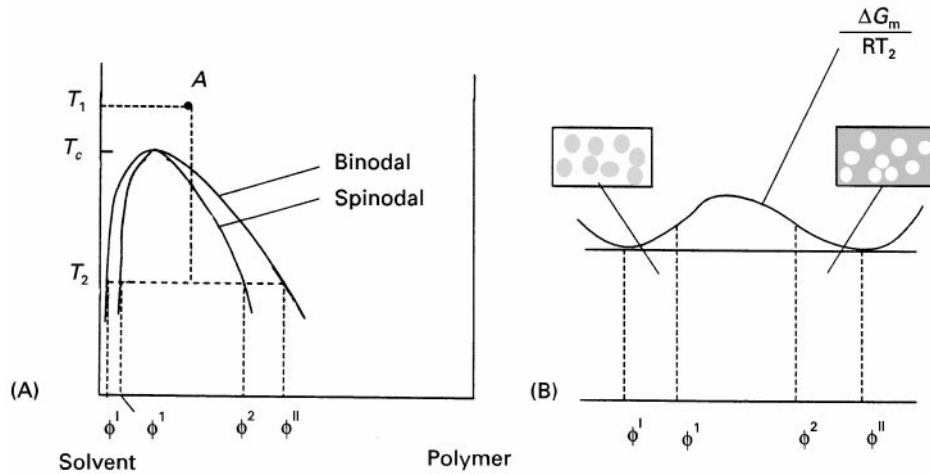

Figure 5 Demixing of a binary polymer solution by decreasing the temperature. T_c is the critical temperature.

chemical potential in phase ϕ^I must be equal to that of phase ϕ^{II} .

Figure 6 gives the curve of ΔG_m plotted against composition at a given temperature (e.g. T_2), together with the first and second derivative. Two regions can clearly be observed from the second derivative

(the lowest figure). Over the interval $\phi^I < \phi < \phi^{II}$ the second derivative of ΔG_m with respect to ϕ is negative, implying that the solution is thermodynamically unstable and will demix spontaneously into very small interconnected regions of composition ϕ^I and ϕ^{II} :

$$\frac{\partial^2 \Delta G_m}{\partial \phi^2} < 0 \quad (\phi^I < \phi < \phi^{II}) \quad [9]$$

Figure 6 Plots of ΔG_m , the first derivative of ΔG_m and the second derivative of ΔG_m against ϕ .

The amplitude of small fluctuations in the local concentration increases in time, as shown schematically in Figure 7. In this way a lacy structured membrane is obtained, and the type of demixing observed is called spinodal demixing. Over the intervals $\phi^I < \phi < \phi^I$ and $\phi^{II} < \phi < \phi^{II}$, the second derivative of ΔG_m with respect to ϕ is positive and the solution is metastable. This means that there is no driving force for spontaneous demixing and the solution is stable towards small fluctuations in composition. Demixing

Figure 7 Spinodal demixing: increase in amplitude with increasing time ($t_3 > t_2 > t_1$).

can commence only when a stable nucleus has been formed. A nucleus is stable when it lowers the free enthalpy of the system; hence over the interval $\phi^1 < \phi < \phi^1$ the nucleus must have a composition near ϕ^{II} , and over the interval $\phi^2 < \phi < \phi^{\text{II}}$ it must have a composition near ϕ^1 :

$$\frac{\partial^2 \Delta G_m}{\partial \phi^2} > 0 \quad (\phi^1 < \phi < \phi^1) \quad \text{and} \quad (\phi^2 < \phi < \phi^{\text{II}})$$

[10]

After nucleation, these nuclei grow further in size by downhill diffusion whereas the composition of the continuous phase moves gradually towards that of the other equilibrium phase. The type of structure obtained after liquid-liquid demixing by nucleation and growth depends on the initial concentration.

Starting with a very dilute polymer solution (see Figure 5), the critical point will be passed on the left-hand side of the diagram and liquid-liquid demixing will start when the binodal curve is reached and a nucleus is formed with a composition near ϕ^{II} . The nucleus formed will grow further until thermodynamic equilibrium is reached (nucleation and growth of the polymer-rich phase). A two-phase system is formed consisting of concentrated polymer droplets of composition ϕ^{II} dispersed in a dilute polymer solution with composition ϕ^1 . In this way a latex type of structure is obtained, which has little mechanical strength. When the starting point is a more concentrated solution (composition A in Figure 5), demixing will occur by nucleation and growth of the polymer-lean phase (composition ϕ^1). Droplets with a very low polymer concentration will now continue to grow until equilibrium has been reached.

As can be seen from Figure 5, the location of the critical point is close to the solvent axis. Hence the binodal curve for a polymer-solvent system will be reached on the right-hand side of the critical point, indicating that liquid-liquid demixing will occur by nucleation of the polymer-lean phase. These tiny droplets will grow further until the polymer-rich phase solidifies. If these droplets have the opportunity to coalesce before the polymer-rich phase has solidified, an open porous system will result.

Liquid-Liquid Demixing (Ternary Systems)

In addition to temperature changes, changes in composition brought about by the addition of a third component, a nonsolvent, can also cause demixing. Under these circumstances we have a ternary system consisting of a solvent, a nonsolvent and a polymer. The liquid-liquid demixing area must now be represented as a three-dimensional surface. The free enthalpy of mixing is a function of the composition, as can be seen from Figure 8, where the ΔG_m surface is depicted at a certain temperature. All pairs of compositions with a common tangent plane to the ΔG_m surface constitute the solid line projected in the phase diagram, the binodal. Figure 9 shows a schematic illustration of the temperature dependency of such a three-dimensional liquid-liquid demixing surface for a ternary system. The demixing area takes the form of a part of a beehive. As the temperature increases the demixing area decreases, and if the temperature is sufficiently high the components are miscible in all proportions. From this figure an isothermal cross-section can be obtained at any temperature as shown in Figure 10.

The corners of the triangle in Figure 10 represent the pure components polymer, solvent and

Figure 8 Schematic drawing of the free enthalpy of mixing (ΔG_m) as a function of the composition for a ternary system consisting of polymer, solvent and nonsolvent.

Figure 9 Three-dimensional representation of the binodal surface at various temperatures for a ternary system consisting of polymer, solvent and a nonsolvent.

nonsolvent. A point located on one of the sides of the triangle represents a mixture consisting of the two corner components. Any point within the triangle represents a mixture of the three components. In this region a spinodal curve and binodal curve can be observed. The tie lines connect points on the binodal curve that are in equilibrium. A composition within this two-phase region always lies on a tie line and splits into two phases represented by the two intersections between the tie line and the binodal curve. As in the binary system, one end point of the tie line is rich in polymer and the other end point is poor in polymer. The binodal curve may be calculated numerically. The tie lines connect the two coexisting phases that are in equilibrium with each other, and these

Figure 10 Schematic representation of a ternary system with a liquid-liquid demixing gap.

have the same chemical potential. By minimizing the following function the compositions of the end points may be obtained:

$$F = \sum f_i^2 \quad [11]$$

with $f_i = (\Delta\mu_i' - \Delta\mu_i'')$ and $i = 1, 2, 3$. The polymer-lean phase is indicated by a single prime (') and the polymer-rich phase is indicated by a double prime (").

The initial procedure for membrane formation from such ternary systems is always to prepare a homogeneous (thermodynamically stable) polymer solution. This will often correspond to a point on the polymer-solvent axis. However, it is also possible to add nonsolvent as long as all the components are still miscible. Demixing will occur by the addition of such an amount of nonsolvent that the solution becomes thermodynamically unstable.

When the binodal curve is reached liquid-liquid demixing will occur. As in the binary system, the side from which the critical point is approached is important. In general, the critical point is situated at low to very low polymer concentrations (see Figure 10). When the metastable miscibility gap is entered at compositions above the critical point, nucleation of the polymer-lean phase occurs. The tiny droplets formed consist of a mixture of solvent and nonsolvent with very little polymer dispersed in the polymer-rich phase, as described in the binary example (see Figure 5). These droplets can grow further until the surrounding continuous phase solidifies via crystallization, gelation or when the glass transition temperature has been passed (in the case of glassy polymers). Coalescence of the droplets before solidification leads to the formation of an open porous structure.

Solid-Liquid Demixing (Crystallization)

Many polymers are partially crystalline. They consist of an amorphous phase without any ordering and an ordered crystalline phase. Crystallization may occur if the temperature of the solution is below the melting point of the polymer. Figure 11 shows the free enthalpy of mixing (ΔG_m) for a binary system of polymer and solvent (or diluent) that shows no liquid-liquid demixing. However, below the melting point the chemical potential of the polymer in the solid state will be smaller than that in the solution. Therefore, the solution can lower its free enthalpy by phase separation into a pure crystalline solid state (ϕ_2) and a liquid state (ϕ_a in Figure 11) that are in equilibrium with each other ($\Delta\mu_{2,L} = \Delta\mu_{2,S}$). The corresponding melting temperature for this mixture ϕ_a is T_1 . This is shown schematically in Figure 11B. T_m° is the melting point of the pure polymer and the melting

Figure 11 Schematic drawing of the free enthalpy of mixing for a binary system in which component 2 is able to crystallize (A) and the melting point curve as a function of the composition (B). ϕ_a is the volume fraction at point a .

point depression for a binary polymer–solvent system, as derived by Flory, is given below:

$$\frac{1}{T_m} - \frac{1}{T_m^o} = \frac{R}{\Delta H_f} \frac{V_2}{V_1} (\phi_1 - \chi\phi_1^2) \quad [12]$$

Here ϕ_1 is the volume fraction of solvent and χ is the polymer–solvent interaction parameter; T_m is the melting temperature of the diluted polymer; ΔH_f is the heat of fusion per mole of repeating units; and V_1 and V_2 are the molar volume of the solvent and of the polymer repeating unit, respectively.

For a ternary system with a semicrystalline polymer a similar ternary diagram can be constructed, as shown in Figure 12. However, it is somewhat more complex since solid–liquid demixing occurs in addition to liquid–liquid demixing. Except for the homogeneous region (I) where all components are miscible

Figure 12 Ternary system of a semicrystalline polymer, solvent and nonsolvent system. I, homogeneous; II, liquid–liquid; III, Solid–liquid; IV, solid–liquid–liquid; V, solid–liquid.

with each other and a region where liquid–liquid demixing occurs (II), other phases can be observed. The curve PQ is the crystallization curve and a composition somewhere in the region of P–Q–polymer will contain crystalline pure polymer that is in equilibrium with a composition somewhere on the crystallization line PQ. A possible morphology of a semicrystalline polymer is shown schematically in Figure 13. Spherulitic structures are frequently observed in semicrystalline polymers.

Many morphologies are possible ranging from a completely crystalline to a completely amorphous conformation. The formation of crystalline regions in a given polymer depends on the time allowed for crystallization from the solution. In very dilute solutions the polymer chains can form single crystals of the lamellar type, whereas in medium and concentrated solutions more complex morphologies occur, e.g. dendrites and spherulites.

Membrane formation is generally a fast process and only polymers that are capable of crystallizing rapidly (e.g. polyethylene, polypropylene, aliphatic polyamides) will exhibit an appreciable amount of

Figure 13 Morphology of a semicrystalline polymer (fringed micelle structure).

crystallinity. Other semicrystalline polymers contain a low to very low crystalline content after membrane formation. For example, PPO (2,6-dimethylphenylene oxide) shows a broad melting endotherm at 245°C. Ultrafiltration membranes derived from this polymer, prepared by phase inversion, hardly contain any crystalline material, indicating that membrane formation was too rapid to allow crystallization.

Gelation

Gelation is a phenomenon of considerable importance during membrane formation, especially for the formation of the top layer. It was mentioned in the previous section that a large number of semicrystalline polymers exhibit a low crystalline content in the final membrane because membrane formation is too fast. However, these polymers generally undergo another solidification process, i.e. gelation. Gelation can be defined as the formation of a three-dimensional network by chemical or physical cross-linking. Chemical cross-linking, the covalent bonding of polymer chains by means of a chemical reaction, will not be considered here.

When gelation occurs, a dilute or more viscous polymer solution is converted into a system of infinite viscosity, i.e. a gel. A gel may be considered as a highly elastic, rubber-like solid. A gelled solution does not demonstrate any flow when a tube containing the solution is tilted. Gelation is not a phase separation process, and it may also take place in a homogeneous system consisting of a polymer and a solvent. Many polymers used as membrane materials exhibit gelation behaviour, e.g. cellulose acetate, poly(phenylene oxide), polyacrylonitrile, poly(methyl methacrylate), poly(vinyl chloride) and poly(vinyl alcohol). Physical gelation may occur by various mechanisms dependent on the type of polymer and solvent or solvent-nonsolvent mixture used. In the case of semicrystalline polymers especially, gelation is often initiated by the formation of microcrystallites. These microcrystallites, which are small ordered regions, are in fact the nuclei for the crystallization process but without the ability to grow further. However, if these microcrystallites can connect various polymeric chains together, a three-dimensional network will be formed. Because of their crystalline nature these gels are thermo-reversible, i.e. upon heating the crystallites melt and the solution can flow. Upon cooling, the solution again gels. The formation of helices often occurs during the gelation process. Gelation may also occur by other mechanisms, e.g. the addition of complexing ions (Cr^{3+}) or by hydrogen bonding.

Gelation is also possible in completely amorphous polymers (e.g. atactic polystyrene). In a number of systems the involvement of gelation in the membrane

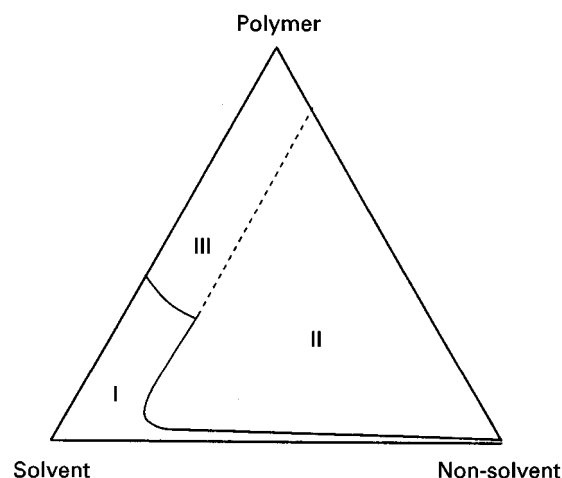

Figure 14 Isothermal cross-section of a ternary system containing a one-phase region (I), a two-phase region (II) and a gel region (III).

formation process often involves a sol-gel transition. This is shown schematically in **Figure 14**. As can be seen from this figure, a sol-gel transition occurs where the solution gels. The addition of a nonsolvent induces the formation of polymer-polymer bonds and gelation occurs at a lower polymer concentration. These sol-gel transitions have been observed in a number of systems, e.g. cellulose acetate/acetone/water, cellulose acetate/dioxane/water, poly(phenylene oxide)/trichloroethylene/octanol and poly(phenylene oxide)/trichloroethylene/methanol.

Vitrification

There are polymers that show neither crystallization nor gelation behaviour. Nevertheless, these polymers finally solidify during a phase inversion process. This solidification process may be defined as vitrification, which is the stage where the polymer chains are frozen in a glassy state, i.e. it is a phase where the glass transition temperature has been passed and the mobility of the polymer chains has been reduced drastically. In the absence of gelation or crystallization, vitrification is the mechanism of solidification in any membrane-forming system with an amorphous glassy polymer.

The glass transition of a polymer is reduced by the presence of an additive, i.e. a solvent or nonsolvent. This glass transition depression can be described by various theories, the Kelley-Bueche theory being widely used. A schematic phase diagram of the system PPO/trichloroethylene/methanol is shown in **Figure 15**. Four regions can be observed:

1. a one-phase region where all the components are miscible with each other;

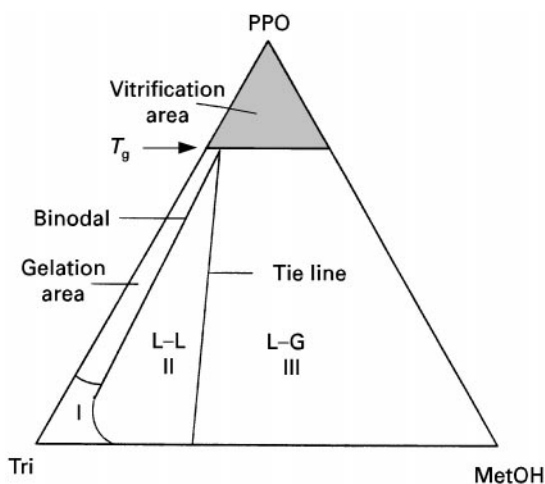

Figure 15 Schematic phase diagram of the quasi ternary system PPO/trichloroethylene/methanol.

- a gel region where the polymer is able to form a three-dimensional network, providing that certain conditions have been established (a sol-gel transition for the system PPO/DMAc has been determined, however a minimum time of 1 h is necessary for gel formation whereas in immersion precipitation the timescale is much shorter);
- a glassy region or vitrification region where the glass transition or the polymer has been passed. During immersion precipitation the diffusion of solvent and nonsolvent proceeds according to their corresponding driving forces independent of whether gelation occurs. The final solidification may be a combined gelation/vitrification process, or in absence of gelation vitrification will be the dominant process.
- a two-phase region where liquid-liquid demixing occurs. In the figure only one tie line is given in which the polymer-rich phase has entered the vitrification area. On the left side of this tie line (II) the (equilibrium) system is still a liquid, whereas on the right side (III) vitrification of the polymer-rich phase had occurred.

Membrane Formation

Thermally Induced Phase Separation (TIPS)

Before describing immersion precipitation in detail, a short description of thermal precipitation or 'thermally induced phase separation' (TIPS) is given.

This process allows the ready preparation of porous membranes from a binary system consisting of a polymer and a solvent. Generally, the solvent has a high boiling point, e.g. sulfolane (tetramethylene sulfone, bp 287°C) or oil (e.g. nujol). The starting

point is a homogeneous solution, for example composition A at temperature T_1 (see Figure 5).

This solution is cooled slowly to the temperature T_2 . When the binodal curve is attained liquid-liquid demixing occurs and the solution separates into two phases, one rich in polymer and the other poor in polymer. When the temperature is decreased further to T_2 , the composition of the two phases follow the binodal curve and eventually the compositions ϕ^I and ϕ^{II} are obtained. At a certain temperature the polymer-rich phase solidifies by crystallization (polyethylene), gelation (cellulose acetate) or on passing the glass transition temperature (atactic polymethylacrylate). Frequently, semicrystalline polymers are used (polyethylene, polypropylene, aliphatic polyamides) which crystallize relatively fast, and hence a solid-liquid phase transition should be included.

Figure 16 shows how the liquid-liquid (L-L) demixing area and the solid-liquid (S-L) for a binary system. In the case of glassy amorphous polymers the melting line may be replaced by a vitrification line. This concept may be applied to various systems, **Table 2** provides some examples of this thermally induced phase separation (TIPS) process.

Immersion Precipitation

An interesting question remains after all of these theoretical considerations: what factors are important in order to obtain the desired (asymmetric) morphology after immersion of a polymer-solvent mixture in a nonsolvent coagulation bath? Another interesting question is: why is a more open (porous) top layer obtained in some cases whereas in other cases a very dense (nonporous) top layer supported by an (open) sponge-like structure develops? To answer these questions and to promote an understanding of the basic principles leading to membrane formation

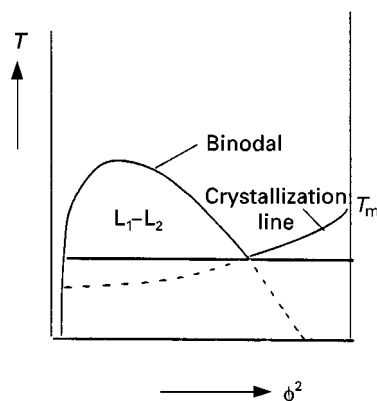

Figure 16 Construction of a T - ϕ diagram for a binary system polymer-solvent. The solidification line is the glass transition temperature line.

Table 2 Some examples of thermally-induced phase separation systems

Polymer	Solvent
Polypropylene	Mineral oil (nujol)
Polyethylene	Mineral oil (nujol)
Polyethylene	Dihydroxy tallow amine
Poly(methyl) methacrylate	Sulfolane
Cellulose acetate/PEG	Sulfolane
Cellulose acetate/PEG	Diocetyl phthalate
Nylon-6	Triethylene glycol
Nylon-12	Triethylene glycol
Poly(4-methyl pentene)	Mineral oil (nujol)

via immersion precipitation, a qualitative description will be given. For the sake of simplicity, the concept of membrane formation will be described in terms of three components: nonsolvent (1), solvent (2) and polymer (3). The effect of additives such as second polymer or material of low relative molecular mass will not be considered because the number of possibilities would then become so large and every (quarternary) or multicomponent system has its own complex thermodynamic and kinetic descriptions.

Immersion precipitation membranes in their most simple form are prepared in the following way. A polymer solution consisting of a polymer (3) and a solvent (2) is cast as a thin film upon a support (e.g. a glass plate) and then immersed in a nonsolvent (1) bath. The solvent diffuses into the coagulation bath (J_2) while the nonsolvent will diffuse into the cast film (J_1). After a given period of time the exchange of solvent and nonsolvent has proceeded so far that the solution becomes thermodynamically unstable and demixing takes place. Finally a solid polymeric film is obtained with an asymmetric structure. A schematic representation of the film–bath interface during immersion is shown in **Figure 17**.

The local composition at any point in the cast film depends on time. However, it is not possible to measure composition changes very accurately with time because the thickness of the film is only of the order of a few microns. Furthermore, membrane

**Figure 17** Schematic representation of a film–bath interface. Components: nonsolvent (1), solvent (2) and polymer (3). J_1 is the nonsolvent flux and J_2 the solvent flux.

formation can sometimes occur instantaneously, i.e. all the compositional changes must be measured as a function of place and time within a very small time interval. Nevertheless, these composition changes can be calculated. Such calculations provide a good insight into the influence of various parameters upon membrane structure and performance.

Different factors have a major effect upon membrane structure. These are:

- choice of polymer;
- choice of solvent and nonsolvent;
- composition of casting solution;
- composition of coagulation bath;
- gelation, vitrification and crystallization behaviour of the polymer;
- location of the liquid–liquid demixing gap;
- temperature of the casting solution and the coagulation bath; and
- evaporation time.

By varying one or more of these parameters, which are not independent of each other, the membrane structure can be changed from a very open porous form to a very dense nonporous variety.

Take polysulfone as an example. This is a polymer that is frequently used as a membrane material, both for microfiltration/ultrafiltration as well as a sublayer in composite membranes. These applications require an open porous structure, but in addition asymmetric membranes with a dense nonporous top layer can also be obtained that are useful for pervaporation or gas separation applications. Some examples are given in **Table 3** that clearly demonstrate the influence of various parameters on the membrane structure when the same system, DMAc/polysulfone (PSf), is employed in each case. To understand how it is possible to obtain such different structures with one and the same system, it is necessary to consider how each of the variables

Table 3 Influence of preparation procedure on membrane structure

Evaporation PSf/DMAc \Rightarrow pervaporation/gas separation

Precipitation of 15% PSf/DMAc in water/DMAc \Rightarrow microfiltration ^c

^aAfter an initial evaporation step.

^bIt will be shown later that integrally skinned asymmetric membranes can be prepared with completely defect-free top layers.

^cTo obtain an open (interconnected) porous membrane, an additive, e.g. poly(vinyl pyrrolidone) must be added to the polymer solution.

affects the phase inversion process. The ultimate structure arises through two mechanisms: (1) a diffusion processes involving solvent and nonsolvent occurring during membrane formation; and (2) demixing processes.

Diffusional Aspects

Membrane formation by phase inversion techniques, e.g. immersion precipitation, is a nonequilibrium process that cannot be described by thermodynamics alone since kinetics have also to be considered. The composition of any point in the cast film is a function of place and time. To know what type of demixing process occurs and how it occurs, it is necessary to know the exact local composition at a given instant. However, this composition cannot be determined very accurately experimentally because the change in composition occurs extremely quickly (in often less than 1 s) and the film is very thin (less than 200 μm). However, it can be described theoretically. Cohen *et al.* were the first to describe mass transport in an immersion precipitation process. Since then many modified models have been published to describe better this highly nonideal complex multicomponent mass transfer system.

The change in composition may be considered to be determined by the diffusion of the solvent (J_2) and the nonsolvent (J_1) (see Figure 17) in a polymer fixed frame of reference. The fluxes J_1 and J_2 at any point in the cast film can be represented by a phenomenological relationship:

$$J_i = - \sum_{j=1}^2 L_{ij}(\phi_i, \phi_j) \frac{\partial \mu_j}{\partial x} \quad (i = 1, 2) \quad [13]$$

where $-\partial\mu/\partial x$, the gradient in the chemical potential, is the driving force for mass transfer of component i at any point in the film and L_{ij} is the permeability coefficient. From eqn [13] the following relations may be obtained for the nonsolvent flux (J_1) and the solvent flux (J_2):

$$J_1 = -L_{11} \frac{d\mu_1}{dx} - L_{12} \frac{d\mu_2}{dx} \quad [14]$$

$$J_2 = -L_{21} \frac{d\mu_1}{dx} - L_{22} \frac{d\mu_2}{dx} \quad [15]$$

As can be seen from the above equations, the fluxes in a given polymer/solvent/nonsolvent system are determined by the gradient in the chemical potential as driving force, while they also appear in the phenomenological coefficients. This implies that a knowledge of the chemical potentials, or better the

factors that determine the chemical potential, is of great importance. An expression for the free enthalpy of mixing has been given by Flory and Huggins. For a three-component system (polymer/solvent/nonsolvent), the Gibbs free energy of mixing (ΔG_m) is given by:

$$\Delta G_m = RT(n_1 \ln \phi_1 + n_2 \ln \phi_2 + n_3 \ln \phi_3 + \chi_{12}n_1\phi_2 + \chi_{13}n_1\phi_3 + \chi_{23}n_2\phi_3) \quad [16]$$

where R is the gas constant and T is the absolute temperature. The subscripts refer to nonsolvent (1), solvent (2) and polymer (3). The number of moles and the volume fraction of component i are n_i and ϕ_i , respectively. χ_{ij} is called the Flory-Huggins interaction parameter. In a ternary system there are three interaction parameters: χ_{13} (nonsolvent/polymer), χ_{23} (solvent/polymer) and χ_{12} (solvent/nonsolvent). χ_{12} can be obtained from data on excess free energy of mixing that have been compiled or from vapour-liquid equilibria. χ_{13} can be obtained from swelling measurements and χ_{23} can be obtained from vapour pressure or membrane osmometry. The interaction parameters account for the nonideality of the system and they contain an enthalpic as well as an entropic contribution. In the original Flory-Huggins theory they are assumed to be concentration independent, but several experiments have shown that these parameters generally depend on the composition. To account for such dependence the symbol χ is often replaced by another symbol, g , indicating concentration dependency.

From eqn [16] it is possible to derive the expressions for the chemical potentials of the components since:

$$\left(\frac{\partial \Delta G_m}{\partial n_i} \right)_{P,T,n_j} = \Delta \mu_i = \mu_i - \mu_i^0 \quad [17]$$

The eventual concentration dependency of the χ parameter must be taken into account in the differentiation procedure. The influence of the different interaction parameters χ (present in the driving forces) on the solvent flux and nonsolvent flux, and thus on the membrane structures obtained, will be described later.

The other terms present in the flux equations (eqns [16] and [17]) are phenomenological coefficients, and these must also be considered with respect to membrane formation. These coefficients are also mostly concentration dependent. There are two ways of expressing the phenomenological coefficients when the relationships for the chemical poten-

Figure 18 Schematic drawing of the immersion process at different times.

tials are known: (1) in diffusion coefficients; and (2) in friction coefficients.

In most cases there is a (large) difference between the casting thickness and the ultimate membrane thickness. This implies that during the formation process the boundary between the nonsolvent bath and the casting solution moves, as is shown in **Figure 18**. For this reason, it is necessary to introduce a position coordinate to correct for this moving boundary.

The immersion process starts at time $t = 0$. At all times $t > 0$, solvent will diffuse out of the film and nonsolvent will diffuse in. If there is a net volume outflow (solvent flux larger than nonsolvent flux) then the film-bath interface is shifted from $z = 0$, i.e. the actual thickness is reduced. This process will continue until equilibrium is reached (at time $t = t$) and the membrane has been formed. In order to describe diffusion processes involving a moving boundary adequately, a position coordinate m must be introduced (eqn [18]).

The film-bath interface is now always at position $m = 0$, independent of time. The position of the film-support interface is also independent of time (see **Figure 18**):

$$m(x, t) = \int_0^x \phi_3(x, t) dx \quad [18]$$

$$(dm)_t = \phi_3 (dx)_t \quad [19]$$

In the m -coordinate:

$$\frac{\partial(\phi_i/\phi_3)}{\partial t} = \frac{\partial J_i}{\partial m} \quad i = 1, 2 \quad [20]$$

Combination of eqns [18]–[20] yields:

$$\frac{\partial(\phi_1/\phi_3)}{\partial t} = \frac{\partial}{\partial m} \left[v_1 \phi_3 L_{11} \frac{\partial \mu_1}{\partial m} \right] + \frac{\partial}{\partial m} \left[v_1 \phi_3 L_{12} \frac{\partial \mu_2}{\partial m} \right] \quad [21]$$

$$\frac{\partial(\phi_2/\phi_3)}{\partial t} = \frac{\partial}{\partial m} \left[v_2 \phi_3 L_{21} \frac{\partial \mu_1}{\partial m} \right] + \frac{\partial}{\partial m} \left[v_2 \phi_3 L_{22} \frac{\partial \mu_2}{\partial m} \right] \quad [22]$$

The main factor determining the type of demixing process is the local concentration in the film. Using eqns [21] and [22] it is possible to calculate these concentrations (ϕ_1, ϕ_2, ϕ_3) as a function of time. Thus at any time and any place in a cast film the demixing process occurring can be calculated; in fact the concentrations are calculated as a function of place and elapsed time and the type of demixing process is deduced from these values. However, one should note that a number of assumptions and simplifications are involved in this model. Thus heat effects, occurrence of crystallization and relative molecular mass distributions are not taken into account. Nevertheless, it will be shown in the next section that the model allows the type of demixing to be established on a qualitative basis and is therefore useful as a first estimate. Furthermore, it allows an understanding of the fundamentals of membrane formation by phase inversion.

Mechanism of Membrane Formation

It is shown in this section that two types of demixing process resulting in two different types of membrane morphology can be distinguished:

- instantaneous liquid-liquid demixing, where the membrane is formed immediately;
- delayed onset of liquid-liquid demixing, where the membrane takes some time to form.

The occurrence of these two distinctly different mechanisms of membrane formation can be demonstrated in a number of ways: by calculating the concentration profiles; by light transmission measurements; and visually.

The best physical explanation is given by a calculation of the concentration profiles. To calculate the

concentration profiles in the polymer film during the delayed demixed type of phase inversion process, some assumptions and considerations must be made:

- diffusion in the polymer solution;
- diffusion in the coagulation bath – no convection occurs in the coagulation bath;
- thermodynamic equilibrium is established at the film–bath interface:

$$\mu_i(\text{film}) = \mu_i(\text{bath}) \quad i = 1, 2, 3;$$
- volume fluxes at the film–bath interface are equal, i.e.

$$J_i(\text{film}) = J_i(\text{bath}) \quad i = 1, 2.$$

In addition, the thermodynamic binary interaction parameters (the χ parameters or the concentration-dependent g parameters) that appear in the expressions for the chemical potentials must be determined experimentally.

- g_{12} , from calorimetric measurements yielding values of the excess free energy of mixing, from literature compilations of G^E and activity coefficients, from vapour–liquid equilibria and from Van Laar, Wilson, or Margules equations or from UNIFAC;
- g_{13} , from equilibrium swelling experiments or from inverse gas chromatography,
- g_{23} , from membrane osmometry or vapour pressure osmometry.

Two types of demixing process will now be distinguished that lead to different types of membrane structure. These two different types of demixing process may be characterized by the instant when liquid–liquid demixing sets in. Figure 19 shows the composition path of a polymer film schematically at

the very instant of immersion in a nonsolvent bath (at $t < 1$ s). The composition path gives the concentration at any point in the film at a particular time. For any other time, another compositional path will exist.

Because diffusion processes start at the film–bath interface, the change in composition is first noticed in the upper part of the film. This change can also be observed from the composition paths given in Figure 19. Point t gives the composition at the top of the film while point b gives the bottom composition. Point t is determined by the equilibrium relationship at the film–bath interface $\mu_i(\text{film}) = \mu_i(\text{bath})$. The composition at the bottom is still the initial concentration in both examples. In Figure 19A places in the film beneath the top layer t have crossed the binodal curve, indicating that liquid–liquid demixing starts immediately after immersion. In contrast, Figure 19B indicates that all compositions directly beneath the top layer still lie in the one-phase region and are still miscible. This means that no demixing occurs immediately after immersion. After a longer time interval, compositions beneath the top layer will cross the binodal curve and liquid–liquid demixing will start in this case also. Thus two distinctly different demixing processes can be distinguished and the resulting membrane morphologies are also completely different.

When liquid–liquid demixing occurs instantaneously, membranes with a relatively porous top layer are obtained. This demixing mechanism results in the formation of a porous membrane (microfiltration/ultrafiltration type). However, when liquid–liquid demixing sets in after a finite period of time, membranes with a relatively dense top layer are obtained. This demixing process results in the formation of dense membranes used for gas separation/permeation. In both cases the thickness of the top

Figure 19 Schematic composition path of the cast film immediately after immersion; t is the top of the film and b is the bottom. Part (A) shows instantaneous liquid–liquid demixing whereas (B) shows the mechanism for the delayed onset of liquid–liquid demixing.

Table 4 Polymers that are frequently used as phase inversion membranes

Polymer	Process
Cellulose acetate	MF, UF, NF, RO, GS
Nitrocellulose	MF
Polysulfone	MF, UF
Polyethersulfone	MF, UF
Polyacrylonitrile	MF, UF
Polyvinylidene fluoride	MF, UF
Polyimide	UF, GS
Aliphatic polyamide	MF, UF
Aromatic polyamide	NF, RO
Polyphenylene oxide	GS

MF, microfiltration; UF, ultrafiltration; NF, nanofiltration; RO, reverse osmosis; GS, gas separation.

layer is dependent on a variety of membrane formation parameters (i.e. polymer concentration, coagulation procedure, additives, etc.).

Polymers for Phase Inversion Membranes

The preparation of phase inversion membranes has only been described briefly. It may be evident that many polymers can be applied as long as they are soluble in a suitable organic solvent. This is the only limitation. Nevertheless, owing to their mechanical, thermal and chemical properties some polymers are more frequently applied. Two of these so-called 'engineering polymers', polysulfone and polyethersulfone, are used as micro- and ultrafiltration membranes or as support material in composite membranes for nanofiltration, reverse osmosis and gas separation. These two polymers have very good film-forming properties and are soluble in a range of solvents. Beside these two polymers a wide variety of other polymers are applied; these are listed in Table 4.

Future Developments

Phase inversion will remain the most important technique for the preparation of polymeric membranes for microfiltration and ultrafiltration membranes and for use as support membranes in composite membranes for nanofiltration, reverse osmosis, gas separation, vapour permeation and pervaporation.

METAL ANALYSIS: GAS AND LIQUID CHROMATOGRAPHY

P. C. Uden, University of Massachusetts,
Amherst, MA, USA

Introduction

Since its inception as a separatory technique, gas-liquid chromatography (GLC) has had great impact in the quantitative resolution of mixtures of volatile compounds. Although the sister discipline of gas-solid chromatography (GSC) is used for inorganic gas analysis along with metalloids and hydrides, the potential of both GLC and GSC for inorganic compounds, metal complexes and organometallics has been less realized. The relative obscurity of inorganic gas chromatography derives from expectations that inorganic compounds are inherently of very low volatility and/or thermally unstable under GC conditions, are incompatible with column substrates, show undesirable reactivity making GC difficult, or are incompatible with conventional detectors. Some of these strictures apply, but there are many examples of GC of metallic and metalloid compounds including organometallics incorporating sigma or pi carbon to metal bonds, and metal complexes with coordinate bonds between oxygen, sulfur, nitrogen, phosphorus, or halogen, and the metal atom. Some metal oxides and halides may be eluted at high temperatures. Chemical derivatization methods may also enable successful elution. There is often considered to be a minimal group of chemical properties to be possessed by a compound before gas chromatography can be successful: volatility, thermal stability, monomeric form, neutrality, relatively low molecular weight, coordinative saturation and shielding of the metal atom(s) by bulky and inert organic functional groups. The compound should appear to the GC column as a simple organic species and free metal atoms should not be exposed to reactive sites. Inertness of column materials, injection and detection pathways are particularly important. Fused silica columns allow GC of previously inapplicable species. Detectors that are more compatible, selective or specific for inorganic compounds have opened the way for quantitative and sensitive analysis.

Liquid chromatography (LC) has been used extensively in thin-layer and ion exchange for metal ion

and compound separations. However high performance column chromatography (HPLC) with different column packings, instrumentation and detectors has given rise to many new capabilities. The literature of LC of inorganics and organometallics up to 1970 was presented by Michal with 700 references while that between 1970 and 1979 was surveyed by Schwedt with over 450 references. MacDonald's (1985) text *Inorganic Chromatographic Analysis* covers all LC and GC methods in a comprehensive review.

The various modes of HPLC allow a wider range of analytes to be chromatographed than in GC. Metal ions may be resolved by ion chromatography, or separated as ion pairs in a reversed-phase regime. Positively or negatively charged metal complexes may be similarly separated. Neutral metal complexes, chelates and organometallics may be chromatographed in reversed- or normal-phase systems. Metal-containing macromolecules such as metalloproteins may be separated by size exclusion. Chemical properties desirable in an inorganic compound for viable liquid partition chromatography include solvolytic stability, minimal adsorptive interactions and shielding of the metal by inert functional groups. As with GC, the analyte should appear to the column as an organic compound and free metal atoms should never be accessible to reactive sites. New detectors that are more compatible or specific for inorganic compounds have also made an impact in HPLC. Diode array UV, electrochemical detection and elemental and molecular mass spectroscopy have proven valuable. The inorganic chromatographer is often faced with a choice between GC and HPLC and each may be valuable in a complementary fashion. Supercritical fluid chromatography (SFC) has been little applied for metal compounds, successful applications following mostly from HPLC methodology.

The primary application of analytical chromatography in metals analysis is clearly in 'speciation' wherein the requirement is resolution and quantitation of specific chemical species incorporating the target metal. Situations occur (i) in which the chemical species is already amenable to the chosen chromatographic technique, and (ii) wherein it may be converted to such by physical or chemical means, as in pyrolysis, derivatization, etc. While total element analysis is less suited to chromatographic methods,

sometimes suitable derivatization techniques enable this as well.

Gas Chromatography

The classes of metallic substances for which GC is viable, either directly or by derivatization, are: binary metal and metalloid compounds such as halides, hydrides and oxides; sigma-bonded organometallic and organometalloid compounds such as alkyls and aryls; pi-bonded organometallics such as metal carbonyls and metallocenes; chelated metal complexes having nitrogen, oxygen, sulfur, phosphorus, etc., as ligand atoms. The text by Guiochon and Pommier (1973) *Gas Chromatography in Inorganics and Organometallics* provides an excellent summary of this topic augmented by Schwedt's coverage.

Binary Metal and Metalloid Compounds

Binary metal compounds with adequate vapour pressures and thermal stabilities at normal GC temperatures include main group hydrides and halides. At 1000°C or higher, some metal oxides have adequate properties.

Among hydrides, those of boron, silicon, germanium, tin, arsenic, antimony, bismuth, selenium and tellurium are viable having boiling points ranging from 112°C to -2°C. Low column temperatures and inert systems are needed. Element-selective spectral detectors are also advantageous. These separations are important for trace-level determinations in electronic grade organometallics. Organo-hydrides are also readily chromatographed. Analysis of environmentally significant arsenic and antimony compounds with microwave plasma emission detection involves reduction of alkylarsenic acids with sodium borohydride to alkylarsines.

Certain metal halides are sufficiently volatile for GC, but difficulty lies in their high reactivity in the vapour and condensed phases, necessitating precautions to ensure maximum inertness of the system. Among chlorides that have been gas chromatographed are those of titanium, aluminium, mercury, tin, iron, antimony, germanium, gallium, vanadium, silicon and arsenic. Problems arise from reaction with even methyl silicone oils and thus inert fluorocarbon packings have been favoured for reactive chlorides and oxychlorides including VOCl_3 , VCl_4 , PCl_3 and AsCl_3 . The less volatile metal bromides are very challenging and high temperature stationary phases such as alkali bromide salts coated on silica are needed. Some metal fluorides have low boiling points, e.g. tungsten (17.5°C), molybdenum (35°C), tellurium (35.5°C), rhenium (47.6°C) and uranium (56.2°C), for which low column temperatures are feasible. The

determination of alloys and metal oxides, carbides, etc., after conversion to fluorides by fluorination appears feasible.

One of the most extreme modifications of GC has been in the area of very high temperature GC for metal oxides, hydroxides and oxychlorides. Bachmann employed temperatures as high as 1500°C for the separation of oxides and hydroxides of technetium, rhenium, osmium and iridium. Quartz granules were used as the substrate and oxygen and oxygen/water mixtures as carrier gases with the necessary equipment modifications.

Organometallic Compounds

Crompton in *Gas Chromatography of Organometallic Compounds*, published in 1982, notes that during the preceding decade more than 1000 papers were published on this topic, relating to compounds of more than 50 elements. At least as many papers have been published since that time.

Sigma-bonded compounds GC is feasible for compounds of Al, Ga and In from Group III; Ge, Sn and Pb from Group IV; P, As, Sb and Bi from Group V; and Se and Te from Group VI. Also included are Hg and possibly Zn and Cd. The elements that have attracted most analytical interest have been silicon and lead, tin and mercury.

The organic functionalities are typically alkyl, aryl and substituted aryl groups; perfluoroalkyl and aryl groups, which typically impart enhanced volatility; and mixed alkyl-chloro and aryl-chloro systems. The two reported separations of aluminium alkyls leave doubts as to possible on-column decomposition. Trimethylgallium has been eluted along with $(\text{CH}_3)_2\text{GaCl}$ and CH_3GaCl_2 , but no GC of organometallic indium or thallium compounds has been reported. The GC characteristics of alkyl germanium, tin and lead compounds resemble those of silicon but with decreasing thermal stability. For alkylstannanes, on-column oxidation, hydrolysis or thermal degradation must be avoided. Selective detection has been widely used for organotin compounds, notably for environmental samples such as bis(tributyltin)oxide (TBTO) in marine paints, triphenylhydroxystannane pesticide after derivatization to triphenylmethylstannane, and tricyclohexylhydroxystannane in apple leaves after derivatization to tricyclohexylbromostannane.

GC of tetraalkyllead compounds is extensive and covers 30 years of developments. Crompton devotes 90 pages to discussion of organolead GC. The electron-capture detector is highly selective for tetraalkylleads, but is prone to contamination. Atomic spectral detection has been widely applied for lead-specific

detection, e.g. flame photometric detection with an oxygen-hydrogen flame at 405.8 nm and graphite furnace electrothermal atomic absorption detection at 283.3 nm. Chau quantitated methylethylleads in water, sediment and fish in an investigation of bioalkylation processes, lead detection limits being between 0.01 and 0.025 $\mu\text{g g}^{-1}$ for solid samples. Plasma atomic emission detection for alkyl leads has been widely used; trimethyl- and triethyllead chlorides have been determined in water in the range of 10 ppb to 10 ppm and also derivatized by butyl Grignard reagent to form the trialkylbutylleads.

The alkyl and aryl derivatives of arsenic and antimony are more labile than those of Group IV elements, and require stringent GC conditions for successful elution. Bismuth compounds have not been chromatographed. Talmi determined As^{3+} and Sb^{3+} in environmental samples as triphenylarsine and triphenylstilbene, plasma emission detection giving limits of 20 pg and 50 pg, respectively.

GC of the environmentally significant organomercurials has attracted much attention, biomethylation of inorganic mercury being important. $(\text{CH}_3)_2\text{Hg}$ and CH_3HgCl have been separated on packed glass columns using plasma emission detection. Non-flame 'cold vapour', atomic absorption spectrophotometry detection has proved useful after catalytic conversion of organomercurials to elemental mercury.

Although they are not formally organometallics, many alkoxides share similar GC characteristics with alkyl compounds. Germanium, tin, titanium, zirconium and hafnium form stable volatile alkoxides, as do some Group III elements, notably aluminium. There have been GC separations reported of oxycarboxylate salts of beryllium and zinc.

Pi-bonded compounds The most gas chromatographed transition metal organometallics are those containing carbonyl, arene and cyclopentadienyl ligand moieties. Their elution characteristics are very favourable with only rare on-column degradation or adsorption reported. Effective separation of $\text{Fe}(\text{CO})_5$, $\text{Cr}(\text{CO})_6$, $\text{Mo}(\text{CO})_6$ and $\text{W}(\text{CO})_6$ is possible and methods may be employed for the highly toxic $\text{Ni}(\text{CO})_4$ since its high volatility permits ready elution. Many results have been reported for arene, cyclopentadienyl and related derivatives of metal carbonyls. Arenechromiumtricarbonyls and molybdenumtricarbonyls are easily gas chromatographed. Cyclopentadienylmanganetricarbonyl ($\text{C}_5\text{H}_5\text{Mn}(\text{CO})_3$) and its derivatives are well suited to quantitative GC. Methylcyclopentadienylmanganetricarbonyl, $(\text{CH}_3\text{C}_5\text{H}_4\text{Mn}(\text{CO})_3)$ -MMT has been determined in gasoline using various detectors. Capillary GC is effective for compounds of this class; spe-

cific element detection simplifies such separations and provides qualitative and quantitative proof of elution. **Figure 1** shows such a capillary column separation with atomic emission detection of organometallics with differing metals and functionalities. Many of these organometallics are of interest as polymerization catalysts, etc.

Among GC of metallocenes, ferrocene, bis(cyclopentadienyl)iron, is the most familiar example. These compounds have favourable GC properties, ferrocene proving an ideal organometallic probe for determining column and system efficiency. Ferrocene derivatives chromatographed have included alkyl, vinyl, dialkyl, acetyl, diacetyl and hydroxymethyl compounds. GC behaviour is determined largely by the substituents; ruthenocene and osmocene have also been separated.

Metal Chelates

Neutral metal complexes deriving from a number of anionic ligands with oxygen, nitrogen, sulfur or phosphorus donor atoms, have been widely studied. The range of organic ligands that has been shown to be suitable for GC analysis has been limited, but a considerable amount of development and application has been done.

Beta-diketonates Beta-diketonates are readily formed with stability arising from multiple chelate rings. Ions with coordination numbers twice their oxidation state such as $\text{Al}(\text{III})$, $\text{Be}(\text{II})$ and $\text{Cr}(\text{III})$ form coordinatively saturated neutral complexes which are good for GC but the non-fluorinated beta-diketonates are generally of marginal thermal and chromatographic stability; they usually require column temperatures too high for thermal degradation to be completely absent. The major breakthrough in metal chelate GC involved fluorinated beta-diketone ligands, giving complexes of greater volatility and thermal stability. Moshier and Sievers gave the major impetus to this development, and a major portion of their monograph summarizes the analytical progress made to that time. Trifluoroacetylacetone (1,1,1-trifluoro-2,4-pentanedione-HTFA) and hexafluoroacetylacetone (1,1,1,5,5,5-hexafluoro-2,4-pentanedione-HHFA) have been the most widely studied and analytically developed of the fluorinated beta-diketonates. HTFA extended the range of metals that may be quantitated to include $\text{Ga}(\text{III})$, $\text{In}(\text{III})$, $\text{Sc}(\text{III})$, $\text{Rh}(\text{III})$ and $\text{V}(\text{IV})$. HTFA chelates of trivalent hexacoordinate metals such as $\text{Cr}(\text{III})$, $\text{Co}(\text{III})$, $\text{Al}(\text{III})$ and $\text{Fe}(\text{III})$ exhibit geometrical isomerism with facial (*cis*) and meridional (*trans*) forms present and interconverting. Numerous analytical applications of HTFA chelates are reviewed in detail by Moshier and

Figure 1 Microwave plasma atomic emission capillary GC detection of organometallics. Left: (A) chromium monitored at 267.7 nm (peak c) and (B) manganese monitored at 257.6 nm (peaks a and b). Right: carbon monitored at 247.9 nm for organometallic mixture. The six peaks afford 'universal' carbon detection. The identities of the eluted peaks are: (a) $C_5H_5Mn(CO)_3$, (b) $CH_3C_5H_4Mn(CO)_3$, (c) $C_5H_5Cr(NO)(CO)_2$ and $(C_5H_5)_2Ni$ (unresolved), (d) $C_5H_5V(CO)_4$, (e) $(C_5H_5)_2Fe$ and (f) $C_5H_5(CH_3)_5Co(CO)_2$. Sievers, Uden and Henderson and in the texts of Guiochon and Pommier and Schwedt.

Since modifications of the beta-diketone structure may be made readily, various such ligands have been evaluated for GC. The two major adaptations have been the replacement of the methyl group by higher branched alkyl groups, notably *t*-butyl, and the incorporation of longer chain perfluoroalkyl groups in the ligand. Sievers used 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione (heptafluoropropanoyl-pivalylmethane (HFOD or HHPM)) for lanthanide separations.

Alternative beta-difunctional chelates The major classes of such ligands are summarized in the schematic diagram in Figure 2. This indicates the mode of formation of the main alternative bidentate ligands

with sulfur donors and bidentate and tetradentate ligands with nitrogen donors.

Beta-thioketonates There are a number of advantages of these chelates. The metals showing favourable GC properties are those whose diketonates are generally unsatisfactory, such as the divalent metals nickel, palladium, platinum, zinc and cobalt. Nickel has been subjected to a complete quantitative analysis, as the monothio-trifluoroacetylacetonate.

Beta-ketoaminates The presence of the nitrogen atom in the ligand dictates an intermediate place between beta-diketonates and monothioketonates in terms of the metals which are readily complexed. The nickel group of metals is favourably complexed, but in addition stable chelates of copper(II) are formed,

Figure 2 Formation of beta-difunctional ligands for metal gas chelate gas chromatography. (Reproduced with permission from Estes SA *et al.* (1980). *Journal of Chromatography and Chromatographic Communications* 3: 471. Copyright John Wiley & Sons Ltd.)

as are those of vanadyl (V(IV)O). The bidentate ketoamines are of only marginal GC stability to sub-microgram elution level, but tetradentate beta-ketoamine ligands form a useful group for GC of

Table 1 Representative tetradentate beta-ketoamine ligands used for chelate formation and gas chromatography of divalent transition metals

en = CH₂-CH₂; pn = CH(CH₃)-CH₂; bn = CH(CH₃)-CH(CH₃).

divalent transition metals. The addition of the extra five-membered ring stabilizes the complexes, which more than offsets their lowered volatility. **Table 1** lists the tetradentate beta-ketoamine ligands that have been evaluated for GC of copper, nickel, palladium and vanadyl complexes. The fluorinated chelates have very great electron capturing abilities affording picogram level detection.

Dialkyldithiocarbamates and dialkyldithiophosphinates The metals complexed by these ligands are parallel to those chelated by the tetradentate beta-ketoamines for GC applications. Zinc, copper and nickel have been determined in marine bottom sediments and in sea sands and muds. In parallel to the development of fluorinated beta-diketone ligands, fluorinated dialkyldithiocarbamates show analytical promise due to their increased volatility over non-fluorinated analogues. Tavlaridis and Neeb first investigated di(trifluoroethyl)dithiocarbamates, eluting zinc, nickel, cadmium, lead, antimony and bismuth complexes at 185°C. Sucre and Jennings reported effective capillary separation of these complexes of nickel and cobalt(III) on 5 metre fused silica columns. It appears likely that further refinement of high resolution columns will broaden the application of these versatile complexes for analytical GC.

Cardwell and McDonagh separated zinc, nickel, palladium and platinum 0,0'-dialkyldithiophosphinates. These complexes are suitable for selective detection by flame photometry with monitoring of either the S₂ or HPO emission modes.

Metalloporphyrins One of the most important demonstrations of the expanded range of sample applications for inorganic GC brought about by high resolution fused silica capillary was of transition metal porphyrin complexes. Marriott achieved capillary GC elution of these closed macrocyclic ring copper, nickel, vanadyl and cobalt aetioporphyrin I, and octaethyl-porphyrin chelates with Kováts indices in the range 5200-5600.

Chromatographic Detection

Of particular value for metal compound chromatography are detectors giving 'selective' or 'specific' information on the eluates. Spectral property detectors such as the mass spectrometer (MS), the infrared spectrophotometer (IRS) and the atomic emission spectrometer (AES) fall into this class. The latter 'element selective' detectors are widely used: the microwave-induced plasma in particular for GC and the inductively coupled plasma mass spectrometer (ICPMS) for HPLC. These detector systems typically

offer nanogram level detection or lower for metal content of analytes. Metals may be determined directly or through derivatization procedures which render them more readily separable and detectable.

High Performance Liquid Chromatography

Size-Exclusion Chromatography (SEC)

SEC separates chemical species by molecular size and shape in a column containing particles of a rigid packing with a defined pore structure. Many applications to inorganic and organometallic species have been reported ranging in size from a few hundred to 10^5 Da or greater; from labile nickel complexes of alkyl substituted phosphorus esters to molecular clusters of inorganic colloids in the 1–50 μm range, aluminosilicate sols, humic acid metal complexes, metalloproteins and metalloproteins. Ferritin, an iron-containing protein which exists in a number of discrete forms, has been analysed using aqueous SEC, good repeatability being found for iron at the nanogram level. Trace levels of Cd, Zn and Cu metalloproteins in marine mussels were determined using SEC with sequenced UV absorption detection before the ICP. In the petroleum field, effective separation and determination of vanadium and nickel metalloporphyrins has been accomplished. Columns of pore size 10 nm in particular are a viable choice for many separation problems of inorganic chromatography.

Reversed-Phase High Performance Liquid Chromatography (RPHPLC)

RPHPLC of inorganic and organometallics may be characterized by the detector used and some examples are noted.

Atomic absorption (AA) The interfacing of column effluent and an AA spectrometer was attained in 1973, tetraalkyllead compounds being separated on C_{18} μ -Bondapak with 70% acetonitrile and 30% water. The superiority of AA detection over UV detection was shown, since gasoline samples have components that mask the tetraalkyl lead compounds.

Inductively coupled plasma (ICP) and direct current plasma (DCP) Plasma spectral detection for HPLC has emphasized the ICP and to some extent the DCP, in contrast to the dominance of the microwave-induced plasmas as element-selective GC detectors. Metal-specific detection is predominant and will probably remain so until more eluate-selective interface systems can be devised. The ICP became

commercially available in 1974 replacing atomic absorption spectroscopy as the method of choice for metal analysis. The technique and DCP has been coupled to HPLC for trace analysis and speciation of real-world samples such as arsenite, dimethyl arsenate and arsenate. A 130 ng mL^{-1} detection limit for arsenic in organoarsenic acids was found for 100 μL samples after hydride formation. Separation of mercury cations employed an alkyl sulfonate anion as ion pair reagent and, after hydride formation, gave detection limits of $50\text{--}100 \mu\text{g L}^{-1}$. A possible solution to overcome the difficulties in quantitative transfer of HPLC eluate involves a total injection microconcentric nebulizer (DIN) which can achieve almost 100% nebulization and transport efficiency. Detection limits down to 4 mg L^{-1} for zinc have been reported. The DCP gave detection for Cr(III) and Cr(VI) linear over at least three orders of magnitude with a detection limit of $10 \mu\text{g L}^{-1}$; applications include biological samples from ocean floor drillings, chemical dump sites, surface well water and waste water samples.

Visible and UV detection Spectrophotometric complexing reagents are widely used for visible spectral determination of many metals at low concentrations, but these complexes are seldom suited to HPLC. Pyridylazonaphthol complexes of copper, nickel and cobalt are separable by reversed-phase LC using acetonitrile/water/citrate buffer at pH 5 (80 : 18 : 2), 0.01 mol L^{-1} ammonium thiocyanate, and other such stable chelates are also amenable. In addition, non-absorbing species may be detected after conversion to chromophores by complexing, ion pairing or other chemical reactions. Neutral metal chelates such as beta-diketonates, beta-ketoaminates, dialkyldithiocarbamates and dialkyldithiophosphinates separable by GC may also be chromatographed by reversed-phase HPLC and less volatile complexes are also amenable to the technique.

Amperometric and differential pulse detection Dithiocarbamates of Cu(II), Ni(II), Co(II), Cr(III) and Cr(VI) have been detected amperometrically after HPLC separation. Although both the oxidation and reduction reactions of these organometallics are well defined, the ubiquitous presence of reducible oxygen dissolved in the polar solvent results in the oxidative process being more desirable. Knowledge of solvent, electrodes and electrochemistry is essential before a correct HPLC-EC protocol can be stated. Cancer chemotherapeutic drugs cisplatin, mitocynin C and mitoxanthrone are separable on C_{18} columns and are easily detected by oxidation, if the cisplatin oxidation

potential is shifted by 0.10 mol L^{-1} chloride to 0.80 V.

Detection selectivity may be improved by differential pulse detection as in the reversed-phase determination of alkyl- and aryl-mercurials, tri-*n*-butyl tin, triethyl tin and triphenyl tin.

Ion Pair Chromatography (IPC)

Combination of ion exchange and partition mechanisms and the performance of 5 and $10 \mu\text{m}$ C_{18} silica bonded phases give high performance ion separation in the direct and ion-paired modes. Pairing ions may be present in the mobile phase or retained on the surface. A C_{18} column coated with C_{20} alkyl sulfate gave baseline separation of Cu(II) , Co(II) and Mn(II) . The eluted metal ions were detected by absorption spectrophotometry at 530–540 nm after post-column reaction with 4-(2-pyridylazo)-resorcinol (PAR). Paired-ion HPLC separation of iron(II), nickel(II) and ruthenium as cationic 1,10-phenanthroline complexes with alkylsulfonic acids was achieved. Crown ethers can form stable complexes with metal cations, reversed-phase HPLC retention being dependent upon the relative size of the cation and the ring of crown ether. A typical elution order is $\text{Li}^+ < \text{Na}^+ < \text{Cs}^+ < \text{Rb}^+ < \text{K}^+$, and $\text{Mg}^{2+} < \text{Ca}^{2+} < \text{Sr}^{2+} < \text{Ba}^{2+}$.

Overall, the choice in inorganic column liquid chromatography is now between reversed-phase, including paired-ion, and ion chromatography, the former typically affording the better resolution.

HPLC-ICP-Mass Spectrometry (HPLC-ICP-MS)

The most extensively developed plasma mass spectral analytical technique is that of ICP-MS. The argon ICP acts as a mass spectral ion source; for a sample solution, after aerosol formation in a nebulizer and spray chamber, analyte is injected into the plasma where it undergoes desolvation, vaporization, atomization and ionization. A portion of the ions is sampled from the centre of the plasma and directed, through a low pressure interface, into the mass spectrometer. ICP-MS combines advantages of ICP-AES such as multi-element analysis, wide dynamic range and speed, with mass spectral acquisition, enhanced detection limits (typically $0.01\text{--}0.1 \text{ mg L}^{-1}$) and capability for isotopic analysis. In HPLC-ICP-MS detection limits as low as 100 pg/peak have been obtained for many elements. Ion exchange and ion pair chromatography were used for speciation of triorganotin species and arsenic speciation has been examined in a number of studies. The technique shows excellent prospects in biomedical and clinical studies in which analyte levels are usually below the capabilities of ICP emission

detection. Interfaced aqueous SEC with ICP-MS was used for element and isotope ratio detection of lead and copper in protein fractions of serum and blood cell haemolysate with molecular weight ranges from 11 kDa to $> 600 \text{ kDa}$ and detection limits in the $1\text{--}10 \mu\text{g L}^{-1}$ range for metallodrugs and their metabolites, measured in samples from patients undergoing gold drug therapy for arthritis. The elements mercury, arsenic, lead and tin have attracted most interest from the trace element environmental point of view.

Conclusions

High performance gas and liquid chromatography of metal compounds have always presented considerable challenges, but have in return provided many analytical and characterization insights, both qualitative and quantitative. In practical terms, the wider adoption of element-specific spectral detection depends on the continual development of commercial instrumentation to permit inter-laboratory comparisons of data and the development of 'recommended' methods of analysis which can be widely used. Many areas of analysis are subject to restrictions designed to ensure high levels of accuracy and precision. Fully integrated units which remove the need for analysts to interface their own GC, emission device and spectrometer may become as familiar in the future as GC-MS and GC-FTIR systems are today. Integrated HPLC and SFC systems will be longer delayed, but their eventual adoption is inevitable in view of the broad scope of these separation methods.

Introduction

Many different and clever methods have been reported in the literature for the separation of metal ions. Most involve chemical reactions in which complexes are formed between the hydrated metal ions and an inorganic or organic ligand. If an organic ligand is employed coordination is usually through oxygen, sulfur or nitrogen atoms, individually or in combination.

In a simplified representation the stepwise and overall formation of metal–ligand complexes can be represented by the following:

where M^{2+} is a divalent hydrated cation (acceptor) and HL is a monoprotic weak acid ligand (donor) that replaces the waters of coordination in a series of steps. The formation and dissociation of the metal–ligand (donor–acceptor) complexes proceeds, often rapidly, by a series of equilibrium reactions, each of which is defined by a formation constant. Because of the metal ion coordination number, the stepwise equilibria, the formation constant, and concentrations of the metal ion and ligand, a series of complexes (see the expression of the total equilibrium steps in eqn [3]) may coexist in the solution. When the ligand is neutral the charge of the resulting complexes are positive. However, the complexes may

associate with solution anions to produce neutral species. Ligands can also be anions, eqns [1]–[3], and thus the complexes that form can be cations, neutral or anionic, depending on the coordination number of the metal ion, the number of ligands bound to the metal ion, the formation constants for the complexes that form, and the metal ion and anionic ligand concentrations.

Conversion of a metal analyte into a complex is important in separations for two major reasons. First, the chemical and physical properties of the metal–ligand complex are sharply different than those of the metal ion hydrate. Solubility, ionic or polar character, and even volatility can be different. Formation constants for the metal–ligand complexes will differ and pH is often an important variable. Thus, the number of separation strategies that are applicable to the separation of metal ions are broadened and the number of variables that can be altered to bring about resolution in the separation of a complex mixture of metal ions is increased. Second, some metal–ligand complexes can be more easily detected, which improves quantitative estimation and even identification, than the metal ion hydrate. For example, metal–ligand complexes can be highly coloured, while some will fluoresce and/or have electrochemical properties that can be monitored.

Using complex formation between a ligand and metal ion to facilitate metal ion separations was an important strategy in the development of low efficiency liquid column chromatographic separations of metal ions, particularly in separations by ion exchange and partition column chromatography. Similarly, complex formation is a key elution parameter in high efficiency liquid column chromatographic separations. Each of these column strategies is briefly described in the following.

Ion Exchange

In ion exchange column chromatography the column is packed with either a cation exchanger, which will

exchange cations, or an anion exchanger, which will exchange anions. The exchangers are like insoluble electrolytes and exchange ions rapidly, reversibly and stoichiometrically. Cation exchange is represented in eqn [4] while eqn [5] illustrates anion exchange.

Here R is the ion exchanger matrix containing either an anionic or cationic ionogenic group, C^+ and A^- are co-cation and co-anion, respectively, and M^+ and X^- are the analyte cation and anion, respectively. The direction of the equilibrium in eqns [4] and [5] is determined by the selectivity coefficient for the exchanger towards the two competing ions. Thus, in the absence of mass action effects the exchanger will prefer the ion with the highest selectivity coefficient. For a mixture of analytes, for example a mixture of metal ions and a cation exchanger, the metal ion with the smallest selectivity coefficient would elute first and the metal ion with the largest selectivity coefficient would elute last when using a mobile phase containing an electrolyte that provides a cation of appropriate selectivity and concentration. To increase elution of the metal ion the electrolyte concentration in the mobile phase is increased, or a different electrolyte that provides a cation of higher selectivity is used.

While low efficiency metal ion separations are possible on cation exchangers, resolution is improved considerably when a ligand is included in the mobile phase and the separation occurs because of the properties of the metal complex. For example, elution of M^+ from the cation exchanger is enhanced with a mobile phase containing the ligand, HL, because of the formation of metal ion–ligand complexes. As shown in eqn [4], M^+ is retained on the cation exchanger through competition with the mobile phase cation C^+ . When the ligand is in the mobile phase, the ligand will form a complex with the metal ion, causing the equilibrium in eqn [4] to shift to the left with the formation of the metal ion–ligand complex. The overall effect of the ligand can be represented by eqn [6]:

From eqn [6] the best mobile phase ligand, assuming formation constants and solubility are favourable, will be one that forms anionic complexes with the metal ion.

On the other hand, if the metal ion–ligand complex that forms is anionic, the complex can be retained by an anion exchanger, or

In this case the metal ion is subsequently removed from the anion exchanger by reversing the equilibrium in eqn [7], which is done by reducing the concentration of the ligand in the mobile phase. This causes the equilibrium in eqn [8] to shift to the left, thus removing the metal ion from the anion exchanger.

Low Efficiency Ion Exchange Separation of Metal Ions

In the 1940s ion exchange was recognized as an excellent strategy for the separation of metal ions. The advantages of including ligands in the mobile phase were soon realized and many different types of inorganic and organic ligands were evaluated to aid metal ion separations. Chloride ion was one inorganic ligand that was studied extensively. Many metal ions complex with Cl^- stepwise and the equilibria describing the stepwise formation of metal ion–chloride complexes are summarized by eqn [9]:

where the complexes that are present depend on the formation constants for the individual steps, the coordination number of the metal ion, and the Cl^- concentration. Depending on these factors, the metal analyte may be a cation, a neutral species or an anion. Thus, the charge of the metal-containing species may not only be altered but actually reversed and separation of the metals can become one of cations from anions.

Separation of metal ions is possible on either a strong acid cation exchanger or a strong base anion exchanger using a HCl mobile phase. With the cation exchanger increasing the HCl concentration shifts the equilibria represented by eqn [9] to the right, thus causing the metal analytes to elute from the cation exchange column as the metal chloro complexes (see eqns [4] and [6]). Those metals that form chloro complexes more readily (more favourable formation constants) will elute first.

The better resolution for metal ion separations is actually obtained when using a strong base type

anion exchanger with Cl^- as the mobile phase ligand. For the separation on an anion exchanger the mixture of metal ions is placed on the anion exchanger from a concentrated HCl solution. This converts the metal ions into chloro complexes (see eqn [9]) and these complexes are retained by the anion exchanger. The HCl concentration is then progressively reduced, the equilibria in eqn [9] shifts to the left, and the metal ions are removed from the column (see eqns [7] and [8]). In this case the more stable metal chloro complexes stay on the anion exchanger the longest and the least stable metal chloro complexes come off the earliest.

The retention of all the metal ions, some at several oxidation states, was determined on a strong base anion exchanger as a function of HCl concentration from $< 0.001 \text{ mol L}^{-1}$ to 12 mol L^{-1} HCl. These data allow one to predict elution order and conditions for the separation. Table 1 summarizes some of these results by listing the elution order for several metal ions on the anion exchanger from 12 mol L^{-1} HCl to dilute HCl. As HCl concentration in Table 1 is reduced, those metal ions above the HCl concentration listed are eluted while those below are retained on the exchanger. Many metal ion separations, including complex mixtures, are possible with the HCl eluent. Figure 1 shows the separation of the transition elements on a strong base anion exchanger by a successive decrease in mobile phase HCl concentration. The column was $26 \text{ cm} \times 0.29 \text{ cm}^2$ and about 6 mg of each cation was separated. Each metal ion was collected and its quantity was determined by chemical or instrumental methodology. Mn^{2+} was determined spectrographically, Fe^{3+} and Zn^{2+} were radioactive tracers and were determined by radioactivity, and Co^{2+} , Ni^{2+} , and Cu^{2+} were determined spectrophotometrically.

Table 1 Elution order for common metal ions on a strong base anion exchanger with an HCl mobile phase

Mobile phase HCl concentration (mol L^{-1})	Metal ion
12	Not retained: Ni^{2+} , Al^{3+} , lanthanoids, Th^{4+} Slight retention: Sc^{3+} , As^{5+} , Cr^{3+} , Mn^{2+}
9.5	Ti^{4+}
8	Hf^{4+}
7.5	Zr^{4+}
7	Fe^{2+}
6	U^{4+}
4.5	Co^{2+} , As^{3+}
3	Cu^{2+}
1	UO_2^{2+} , Fe^{3+}
0.02	Zn^{2+}
0.001	Cd^{2+}

Success with chloride ion as the eluent ligand led to studies with many other inorganic ligands. Like Cl^- , F^- is also an important mobile phase ligand and was employed in a mobile phase that was 1 mol L^{-1} HF as a function of HCl concentration. The presence of the F^- is particularly useful because it forms complexes with Group IV and V elements such as Zr^{4+} , Hf^{4+} , Nb^{5+} and Ta^{5+} and aids their separation. Other inorganic ligands have also been shown to be useful but typically do not have the broad scope of applications characteristic of the HCl and HCl/HF elution systems. These ligands include NO_3^- , SO_4^{2-} , Br^- , I^- , SCN^- , CO_3^{2-} and CN^- . While the analytical applications of these ligands may be limited, several have been shown to be particularly useful in commercial recovery and purification applications, for example the isolation of uranium and thorium from low grade ores. Figure 2 illustrates an elution diagram that was used for the separation of a multicomponent high temperature alloy on a strong base anion exchanger using a combination of the HCl and HCl/HF elution scheme. Note that the column dimensions and sample size of 1 g are large and by today's standards this would be called a prep column and separation. Because each metal analyte was separated in such a large quantity each metal ion was determined by chemical methodology, namely by ethylenediaminetetraacetic acid (EDTA) titration or by gravimetry.

Organic ligands have been used in eluents to improve resolution in low efficiency ion exchange metal ion separations. Iminodiacetic acid, nitrilotriacetic acid and EDTA are examples of mobile phase ligands that have been used that form very stable complexes with many metal ions, while citric

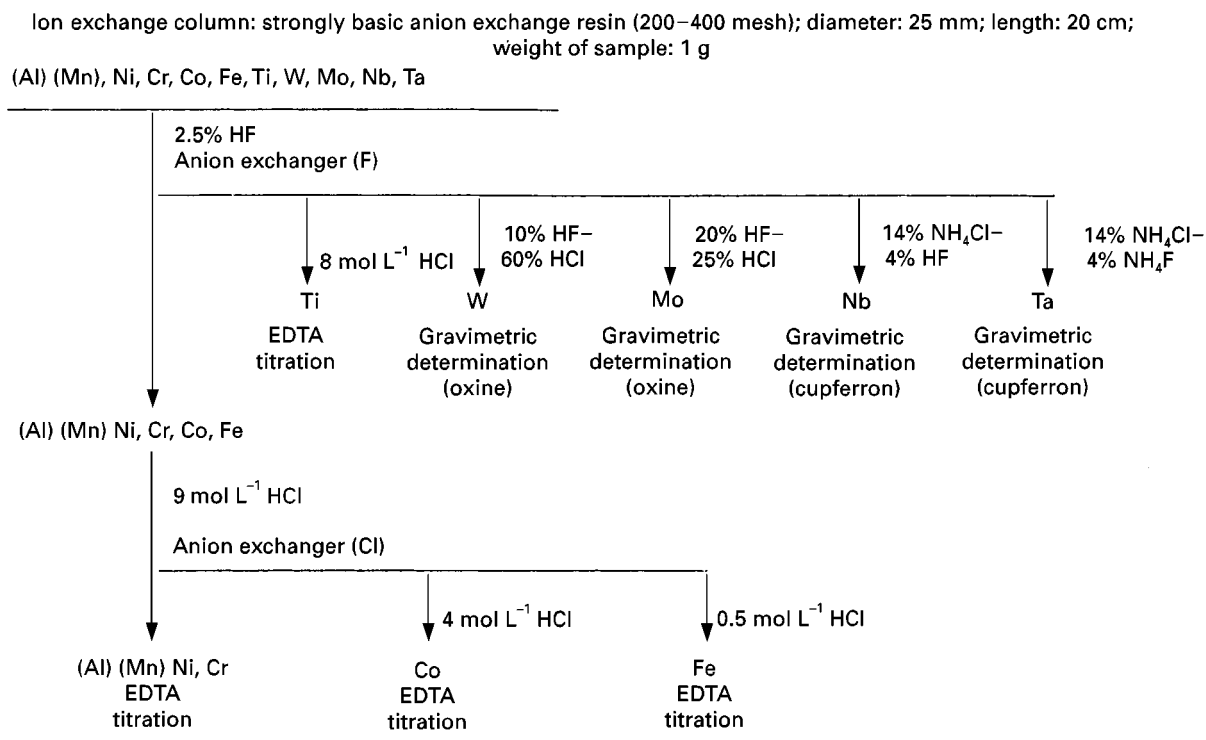

Figure 2 A flow diagram for the separation of a high temperature alloy on a strong base anion exchanger. The anion exchanger is a 40–75 μm , 2.5 cm \times 20 cm strong base anion exchange column and the sample size is about 1 g. (Reproduced from Wilkins, 1959. acid, tartaric acid, malonic acid, oxalic acid, diglycolic acid and α -hydroxyisobutyric acid (HIBA) are examples of useful ligands that form metal ligand complexes of modest stability. In addition to formation constants, pH is also an important mobile phase variable that can be optimized to enhance resolution because all of these ligands are weak acids. Another mobile phase parameter that can be altered to influence elution is to use a mixed solvent for the mobile phase. The presence of the organic solvent in the mixture has a pronounced effect on the formation constants for the complexes as well as the exchange equilibrium with the exchanger. The type of organic solvent and its concentration then become variables in influencing elution time and resolution.

The unique complexing properties of organic ligands have been used to isolate and concentrate metals from ores and other geological samples. For example, one of the more successful applications of this kind was the isolation and separation of the lanthanoids on cation exchangers from mobile phases containing an organic ligand. Prior to this development individually pure lanthanoids were not readily available. Similar success was subsequently achieved in the isolation and purification of uranium and other actinoids, hafnium and zirconium, and many other less familiar metals from natural occurring ores and minerals.

Table 2 lists several elution conditions that have been used for the low efficiency separation of lanthanoids on anion or cation exchangers using a ligand in the mobile phase. The separation of the lanthanoids on a strong acid cation exchanger with lactate as the mobile phase ligand and a small pH increase during the elution is shown in **Figure 3**. Each lanthanoid was collected in a series of fractions and the lanthanoid in each fraction was determined spectrophotometrically by complex formation with 1-(2-pyridylazo)-2-naphthol (PAN). The pH and the formation constants for the lactate complexes determine the elution order. When HIBA is used as the ligand instead of lactate, the same elution order is obtained for the lanthanoids. In another example cation exchange was used to separate 35 metal ions into six separate groups by using mobile phase ligands citric acid, *N*-hydroxyethyl(ethylenedinitrilo)triacetic acid, EDTA, HCl and pH control in a predetermined elution programme.

Ligands in the Separation of Metal Ions by Partition Chromatography

Column liquid–liquid partition chromatography of metal ions can be one of two types. In one case the stationary phase is a nonaqueous immiscible solvent

Table 2 Mobile phase ligand conditions used for the separation of the lanthanoids on anion and cation exchangers

Mobile phase conditions	Exchanger	Application
HIBA at pH = 5.2	Cation	Early lanthanoids
HIBA at pH = 4.7	Cation	Lanthanoid radionuclides
HIBA, pH gradient from 3.4 to 4.0	Cation	Lanthanoids and fission products
0.24 mol L ⁻¹ lactate at 87°C	Cation	Lanthanoids
1.1–1.25 mol L ⁻¹ lactate and 3.1 to 3.25 pH gradient at 87°C	Cation	Lanthanoids
Ammonium lactate gradient at pH 5 and 95°C	Cation	Radiochemical separation of lanthanoids from fission products
26 mmol L ⁻¹ EDTA at pH 3.62 and 87°C	Cation	Ce, Pr, Nd, Sm, La
5–6 mol L ⁻¹ HNO ₃	Anion	La, Ce, Pr group separation
EDTA	Anion	Lanthanoids
Citrate	Anion	Lanthanoids

held up by an inert support and the mobile phase is usually an aqueous solution containing electrolyte, buffer, and a ligand. This type of column chromatography is called liquid–liquid reversed-phase partition chromatography (RPPC). The other strategy is the opposite – the stationary phase liquid is a polar or aqueous solvent held up by the inert support and the mobile phase is an immiscible organic solvent or solvent mixture of less polarity. In both cases the additives cause the metal ions to distribute between the two phases as the metal ions pass through the column. Separation occurs because of differences in the equilibrium positions imposed by the additives, namely the ligand, the resulting formation constants, the pH, and the properties of the two solvents that make up the two phases.

These techniques, which may also be carried out with solvent combinations that are partially miscible suffer from gradual changes in the stationary phase liquid over prolonged column use. This means it is difficult to maintain or reproduce a uniform,

constant stationary liquid phase, sometimes even in a single elution run and often over repeated runs. Even solvents that are thought to be completely immiscible will have a low level equilibrium distribution of one solvent into the other when they are brought together. Thus, the stationary liquid phase will be slowly removed (solvent bleed) from the inert support.

Because of solvent bleeding high efficiency liquid–liquid partition chromatography is rarely used and as a separation strategy it has been replaced by high efficiency reversed-phase and normal-phase column chromatography. Nevertheless, many difficult separations of metal ion mixtures are possible by RPPC and RPPC can be readily applied to cases where the chromatographer needs to separate large quantities of metal ions and is not faced with requirements of short analysis times, the best detection limits, and/or regulatory method controls. Several examples of RPPC described below illustrate the scope of using ligands in RPPC separations of metal ions.

Figure 3 Separation of the lanthanoids on a strong acid cation exchanger. The cation exchanger column is a 40–75 μm , 0.5 cm \times 100 cm column at 80°C and the mobile phase is a lactate buffer solution and pH gradient at about 0.7 mL min⁻¹. RPPC shares many features with solvent extraction and a wealth of information is available in the literature on the solvent extraction of metal–ligand complexes from one phase to another. In most cases a successful extraction depends on the properties of the complex that forms between the ligand and the metal ion. Complex formation constants, metal coordination, solubility of the ligand in the aqueous phase and the nonaqueous phase, solubility of the complex in each of the two phases, and pH are the main factors that determine the percent extraction and the selectivity in the extraction, and consequently the ability to resolve one metal ion from another. These same factors influence metal ion resolution in RPPC and must be optimized to obtain a successful separation.

Two of the more successful inert stationary phases for RPPC are polystyrene–divinylbenzene and acrylic acid-based macroporous copolymers. These are capable of holding up appreciable quantities of nonpolar organic solvents, many of which are desirable for partitioning procedures. Table 3 lists several RPPC quantitative metal ion separations that have been carried out where an inorganic or organic ligand is employed in the two-phase system to complex metal ions and bring about resolution on either the styrene or acrylic acid-type copolymers as the inert stationary phase.

Chelating Ion Exchanger

Instead of adding a ligand to the mobile phase, a chelating group can be chemically bound to a solid, inert matrix. In this case coordination occurs between the metal ion and the bound chelating group. Resolution is possible because of differences

in formation constants for the differential metal complexes that form with the stationary phase-bound chelating group, the mobile phase pH, and the ionic strength. Employing a second chelating group or ligand in the mobile phase to establish a competition between the bound chelating group and the mobile phase ligand towards the metal ion analytes is also an excellent elution procedure to effect resolution of the metal ion mixture.

Chelating ion exchangers often have several disadvantages, even though metal ion retention can be high and selectivity can be favourable. First, the kinetics for the exchange or dissociation of the metal ion from the chelating group bound to the stationary phase can be slow, and this causes poor elution behaviour. Second, few chelating ion exchangers are commercially available. One notable exception is a chelating ion exchanger that has the iminodiacetic acid group, $-\text{CH}_2\text{N}(\text{CH}_2\text{CO}_2\text{H})_2$, attached to a polystyrene–divinylbenzene copolymer. And third, because most chelating ion exchangers have to be synthesized in the laboratory, reproducibility from column to column is only fair. Furthermore, column efficiency in analytical separations is rarely exceptional because the kinetics are usually not favourable.

The major advantage of a chelating ion exchanger, which is very important to environmental and ultra-trace metal analysis, is that the exchanger can be used to isolate trace levels of metal ions from samples and/or to concentrate the trace metal ions prior to their determination. This has been proven to be particularly valuable for the isolation/concentration of metal ions other than the Group I metal ions, particularly transition metal ions, the lanthanoids and the actinoids. Often this can be done from solutions that may contain substantial quantities of

monovalent electrolyte, for example brine solution, boiler water and sea water. Table 4 lists several chelating ion exchangers that have been synthesized in the laboratory and some typical applications of these chelating ion exchangers.

High Efficiency Column Chromatographic Separation of Metal Ions and the Influence of Ligands on their Resolution

The analytical chemistry and role of the ligand in high efficiency or high performance liquid column chromatographic (HPLC) separations of metal ions is much the same as in low efficiency liquid column chromatographic separations. Mobile phase concentration of reagents including the ligand and metal ion analyte concentration are much lower due to more favourable chromatographic properties of high efficiency columns. Selectivity, retention, and particularly detection limits are improved. Formation constants, stepwise equilibria, coordination number, and formation of positive, anionic or neutral complexes are still crucial factors that influence separation. In addition, the rate of complex formation and dissociation is a major contributing factor because of the significant increase in linear velocity of the analyte in the high efficiency column.

Cation exchangers, anion exchangers, chelating exchangers, and reversed stationary phases are the major column stationary phases that are employed in high efficiency metal ion analyte separations. These modern, high efficiency stationary phase particles are available as small (5 and 10 μm), uniform, and spherical-sized particles of considerable physical strength that can be packed uniformly and reproducibly into columns to yield very favourable mass transfer, and thus high efficiency. All of these are properties that the column must possess in order to exhibit high efficiency. Columns that satisfy these criteria are commercially available.

Examples illustrating the scope of modern applications of ligands to improve the resolution in the separation of metal ions on high efficiency columns of cation and anion exchangers, reversed stationary phases and chelating exchangers are outlined in the following sections.

High Efficiency Cation Exchangers

Metal ions, particularly multivalent cations, are highly retained on high efficiency strong acid-type cation exchangers, even though exchange capacities may be very low. One approach to elute metal ions, particularly multivalent cations, from the cation exchanger is to use a mobile phase cation derived from ethylenediamine, $\text{H}_2\text{NCH}_2\text{CH}_2\text{NH}_2$, (En). In an acidic solution En, which is basic, will exist as the dication, $^+\text{H}_3\text{NCH}_2\text{CH}_2\text{NH}_3^+$ (H_2En^{2+}), providing the pH is low enough. Thus, the eluent strength of the mobile phase is determined by the mobile phase H_2En^{2+} concentration and metal ion analyte elution on a typical high efficient cation exchanger follows ordinary cation exchange. A second approach is to use a ligand in the mobile phase. A successful ligand is one that will form neutral or anionic complexes with the analyte metal ions that are stable (formation constants will influence elution order) and form and dissociate rapidly. It should be noted that although En is a ligand for many multivalent cations, in the diprotonated form its complexing ability is sharply reduced. When a ligand, for example citric acid, which forms complexes with metal ions, is included in the buffered mobile phase along with the H_2En^{2+} , resolution now depends on pH. This influences dissociation of citric acid (and also the eluent cation H_2En^{2+} and its potential complexing ability), the formation constants for the metal ion citrate complexes (and metal ion En complexes if they form), and the concentration of the citric acid ligand. The more stable the metal ion citrate complex and the higher the concentration of the citrate, the more quickly the metal ions are eluted. Figure 4 illustrates the high efficiency separation of several divalent metal ions on a strong acid high efficient cation exchanger using the combined effect of citrate as the ligand and H_2En^{2+} as a divalent mobile phase cation. A similar separation is possible using tartrate or oxalate rather than citrate as the mobile phase ligand.

Because complex formation constants differ, small differences in selectivity and elution order are obtained when the elution behaviour of citrate, tartrate and oxalate as ligands are compared. Consequently, metal ion elution order and selectivity for given metal ions, for example for transition metals, can be changed through the selection of the ligand.

Figure 4 Separation of alkali, alkaline earth, and transition element metal ions on a cation exchanger. The column is a TSK IC cation SW column and the mobile phase is $3.5 \text{ mmol L}^{-1} \text{ H}_2\text{EN}^{2+}$, 10 mmol L^{-1} citric acid, pH 2.8, at a flow rate of 1.0 mL min^{-1} with conductivity detection. Peaks are: 1, Na^+ ; 2, K^+ ; 3, Cu^{2+} ; 4, Ni^{2+} ; 5, Co^{2+} ; 6, Zn^{2+} ; 7, Fe^{3+} ; 8, Mn^{2+} ; 9, Cd^{2+} ; 10, Ca^{2+} . (Reproduced from Timberbaev and Bonn (1993). Reprinted by permission of Elsevier Science Publishing.)

Figure 5 illustrates the separation of several transition metals using a mobile phase that contains both oxalate and citrate as ligands and gives an elution order slightly different from the order obtained in Figure 4. Metal ion complex formation is also very important in detection in high efficiency ion exchange separations of metal ions. In Figure 5 the metal ions are converted into complexes post-column online by reaction of the metal ion with 4-(2-pyridylazo)resorcinol (PAR) and the complex is detected by absorbance at 520 nm.

HIBA at pH 4.6 is a good ligand to use to separate lanthanoids on a cation exchanger. This separation is shown in Figure 6, where a gradient of $0.018\text{--}0.070 \text{ mol L}^{-1}$ HIBA is used for the elution of the lanthanoids on a Nucleosil SCX column, a sulfonated bonded phase-type cation exchanger. In Figure 6 detection was by a postcolumn reaction, which produces the highly coloured complex between the ligand, 3-(2-arsenophenylazo)-4,5-dihydroxy-2,7-naphthalene disulfonic acid trisodium salt (Arsenazo 1) and each of the lanthanoids as they are separated. If H_2En^{2+} is also included in the mobile phase with HIBA, separation of the first seven lanthanoids is obtained without employing an HIBA mobile phase gradient.

The properties of the cation exchanger used in the column will also influence the selectivity, even caus-

ing a reversal. For example, Figure 5 is a separation on a surface-sulfonated cation exchanger, while the cation exchanger used in Figure 4 is a surface/interior-sulfonated cation exchanger.

The latex-based exchanger affects elution order when ligands are used in the mobile phase because of the exchanger's composition. The latex-based cation exchanger, which is commercially available from the Dionex Corporation, for example Ion Pac CS5, is composed of a surface-sulfonated substrate as its central core, uniformly coated with a thin layer of aminated latex particles. This basic surface is then coated by a thin, uniform layer of sulfonated latex particles. The cation exchange groups ($-\text{SO}_3\text{H}$) are on the surface while the aminated or anion exchange groups ($-\text{NR}_4^+$) are in the interior

Figure 5 Separation of the transition element metal ions on a surface-sulfonated cation exchanger. The column is an Ion Pac CS2 column and the mobile phase is 0.01 mol L^{-1} oxalic acid, $0.0075 \text{ mol L}^{-1}$ citric acid, pH 4.2, at a flow rate of 1.0 mL min^{-1} . Detection is postcolumn absorbance at 520 nm after reaction with PAR. Sample injection is $50 \text{ }\mu\text{L}$ containing 5 ppm Fe^{3+} , 0.5 ppm Cu^{2+} , 0.5 ppm Ni^{2+} , 0.5 ppm Zn^{2+} , 1 ppm Co^{2+} , 10 ppm Pb^{2+} , and 5 ppm Fe^{2+} . Figure 6 Separation of the lanthanoids on a sulfonated silica-bonded phase cation exchanger. The column is a 10 μm , 0.4 cm \times 10 cm, Nucleosil 10 SA column and the mobile phase is a linear gradient of 0.018 mol L⁻¹ to 0.070 mol L⁻¹ HIBA at pH 4.6. Sample injection is 10 μL containing about 10 $\mu\text{g mL}^{-1}$ of each lanthanoid. (Reproduced from Elchuk and Cassidy, 1979. Reprinted by permission of American Chemical Society.)

of the particle. Thus, the observed elution for metal ions on the Ion Pac CS5 will be influenced by both cation and anion exchange and the equilibria that favour cationic or anionic metal–complex formation. For example, the transition metal elution order in **Figure 7** on the Ion Pac CS5 column with oxalate as a mobile phase ligand is quite different from the order found in either **Figure 4** or **5** and is due to retention of anionic oxalate complexes that form between several of the transition metal ions and oxalate. When the Ion Pac CS5 column is used with a mobile phase containing pyridine-2,6-dicarboxylic acid (PDCA) as the ligand at pH 4.8, the elution order that is obtained is similar to that obtained by the sulfonated, nonlatex-type cation exchangers used in **Figures 4** and **5**.

High Efficiency Anion Exchangers

Some ligands will form very stable complexes with metal ions that are also anionic. It is often possible in these cases to separate the anionic metal–ligand complexes on high efficiency anion exchangers. For example, transition metal–PAR complexes are anionic and these complexes can be separated at high efficiency. Since the complexes are also highly coloured, detection of the separation is readily done at favourable detection limits by absorption. In another example the anionic complexes that form between multivalent cations and EDTA are anionic at the appropriate pH and can also be separated on

anion exchangers using an $\text{HCO}_3^-/\text{CO}_3^{2-}$ mobile phase that is common to ordinary ion chromatographic separation of anionic analytes. The basic requirement of the formation of a very stable anionic complex between the metal ion and the ligand is often a limiting factor and for this reason separation of metal ions in the presence of a ligand on a high efficiency cation exchanger is often a more versatile separation strategy.

The latex-based cation exchanger that possesses both cation and anion exchanger properties, such as the Ion Pac CS5, however, does provide a way to separate metal ion mixtures in the presence of mixed ligands where both cation and anion exchange are involved. This is illustrated in **Figure 8**, where both transition metals and lanthanoids are separated in one run on the high efficiency Ion Pac CS5 column using a complex gradient at the appropriate pH where the concentration of the ligands oxalic acid, diglycolic acid and PDCA are varied as a function of elution time. The PDCA causes the elution of the transition metals to be similar to that found on the

Figure 7 Separation of several transition element metal ions with oxalic acid as the mobile phase ligand. An Ion Pac CS5 column and a 0.5 mol L⁻¹ oxalic acid, pH 4.8, mobile phase at 1 mL min⁻¹ was used. Injection volume was 50 μL and contained 4 ppm Pb²⁺, 0.5 ppm Cu²⁺, 4 ppm Cd²⁺, 2 ppm Co²⁺, 2 ppm Zn²⁺, 4 ppm Ni²⁺. (Reproduced from Weiss, 1995, p. 199. Reprinted by permission of VCH Publishers.)

Figure 8 Separation of the transition elements and lanthanoid metal ions using a three-ligand mobile phase. An Ion Pac CS5 column and a mobile phase gradient of PDCA, oxalic acid, diglycolic acid, and LiOH for pH adjustment at 1 mL min^{-1} was used. Injection volume was $50 \mu\text{L}$ and contained 2 ppm Fe^{3+} , 1 ppm Cu^{2+} , 3 ppm Ni^{2+} , 4 ppm Zn^{2+} , 2 ppm Co^{2+} , 1 ppm Mn^{2+} , 3 ppm Fe^{2+} , 7 ppm of each lanthanoid. (Reproduced from Weiss, 1995, p. 205. Reprinted by permission from VCH Publishers.)

sulfonated cation exchanger (see Figure 5), while the lanthanoids remain on the column as trivalent anions. In the later stages of the gradient oxalic acid and diglycolic acid become more significant in concentration and cause the lanthanoids to be eluted in reverse order to that obtained by the high efficiency cation exchange separation of the lanthanoids (see Figure 6). If only the lanthanoids are to be separated, they can be separated in the order shown in Figure 8 on the Ion Pac CS5 column in about 25 min with the oxalic acid/diglycolic acid gradient. Detection is also made possible by the formation of metal complexes. In this example effluent from the column is combined with PAR to give the highly coloured metal ion–PAR complexes, which are readily detected by absorbance at 520 nm.

Reversed Phase

Separation of metal ions as anionic complexes on high efficiency reversed stationary phases, such as a C_{18} bonded phase silica or a polystyrene–divinylbenzene copolymer, requires a mobile phase that must also include an ion interaction reagent, for example a quaternary ammonium salt ($\text{R}_4\text{N}^+\text{C}^-$) having lipophilic character. The metal ion–ligand anionic complex interacts with the $\text{R}_4\text{N}^+\text{C}^-$, which in turn interacts with the reversed stationary phase, A, as shown below:

where M^{2+} is the metal ion analyte and ML_2^- represents the anionic metal–ligand complex. The direction of the equilibrium and subsequently the elution of the metal–ligand complex is controlled by the selection of the reversed stationary phase and the $\text{R}_4\text{N}^+\text{C}^-$ salt, the concentration of the $\text{R}_4\text{N}^+\text{C}^-$ salt, the counter-anion X^- and its concentration via inert electrolyte, pH, solvent composition, the ligand, and the ligand concentration. This chromatographic strategy, or ion interaction chromatography (IIC), is known by several different terms and has been the subject of many studies to establish the nature of the interactions between the analyte, mobile phase components and stationary phase that are present. Clearly, several equilibria are involved and the success of the separation strategy in analytical applications requires careful control of all the equilibria.

Transition metal–PAR complexes are anionic and separations of these anionic complexes are possible on a reversed stationary phase. Other ligands can be used; the most useful ones are ligands that form kinetically stable anionic complexes with very high formation constants. Often the complexes are highly coloured and/or fluoresce and these properties allow sensitive detection.

Inorganic ligands that form very stable anionic complexes with metal ions can be used in a mobile phase that also contains a $\text{R}_4\text{N}^+\text{C}^-$ salt to separate the metal ions as complexes on a reversed stationary phase. Figure 9 illustrates the separation of transition metals as anionic cyanide complexes on a C_{18} reversed stationary phase column using a $\text{R}_4\text{N}^+\text{C}^-$ (Waters PICA additive) mobile phase. Detection in this separation is by absorbance at 214 nm.

Figure 9 Ion interaction chromatographic separation of metal ions as cyano complexes. A 5 μm , 0.39 $\text{cm} \times 15$ cm , Waters Nova Pak C_{18} column and an $\text{H}_2\text{O}/\text{CH}_3\text{CN}$ (23 : 77) 5 mmol L^{-1} tetramethylammonium hydroxide mobile phase at 1.0 mL min^{-1} was used. Sample injection was 10 μL and contained 0.15 $\mu\text{g Cu}^{1+}$, 1.5 $\mu\text{g Ag}^{1+}$, 0.02 $\mu\text{g Fe}^{2+}$, 0.2 $\mu\text{g Co}^{3+}$, 0.3 $\mu\text{g Fe}^{3+}$, 2.0 $\mu\text{g Au}^{1+}$, 0.4 $\mu\text{g Pd}^{2+}$, 0.2 $\mu\text{g Pt}^{2+}$ as cyano complexes. (Reproduced from Hilton and Haddad, 1986. Reprinted by permission from Elsevier Science Publishing.)

IIC with an anionic lipophilic reagent, such as an alkane sulfonic acid ($\text{RSO}_3^- \text{H}^+$), is also an important strategy for the high efficiency separation of metal ions. However, in this case the ligand in the mobile phase removes the metal ion from the reversed stationary phase according to the metal ion–ligand complex formation constants. The equilibria that are involved and which must be controlled for a successful separation are represented below (equilibria for complex formation are not shown – see eqns [1]–[3] where L is CN^-):

where A is the reversed stationary phase, $\text{RSO}_3^- \text{H}^+$ is the lipophilic ion interaction reagent, M^{n+} is the metal analyte ion, and L^{x-} is the mobile phase liquid.

Examples where this separation strategy has been successfully used are in the separation of transition metals or lanthanoids on a C_{18} stationary phase and octanesulfonic acid as the IIC reagent in the buffered mobile phase. The former metal analytes are eluted with tartrate in the $\text{RSO}_3^- \text{H}^+$ mobile phase and the elution order is Cu^{2+} , Pb^{2+} , Zn^{2+} , Ni^{2+} , Co^{2+} , Mn^{2+} , which differs from the tartrate elution of these cations on the sulfonated cation exchange column and the latex-based exchanger (see Figures 4, 5 and 7). The lanthanoids are separated by including the ligand HIBA in the $\text{RSO}_3^- \text{H}^+$ mobile phase and the elution order is the same as that indicated in Figure 6.

High Efficiency Chelating Exchangers

Few high efficiency chelating exchangers are commercially available. Even though various chelating groups have been chemically bonded to high efficiency silica or polystyrene–divinylbenzene copolymer particles, and metal ion retention is very high on these stationary phase particles, efficiencies generated on these columns are usually not comparable to efficiencies found for metal ion–ligand separations on ion exchangers or by reversed-phase ion interaction chromatography. In general, high efficiency is difficult to obtain, even when the core particle of the chelating exchanger meets high efficiency properties, because the complex between the metal ion and the bound chelating group often forms and dissociates slowly. Thus, metal ion analyte bands in elution can be broadened appreciably.

Using a ligand in the mobile phase to aid elution can sometimes reduce the analyte peak broadening. For example, the separation of transition metal ions on a high efficiency silica particle containing chemically bound iminodiacetic acid groups was achieved by using citrate, tartrate, nitrilotriacetic acid or PDCA in the buffered mobile phase. Since two complexing reactions are taking place, the metal ion elution order is dependent on the formation constant for the metal ion complex with the bound chelating group and with the mobile phase ligand in addition to pH. Other laboratory synthesized chelating exchangers where the chelating group (several of these are listed in Table 4) is bound to a high efficiency matrix, such as silica, have been evaluated for metal ion separations.

While metal ions can be separated on chelating ion exchangers, the more useful applications of chelating exchangers is still one of isolating and preconcentrating of metal ions from a complex sample matrix. Metal ions can be preconcentrated from biological samples, environmental samples and concentrated electrolyte solutions, such as seawater, brine and

other industrial waters, and strong alkali solutions. It is possible to automate fully the preconcentration and separation/analysis procedure. In an example of this trace levels of Mg^{2+} , Ca^{2+} and transition metals in biological and environmental samples are preconcentrated on two iminodiacetic acid-type chelating ion exchanger and one strong acid cation exchanger connected in series. The preconcentrated metal ions are then removed from the three columns and the concentrated metal ion mixture is separated on an analytical Ion Pac CS5 column by an elution programme that takes into account pH, ammonia/ammonium ion buffer concentration and PDCA concentration. Detection is by absorption after postcolumn reaction of the metal ions with PAR.

METAL MEMBRANES: MEMBRANE SEPARATIONS

Y. S. Lin and R. E. Buxbaum, University of Cincinnati, Cincinnati, OH, USA

Introduction

The use of metal membranes for hydrogen separation was first demonstrated over a century ago. Graham discovered in 1866 that palladium absorbs a surprising

amount of hydrogen. Graham went on to show that palladium and palladium-silver membranes permeate only hydrogen, paving the way for the use of metal membranes for hydrogen extraction and purification. Much of the earlier knowledge in metal membranes is summarized in three reference books published in 1967-1968 (see Further Reading). Recent academic research is reviewed in several monographs on inorganic membranes and review articles. This article gives an overview of the general properties of metal membranes, followed with a description of methods that have been developed for membrane fabrication. Applications of the metal membranes in separation and chemical reaction processes and design of the metal membrane separation processes are described later in the article.

General Properties of Metallic Membranes

A surprising amount of hydrogen can be absorbed reversibly by palladium alloys and by many transition metals over a large temperature range. The absorption proceeds via interstitial incorporation in the metal, generally leaving the crystalline structure intact. Thus, for example, face-centered cubic palladium retains its structure to the metal hydride phase, with the hydrogen progressively occupying tetrahedral and octahedral sites. The nature of the chemical bonding is still not well understood, but a widely used model assumes that the hydride is an alloy (in the usual metallic sense) of hydrogen and the host metal. Electrons from the hydrogen progressively occupy the d-bands of the transition metal, and the hydrogen exists essentially as slightly shielded protons in the host lattice. The other model is based on a predominantly covalent bond between the metal and hydrogen. In this model molecular hydrogen is dissociated to become atomic hydrogen, which subsequently forms chemical-type bonds to the host metal.

Figure 1 shows hydrogen solubility relationships for several transition metals at different temperatures. At constant pressure, the hydrogen solubility of some metals increases with increasing temperature, while for some other metals it decreases. Figure 2 shows typical relationships of hydrogen solubility (presented in the atomic ratio of hydrogen to metal) versus hydrogen partial pressures at different temperatures. The dashed curve in Figure 2 encloses the two-phase region of the palladium hydride system with α -phase to its left and β -phase to its right. For all metals below their hydride phase transition, the solubility increases with hydrogen pressure. The most common relationship for this is

Figure 1 Hydrogen solubility of several transition metals at different temperatures ($P_{H_2} = 1$ atm). (Copyright REB Research & Consulting with permission.)

the Sievert's relation:

$$C = K_s P_{H_2}^{1/2} \quad [1]$$

That is to say that the hydrogen concentration, expressed as the ratio of hydrogen:metal or as the volume of hydrogen per gram of metal, is proportional to a temperature dependent constant (K_s) times the hydrogen pressure to the power $\frac{1}{2}$. The power $\frac{1}{2}$ in eqn [1] comes from the entropic effect of every molecule of hydrogen dissociating into two hydrogen atoms in the metal.

Aside from solubility, the most important qualities of a metal for use in metallic membranes are the hydrogen diffusivity in metal and the rates of dissociation and recombination reactions on the membrane surfaces. At the upstream membrane surface the surface reaction step consists of adsorption of H_2 , dissociation of this adsorbed H_2 into two hydrogen atoms (or charge-transfer reaction to form protons), and absorption of the atoms into the bulk metal. In the bulk there is a net transport of hydrogen atoms from high to low partial pressure sides along the concentration gradient. At the downstream membrane surface there is another surface reaction step including the formation of hydrogen molecules from hydrogen atoms (or protons) and desorption of hydrogen molecules from the surface to the gas phase.

Figure 2 Hydrogen solubility of palladium at different hydrogen pressures and temperatures (°C) (From Lewis FA (1967) *The Palladium Hydrogen System*. Fig. 2.3, p. 17. New York: Academic Press.)

Based on the Mass Action Law, the following simplified equations can be obtained to describe the combined effects on hydrogen permeation flux:

$$J = K_R(P_{UH} - P_I) \tag{2}$$

$$J = (DK_s/2L) (P_I^{1/2} - P_{II}^{1/2}) \tag{3}$$

$$J = K_R(P_{II} - P_{DH}) \tag{4}$$

where P_{UH} is the upstream hydrogen pressure, P_{DH} is the downstream hydrogen pressure, P_I is the imaginary pressure in equilibrium with the upstream surface of the metal, and P_{II} is the imaginary pressure in equilibrium with the downstream surface. K_R is a lumped rate constant for the surface reaction step. In eqn [3], DK_s is the product diffusivity and Sievert's constant in the bulk metal membrane and L is the membrane thickness. Often $DK_s/2$ is called the hydrogen permeability and is plotted in Figure 3 for several metals. It should be noted that

metal membranes are practically impermeable to other gases such as helium or nitrogen due to their low solubility and diffusivity in the metals. Although for all the metals of interest to separation applications, the hydrogen diffusivity increases and solubility decreases with increasing temperature, we find for some metals (e.g. palladium) the permeability increases with temperature, while for others (e.g. tantalum, niobium) it decreases. The determining factor is the relative temperature dependency of diffusivity and solubility. Because of slow reaction steps (eqn [2] and eqn [4]), permeation membranes of Nb, V and Ta must be coated with palladium to be used for separation applications.

For most metal membranes, bulk diffusion is rate-limiting. That is, $(DK_s/2L)$ is typically smaller than K_R . For such membranes eqn [3] describes the flux with P_{II} and P_I replaced by P_{UH} and P_{DH} . In this case, the hydrogen permeance is inversely proportional to the membrane thickness with permeation flux exhibiting a $P_{H_2}^{1/2}$ dependence. This relationship is referred to as the Richardson's law. If the surface steps are rate-limiting, i.e. $(DK_s/2L)$ much larger than K_R , the hydrogen permeation flux is proportional to the transmembrane pressure drop. When resistances of both surface and bulk steps are equally important, the above equations are sometimes approximated with $P_{H_2}^{0.7}$ dependencies or similar simplified relations.

Figure 3 Hydrogen permeability of various transition metals at different temperatures. (Copyright REB Research & Consulting with permission.)

Another critical behaviour for any metallic membrane is durability. Figure 2 shows that below a critical temperature (310°C) palladium hydride can exist either in the α -phase or β -phase, depending on hydrogen pressure and temperature. Above the critical temperature, palladium hydride remains in the α -phase regardless of the hydrogen partial pressure. Both the α -phase and β -phase have the same face-centered cubic lattice structure, but the lattice constant of the latter is as much as 3% larger than the former. Thus, a hydrogen pressure swing below the critical temperature or a temperature swing (above the critical pressure) will cause large mechanical strains during phase transformation of the palladium hydride between the two phases. These lattice strains would destroy the mechanical integrity of a membrane made of palladium alone. This phenomenon is referred to as 'hydrogen embrittlement'. For practical application this is avoided by alloying the palladium and by lowering the hydrogen pressure sharply before the membrane cools to room temperature. The same problems and solutions are also applicable to Pd-coated transition metals.

Alloying palladium with silver results in a phase diagram with a decreased critical temperature and pressure. If we accept the metallic alloy model for metal-hydride systems, the role of silver can be explained as an electron-donating behaviour where electrons from silver and hydrogen atoms compete for filling the 4d-band of palladium. Since 4d-band filling is associated with β -phase formation, 40% silver prevents β -phase formation entirely although most common alloys do not employ quite so much silver. Once the 4d-band is filled, electrons from further hydrogen absorption contributes to 5s-band filling and the net effect is decrease in both critical temperature and pressure in the phase diagram. Common palladium-silver (23–25% silver) membranes and palladium-copper membranes can be operated at much lower temperatures than pure palladium membranes without significant hydrogen-embrittlement problems. This is especially true if care is taken at start-up and shutdown to avoid exposure of the membranes to high-pressure hydrogen at room temperature.

Metal membranes are susceptible to surface poisoning. Prolonged exposure of many metal membranes to sulfur or even carbon containing gases under some conditions could deactivate the membrane surface or change the bulk structure of thin metal membrane, affecting adversely the membrane permeation and separation properties. The current approach is to avoid this problem by removing poisoning impurities from the gas stream prior to the contact with the membrane surface. Modification of

the metal surface to improve its resistance to surface poisoning may provide an inherent solution to this problem. Research efforts in finding a suitable modification method have been limited, but are expected to increase in the future.

Fabrication of Metal Membranes

Casting/rolling is the current method for commercial production of palladium-based metal membranes. This method involves several steps. Membrane raw materials are melted at a high temperature to form ingots which go subsequently through hot or cold forging or pressing to produce tube or sheet. The final membrane has a thickness typically in the range of 50 to 75 μm (0.002–0.003 in). The metal membranes prepared by this method are polycrystalline with large grains (submicron or micron size). Furthermore, cold rolling often generates lattice dislocation and it can enhance hydrogen solubility in palladium and some of its alloys due to the accumulation of hydrogen around the dislocation. As a result, these polycrystalline metal membranes have very high hydrogen solubility.

Based on the Richardson equation (eqn [3]), thin metal membranes are more desired than thick ones in terms of hydrogen permeance and metal cost savings. The problem has been in forming such membranes and keeping them stable during temperature and pressure cycling. To improve the durability, thin metal membranes have been formed by coating on porous metallic or ceramic support. Several methods have emerged in the past decade for this including liquid-phase electroless plating and chemical vapour deposition (CVD).

Electroless plating involves autocatalysed decomposition of a selected metastable metal precursor such as $\text{Pd}(\text{NH}_3)_4\text{X}_2$ where X can be NO_3 , Cl or Br in alkaline aqueous solution at around 50°C. To avoid autodecomposition of the metal precursors a stabilizer such as ethylenediaminetetraacetic acid (EDTA) is often added. For nonmetallic supports, the surface (substrate) should be activated, e.g. by $\text{SnCl}_2/\text{PdCl}_2$ prior to electroless plating. Palladium or palladium-silver films with a thickness ranging from 5 to 30 μm have been prepared by this method on supports of porous alumina and stainless steel and on non-porous niobium, tantalum or vanadium alloy.

Thin metal membranes can also be prepared by CVD of metal salts and metal organic compounds, such as PdCl_2 and $\text{Pd}(\text{O}_2\text{C}_5\text{H}_7)_2$ and can also be produced by sputter coating of a solid metal. For CVD, the precursor vapour, with or without a reducing agent (hydrogen), is brought in contact with one surface of the porous support at a high temperature.

Reduction of the precursor occurs directly or by countercurrent exposure to the reducing agent at 200–400 °C. Palladium films as thin as 0.5 µm have been deposited on or inside porous alumina support this way. For sputter deposition a metal target of desired composition is placed apart from the substrate in a sputtering chamber filled with a working gas (argon) at low pressure (about 10^{-3} torr). A DC or radiofrequency AC electric-field gradient plasma is generated in the working gas and bombards the target. Fine metal particles or atoms dislodged from the target move towards the substrate and subsequently deposit. Thin palladium and palladium–silver membranes have been coated on porous γ -alumina and dense polymer substrates by this method.

Metal membranes prepared by the vapour methods are usually nanocrystalline with grain size in the range of a few tens of nanometers. Electroless-plated metal membranes appear to be more coarse-grained. For palladium on substrate membranes, the bulk diffusion step in the substrate is generally the rate-limiting step. Furthermore, fine-grained thin metal membranes appear to have a lower hydrogen permeability than coarse-grained thick metal membranes. Thus, while the metal cost for Pd-coated ceramics is typically much lower than for symmetric metal membranes, the flux is usually fairly similar and can even be lower than traditional metal membranes, and is typically proportional to the pressure dependence and not to $P_{\text{H}_2}^2$ as in eqn [3]. Similar membranes prepared by different methods can exhibit different dependency, and specific relationships should be obtained in order to design separation and reaction processes involving these metal membranes.

Metal Membrane Applications

The major large-scale application for metal membranes today is hydrogen purification, with most of that hydrogen used for integrated circuit manufacture. Different circuit technologies differ in the purity of hydrogen they require, and the current needs are between 5 nines (99.999%) and 8 nines (99.999999%) hydrogen, or 0.01 to 10 ppm impurities. The largest user, silicon-based semiconductor manufacture requires the lower levels of purity, and gallium arsenide the highest. These purity levels are expected to increase over time as transistor densities rise, doubling approximately every two years. Silicon applications should thus need 7 nines and gallium arsenide applications 9 nines hydrogen by 2005.

Metal membrane purification competes with adsorption technology for the market in electronic component manufacturing. The metal membrane market

is valued at only \$10 millions/year, but the ultrapure hydrogen delivery market is at least 100 times bigger suggesting significant room for growth in purifier sales. For electronic component manufacturing using cylinder hydrogen (the only choice in much of the Far East) there is no real alternative to membrane purification using tubular membranes of palladium–silver alloy (23–25% silver). The leading companies in this market are Johnson Matthey (75% market share) and Japan Pionics (25% market share.) Cylinder hydrogen is so impure that competing getter technology is not cost effective. Competing getter technology is often preferred with liquid hydrogen sources (available in the USA and Europe) because the pressure drop is lower and since the delivered hydrogen is purer, the cost is lower as well. Even here, membranes are often used for high value-added parts since getters tend to release small amounts of oxide dust as they saturate with impurities. This oxide can interfere with semiconductors manufacture and presents a safety hazard, e.g. released vanadium oxide dust is highly toxic with an exposure limit of 0.05 mg m^{-3} . Membranes are also safety favourites since the main getter alloys are flammable in contact with air at operating temperatures as high as 600°C.

A second major application for metal membrane purified hydrogen is as a carrier gas for gas chromatography. This is true particularly in Europe and the Far East where helium is scarce, but also in the USA for fast-response, high-sensitivity applications. The purity need here could be met by ultrapure cylinders, especially backed by a getter trap, but it is cost effective to use a membrane. An 'A-size' cylinder, containing 65 ft³ (STP) (1900 L (STP)) of ultrapure zero-grade hydrogen costs approximately \$220 currently. Continuous use as a carrier and reference gas consumes about 150 cm³ (STP) min⁻¹, emptying the cylinder in slightly over a week, and costing the customer \$10 000 annually. A membrane purifier of very modest size will allow the customer to use a much cheaper, lower grade of hydrogen, returning the purchase cost in six months or less.

Palladium membranes are also used for isotope enrichment providing a separation factor of about 1.4 for protium over deuterium, and about 1.7 for protium over tritium. While the hydrogen volume need for this application is small, the low separation factor ensures that quite a lot of membrane is needed.

A rather new line of metal membrane applications is for membrane reactors, mainly to generate hydrogen for fuel cells, but also to promote thermodynamically unfavourable reactions like methane splitting and ethylene production. A membrane reactor combines, in one unit, a catalytic reactor bed and a membrane separator to remove a desired

product (hydrogen) as it is formed. As a result membrane reactors drive the reaction towards completion and achieve advantages of enhanced catalyst use, higher feed space velocity and fewer side products.

Another benefit of membrane reactors, particularly for fuel cell applications that require high-purity hydrogen from source gases like methanol or gasoline, is that a membrane changes the way pressure affects extent of reaction and product recovery. Without the membrane in the reactor, a reforming reaction of this type would require low pressure operation to achieve high conversion, and would require a difficult hydrogen purification for the intended use. A membrane reactor allows the reaction to be driven by high pressures, greatly increasing the ease of hydrogen product recovery. At present, several membrane reactors are in trial and one at the pilot-plant scale for the production of hydrogen. Typical pressures of operation are at 17 atm, with operation temperatures dictated by the catalyst and material of construction. The size of the fuel cell market is currently small, but is believed to be rising fast.

Designs of Metal Membrane Separation Processes

Figure 4 shows the basic design of a hydrogen purifier. Prominently shown is a heat exchanger set between the input hydrogen feed and the purified hydrogen product. Heat recovery of this type is critical because the membranes typically operate at 350–400°C in an environment where the source gas and product application are near room temperature. Heat exchange cools the output gas and reduces the electric heating costs. Heat exchange also promotes temperature uniformity within the purifier; this is an important consideration since for most of the hydrogen permeable alloys a 100°C temperature gradient in

Figure 4 Schematic diagram of a metal membrane hydrogen purifier process. (Courtesy of Johnson Matthey, plc.)

the membrane would mean that part of the membrane would have to operate at significantly below their optimal temperature for flux, and part of the membrane would operate at significantly above the optimal temperature for long life.

Figure 4 also shows a bleed valve to control the removal of impurities from the purifier, and a system to provide inert gas (nitrogen) flushing. Setting these systems is something of an art, since with too little bleed, impurities would build up in the purifier reducing the hydrogen output. Too much bleed, by contrast, results in a loss of heat and pressure resulting in a similar reduction in output. Most larger purifiers provide a nitrogen purge system as shown, to help extend the life of the membrane by reducing hydrogen embrittlement of the palladium alloys. This purge system can also be a source of problems as purging can result in hydrogen being sucked back into the purifier. If the sucked back hydrogen is contaminated with other electronic gases (particularly arsine) this will result in an irreversibly poisoned membrane.

There are basically two types of tubular membrane based commercial purifier designs: pressure-outside and pressure-inside. Until recently, large-scale hydrogen purification ($>100 \text{ L (STP) min}^{-1}$) was limited to pressure-outside design. Figure 5 shows schematic of a pressure-outside design. The inlet flow of fluid containing a mixed gas includes hydrogen flows over the outer surface of the metal membrane tubes housed inside a pressure vessel. The metal membrane tubes are operatively connected at one end to a header and the other end of the tubes are either capped or can be operatively attached to a floating head. Hydrogen permeates from outside into the inside of the metal membrane tubes, and leaves the membrane module through the outlet port. Pressure-outside designs (Johnson Matthey, Japan Pionics, and REB Research & Consulting) have longer life than the pressure-inside designs since the former do not require a braze seal at both ends of the membrane tube.

Pressure-inside designs, supplied by REB Research & Consulting, RSI and Power & Energy, are believed to output somewhat purer hydrogen because the impure gas flow past the membrane is more uniform than with pressure-outside designs. In the pressure-inside designs, the pressure drop and vibration effects in the tubes become excessive as tube lengths exceed 25–50 in. (63–127 cm). These effects could be effectively minimized by a scheme for placing several short lengths of Pd–Ag or similar tube in parallel while balancing the flow through each using matched, internally located flow restrictors. Forces of expansion and contraction by the membranes against the seals are believed to be a major

Figure 5 Schematic diagram of a pressure-outside design of metal membrane module: 1. Feed gas inlet. 2. Feed gas outlet. 3. Pressure vessel. 4. Metal membrane tubes. 5. Header. 6. Pure hydrogen outlet. (From US Patent 5,931,987, 1999.)

cause of fatigue failure in pressure-inside designs, as is burnthrough. Burnthrough is believed to be a bigger problem with pressure-inside designs since metals are inherently more stable in compression than in tension. That is a tube in compression will flow somewhat to heal a thin spot, but will flow away in tension turning a thin spot into a hole.

A third type of purifier using flat plates of Pd-Cu was recently demonstrated by Northwest Power. As flat plates can be made thinner than metal tubes the output flux with these membrane is exceptional. Unfortunately welded seals are much less reliable in this configuration than with tubes and instead graphite seals are used. The degree of purification from these devices is unacceptable for integrated circuit manufacture, but appears to be acceptable for use with fuel cells.

Almost all commercial metal membrane separation systems use the symmetric solid metal membranes fabricated by the conventional casting/rolling method. The only commercial attempt at using porous substrate supported metal membranes was in the 1950s and 1960s by Union Carbide who applied a thin layer of palladium-silver alloy on a porous ceramic substrate. By choosing the pore size and

thickness appropriately, metal cost per unit area could be decreased significantly while flux could be increased somewhat. The early membranes did not prove durable though, and had to be removed from service. Results with all of these alternatives is encouraging but it is fair to say that the commercial metal membrane market is still dominated by unsupported palladium alloys. The main reason is purity and durability: both the Pd-coated refractory metals and the Pd coated porous substrates have shown less cycling durability than typically associated with the solid Pd alloys, and the purity of hydrogen purified through the newer membranes has still to reach the very high levels of solid membrane purifiers. This latter is particularly significant for the high value added applications that dominate the metal membrane market currently.

Concluding Remarks

Metal membranes are the most hydrogen perm-selective inorganic membranes in the temperature range of 200–500°C. They are expected to remain so in the near future. Much progress has been made in understanding metal membrane properties and development of various methods for metal membrane fabrications. However, applications of metal membranes have been limited to hydrogen purification. In addition to the structural stability and cost problems, another major problem for metal membranes is their susceptibility to surface poisoning. This problem has to be solved in order for the metal membranes to gain wider acceptance in processes for separation of hydrogen containing gases of industrial importance.

Introduction

Microorganisms and biomaterials can be used for the removal/recovery of metals from process liquors and liquid wastes. The mechanisms involved in capturing metals from solution by microorganisms and related materials are now commonly referred to as biosorption. Biosorption has been defined as the removal of metals or metalloid species, compounds and particulates from solution by biological material. It is one of the fields in environmental biotechnology, which is itself a small, but growing, component of the biotechnology industry (Figure 1).

The use of microorganisms to treat waste liquors on a commercial scale dates back to the end of the nineteenth century when the first communal sewage plants in Berlin, Hamburg, Munich, Paris and other major cities came into operation. In the intervening 100 years the use of microorganisms and plants to protect the environment has developed into a multi-billion dollar (US\$) industry. However, the foundations of this environmental biotechnology industry are still with the treatment of municipal/domestic effluents.

Although nature has demonstrated some subtle and intricate mechanisms for selectively controlling the mobility of pollutants in the environment, the conversion of this science to technology and to application has been very disappointing. In explaining this lack of application, it is important that these mechanisms

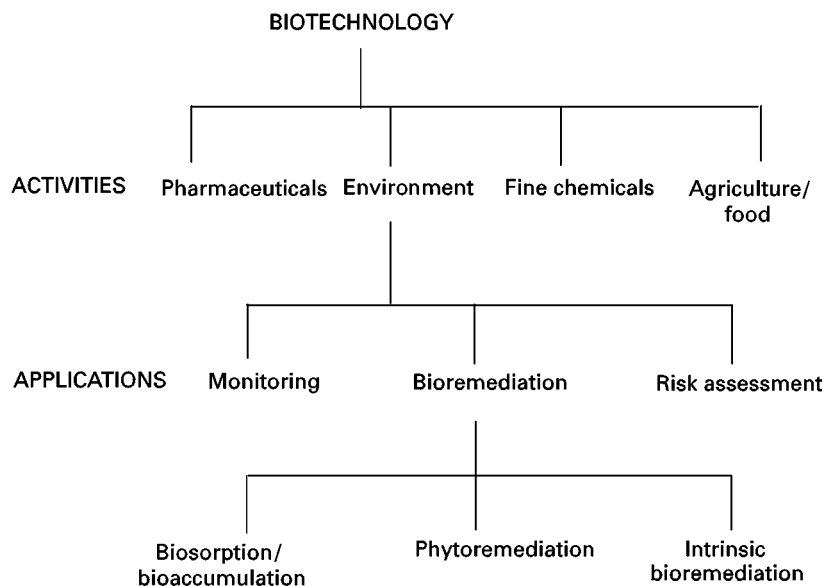

Figure 1 Biotechnology activities and applications. (This is an original developed by H Eccles.)

are appreciated; factors that influence their effectiveness need to be addressed to engineer robust and reliable processes.

Microorganisms and Biomaterials for Metal Removal

The biological systems studied for metal removal/recovery range from living microorganisms and dead cell systems to other biomaterials such as peat, coconut shells and eggshell membrane. All these systems have at least one common characteristic, namely their absorptive surfaces, and (in the case of living microorganisms within the cell structure) have at least one chemical moiety (functional group) that has an affinity for metal(s). This affinity can be accomplished by active and passive mechanisms that may act singly or in combination. The mechanisms can be microbiologically dependent, for example active transport across the cell membrane, or physicochemical and chemical-dominated reactions such as adsorption, cation exchange, complexation, chelation and precipitation. Essentially, active transport is a function of living cells, such as bacteria, algae and fungi. The remainder of the mechanisms are passive and may occur with living or dead cells or with other biomass.

Passive uptake mechanisms generally occur at the cell wall level (see Table 1) and the biomasses involved are generally tolerant to their environment. In their interactions with metals, dead cell systems and biomaterials behave as surrogate ion exchange materials. Ion exchange is a proven commercial technology that is widely used for the removal of metals from various liquors. Where major differences occur between biosorption and conventional ion exchange is when living microorganisms are involved, which results in the participation of other metal-removal mechanisms.

The basis for these differences and also for variations in metal-accumulation abilities is partly the result of cell surface characteristics. Microbial cell

Table 1 Cell wall metal functional groups

Cell wall functional group	Metal affinity
Carboxyl	Ca, Mg, Cu, Zn
Imidazole	Cu, Pb
Sulfhydryl	Zn
Amino	Co, Ni, Cu
Phosphate	Ca, Mg, Fe, U
Sulfate	Ba, Ca, Sr
Thioether	Cu(I)
Amide	Cu, Co, Ni, Fe
Hydroxyl	Ca, Pb, Cu, Sr, Ba, Ni, Co, Zn

Table 2 Cell wall macromolecules

Cell wall macromolecules	Microorganism
Polysaccharides, proteins, lipids, peptidoglycan	Bacteria
Mannan polysaccharides, chitin, galactosamine, proteins, lipids	Algae and fungi

walls are complex and are normally charged. Certain cell wall properties, such as the type of polar groups present and the charge within the cell wall macromolecules, may influence the metal capacity and selectivity. The types of macromolecules present in cell walls for bacteria, fungi and yeast are shown in Table 2.

Classification of bacteria, algae and fungi is based on aspects other than cell wall composition. Living organisms can be divided into two groups, prokaryotes and eukaryotes, based on cell structure. Bacteria belong to the prokaryote group, while algae and fungi belong to the eukaryotes. Further simple distinctions are that bacteria lack a nucleus and membrane-bound organelles and most bacteria have cell walls. Bacteria are without question the oldest and simplest organisms. Eukaryotic organisms have both a nucleus and membrane-bound organelles. Fungi are distinct from algae in that they have filamentous growth, lack chlorophyll and motile cells, and have chitin-rich cell walls (Figure 2).

Although these simple descriptions may be helpful in understanding the different behaviour of bacteria, fungi and algae with metals, they are by no means rigorous biological definitions, and the purist microbiologist may find them too superficial. It is probable, however, that the more rigorous and sophisticated explanations have contributed to the restrictive use of biotechnology in the environmental arena. This point will be discussed in more detail later.

Figure 2 Chemical structure of (A) chitin and (B) chitosan. (Hardman DJ, McEldowney S and Waite S (eds), *Pollution: Ecology and Biotreatment* (1993), p. 284, Addison Wesley Longman Ltd, UK.)

The complex nature of cell walls bestows some unique abilities on living microorganisms and to a lesser extent dead cell systems and biomaterials. Equally this complexity confers some serious drawbacks, as modelling of metal-removal mechanisms and predicting process efficiencies are extremely difficult when more than one metal functional group is available.

Notwithstanding these reservations, numerous microorganisms and biomaterials have been evaluated for a diversity of metals by many scientists worldwide. Some of the more definitive work is discussed in the following sections.

Dead Cell Systems and Biomaterials

Dead cell systems can be derived from living cells by subjecting them to a physical or chemical method to terminate the living cell metabolic activity. As growth conditions can confer some metal affinity characteristics on living cells, it is prudent to explain briefly the growth phase and the various parameters that may be controlled to achieve the desired goal. The more important growth phase conditions that can confer metal adsorption characteristics are:

1. time of cell harvesting;
2. composition of nutrient medium.

The growth of bacterial populations is normally limited either by the exhaustion of available nutrients or by the accumulation of toxic products of metabolism. This is particularly true for batch growth conditions. As a consequence, the rate of growth declines after the exponential phase and growth eventually stops. At this point a culture is defined as being in the stationary phase (Figure 3). The transition between the exponential phase and the stationary phase involves a period of unbalanced growth during which

Figure 3 Generalized growth curve of a bacterial culture. Stanier RY, Ingraham JL, Wheelis ML and Painter PR (eds) *General Microbiology* (1986), 5th edition, p. 185, Prentice-Hall Inc, NJ.)

the various cellular components are synthesized at unequal rates. Consequently, cells in the stationary phase have a chemical composition that is different from that of the cells in the exponential phase. In general, cells in the stationary phase are small relative to cells in the exponential phase and they are more resistant to adverse physical and chemical agents.

Bacterial cells held in a nongrowing state eventually die, largely due to the depletion of the cellular reserves of energy. When cells are transferred from a culture in the stationary phase to a fresh medium of the same composition they undergo a change of chemical composition before they are capable of initiating growth. This period of change is called the lag phase.

Culture age affects the biosorption properties of microorganisms. For example, younger cells (12 h growth) of *Saccharomyces cerevisiae* removed approximately five times more uranium than older cells (24 h-growth).

The surface charge of living cells can vary both their age and with the nature and composition of the growth medium. With respect to metal adsorption, surface charge will have a predominant, if not the prime, influence. The cell wall surface charge is itself strongly affected by the pH value of the growth medium. This pH influence is due to the different ionogenic groups at the cell surface being susceptible to protonation/deprotonation reactions. Experimental evidence involving bacterial cells shows that carboxyl groups are present in excess over amino groups, and thus they dominate electrokinetic behaviour.

Physical methods that have been used to kill living cells include vacuum and freeze drying, boiling, autoclaving and mechanical disruption such as ultrasonics. Chemical methods include contacting the cells with various organic and inorganic compounds. The main aim of controlling the growth conditions coupled with the appropriate killing stage is to produce a biomaterial that has metal affinity properties superior to those of the parent living cell. The advantages of dead cells over living cells are:

- the metal removal process is largely independent of toxicity limitations;
- there are no requirements for growth media and nutrients;
- biosorbed metals can be eluted and the dead cells re-used;
- there is an ample and ready supply of some biomasses (dead cells);
- pretreatment of the biomass can enhance the metal biosorptive characteristics;
- the process is simpler and akin to ion exchange;

Table 3 Pretreatment methods to improve metal selectivity

Biomass type	Pretreatment method	Metal studied
<i>Penicillium digitalum</i>	0.1 mol L ⁻¹ sodium hydroxide	Ni, Cu, Zn, Cd, Pb
	Contacted with dimethyl sulfoxide for 90 min	U
	Trichloroacetic acid	U
<i>Saccharomyces cerevisiae</i>	10% (v/v) nitric acid, 30 min boiling	Cu
	10% (w/v) formaldehyde	Cd, Zn
	Detergent	Th
<i>Aspergillus niger</i>	Freeze-dried	U
	5% KOH	Cu, Cd, Zn, Co, Ni

- disposal of spent and/or excess nutrient media or surplus cells does not present a problem;
- the shelf-life of the dead biomass is nearly infinite.

If the required metal affinity characteristics have not been achieved at the harvesting stage and by the process used to kill the living cells, the dead biomass can be treated to enhance the key metal biosorptive properties such as metal capacity, metal selectivity and rate of uptake.

In Table 3 are reported some of the pretreatment methods employed and their effect on metal removal. Alkali treatment of fungal biomass has been shown to increase significantly the metal sorption capacity of *Aspergillus*, *Mucor* and *Penicillium*, and deacetylation of chitin in the cell wall to form chitosan–glucan complexes results in higher affinity for metal ions.

In what follows dead cell systems and biomaterials will be regarded as being equivalent, but any specific subtle differences will be highlighted. The biomaterials that have attracted most attention are those that are readily available in significant quantities, with or without pretreatment to enhance their metal uptake capability. To date these materials have included: peat, lignates, seaweed waste (dealginated seaweed), yeast from brewing operations, algal and

fungal biomasses and activated carbon from a variety of sources.

The last material is presently used commercially in the treatment of water for the removal of nonmetallic species; numerous papers have been published on the uses of activated carbon. In evaluating the above materials one feature regularly considered has been their particle size and the implications to scale-up. In their behaviour to metals these materials resemble ion exchange resins, which are invariably packed into columns. Thus laboratory studies have included the immobilization of biomaterials into particles of appropriate shape and size. Spherical particles 1–3 mm in diameter appear to be acceptable.

As the metal-removal processes are passive and of a chemical/physicochemical nature, the parameters considered are like those for ion exchange, namely pH, temperature, competing cations and metal speciation. These parameters are equally important to metal removal by living cell systems. Without doubt, pH is by far the most dominant influence on metal uptake. The optimal pH values for a variety of metals and biomaterials are presented in Table 4.

The efficiency of metal removal by the biomaterial as a function of pH will be related to: (1) the functional group involved and (2) metal speciation chemistry. At low pH values, i.e. about 3 or less,

Table 4 Optimal pH values for metal uptake by various biomaterials/microorganisms

Biomaterial / microorganism	Optimal pH value for metal removal	Metal(s)
Peat	1.5	Cr(vi)
	5.0	Cu(II)
	7.0	Ni(II)
Seaweed	4.0	Au
	5.0–6.0	Cu, Zn, Pb, Cd, Cr, Ni, Fe
<i>S. cerevisiae</i>	1.5	Mo(v)
	3.0–4.0	U(vi)
<i>Penicillium digitatum</i>	7.0	Cd
<i>Bacillus subtilis</i>	4.1	U
<i>Chlorella salina</i>	4.0	Tc(vii)
	8.0	Co

metal(s) uptake will be comparatively low as the metal(s) will be in competition with the hydrogen ion and most functional groups with an exchangeable hydrogen ion will be undissociated. On increasing the pH, competition with the hydrogen ion diminishes, dissociation of the hydrogen of the functional group increases and the speciation of the metal(s) changes from being a hydrated cation to hydroxy metal species thus:

This progressive displacement of the inner sphere of water molecules with increasing pH results in the metal ion becoming more amenable to adsorption by the biomaterial.

Temperature increases within a modest range, i.e. 20°C to 60°C, have little or no effect, either thermodynamically or kinetically, on metal removal for most biomaterial and metal systems. In general, optimal metal uptake will occur at 25°C for most dead cell systems and at a similar value (25–30°C) for biomaterials.

Metal affinity by many dead cell systems measured using single metal systems has been shown to comply with the Irving–Williams series. Most dead cell systems exhibit selectivity for heavier metals, such as Zn, Cu and Ni, over the lighter alkali metal ions. The selectivity of dead cell systems and biomaterials for a particular metal is highly dependent on the pH value of the solution under investigation and the functional group involved in the metal adsorption process. The determination of metal selectivity for dead cell systems and biomaterials is complicated in that more than one functional group may be involved in the biosorption process. These interactions (biosorption processes) may operate independently or may be interrelated. For example, Tsezas and Volesky indicated that three mechanisms are operative in uranyl ion biosorption by *Rhizopus arrhizus*. Two of the mechanisms occur simultaneously and rapidly (< 60 s to equilibrium). In the first process, uranyl ions coordinate with the amino nitrogen of the cell wall chitin, facilitating the second process in which the complexation sites acted as nucleation points for deposition of additional uranium. These two mechanisms accounted for 66% of the total uptake capacity (0.05 mmol U per g cell dry weight). The third process is considerably slower, only reaching equilibrium after 30 min, and involves the precipitation of uranyl hydroxide within the cell wall microcrystalline chitin.

Although most of the available literature is concerned with single metal experiments, a limited num-

ber of studies have involved binary metal systems or multimetal solutions. These studies demonstrate that copper generally has the highest binding capacity and exerts the largest competing effect.

The presence of anions in the metal solution under consideration will have an impact on metal biosorption, depending on the concentration of the anion and its metal-complexing ability. The more common anions, such as nitrate, chloride and sulfate, rarely affect the biosorption of metals when in near stoichiometric concentrations to the metal. Increasing their concentration will affect the biosorption (lower it), but this will depend on the ability of the metal to form anionic species. When the anion species such as EDTA²⁻, phosphate, citrate, etc., is capable of coordination/complexation with the metal, the metal capacity will be strongly reduced.

Living Cell Systems

Living cells systems offer some unique and subtle metal-accumulation mechanisms not possible with dead cell systems, biomaterials or conventional ion exchange resins. These active metal-accumulation mechanisms, in addition to the passive ones, are generally coupled with the metabolic activity of the algal, bacterial, fungal living cells.

Many organisms have developed detoxification mechanisms to overcome the detrimental effects of metals. For the purpose of this article two mechanisms will be taken as predominant, namely bioaccumulation and bioreduction. Although these mechanisms are generally encompassed by the term biotransformation, this terminology is far more appropriate to the treatment of organic pollutants using microorganisms, as these pollutants can be biodegraded to benign metabolic end products such as carbon dioxide and water. Metals are persistent and their toxicity is infinite. Microorganisms can only affect their physical and/or chemical state and transform them into more immobile forms that are less bioavailable to plants and other higher organisms. In achieving the biotransformation of metals, microorganisms are behaving as minute chemical factories generating chemicals, for example hydrogen sulfide, alkali and inorganic phosphate, or providing electrons from interconnected redox processes. These processes are summarized in Table 5. One process in particular will now be described in more detail.

In the natural environment the major mechanism for bacterial metal precipitation is through the formation of hydrogen sulfide and the immobilization of metal cations as metal sulfides. The bacteria involved in this process are the sulfate-reducing bacteria including members of the genera *Desulphovibrio*

Table 5 Metal bioaccumulation and bioreduction processes

Process	Metal-removal mechanism	Microorganism
Bioaccumulation	Sulfide precipitation	Sulfate-reducing bacteria
	Phosphate precipitation	<i>Citrobacter</i> sp.
	Hydroxide precipitation	<i>Alcaligenes eutrophus</i>
Bioreduction	Hydroxide/oxide precipitation	<i>Shewanella alga</i>
	Sulfide precipitation	Sulfate-reducing bacteria

and *Desulphotomaculum*. Sulfate-reducing bacteria (SRB) are widely distributed in anaerobic environments such as sediments and bogs. Sulfide production by sulfate-reducing bacteria is a consequence of their energy-generating processes. They couple the reduction of oxidized forms of sulfur, e.g. sulfates and sulfur, with the oxidation of reduced carbon in the form of simple organic molecules such as lactose or ethanol. The optimal chemical environment for effective sulfate reduction to sulfide is a pH value between 5.5 and 6.5 with a negative redox value of about 200–400 mV.

One of the underpinning features for the effectiveness of a SRB metal-removal process is the extremely low solubility product value for metal sulfides, as reported in Table 6. Other process advantages are:

- removal of metal anions such as chromate with initially the reduction of Cr(VI) to Cr(III) by the biogenic hydrogen sulfide;
- the ability of the microorganisms to nucleate the sulfide precipitation and thus assisting in the coagulation of metal sulfide particles;
- maintaining (slightly increasing) chemical neutrality of the process sulfate liquor due to the carbonate formed from oxidation of lactose or ethanol, or other suitable carbon sources, and sulfide from reduction of sulfate;
- the ability to remediate inorganic pollutants, for example toxic heavy metals and sulfate, as well as organic pollutants.

Table 6 Solubility product values for metal sulfides and hydroxides at 25°C

Metal	Hydroxide	Sulfide
Ag	2×10^{-8}	1.6×10^{-49}
Cu(II)	1×10^{-20}	8.5×10^{-45}
Zn	1×10^{-17}	1.2×10^{-23}
Ni(II)	1×10^{-15}	1.4×10^{-24}
Co(II)	1×10^{-15}	3.0×10^{-26}
Fe(II)	1×10^{-15}	3.7×10^{-19}
Cd(II)	1×10^{-14}	3.6×10^{-19}

These advantages may have been behind the development by Shell Research Ltd. of a biological process in preference to chemical ones for the removal of zinc, cadmium and sulfate from contaminated groundwater accumulating below a zinc smelter site. This process is the only biological metal-removal system employing specifically SRB operating on a commercial scale. The reasons for this unique situation is addressed in the next section.

The active metal biotransformation processes that rely on the precipitation of the offending metal(s) are not selective. The microorganisms require carefully controlled conditions both for their growth and to maintain enzyme activity, which are usually pH values ranging from 5.0 to 7.0, slightly aerobic 0 to +200 mV or anaerobic –200 mV to –400 mV.

Metals capable of forming insoluble hydroxides/oxides, phosphates or sulfides will precipitate effectively under these conditions. Consequently, competing cations that form such insoluble materials are only a problem in that they consume the precipitant, which in turn generally requires more carbon substrate. Interfering anion conditions will apply, similar to those already discussed above.

Although dead and living cell systems have been shown to have some unique capabilities for metal removal, the transfer to commercial technology has been very limited. The reasons for this will now be discussed.

Engineering and Process Considerations

Although dead cell systems, biomaterials and living cells have some distinct advantages compared with conventional ion exchange resins in the removal of metals from aqueous waste liquors, the number of recorded pilot-plant and commercial processes is extremely small, as illustrated in Table 7.

It would appear that even the rapid metal uptake by dead cell systems (less than 60 s for outer wall adsorption) combined with potentially cheap biosorbents and greater versatility of living cell systems such as SRB, capable of accommodating more than one

Table 7 Biological metal-removal pilot plants and commercial facilities

Process	Biomaterial/ microorganism	Target metal(s)	Process conditions
AMT-Bioclaim	<i>Bacillus subtilis</i>	Pb, Zn	Pilot plant (PP) Capacity 20 BV h ⁻¹ Columns 18 L BV ⁻¹

BV, bed volume; USAB, upflow anaerobic sludge blanket reactor.

pollutant such as sulfate and metals, are generally insufficient to convince potential users to install, or even consider, a biological process in preference to a chemical/physicochemical process.

In considering process technologies for removal of metals from waste liquors, certain criteria need careful and critical appraisal. These process criteria and their implications to biological systems are briefly reviewed.

Robustness

Dead cell systems and other biomaterials exhibit similar robust chemical properties to conventional ion exchange resins. They lack equality, however, because of their mechanical properties. Living organisms are significantly less robust as it is crucial to maintain cell growth and/or metabolic activity, which requires a carefully controlled environment. It is however possible, by judicious design, to arrange the biological stage of the process remote from and/or independent of the metal removal stage.

Selectivity

The metal selectivity of dead cell systems and biomaterials can be significantly improved by a variety of chemical treatments, but obviously at a cost and in some instances to the detriment of other process considerations, e.g. chemical treatment may result in a lowering of the total metal affinity.

However, metal selectivity may not be a prime consideration as effluents often contain several offending metals, in which case living cell systems are more appropriate as they are less discriminatory.

Compatibility

By definition effluent treatment processes have to be compatible with upstream, and in some instances downstream, operations. In many circumstances the compatibility requirement is exacerbated as effluent processes are retrofitted. Chemicals used in the biological metal-removal processes such as regeneration liquors for dead cell/biomaterial systems and excess sulfide and/or carbon substrate in SRB processes will require careful examination, in particular when water from the treated effluent is to be recycled.

Reliability

Site effluent treatment systems operate continuously, virtually 365 days a year. Biological processes are equal in reliability to their chemical competitors but may require greater control to ensure that environments are maintained, in particular for living cell metal removal processes.

Reliability can be enhanced by the installation of duplicate facilities and/or buffer storage, but with a cost penalty.

Simplicity

Modern automation has allowed effluent treatment facilities to be left unattended for significant periods. The greater the simplicity of metal removal, the lower the automation requirements. Dead cell/biomaterial systems are no more complicated than ion exchange resin processes, but this is not the case for living cells. Ensuring the activity of appropriate enzymes requires added process considerations.

Predictability

At the outset, effluent treatment designers will have to be confident that appropriate scientific and engineering information is available to meet all eventualities, in particular maloperation of the facility and the environmental impact this may have.

When more than one metal-removal mechanism may be participating, either synergistically or antagonistically, such information may not be readily available. Even when this information is available, predictability becomes more complex and difficult. Dead cell/biomaterial systems may fall into this category.

Efficiency

The biological process should have high metal-accumulation capacity and accumulation should be sufficiently rapid and efficient to compete with those of conventional technologies. In order to be competitive, the process should remove at least 99% of the target metals. There is clear evidence that biological systems can compete in efficiency with existing technologies, some reaching a sorption capacity of greater than 200 mg per g dry weight of dead cell systems.

The rate of heavy metal accumulation by biosorbents also compares favourably with existing separation techniques.

Versatility

Since waste streams are highly variable, the efficiency of metal removal should ideally be unaffected by other waste stream constituents and should be relatively stable to variations in pH. This presents one of the biggest challenges in the development of liquid waste treatment. The effect of pH on metal removal is often significant and varies with the biomass and metals. The presence of inorganic and organic components other than the target metal or metals common in waste streams. Such components have often been found to alter the efficiency of sorption. There are several possible mechanisms for this effect, ranging from direct competition for the binding sites resulting in lower uptake of target metal(s), to organic pollutants forming soluble complexes with metal(s) and thus reducing removal efficiency.

Economics

The dead cells/biomaterials and living cells should be cheap to grow and/or harvest. Clearly it is economically desirable to utilize waste biomass or material from other processes since the production cost will be

Table 8 Sources of waste biomass for use in heavy metal removal

<i>Waste biomass</i>	<i>Source</i>
Activated sludge, digested anaerobic sludge	Wastewater treatment
<i>Saccharomyces cerevisiae</i> (yeast)	Brewing
<i>Bacillus subtilis</i> (Gram-positive bacterium)	Enzyme production
<i>Penicillium chrysogenum</i> (fungus)	Penicillin production

reduced. Waste biomass is produced from a number of industrial processes (Table 8) but the use of waste biomass should not, however, be at the expense of process efficiency.

Realizing the Potential of Biosorption/Bioaccumulation of Metals

The understanding of the interactions of microorganisms with metals for a variety of applications such as health care, environmental protection and process technology (biocatalysis) has been pursued for nearly half a century. In this time numerous microorganisms have been isolated, characterized and evaluated for a diversity of metals. Notwithstanding this colossal effort, to date there are few installations, possibly no more than five major ones, that use microorganisms (excluding activated sludge processes) to remove and/or recover metals from waste waters/liquid wastes. Why is this? First, we need to consider what microorganisms are capable of – they are no different to their chemical counterparts, in that they cannot, for example, convert lead to gold or ‘eat’ plutonium! The perception of microorganism capabilities for dealing with metal pollutants is for the nonbiologists clouded by the great successes, reported worldwide, that these minute chemical factories have secured in dealing with oil spillages and land contaminated with a variety of organic pollutants. Without a doubt the microbial degradation of such pollutants is truly the ‘green ticket’, assuming of course that these pollutants are ultimately and quickly degraded to carbon dioxide and water.

One major reason hampering potential is the approach taken by microbiologists. In the past, and in many instances even today, screening for new microorganisms has been a major preoccupation and many person-years effort are expended in the laboratory with little thought as to how these microorganisms can/will be engineered into a technological process. The interaction between microbiologists and

workers in other scientific disciplines, in particular chemists, is now more strongly evident, largely because an array of scientific techniques is needed to characterize the microorganisms. The involvement of engineers is still lacking and consequently key questions are missed or omitted when considering the potential of microorganisms to treat complicated waste streams. Many engineers are surprised at the microbiologist's approach in tackling a seemingly new pollution problem. The technique of screening the polluted environment for thriving microorganisms is logical to the microbiologist, but curious to the engineer, who may not understand the subtleties of genera and strains.

It is this fusion of scientific and engineering approaches that is needed to enable bioremediation, and hence environmental biotechnology, to achieve its true potential.

Environmental legislation is now stringent and is likely to become even more so in the future. In this situation it is important not only that the process technology is understood, but also that the implications and consequences of perturbations to this technology can be accurately predicted. With environmental processes perturbations will undoubtedly arise, as to date there is no specification for effluents that is definitive.

Unfortunately, in the present commercial environment, the quest for scientific knowledge is too often perceived as no longer valuable or affordable. In this respect the success of biotechnology in other areas, e.g. pharmaceuticals, may well have a positive benefit to other markets, persuading nonscientists that knowledge and intellectual property is valuable and ignorance is unaffordable.

Classification and Characteristics of Metalloproteins

Metals are known to play essential roles in catalysis, macromolecular structure and membrane stabilization as well as hormonal and genetic regulation. Metals present at very low concentrations in tissues and biological fluids are termed oligoelements. Usu-

ally they do not occur in the biological matter as free ions, but as metal-protein complexes. The term metalloprotein is used to define a large group of proteins containing one or more atoms of metal bound to specific sites in the polypeptide chain. The binding sites on the protein are provided by histidine nitrogens, glutamate or aspartate oxygens and cysteine sulfurs; the metal ligand is usually represented by calcium, selenium, iron, zinc, copper and other heavy metals.

Metalloproteins can be divided into two groups: biologically active metalloproteins and proteins with

no apparent biological activity. The first ones include metalloenzymes and zinc-containing DNA-binding proteins. Metalloenzymes are particularly suited to studies on metal-protein interaction aimed at a better understanding of the enzymatic mechanisms; their activity is measured by means of specific assays with an appropriate substrate. The metal can either stabilize the protein structure or be part of the active catalytic site; sometimes distinct atoms of the same metal may have structural or catalytic roles, depending on the site to which they are bound.

Metalloproteins that do not exhibit biological activity can be isolated by simply monitoring the metal. The most widely used technique for metal determination is atomic absorption spectrometry (AAS); however, alternative methods are also available, such as flame atomic emission spectrometry, plasma emission spectrometry, differential pulse polarography and the neutron activation analysis.

Metalloenzymes

Metalloenzyme Preparation

Metalloenzymes are widely represented in almost every group of enzymes. The methods used for the purification and separation of these enzymes from other components do not differ substantially from those usually employed for enzymes not containing metals as prosthetic groups. These methods include techniques such as gel permeation, ion exchange, affinity chromatography and high performance liquid chromatography (HPLC). The reader is referred to these specific topics for details on the chromatographic techniques.

The purification strategy varies from one enzyme to another; however, an effective procedure for some enzymes is affinity chromatography. Alcohol dehydrogenase, for example, can be extensively purified by affinity chromatography based on the interaction of the coenzyme with a Blue A column and subsequent elution of the enzyme with NAD^+ .

Good recovery of the metalloenzymes from chromatographic columns may depend on the precautions adopted during the separation procedures. In particular, special care is required to preserve the integrity of the metal-protein complex during chromatography by avoiding conditions that may affect metal binding. A loss of metal can occur in the presence of chelating agents such as ethylenediaminetetraacetic acid (EDTA) or as a result of decreasing the pH of the medium. Buffer complexation with metals may also affect metalloenzyme stability. The use of inorganic buffers should be avoided as they may remove metals

essential to enzymatic activity. To avoid problems of metal chelation, the use of Good buffers (made of *N*-substituted taurine and glycine) is useful. Certain substances usually added to protein solvents may affect the metal binding; high concentrations of reducing agents such as dithiothreitol may remove metals with low binding affinity. In these cases, the best choice is to use 0.5% (v/v) mercaptoethanol as a reducing agent, as this substance does not remove metals.

Separation of Protein and Metal Moieties

Metal-free enzymes are well-suited to the study of the interaction of protein and metal ions and the effect of such interaction on the structure and function of the enzyme. Separation of metal from protein is easily performed using chelating agents at a pH between 5.5 and 7.5. The most commonly used chelator for apoenzyme preparation is 1,10-phenanthroline, but it is a good rule to test several chelating agents for their efficacy. A list of chelating agents used to remove the metal from various metalloenzymes is given in Table 1. The use of EDTA as chelator is not recommended because it binds to protein and laboratory glassware; if its usage cannot be avoided, it is advisable to add a trace amount of ^{14}C -EDTA to check its complete removal.

The procedure for apoenzyme preparation requires that the enzyme, at a concentration of 0.1–1 mmol L^{-1} , is dialysed against several volumes of chelator solution with several changes. Dialysis tubings may contain heavy metals, hence they should be heated at 70–80°C for 2 h in metal-free water (see below) before use. Metal-free dialysis membranes (Spectra/por) are also commercially available. The chelator is removed by extensive dialysis against metal-free buffer (see below). If 1,10-phenanthroline or 8-hydroxyquinoline is used to chelate the metal, their removal can be monitored by following the optical densities of the dialysate, because these

Table 1 Chelating agents commonly used for the preparation of metal-depleted enzymes

substances absorb light. The chelator can also be removed by gel filtration chromatography. A suitable chromatographic system is represented by a Bio-Gel P polyacrylamide pre-loaded column (Bio-Rad). For most proteins, an exclusion limit of 6000 may allow recovery of the apoenzyme in the void volume with little dilution of the sample.

An alternative procedure for apoenzyme preparation is provided by the use of Chelex 100. The sodium form of the resin, previously equilibrated in metal-free buffer, is mixed with the metalloenzyme solution at a ratio of about 20% in volume. If the metal is essential for catalytic activity, a time-dependent loss of enzyme activity may be observed during the treatment with Chelex 100. The advantage of this method is that the apoenzyme so prepared can be stored in the presence of the resin, thus avoiding its reactivation by adventitious metals.

In order to maintain the protein in a metal-free form, it is important to minimize the presence of contaminating metals. One of the first precautions for preventing an unwanted reassociation with metals is the use of metal-free water in all purification and separation procedures. Ultra pure water suitable for apoenzyme preparation can be obtained by repeated distillation or by using a Milli-Q apparatus (Millipore). The latter system can supply water with a metal content below the detection limits of sophisticated analytical methods such as AAS, provided the cartridge is changed frequently.

Although metal-free water is indispensable, sometimes its use is not sufficient to eliminate contamination unless polystyrene metal-free containers are used for its storage. Of course, even the use of high purity water will not avoid unwanted problems if reagents, glassware and buffers themselves are sources of contamination. The use of polystyrene labware must be preferred in place of polyethylene and polypropylene, because these may be sources of metal ions. The ubiquitous presence of metals such as zinc, mercury, iron and aluminium in many laboratory reagents is another factor that has to be controlled. It is advisable to remove these metals from buffers and solutions before using them in separation procedures. The most widely recommended methods for eliminating metals from aqueous media are dithizone extraction or treatment with a chelating resin.

Dithizone (diphenylthiocarbazone) is used as a complexing reagent to remove heavy metals from aqueous solutions by exploiting its high solubility in organic solvents compared to the low solubility in water. Dithizone may be recrystallized by dissolving 2 g of substance in 100 mL chloroform. The volume of this solution is then reduced to one-half by evaporation under a nitrogen stream. The crystals are col-

lected by filtration, washed with carbon tetrachloride and dried under vacuum. All the manipulations with organic solvents must be carried out in a hood. The solution to be extracted is shaken for 5 min with 0.1 vol of a freshly prepared dithizone solution (0.02% in chloroform) in a separatory funnel equipped with a Teflon stopcock (do not grease the stopcock). The extraction procedure must be repeated several times with different aliquots of dithizone solution. At the end, any trace of organic solvent present in the aqueous phase is removed under reduced pressure. This procedure works very well for ions such as Zn^{2+} , Cd^{2+} , Co^{2+} , Cu^{2+} , Fe^{2+} and Ni^{2+} , but is not as effective for Mn^{2+} . In addition, dithizone extraction cannot be used with buffers with a pH above 8, because at this pH dithizone solubility in water increases.

An alternative method uses a column of Chelex 100 as metal chelator. The resin is washed with 2 vol of 0.5 mol L^{-1} HCl, 5–6 vol of water and 2 vol of 0.5 mol L^{-1} NaOH. After a final wash with 5 vol of water, the resin is packed in a chromatographic column. The buffer to be demetallized is passed through the column at a flow rate of $10\text{--}20 \text{ mL min}^{-1} \text{ cm}^{-2}$, and collected after several bed volumes have been discarded.

Metalloproteins with no Enzymatic Activity

Detection of Metal-binding Proteins in Chromatographic Eluates

Most of the metalloproteins lacking catalytic activity are metal-binding proteins. In general, these molecules are characterized by a high metal-to-protein stoichiometry: usually from 4 to 7 atoms of heavy metal are bound to cysteinyl, glutamyl, aspartyl residues of the polypeptide chain. The best known among the metal-binding proteins are metallothioneins (MT), a family of cysteine-rich low molecular weight polypeptides present in all animal phyla, as well as in fungi, plants and cyanobacteria. Mammalian MT are single chain proteins made of 60 amino acids, including 20 cysteines arranged in two domains of metal-thiolate clusters containing 7 equivalents of metal (usually zinc, copper or cadmium).

Purification and separation of metal-binding proteins are performed by column chromatographic procedures, generally involving gel permeation and anion exchange methods and HPLC. As many metal-binding proteins do not exhibit evident biological activity, a widely used technique for monitoring chromatographic eluates is the determination of the metal by AAS. Flame AAS is mostly used for samples

in solution, provided the analyte concentration is in the order of p.p.m. (1 p.p.m. = 1 mg L⁻¹) and enough volume of sample (at least 1 mL) is available for analysis. If the analyte concentration is in the range of p.p.b. (1 p.p.b. = 1 µg L⁻¹), or if one wishes to minimize the volume of sample to be employed in the analysis, the technique of choice is the furnace AAS.

This technique, initially proposed by L'vov, became commercially available in 1969. A small amount of sample (20 µL) is introduced in a graphite furnace that is rapidly brought to high temperature by electrical heating. The sample is converted in atomic vapour and part of a light produced by a lamp containing the element to be analysed is absorbed by the analyte. In some cases, the sample is placed on a small platform added to the furnace to delay vaporization until the temperature within the furnace has reached a stable plateau. The addition of a matrix modifier may help to stabilize the analyte to high temperatures. A drastic reduction of the background influence is achieved by the Zeeman correction. The experimental conditions for the determination of the elements most commonly found in metalloproteins are reported in **Table 2** for graphite furnace AAS.

In general, the quantification of the MT-bound metal in chromatographic eluates does not require pretreatment of the sample such as digestion with oxidizing agents or ashing. However, the extent of matrix interference should be evaluated by measuring the absorbance of a known standard in the presence of the sample (internal standard technique). If metal concentration is high, interference may be reduced by appropriate dilution of samples. The determination of volatile elements such as cadmium and mercury requires the addition of a modifier (**Table 2**).

Separation of Metallothionein from High Molecular Weight Proteins

The procedure currently employed for MT isolation is gel permeation chromatography. In a typical preparation, 1 vol of an ethanol chloroform solution (1.05/0.08 v/v) is added dropwise to 1 vol of a tissue

extract, previously centrifuged at 100 000 g. After the precipitate is centrifuged at 20 000 g for 15 min, the supernatant is mixed with 3 vol ethanol prechilled at -20°C and maintained at the same temperature overnight. The resulting pellet, collected by centrifugation at 20 000 g for 20 min, is dissolved in 20 mmol L⁻¹ Tris/HCl buffer pH 8.6 and loaded on a Sephadex G-75 column equilibrated with 10 mmol L⁻¹ Tris/HCl pH 8.6. The column is eluted with the equilibration buffer and the eluate is monitored for metal content. Such a procedure is particularly suitable for low molecular weight proteins like MT, because these can be easily separated from the bulk of high molecular weight proteins. MT usually elutes at the level of standard cytochrome *c* (mol wt about 12 000) because of molecular asymmetry (**Figure 1**).

One should be aware, however, that the original metal composition of MT may be altered by the presence of adventitious metals. As zinc usually found associated with tissue MT can be exchanged for other heavy metals with higher affinity for thiol groups, such as cadmium and copper ions, that may be present as contaminants in chromatographic media or glassware, it is advisable to render these sources metal-free before use. The methods for removing heavy metals from buffers have been described above. It is advisable to wash the gel permeation column with 3 bed vol of 2 mmol L⁻¹ 1,10-phenanthroline to remove trace metals from the matrix. The column is then washed with metal-free buffer until disappearance of the absorbance at 320 nm.

Separation of Metallothionein Isoforms

Genetic polymorphism is a typical feature of metallothionein. One or more MT isoforms have been found in most animal tissues; their intracellular levels may vary from tissue to tissue. These isoforms are often very similar, with only a few amino acid substitutions in their amino acid sequences. Because they are so similar it is sometimes difficult to separate these proteins; however, if two isoforms have different

washed with the low ionic strength buffer and eluted with a linear gradient of NaCl.

A suitable procedure for separation of MT isoforms is HPLC, and this can be performed with various types of column systems. Conditions most usually applied for the HPLC separation of MT are given in Table 3. Since MT are converted in the corresponding metal-free apoforms at acidic pH, the use of neutral buffer systems is recommended. A suitable system is a μBondapak C₁₈ column eluted with a two-step linear gradient of acetonitrile in phosphate buffer (Figure 3).

Preparation of Metal-free Metallothionein for Metal Reconstitution

Metal substitution in MT is a common procedure to produce a complex with a defined metal composition for structural studies. It must be remembered that certain metals form complexes with different coordination numbers: while Zn and Cd in MT are tetrahedrally coordinated, Cu forms tridentate complexes. To perform metal substitution it is necessary first to prepare the metal-free MT. In doing so, it is recommended that adventitious metals in reagents and glassware are avoided by following the procedures described above.

Metal-free MT can be prepared by lowering the pH of the protein solution to 2. Under these conditions, the metal moiety dissociates from the protein; the apothionein is then separated from the metal by gel permeation chromatography on a Sephadex G-25 column. An acidified sample of about 5 mL containing approximately 15 mg of protein can be separated

Figure 3 Separation of rabbit metallothionein isoforms by reversed-phase HPLC. The separation was performed on a μBondapak C₁₈ column using a two-step linear gradient of acetonitrile in 10 mmol L⁻¹ NaH₂PO₄ pH 7.0 at a flow rate of 3 mL min⁻¹ (0–6% from 0 to 5 min, 6–15% from 5 to 20 min). The amount of purified MT used in each run ranged from 50 to 100 μg. Modified with permission from Richards MP (1991) Purification and quantification of metallothioneins by reverse-phase high-performance liquid chromatography. *Methods in Enzymology* 205: 217.

from the metal on a 2×20 cm column in 0.1% trifluoroacetic acid, by recovering the apothionein in the void volume. The addition of a reducing agent is not required as the sulfhydryl groups of cysteines are maintained in the reduced form as long as the pH is acidic. The apothionein so prepared can be stored at -80°C in an atmosphere of argon in a sealed ampoule. Prolonged storage should be avoided, as apothionein has a strong tendency to be oxidized. Anaerobic conditions are strictly required to prevent oxidation of the sulfhydryl groups with formation of large protein aggregates. The concentration of the demetallized protein can be determined by titrating the sulfhydryl groups with Ellman's reagent (5,5'-dithiobis(2-nitrobenzoic acid)), or by measuring the absorbance at 220 nm and assuming an extinction coefficient of $7.9 \text{ mg cm}^{-1} \text{ mL}^{-1}$ at pH 2. Metals such as zinc and cadmium are completely removed from the protein at low pH, but the procedure is not as effective for copper.

Removal of copper from Cu-thionein requires the use of chelating agents such as diethyldithiocarbamate (DTC). A solution of Cu-MT, brought to pH 5 by adding $30 \mu\text{L}$ of 3 mol L^{-1} acetate buffer pH 5 per mL of solution, is mixed with solid DTC (1 mg mL^{-1} of MT solution) and incubated at room temperature for 1 h. The colloidal precipitate of Cu-DTC is then removed by filtration on a $0.22 \mu\text{m}$ Millipore filter, and the filtrate containing the apothionein is desalted on a Sephadex G-25 column equilibrated and eluted with 0.1% trifluoroacetic acid.

Metal substitution is performed by mixing an argon-purged acidic solution containing 20 mg apothionein with 7–8 equivalents of metal (Zn, Cd, Hg, Bi or Pb). The solution is then rapidly titrated to pH 8.6 (7.6 for Pb-MT) with an oxygen-free solution of 0.5 mol L^{-1} Tris base under fast stirring. Immediately after titration, the solution is mixed with a small aliquot of a Chelex 100 suspension in 20 mmol L^{-1} Tris/HCl pH 8.6 (7.6 for Pb-MT) and stirred for 5 min. The resin is then removed by centrifugation and the solution is concentrated by ultrafiltration. MT is purified by gel permeation chromatography on a Sephadex G-50 column equilibrated and eluted with 20 mmol L^{-1} Tris/HCl pH 8.6.

Reconstitution with Cu(I) is more troublesome as this ion has a marked tendency to oxidation. A stable form of Cu(I) can be prepared by dissolving Cu_2O in acetonitrile containing 2 mol L^{-1} HClO_4 at 100°C . The solution is evaporated at room temperature to obtain crystals. Reconstitution is carried out by mixing apometallothionein with increasing amounts of a solution of Cu(I)-acetonitrile at pH 2 followed by titration to pH 7 with Tris/acetate buffer. The whole procedure must be carried out under anaerobic conditions.

Conclusions

Developments in the field of metalloprotein research are strictly related to any future progress achieved in protein separation techniques. For metalloproteins, the main goals are reduction in the amount of the biomass required for their preparation, and decrease in separation time. Large amounts of protein are expected to be produced by expanding the use of recombinant DNA techniques combined with effective separation procedures such as affinity chromatography. Immunochemical methods can be applied for the detection of small protein quantities present in chromatographic eluates, and can be particularly useful for proteins lacking enzymatic activity. Techniques coupling HPLC and AAS may contribute to decreasing the time gap between sample separation and metal detection.

MICROWAVE-ASSISTED EXTRACTION: ENVIRONMENTAL APPLICATIONS

G. N. LeBlanc, CEM Corporation, Matthews, NC, USA

Copyright © 2000 Academic Press

Speed and efficiency are always prime considerations of an analytical technique. In addition, we are seeing environmental considerations – ‘greening’ of methods – becoming another important factor. A solvent extraction technique that reduces extraction time, improves extraction efficiency and reduces solvent consumption by a factor of 10 is an important one. The latter is critical since it is estimated that about 100 million litres of organic solvent are used annually in organic analytical laboratories worldwide. The use of microwave heating for the extraction of compounds from a variety of sample matrices has been performed since 1985. This review article provides information on the development of the microwave-assisted extraction (MAE) technique, microwave instrumentation and its capabilities, and a perspective for extraction applications.

Development

Microwave heating was first introduced commercially in 1947. It took some time to catch on but it is now a standard item in most kitchens for cooking uses. Its use in the chemistry laboratory has significantly lagged behind domestic applications. Microwaves were first used in 1975 as a heating source for acid digestion under atmospheric conditions. The sample preparation step was reduced from 1–2 h to under 15 min, producing an overall reduction in analysis time. This work initiated the use of microwave energy as a heating source for the chemistry laboratory. Other applications include distillation, organic and inorganic synthesis, evaporation and solvent extraction.

The early applications for MAE were for the extraction of compounds with nutritional interest from

plant and animal tissues. From 1986 to 1990, Ganzler and co-workers published a series of four papers exploring the use of microwave energy to partition various compounds from soils, seeds, food and animal feeds as a sample preparation method prior to chromatographic analyses. The extraction step was performed under atmospheric conditions. They extracted a variety of compounds that included anti-nutritives, crude fat and pesticides. They used solvent schemes similar to their traditional Soxhlet technique to allow a direct comparison of the recoveries between the two techniques. The heating programme consisted of multiple 30 s microwave heating cycles (up to seven cycles) followed by a cooling step. This approach allowed observation of the samples in the microwave cavity to prevent sample boil-over.

The microwave extracts gave recoveries that were 100–120% of the Soxhlet technique. However, the MAE times were a factor of 100 less than the traditional Soxhlet approach. The authors postulated that improved extraction efficiency was due to the polar nature of the extracted compounds or the water contained in the materials. They also noted a decrease in extraction efficiency for the recovery of non-polar compounds when a nonpolar solvent was used.

The published work of Freitag and John in 1990 expanded the application and technique. These authors explored the use of microwave heating at elevated temperatures and pressure for the extraction of additives from polyolefins. The additives were anti-oxidants, Irganox 1010 and Irgafos 168, and the light stabilizer Chimassorb 81. The polyolefin matrices were polyethylene and polypropylene with a particle size of 20 mesh and a sample size of 1 g. The MAE was performed with 30 mL of 1,1,1-trichloroethane or a mixture of acetone and *n*-heptane. They obtained 90–100% recoveries of the additives with extraction times of 3–6 min without degradation of the analytes at the elevated temperatures of the extraction. This

compared favourably with the conventional 16 h Soxhlet or 0.5–2 h reprecipitation techniques.

Pare *et al.* from the Ministry of Environment of Canada introduced the microwave-assisted process (MAP™) through a US patent in 1991. In this work, Pare used microwave energy to extract a variety of essential components from natural products and foods, such as biologicals and consumer products. The primary examples are the extraction of essential oils from peppermint, garlic and cedar. The major feature of this work is the release mechanism for the compounds of interest from the substrate. The microwave energy was used to disrupt the glandular and vascular system of the tissue without damaging the surrounding tissue. The solvent was used to trap and dissolve the compounds released from the tissue.

In general, the mechanism involves localized heating of the free water present in the sample. Once the water is at or above its boiling point, the water causes the cell membrane to rupture. This water, as steam, transports the target analyte from the solid to the nonabsorbing solvent. In this type of work, the sample is a good dielectric while the solvent is a poor dielectric. The microwave process gave higher yields than the traditional steam distillation process. The authors postulated that the improved efficiency was due to the lower bulk temperatures and shorter extraction times.

In 1992, Bichi *et al.* published work from the pharmaceutical area based on MAE using closed-vessel technology with temperature-feedback control. They extracted pyrrolizidine alkaloids from dried plants using 25–50 mL of methanol. The extractions were performed over a temperature range of 65–100°C for 20–30 min. The MAE technique gave qualitatively and quantitatively identical chromatographic results relative to the samples extracted by the Soxhlet procedure with a significant reduction in extraction time and solvent consumption. The temperature feedback control provided highly reproducible extractions.

In 1993, Onuska and Terry published the first data on the use of MAE for pollutants from environmental samples. They successfully extracted organochlorine pesticide residues from soils and sediments using a 1 : 1 mixture of isooctane–acetonitrile using sealed vials. The samples were irradiated for five 30 s intervals. This produced faster and more reliable results than the conventional methods. They also studied the use of a nonpolar solvent, iso-octane, for the extraction of wet sediment samples. Pesticide residue recoveries increased as the moisture content increased to a maximum of 15% and then levelled off. This shows the importance of a polar co-solvent when using a nonpolar extracting solvent for MAE tech-

niques that are temperature-dependent. In 1994 Lopez-Avila *et al.* published their work to expand the use of MAE to 187 volatile and semivolatile organic compounds from soils. The compounds included polyaromatic compounds (PNA), phenols, organochlorine pesticides and organophosphorus pesticides. This work was performed using a temperature feedback-controlled microwave heating system with closed vessels. This demonstrated the viability of the technique for the extraction of many compounds of interest to the US Environmental Protection Agency with relatively small volumes of solvent and extraction times of only 10 min. This culminated in 1998 with the approval of the microwave extraction technique by the SW-846 Organic Methods Workgroup of incorporation into SW-846 as the latest of the 'green' methods.

In 1997 there were a number of significant extensions of the technology. Incorvia-Mattina *et al.* investigated the use of MAE to extract taxanes, used in ovarian and breast cancer research, from *Taxus* biomass. MAE offered significant time savings versus the standard shaking technique and improved yields versus synthetic approaches. Stout *et al.* combined MAE with liquid chromatography–electrospray ionization–mass spectrometry for the determination of imidazolinones in soils at concentrations of less than 1 p.p.b. McNair *et al.* reported the combination of MAE with solid-phase microextraction for the analysis of flavour ingredients at concentrations of 2–10 p.p.b. in solid food samples. This technique showed good selectivity for the target analytes in a variety of foods.

Instrumentation

MAE is the process of heating solid sample–solvent mixtures with microwave energy and the subsequent partitioning of the compounds of interest from the sample to the solvent. The most common approach is to perform the extraction in a sealed vessel that is microwave-transparent. This allows a temperature elevation significantly above the atmospheric boiling point of the solvent (Table 1) and hastens the extraction process.

The alternative approach is to perform the extraction in an open vessel at atmospheric conditions. This approach is common when the solvent is nonpolar or microwave-transparent and the sample is a biological or agriculture tissue that has a polar constituent, usually water. This is the basis for the patent issued to Environment Canada for the MAP™.

For the scope of this review article, we will limit the instrumentation discussion to the closed-vessel microwave heating system. In approaching MAE

Table 1 Solvent boiling point – closed vessel temperature comparison

Solvent	Boiling point (°C)	Closed vessel temperature (°C) ^a

^cUsing carboflon heating insert.

applications, it is first necessary to understand the analysts' objectives. These objectives include:

1. Selection of the optimum solvent for the analytes of interest.
2. Minimization of any steps prior to the extraction step.
3. The use of a minimum amount of solvent for the extraction step.
4. Effective and reproducible extraction conditions.
5. High sample throughput.
6. Safe operation.

Considering these objectives, a microwave-assisted extraction system was designed that was a derivative of the successful microwave acid digestion system. The key components are:

1. Microwave instrumentation
2. Solvent safety features

3. Vessel technology
4. Temperature control system
5. Indirect heating source (for heating nonpolar solvents)
6. Stirring mechanism

Each component is reviewed in terms of its technical merit and how it assists in meeting the analysts' objectives for the extraction step.

Microwave Instrumentation

Figure 1 shows the major components of the microwave system, including the magnetron, isolator, wave guide, cavity and mode stirrer. Microwave energy is generated by the magnetron, propagated down the wave guide and introduced into the cavity. The mode stirrer distributes the energy in various directions while the cavity acts as a containment housing for the energy until it is absorbed by the sample load within the cavity. The isolator protects the magnetron from

Figure 1 Microwave system components.

reflected energy that would decrease its power output. A good analogy is a one-way mirror – it allows energy to go from the magnetron to the cavity but will not allow it to go from the cavity to the magnetron. A turntable can be used to rotate the sample load within the cavity to ensure even energy distribution.

Microwave heating is significantly different from conductive heating methods. Conductive heating is sample-independent. All samples placed inside a conduction heating oven will equilibrate to the programmed temperature. This can take quite some time. Microwave heating is sample-dependent. The temperature rise rate of samples will depend on their microwave-absorbing characteristics. The microwave design provides the ability to heat uniformly a large number of samples in a short period of time based on the sample load characteristics.

Solvent Safety Features

Due to the flammable characteristics of many organic solvents, there is a major safety issue when heating a solvent in a microwave field. This safety issue is magnified when heating these solvents in sealed vessels at temperatures up to 100°C above their atmospheric boiling point. The microwave system should have redundant safety features, each acting as a backup to prevent possible fire or explosion from occurring inside the cavity. Instruments should be designed to eliminate possible ignition sources, to detect solvent leaks and to remove leaking solvent. **Figure 2** is an illustration of the interior of a commercially available microwave extraction system. The safety aspects are an exhaust fan which evacuates the cavity air

volume approximately once per second. If the exhaust fan fails or there is a block downstream of the fan, the air flow switch shuts down the system. The solvent detector monitors the cavity for the presence of solvent. The detector shuts the system down if solvent concentrations reach one-tenth of the lower explosive limit for acetone, sets off an alarm and posts a message for the operator. The cavity is Teflon-coated to minimize the potential of high energy discharges. The system door is designed to withstand an event equivalent to the explosion of 1 g of TNT. It will partially open, allowing gases to escape, and then the compression springs will pull it closed. This will contain any of the contents associated with a vessel-related event inside the system's cavity.

Vessel Technology

The closed vessels used for MAE are designed for temperatures up to 200°C and pressures of 200 psi (14 bar). The materials of construction for the components that are in contact with the sample-solvent mixture, either Teflon or glass, are inert to solvents. However, since these materials are relatively weak, an outer body is used that is much stronger – either a reinforced thermoplastic or a frame of polypropylene, or both. In addition, these materials of construction absorb a minimal amount of microwave energy. **Figure 3** illustrates a standard extraction vessel and a control extraction vessel. The vessels are composed of glass or Teflon liners, Teflon, PFA® seal cover, polyetherimide load disc and sealing screw, glass-filled polyetherimide sleeve and polypropylene support frame. The vessel has a built-in pressure relief

Figure 2 Safety exhaust and solvent detector.

Figure 3 (A) Exploded view of a microwave extraction vessel. (B) Cut-away view of microwave extraction vessels.

mechanism for safety purposes. If the pressure inside the vessel exceeds the operating limits, the vessel will automatically vent. The control vessel is modified to accept a probe to monitor and control the extraction temperature. A turntable of 14 extraction vessels is placed into the instrument's cavity for batch processing. The ability to rapidly achieve elevated solvent temperatures under controlled conditions for a large batch of samples is a major advantage of the MAE technique.

Temperature Control System

Temperature control is necessary to optimize the extraction efficiency, prevent thermal degradation

of the target analytes, and to provide reproducible operating conditions. This is achieved with a temperature measurement system that is microwave-transparent so it does not cause any self-heating. The temperature probe is inserted directly into the control vessel to measure the temperature of the solvent-sample mixture. It is then used in a feedback control loop to regulate the microwave power output to achieve and maintain the operator-selected extraction temperature. This approach provides temperature control for one of the samples in the batch and assumes equivalent reaction conditions for all the other samples. This control technique is augmented with an indirect infrared temperature measurement system. The infrared sensor is located underneath the cavity floor. It monitors the temperature of each vessel as it passes over the sensor. This temperature reading is correlated to the direct temperature reading from the control vessel to provide temperature data for all of the samples in the batch.

Indirect Heating Source

In some extraction applications, the solvent of choice for the target analytes is nonpolar and therefore does not heat when exposed to the microwave field. This would normally preclude the use of the MAE technique unless the analyst is willing to alter the solvent scheme to include a polar co-solvent. This is not desirable since it alters the extraction efficiency (or selectivity). This problem is overcome with the use of an insert that is a chemically inert fluoropolymer filled with carbon black, a strong microwave absorber. The insert is placed into the vessel with the solvent-sample mixture. The insert absorbs microwave energy and transfers the thermal energy it generates to the mixture. The performance characteristics of the heating inserts for heating with *n*-hexane in a microwave field are seen in Table 2. The use of the heating insert allows transfer of existing methods to the MAE technique without a change in the solvent scheme.

Stirring Mechanism

Stirring increases the surface area contact between the sample and solvent. This offers the benefit of improved extraction efficiency and decreased solvent consumption. Stirring is achieved with the use of a rotating magnet below the cavity floor and the placement of a magnetic spinbar in the extraction vessel. The magnet creates a rotating magnetic field that couples with the spinbar in the vessel to create a stirring effect. The spinbars are either coated with an unfilled fluoropolymer for applications using polar solvents or a carbon black filled fluoropolymer for applications with nonpolar solvents.

Table 2 MAE heating rate for *n*-hexane using heating insert

Temperature set point (°C)	Time to temperature (min)		
	1 Vessel	6 Vessels	12 Vessels
100	1:45	2:45	3:45
125	2:30	4:15	6:15
150	3:35	6:15	9:30

Notes: Each vessel contained 50 mL of *n*-hexane and 1 heating insert. The starting temperature was 25°C. As a point of reference, 12 vessels containing 50 mL of acetone will reach 125°C in 5 min under equivalent conditions.

These components create a system to perform MAE. This technique has the capability to reduce extraction time, reduce solvent consumption and improve extraction efficiency. However, it does not come without a cost. The extraction step is but one of many necessary steps to obtain the final analytical result. The analyst must take into account the differences in using the MAE technique versus their existing approach. The primary difference is the finished sample form. It is the same sample-solvent mixture originally placed into the vessel. The analyst needs to separate the sample from the solvent at the completion of the extraction step. If the analyst can work with an aliquot of the solvent for analysis, this objection can be overcome with the use of a syringe filtration technique. A secondary consideration is the vessel manipulations used with MAE. These manipulations will be new for the analyst.

Applications

MAE has been applied to a wide variety of samples in which traditional Soxhlet extractions are performed. Table 3 gives a performance comparison of MAE versus conventional extraction techniques for a variety of sample types. For the scope of this work, we will limit the application discussion to the extraction of plastics and polymers, pesticides and environmental samples.

Plastics and Polymers

The additive package used in the production of polyolefins is designed to improve processing efficiency or to impart specific performance characteristics. The package can contain antioxidants, antistatic agents, slip agents, anti-block agents, UV stabilizers or antifogging agents. It is important for production efficiency and product quality that the appropriate amount of each additive is present. A fast and reliable method is needed to determine the additive concentration level. The conventional extraction approach is a reflux technique with an appropriate sol-

vent for 1–48 h followed by high performance liquid chromatography (HPLC) analysis. An alternative extraction technique is sonication for 30–60 min, but the gain in speed is offset by a loss in extraction efficiency. MAE has the ability to address the time and extraction deficiencies of the reflux and sonication techniques. Freitag and John first demonstrated the potential for MAE when they obtained excellent antioxidant recoveries from polypropylene and polyethylene.

Pesticides and Herbicides

Pesticides and herbicides are used to protect a wide variety of agricultural commodities. There is an interest in pesticides, herbicides and their degradation product concentrations in plant and animal tissues and soil and sediment samples. The underlying assumption is that extractable compounds are labile in the environment and constitute a threat to the environment if they are hazardous. Specific examples are from the work of Fish and Revesz on chlorinated pesticides from soils and the work of Stout's group on imidazolinone herbicides in plant tissues. Fish and Revesz showed chlorinated pesticide recoveries from a Certified Reference Soil greater than or equal to those achieved using the standard Environmental Protection Agency Soxhlet technique, method 3540. This was achieved with extraction times of only 20 min and solvent volumes of 50 mL. Stout *et al.* incorporated the use of MAE with liquid chromatography-electrospray ionization-mass spectrometry to shorten the clean-up procedure and method development time of residue methodologies for determining the imidazolinones and their metabolites in crops. This application area is of concern not only to the traditional commercial testing laboratory, but to agro-chemical producers.

Environmental

The organic side of the environmental laboratory market constitutes the majority of the analytical testing load. The extraction of priority pollutants, as well

as other organic molecular species, from solid samples is a primary concern. The workload in the environmental laboratory is expected to increase significantly and will thus require extraction techniques that offer increased throughput, reduced solvent consumption, improved efficiency and reproducibility. MAE has the potential to address these needs. McMillin of US Environmental Protection Agency-Region VI demonstrated this in a comparison of various soil extraction techniques for semivolatile analysis. He used an abbreviated MAE technique consisting of a small modification to regular MAE. He worked with only 10 mL of solvent versus the conventional 30 mL. This eliminated the subsequent concentration step and allowed the sample to be injected straight from the extraction vessel into a GC. The abbreviated MAE provided better extraction efficiencies and reproducibility than the three conventional techniques. The extraction time averaged 16 min per sample with a solvent use of 10 mL per sample.

One difficulty in the use of MAE for the environmental laboratory market is Environmental Protection Agency approval. The methodology has been approved by the SW-846 Organic Methods Workgroup for incorporation into SW-846. However, the method has not been promulgated and thus can only be used when regulations do not specifically require SW-846 methods.

Future Developments

The instrumentation for MAE will continue to evolve, as will its potential applications. There will be developments in the vessel technology to address the separation issue of the sample and solvent after the extraction step. This will allow the technique to be a true replacement for the Soxhlet. There is also a need for larger vessel sizes. The current vessel has a working volume of 100 mL. There is a need to increase this to 250 mL and even higher for bulky samples and the inevitable push for lower detection limits. Finally, the microwave system's use should be extended to concentration of the sample after the extraction step. This will create a multi-tasking tool for the analytical laboratory.

MAE has focused on extraction applications from solid matrices. However, its speed and efficiency suggest that this technique will be used for isolating pharmaceutical compounds during the drug dis-

covery process. The recent addition of sample stirring suggests that it can be extended to liquid-liquid extraction applications. It could also be coupled with solid-phase microextraction to lower detection limits significantly. As MAE becomes more widely accepted and instrumentation evolves, we should see a significant increase in its applicability.

MOLECULAR IMPRINTS FOR SOLID-PHASE EXTRACTION

P. A. G. Cormack, University of Strathclyde,
Glasgow, UK

K. Haupt, INTS-INSERM, Paris, France

Copyright © 2000 Academic Press

Among the most important fields in analytical chemistry are medical, food and environmental analysis, where the target analytes are often present at very low concentrations in rather complex matrices. Methods currently used for analysis, such as liquid chromatography, gas chromatography or capillary electrophoresis, must therefore be preceded by a selective isolation and concentration step. Commonly used techniques for the extraction and clean up of analytes from environmental and biological samples are liquid-liquid extraction (LLE) and solid-phase extraction (SPE). Supercritical-fluid extraction (SFE) has also attracted interest, although it has not found widespread application thus far because of the specialized equipment required. The advantages of SPE compared with LLE are that it is faster, more reproducible, cleaner extracts are obtained, emulsion formation is not an issue, solvent consumption is reduced, and smaller sample sizes are required. It may also be cheaper than LLE when the costs for solvent disposal are taken into consideration. Moreover, SPE can be easily incorporated into automated analytical procedures. For a detailed introduction to SPE, the reader is directed to the relevant chapters in the Encyclopedia.

Solid phases currently employed for SPE include polystyrene divinylbenzene resins and chemically modified silica with either hydrophobic or ion-exchange groups. These materials generally yield satisfactory results if the conditions for extraction, washing and elution are carefully determined according to the chemical characteristics of the analytes and the other components in the sample. Nevertheless, due to the non-specificity of hydrophobic or ionic interactions, a large number of contaminants are often co-extracted, particularly if the sample matrix is very complex. A solution to this problem can be to use affinity sorbents, thus taking advantage of the specificity of biological recognition.

Theoretically, biomolecules like antibodies or receptors have the potential to meet the analytical demands for almost any target analyte since, with the

advent of phage display antibody libraries and recombinant antibodies, a suitable recognition element can be found in many cases, even if a natural receptor does not exist. Unfortunately, biomolecules also have a major drawback, which is their poor stability, particularly in the presence of organic solvents. Artificial receptors have therefore been gaining in importance as a possible alternative to natural systems. Molecular imprinting is becoming increasingly recognized as a versatile technique for the preparation of synthetic polymers bearing tailor-made recognition sites. These molecularly imprinted polymers (MIPs) are obtained by copolymerizing functional and cross-linking monomers in the presence of the analyte, which acts as a molecular template. The molecular imprinting technique is reviewed in more detail elsewhere in the Encyclopedia (*see* Affinity Separation/Imprint Polymers). Molecularly imprinted polymers combine the advantages of biological antibodies or receptors (very specific binding) with those of synthetic polymers (high physical and chemical stability, compatibility with both aqueous and organic solvents). Their use in sample preconcentration and clean up by solid-phase extraction is therefore highly attractive.

Analytical-Scale SPE

The applicability of imprinted polymers for SPE has been demonstrated on a number of compounds such as herbicides and drugs, which have been selectively extracted even from complex samples like beef liver extract, bile, blood serum and urine. **Figure 1** shows the principle of molecularly imprinted solid-phase extraction (MISPE). Typically, the sample is brought into contact with the imprinted polymer. This results in binding of the analyte and some impurities. Adsorption of the sample onto the polymer can be either from aqueous solution or from an organic or aqueous/organic solution after a solvent extraction step. The latter is often necessary to recover the analyte from solid or semi-solid samples, for example, soil or tissue. In both cases, the adsorption step is followed by a first elution step where impurities are washed away, whereas the specifically bound target analyte remains bound to the imprinted polymer. The last step is the elution of the analyte in concentrated and purified form using, for example, a competitor.

It has been shown that the target analyte can be recovered from samples at concentrations in the

Figure 1 Principle of solid-phase extraction with an imprinted polymer. The sample is loaded onto the imprinted polymer, resulting in binding of both the analyte and some contaminants (step 1). A first elution step removes contaminants and the analyte remains in the specific binding sites (step 2). The analyte is then eluted from the polymer (step 3). ●, analyte; ■, other sample components.

lower $\mu\text{g dm}^{-3}$ to the mg dm^{-3} range. The lower limit is determined by the dissociation constant of the analyte binding to the polymer. The upper limit is set by the binding capacity of the polymer. If the quantity of polymer used for extraction is increased, more analyte will bind, although non-specific binding of contaminants will also increase considerably. It is therefore necessary to optimize the extraction protocol for a specific application in terms of the amount of polymer used, the sample load, and the adsorption, washing and elution conditions, etc.

The quantification of the herbicide atrazine in beef liver is a good example of the utility of imprinted polymers in SPE. In a first step, atrazine was extracted from liver tissue with chloroform. The imprinted polymer was then used to clean the chloroform extract and to further concentrate the analyte prior to quantification. In this specific example, the binding capacity of the polymer for atrazine in chloroform was found to be $19 \mu\text{mol g}^{-1}$. The analyte was eluted from the polymer with a suitable solvent (acetonitrile containing 10% acetic acid) and quantified, after drying and reconstitution in acetonitrile or buffer, by reversed-phase high performance liquid chromatography (RP-HPLC) or enzyme-linked immunosorbent assay (ELISA). When comparing the purified with the non-purified chloroform extracts in RP-HPLC, the SPE step with the imprinted polymer considerably improved the accuracy and precision of the HPLC method and lowered the detection limit from $20 \mu\text{g dm}^{-3}$ to $5 \mu\text{g dm}^{-3}$. This was achieved due to the removal of interfering components in the sample, resulting in baseline resolution of the atrazine peak. Furthermore, analyte recovery was increased from 60.9% to 88.7% (quantification by HPLC) and from 79.6 to 92.8% (quantification by ELISA).

Preparative-Scale SPE

What has been described thus far is, by and large, the use of molecular imprints as solid-phase extraction media in *analytical* applications, where the inherent selectivity of the imprints enables *efficient* clean up and/or preconcentration of samples prior to analyte quantification. Imprinted polymers are well suited to this purpose, and their functional capacity (the mass of analyte that can be bound per unit mass of polymer) places no undue restrictions on their widespread usage. In contrast, capacity is an important consideration in preparative-scale SPE, even if the solid-phase can be regenerated many times. Bearing in mind that the functional capacities of imprinted polymers prepared thus far have been moderately low, it is relatively easy to appreciate why only a few reports describing their potential use in preparative-scale work have appeared. However, there are certain niche applications that could conceivably be serviced by state-of-the-art materials where the low capacity is more than compensated for by the additional benefits that imprints confer, e.g. stability, selectivity, etc. In the long term it is certain that numerous opportunities will exist for the use of imprinted polymers in preparative-scale SPE once the low capacity issue has been addressed satisfactorily. They are well suited to product recovery from fermentation broths, production waste streams, and during chemical and enzymatic syntheses.

The term *facilitated chemical synthesis* in the context of preparative-scale SPE refers to chemical reactions that are performed and/or worked up in the presence of imprinted polymers. In the simplest case, this involves the addition of a polymer imprinted against the product to a vessel containing the crude reaction mixture. The imprint selectively binds the

product in preference to reactants, reagents, catalysts, etc., and is readily separated from the other components by virtue of its cross-linked insoluble character (the use of magnetic imprinted polymer particles or beads, which are available, would make this process even simpler). Alternatively, the crude reaction mixture can be passed through an appropriately sized SPE column, or the imprinted polymer can be placed in a product stream. Following selective adsorption, the product is washed out from the imprinted polymer and isolated. It can then be purified further if required. Another possibility for simple, inexpensive, and large-scale separations using imprinted-polymer particles is adsorptive bubble fractionation. The target compound is selectively adsorbed to the imprinted polymer in suspension within a cylindrical column containing a glass frit at the base of the column. Bubbles are formed when a gas is injected through the frit and they rise to the top of the column. Imprinted-polymer particles, which adhere to the gas bubbles, are transported to the top of the column where they accumulate and can then be easily recovered. It has been shown that enantiometric enrichment of L-phenylalanine anilide from a racemic solution can be achieved in this way, using an L-phenylalanine

anilide-imprinted polymer. Overall then, imprinted polymers appear to offer an efficient general method for product isolation and purification, at least in principle.

Bearing in mind the functional capacity limitations associated with imprinted polymers at present, it should be clear why preparative-scale MISPE is currently not an attractive option. For the time being, it is more practical to use state-of-the-art imprinted materials in the selective extraction of impurities that are present in low or trace concentrations in crude reaction mixtures, where the functional capacities of imprinted polymers place considerably fewer restrictions on their application. In the following example, a recently reported model system focused on the chemical synthesis of the artificial sweetener α -aspartame (Figure 2). In the synthetic sequence, Z-protected L-aspartic acid anhydride (2) was reacted with L-phenylalanine methyl ester (3) to give Z- α -aspartame (4). The α -aspartame product (1) was obtained following removal of the Z-protecting group from the intermediate (4). The key feature about this reaction sequence was that a by-product, Z- β -aspartame (5), was formed during the first step, which then had to be removed. The typical composition of the crude

Figure 2 The chemical synthesis of α -aspartame. (1) α -aspartame, (2) Z-protected L-aspartic acid anhydride, (3) L-phenylalanine methyl ester, (4) Z- α -aspartame, (5) Z- β -aspartame.

reaction mixture was as follows: Z- α -aspartame, 59%; Z- β -aspartame, 19%; Z-L-aspartic acid, 22%. A polymer was imprinted against the by-product Z- β -aspartame (5) and used in the SPE mode for the selective removal of the by-product from the crude reaction mixture. After five passes through a solid-phase extraction column, the product purity was increased from 59 to 96%. In a control experiment using a nonimprinted polymer, the final purity achieved was only 86%.

It is also possible to use imprinted polymers advantageously *during* chemical reactions, to drive chemical equilibria in particular directions and thus influence product distributions in a controlled fashion. To prove this concept, the enzymatic condensation of Z-protected L-aspartic acid (6) with L-phenylalanine methyl ester (3) using the enzyme thermolysin was studied (see Figure 3). The equilibrium for this reaction, which normally lies to the left thus favouring reactants, can be driven to the right, in the direction of products by working in a nonsolvent for Z- α -aspartame. Another way of achieving the same effect would be to use a product-trap (product-sink) in the reaction itself, for example, a polymer imprinted against the product Z- α -aspartame. Indeed, when the reaction was carried out in the presence of

a Z- α -aspartame-imprinted polymer, the reaction yield was found to increase from 15 to 63%.

Present Limitations and Remedial Solutions

Any sorbent used in SPE must satisfy a range of performance criteria for a given application. Criteria that are of importance for imprinted polymers include: (1) Strong, selective, and reversible binding to the analyte; (2) fast mass-transfer kinetics; (3) high functional capacity; (4) minimal interaction of analyte with polymer backbone; (5) effective displacers available; (6) zero bleeding of template; (7) compatible with many solvents; (8) pressure resistant; (9) batch-to-batch reproducibility; (10) physical form of imprinted polymer; and (11) economics. Whilst imprints perform very well in many respects, there are certain limitations that need to be overcome in specific applications.

One of the most unsatisfactory features associated with the application of imprinted polymers as SPE sorbents in ultra-trace analysis is template leakage. Generally, once an imprinted polymer has been prepared, it is exhaustively extracted to remove the template from the polymer matrix. The difficulty in extracting 100% of the template molecule from an imprinted polymer has long been recognized, although until relatively recently it was widely believed that the few per cent of template remaining within the polymer was permanently entrapped. Recent work clearly demonstrates that this is not necessarily the case. What can and does occur is slow leakage of a portion of the remaining template from the polymer matrix over a period of time, even after exhaustive (solvent) extraction of the polymer beforehand. This template *leakage* or *bleeding* can have serious implications when the polymer is being used as an SPE sorbent in ultra-trace analysis, although is of much less concern in trace analysis.

Whilst a general solution to the bleeding problem is being sought by researchers across the globe, a possible method of circumventing the bleeding problem entirely is to use a template analogue during the imprinting step, rather than the template itself. One of the first demonstrations of this approach was described by Andersson *et al.* in a paper detailing the use of MISPE for the preconcentration of the drug sameridine (7) in human plasma, prior to its quantification via gas chromatography (GC). At the nanomolar concentration levels used in the study, leakage of template from the polymer matrix during sample handling was considerable and easily detectable via GC analysis. Bearing in mind the application and the concentration window, such leakage was completely

unacceptable because it led to large errors in the precision of the analytical measurement. Rather than take steps to minimize or eradicate leakage, a close structural analogue of sameridine (8) was used as the template molecule in the imprinting step, which yielded an imprinted polymer that still displayed a strong affinity for sameridine.

Following solid-phase extraction of sameridine from human plasma using this polymer, leakage of the analogue from the polymer matrix did occur, but sameridine and the analogue were readily resolved using GC and the sameridine was subsequently quantified. The results obtained were as good as those obtained via a standard liquid-liquid extraction method, with the added advantage that the plasma sample contained fewer matrix contaminants with MISPE than for LLE, i.e. the sample for assay was much cleaner (Figure 4).

The template-analogue method does rely upon the availability of a close structural analogue of the analyte, and also a strong affinity between the polymer imprinted against the analogue and the analyte. One or both of these criteria may not always be fulfilled, therefore new approaches are required to tackle the bleeding issue.

In a solid-phase extraction operation, one ideally wants strong binding of the analyte to the sorbent during the loading and washing steps, and rapid stripping of the analyte from the sorbent during the elu-

tion step, ideally in as small a volume as possible. Efficient loading and washing is therefore favoured by a strong affinity between the polymer and the analyte, whereas efficient elution is obtained when the affinity is moderate to weak. In some cases, MIPs can actually bind analytes too strongly, which means that stronger displacers or larger volumes of eluting solvent are required than would otherwise be considered ideal. In some circumstances, therefore, having an MIP of lower affinity but with the same selectivity would be desirable. One way of achieving this goal might be via thermal pretreatment of the polymer at high temperature prior to use, which can have the effect of killing off a proportion of the high-energy binding sites.

As indicated already, the low functional capacity of imprinted polymers does not unduly limit their potential in analytical applications, although it does place restrictions on their immediate value in preparative-scale solid-phase extractions. With the advent of new developments in the imprinting area, and the advantageous knock-on effect this is likely to have on capacities, it is expected that preparative-scale applications will become more feasible in the future. Scale-up of the polymerization process to an industrial scale must also be addressed. In future developments, the elaboration of imprinting methodologies in polar environments is also expected; at present, it is a challenge to prepare good imprints in these

'competitive' environments. Although it is possible to imprint certain templates in polar environments, polar solvents (e.g. water) tend to interfere to an unacceptable level with the non-covalent interactions between template and functional monomer that are often relied upon in imprinting protocols. What is more common and easier to deal with, however, is the use of imprints effectively in buffer and/or polar environments. Finally, the imprinting of larger templates (e.g. proteins) is rather challenging at present due to their 'fragile' nature. New synthetic developments should lead to progress in this area also.

Conclusions

Molecularly imprinted polymers constitute a new class of sorbents which combine the robust character of cross-linked polymers with the attractive properties of natural receptors. In sample clean up and concentration for trace and ultra-trace analysis, they offer distinct advantages over both liquid-liquid extraction and solid-phase extraction using classical sorbents and immunosorbents. Besides analytical applications, imprinted polymers are being increasingly considered for preparative-scale SPE applications, even though their present low functional capacity sets a limit on their widespread utility. However, concomitant with improvements in their capacity, it will become increasingly appealing to use imprinted polymers to remove products and/or by-products from reaction vessels/streams, and to influence directly the course of chemical reactions by 'equilibrium shifting'. Finally, it is worth noting that the area of molecular imprinting as a whole is undergoing rapid expansion at present. What this implies for MISPE is that one can expect tailored, high-performance imprinted polymers to become increasingly attractive and more widely available as methodologies improve and breakthroughs are made.

Selective ion recognition, binding and transport are important processes in living systems. From the active

sites of metalloproteins, such as amine oxidase, to lower molecular weight ligands like valinomycin, the K⁺-selective macrocyclic antibiotic, the underlying principles of such selective ion binding and utilization have for some time been the subject of intensive investigation and modelling by many researchers.

Pedersen, Lehn and Cram (1987)	Nobel Prize in chemistry

Many new branches of chemistry have developed which aid the challenge, including supramolecular chemistry, the study of the formation and properties of larger molecular aggregates from the self-assembly of smaller complementary molecules through non-covalent intermolecular forces. Specifically, the creation of pre-organized cavities in synthetic host molecules for the selective reception of a neutral or ionic species is described as host-guest chemistry or molecular recognition, an approach gleaned from enzyme-substrate interactions. Macrocyclic ligands have received particular attention, as host molecules, since the pioneering work of Pedersen on the synthesis and metal extraction properties of crown ethers. This began a revolution in macrocyclic ligand and receptor design, acknowledged with the award of the Nobel Prize in chemistry in 1987 to three of the main contributing scientists, Pedersen, Lehn and Cram (Table 1), a revolution which continues today as new host molecules with unique selectivities of binding and mechanisms of release are produced.

Many macrocyclic ionophores are host molecules, which vary in the extent to which they are pre-organized for selective recognition of guest species and the fitting of guest to host in a complementary fashion. Some of the most important macrocyclic ligands are listed in Table 2. Cram recognized that the more highly organized the host was for binding and low

solvation, prior to complexation, the greater would be complex stability. Greater cation selectivity resulted, using fixed pre-organized host cavities of controlled size, provided by such macrocycles as cryptands and spherands. The chemical structures of representative macrocyclic host molecules are given in Figure 1, alongside the ions which have been shown to reside selectively in the guest cavities. The concepts that cavity size and shape could be tailor-made and fine-tuned to suit the selected cation diameter, and that donor atom choice determines the cation selectivity, have caught the imagination of many chemists over the last 30 years. In particular, separation scientists have been quick to demonstrate selective metal extractions, such as the separation of trace amounts of silver from mercury using 14-thiacrown-4 and the extraction of mercury and lead by 18-crown-6. Important studies were carried out on monocyclic aza crowns and cryptands, which are macrobicyclic compounds, where the complexed cation is completely enclosed by ligands, containing O and N, in a central cavity. More recently, attention has been focused on calixarenes, which are a class of functionalized metacyclophanes possessing convergent phenolic groups arranged around the periphery of a central aromatic cavity. These macrocycles have been described by Shinkai as the third host molecule after cyclodextrins and crowns as the first two major impact host molecules. The unique ionophoric properties of functionalized calixarenes have been clearly demonstrated using nuclear magnetic resonance (NMR) spectroscopy and liquid-liquid extraction studies. Functionalization, at the upper and lower rim, can lead to an enormous number of derivatives, water- or organic-soluble, with varied ionophoric selectivities.

In this review, representative examples of these molecular recognition reagents and their roles in selective metal ion extraction are presented. The emphasis is on illustrating through examples the influences that contribute to selectivity of complexation and extraction, and on the new materials and

experimental approaches that have been adapted to demonstrate analytical and preparative-scale selective metal ion extraction using molecular recognition reagents.

Selectivity of Metal Ion Complexation

Determination of the selectivity of complexation is an important goal, since it gives further pointers to where the synthetic effort should focus, and it is a necessary step in assessing how far the synthetic design has progressed to meet the challenge presented by such natural ionophores as valinomycin.

The selectivity of molecular recognition ligands for metal ions is chiefly described in two ways, as the ratio of the measured stability constants for a pair of ions or from phase transfer and transport studies of selected cations from aqueous solution into organic solvents.

Ratio of Stability Constants

The stoichiometric stability constant K_s (sometimes symbol β) for the complexation of a metal ion, M , by a ligand, L , in solution at a constant ion strength, is defined as:

$$K_s = [ML]/[M][L]$$

in the simplest situation where a 1:1 complex is formed and where the square brackets refer to molarities of complex, free metal and free ligand in solution. This is commonly the situation when macrocyclic ligands are involved. Thus, when comparing the relative stabilities of complexation of two metal ions, M_1 and M_2 , with the same macrocyclic ligand, the ratio of the stoichiometric stability constants is a useful measure of selectivity:

$$\text{Complexation selectivity } S_{M_1/M_2} = K_s(M_1L)/K_s(M_2L)$$

Extraction Selectivity

The picrate extraction method introduced by Pederesen places the MR reagent in an organic solvent, such as dichloromethane, in contact with an aqueous metal picrate solution. If complexation occurs the metal ion extraction is monitored by spectrophotometry, following the co-extraction of the highly coloured picrate counterion ($\lambda_{\max} = 355 \text{ nm}$, $\epsilon = 14\,416 \text{ mol}^{-1} \text{ L cm}^{-1}$) into the organic solvent. The percentage cation extraction is calculated as the ratio $100 \times (A_0 - A)/A_0$, where A_0 is the measured absorbance of an aqueous blank metal picrate solution without complexation reagent and A is the absorbance recorded in the aqueous layer after equili-

bration. The method is particularly suited to the extraction of alkali and alkaline earths, but has also been applied to the assessment of the percentage extraction of transition metal ions. Thus, a liquid-liquid extraction method is used to determine the percentages of extraction for a series of metal ions and frequently tabulated or plotted against ionic radii to illustrate the ion preference of the reagent.

Selectivity of Molecular Recognition Ligands

Among the factors that contribute to the selectivity of metal complexation by macrocyclic receptors is the complementarity in size of the host cavity to the cation diameter. In Figure 1 this is readily seen with the crown ethers, where selectivity moves from Li^+ to Cs^+ as the host varies from 12-crown-4 up to the larger 21-crown-7. This matching of cation diameter and cavity size is also evident in the illustrated cryptand and calixarene series, with, for example, in the latter, Cs^+ selectivity being displayed by the calix[6]arene hexaester derivative. The principle of pre-organization of the host cavity is evident in the ion complexation by macrocycles such as the cryptands and spherands, which display greater complexing power than the earlier crown ethers. The influence of the nature of the donor atom on the selectivity of complexation is also evident in the illustrated macrocyclic compounds. The hard and soft acid-base theory of Pearson is a useful guideline as to the behaviour, with oxygen donor atoms considered to be hard bases and nitrogen and sulfur soft bases. Alkali and alkaline earth metal cations, considered hard acids, are preferred by hard bases, while soft acids such as heavy metals are preferred by soft bases. Shifts towards the complexation of soft cations such as Ag^+ , Pb^{2+} and Hg^{2+} are seen in the aza and thia crowns. It is also clearly seen in the versatile calixarene series, as for example among the tetrameric series where the change from ester to amide to thioamide moves the ion preference from Na^+ , to Ca^{2+} and on to Pb^{2+} and Ag^+ . Hancock has emphasized the role of chelate ring size within the macrocycle – an effect which influences the stability of complexation by such macrocycles as the azacrowns and the calixarene tetrahydroxamate, shown in Figure 1.

Of particular note is the influence of conformation on the stability and extraction of metal ions by molecular recognition compounds. This has been powerfully illustrated recently with calixcrowns, which are capable of cone, partial cone and 1,3-alternate conformations. Calixcrowns derived from calix[4]arenes, unsubstituted on the upper rim, can be fixed in the 1,3-alternate conformation, as shown in Figure 1.

Table 3 Percentage extraction and log β values for alkali and alkaline earth metal ion complexation by selected functionalized calixarene derivatives

Host macrocycle		Li	Na	K	Rb	Cs	Mg	Ca	Sr	Ba
<i>p-t</i> -Bu-Calix[4]arene-tetraethylester	%E	15	94.6	49.1	23.6	48.9

<i>p-t</i> -Bu-Calix[4]arene-tetraethylamide	%E	63	95.5	74	24	12	9	98	86	74
$S_{Ca/Mg} > 7.8$ log units	Log β	3.9	7.9	5.8	3.8	2.4	1.2	> 9	> 9	7.2
1,3-Dialkoxycalix[4]arene-crown-6	%E	2.5	2.6	13.8	41.7	63.5				
$S_{Cs/Na} > 4.9$ log units	Log β	< 1.5	< 1.5	4.3	6.0	6.4				
1,3-Dialkoxycalix[4]arene-crown-5		–	–	–	–	–				
$S_{K/Na} = 5.53$ log units	Log β	4.78	4.30	9.83	9.41	6.87				
Valinomycin		–	–	–	–	–				
	Log β	5.83	6.09	9.35	9.83	8.97				

Data compiled from Arnaud-Neu *et al.* (1989) and (1991), Dozol *et al.* (1997) and Casnati *et al.* (1996). Bold figures, highest selectivity and extraction.

While the extraction and complexation profiles are strongly dependent on the size of the crown, the behaviour is dependent on the conformation, with the highest extraction and complexation levels found for the 1,3-alternate ligands. Two striking selectivities have been achieved, as shown in Table 3. Remarkable Cs^+/Na^+ selectivity ($S_{Cs/Na} > 4.9$ log units) was obtained for the 1,3-alternate calix[4]-crowns-6, making applications to the extraction of caesium from radioactive waste possible. The conformation has a direct bearing on the relative stabilities, with cation- π interactions possible for caesium but not for the smaller sodium in the rigid conformation. In addition, 1,3-alternate-calix[4]arene-crown-5 conformers have been shown in extraction experiments from water to chloroform to have better K^+/Na^+ selectivity ($S_{K/Na} = 5.53$ log units) than the naturally occurring ionophore, valinomycin.

Numerous functionalized calixarenes and, more recently, calixcrowns have been studied for their ability to extract metal ions and the stabilities of the metal-ligand complexes measured. In general, changes in the extraction profiles as the ion is varied mirror the changes in stability of the complexes. Four representative examples chosen to illustrate the influences of donor atoms and conformation on extraction and selectivity are provided in Table 3, alongside stability data reported for valinomycin.

Molecular Recognition Ligands in Inorganic Extraction

Solvent Extraction of Metal Cations

The Pedersen picrate extraction method is particularly suited to alkali and alkaline earths; using it McKervey *et al.* were able to show that *p-t*-butylcalix[4]arene esters and ketones were Na^+ -selective

over other alkali metal ions and that calixarene complexation of metal ions is determined by the cavity size and the type of functionalization.

In sample preparation prior to trace metal analysis, a well-established procedure is the extraction of transition and heavy metal ions such as Cu^{2+} and Pb^{2+} into methylisobutylketone using extraction reagents such as sodium diethyldithiocarbamate and dithizone. Extraction can be monitored by spectrophotometry, as many of the complexes are coloured, or by atomic absorption spectroscopy. While such liquid-liquid extraction methods using conventional extraction reagents achieve preconcentration and sample clean-up, today the challenge is for greater selectivity of extraction, even as far as the extraction of specific metal ions from complex matrices. This can be achieved by molecular recognition technology. As far back as 1983, Izatt *et al.* demonstrated selective extraction of Cs^+ through organic liquid membranes by macrocyclic *p-tert*-calix[n]arenes through the formation of neutral complexes following proton loss. Another illustrative example is the challenge of selective extraction of uranium from sea water, where lipophilic calix[6]arene carboxylates and phosphonates have been reported as uranophiles, capable of selective transport of UO_2^{2+} ions from water into organic media. In this manner, calixarenes functionalized with ionizable or chelating groups have been extensively studied over a range of pH for the extraction of transition and heavy metal ions from aqueous to organic solution. In particular, Shinkai has studied calix[5]- and calix[6]arenes with sulfonate, phosphonate, carboxylate and hydroxamate groups as uranophiles in extraction and transport experiments. The great strength of calixarenes as selective metal extraction reagents is that any chelating moiety can be attached to the macrocycle at the upper or lower rim for targeted metal ion extraction.

Extraction of Metal Ions using Molecular Recognition Solid Phases

The immobilization of extractants onto supports for solid-phase extraction has many advantages over liquid-liquid extraction, including minimization of the use of organic solvents and amenability to automation. Important approaches taken to immobilize extractants include dissolution in a support-held organic liquid and chemically bonded solid phases.

Supported liquid membrane enrichment technique The supported liquid membrane (SLM) enrichment technique involves using a solid membrane, such as porous polytetrafluoroethylene, which is impregnated with an organic solvent which acts as a stationary liquid positioned between two aqueous solutions (Figure 2A). When the membrane separator is configured to allow the use of flowing aqueous solutions, the technique can combine the selectivity and enrichment capabilities of liquid-liquid extraction with efficient matrix constituent removal for automated sample preparation. While the use of liquid membrane technology for extraction in industrial processes is well established, the use of SLM technology for analytical applications began in the mid 1980s for trace organic extraction. For trace metal extraction, recent examples have focused on the use of extractants such as 8-hydroxyquinoline and organophosphates. The use of a lipophilic diazo-18-crown-6 in an SLM for the separation of Cu^{2+} from natural water samples has been studied. SLM technology has in particular been used to complement liquid-liquid extraction studies in determining the selectivities of some of the more recently synthesized calixarene ligands. Further studies on the use of molecular recognition reagents in SLMs are likely to lead to further useful demonstrations of enhanced selectiv-

ities of extraction using molecular recognition ligands.

Solid-phase extraction technology This approach to the extraction of metal ions involves the partitioning or complexation of the metal species from the aqueous phase onto a solid phase, usually a polymer or silica. From literature reviews of solid-phase extraction, it is clear that chemically bonded phases derived from liquid chromatography are generally used for organic solute extraction. For metal ions, ion exchange and chelating phases have been widely used and have clear advantages over liquid sorbent-based approaches. How molecular recognition has impacted and can further impact on this approach to extraction will be seen from the next illustrative examples.

Silica-bond thiocrown macrocycles Considerable work has been done on the chemical attachment of crown ethers to silica and polymeric supports for chromatographic separation of ions and chiral solutes. Separations of alkali and alkaline earths using water-based eluents have been demonstrated and ion-modulated separations carried out. For inorganic extraction, by far the greatest impact has been made with silica-bonded thiocrown phases. Highly selective silica-bonded, sulfur-containing crown phases are commercially marketed in packed beds or columns as SuperLigTM and AnaLigTM (for industrial and analytical separations, respectively) by IBC Advanced Technologies (Provo, UT, USA). These molecular recognition materials have resulted from the research work of Izatt *et al.* at Brigham Young University, and have been applied to the extraction of targeted metals in complex matrices, such as the large scale removal of Pd^{2+} from AgNO_3 streams, the removal of Cs^+ , Sr^+ and Pb^{2+} from nuclear waste streams, and for analytical extractions, to the concentration and analysis of low level Hg^{2+} . The selectivity of silica-bound 1,4,7,10-tetrathia-18-crown-6 for Hg^{2+} over Ag^+ is reported as 10^6 ; in comparison, the selectivity of a typical ion exchange resin for Ag^+ over Hg^{2+} is 1.06.

Particle-loaded membranes The incorporation of solid-phase extraction particles into a web of microfibrils to form an extraction membrane with fast mass transfer kinetics has been described (Figure 2B). Highly selective and efficient removal of metal ions from solution is possible; for example, rapid sample processing and determination of radioactive strontium, counted from the surface of the membrane disc, can be achieved using EmporeTM Strontium Rad Disks, containing AnaLigTM molecular recognition technology.

Figure 2 (A) Supported liquid membrane and (B) particle-loaded membrane.

Silica-bound molecular baskets for extraction and chromatography Molecular baskets, as calixarenes have been described, can be immobilized onto solid supports to yield new molecular recognition materials for extraction and chromatography. The obvious supports are polymer and silica phases. The nature of the surface silica-bound species in chemically bonded molecular baskets on silica has been elucidated using solid-state NMR spectroscopy. When packed as a chromatography column, a silica-bonded calix[4]arene tetraamide phase displayed significant retention of Ca^{2+} over Mg^{2+} , a result in keeping with the reported high complexation selectivity of the calixarene for Ca^{2+} over Mg^{2+} ions. For transition metal ion extraction, a macrocycle that combines the sequestering ability of siderophores with the ionophoric properties of calixarenes is another interesting example of these new phases. Calix[4]arene tetrahydroxamic acid can be chemically bonded to silica particles or partitioned onto a solid support. Metal uptake profiles as a function of pH have been determined using solid-phase extraction cartridges filled with these new molecular recognition phases and the phases have been characterized by diffuse reflectance infrared Fourier transform (DRIFT) and solid-state NMR spectroscopy. The molecular recognition phase is capable of selective removal of Pb^{2+} and Fe^{3+} from acidic aqueous solution with Ni^{2+} ,

Zn^{2+} , Co^{2+} , Mn^{2+} and Cd^{2+} . The complexation of Pb^{2+} takes place at a more acidic pH than is achievable with linear hydroxamic acids, as a result of host-guest complexation in the basket cavity. The structure of the silica-bonded molecular basket is schematically given in Figure 3, with coupling through two of the three available ethoxy groups on the derivatized upper rim. The sites for complexation of metal ions are shown on the lower rim. (It is acknowledged that there is a redundant hydroxamate group in the tetrahydroxamate when metal ions are complexed in an octahedral fashion.)

Supercritical Fluid Molecular Recognition Technology for the Extraction of Metal Ions

Instead of carrying out liquid-liquid extractions or solid-phase extractions for the pretreatment and pre-concentration of metal ions from solid and liquid matrices, it is possible to send in a selective courier molecule to permeate through the sample, grab on to the targeted metal and deposit it in concentrated form into a collection vessel for further analysis. Such a technology utilizes the solvating power of supercritical CO_2 and the metal-ion complexing power and selectivity of organic ligands, and is currently the focus of considerable research attention. Several studies have been reported on the supercritical fluid extraction (SFE) of metal ions via the formation of

Figure 3 Proposed structure of silica-bonded calix[4]arene tetrahydroxamate phase.

Figure 4 Schematic diagram of selective SFE of targeted metal ions using macrocyclic extractants. Filled circles, targeted metal ions; filled squares, diverse metal ions.

neutral metal–ligand complexes resulting in useful solubilities in supercritical CO_2 . These solubilities can be improved by several orders of magnitude by substituting fluorine for hydrogen in the chelating ligand. For example, β -diketones and dithiocarbamates have been fluorinated and successfully used as metal extraction reagents in SFE.

More advanced complexation in SFE is achievable using molecular recognition ligands, where enhanced selectivity of extraction is achievable by careful choice of donor atoms and host cavity size in a macrocyclic reagent, as illustrated in **Figure 4**.

Recently, such selective extractions using macrocyclic reagents in SFE has been demonstrated. The selective extraction of mercury from sand, and cellulose filter paper using ionizable dibenzobistriazolo crown ether in methanol-modified supercritical CO_2 has been reported. The synthesis and use of fluorinated molecular baskets for metal extraction in unmodified supercritical CO_2 has been described. Fluorinated calixarenes are the templates on which carefully selected chelating groups can be incorporated around the cavity to yield selective extractants for targeted metals. The ability of one such molecular basket, a fluorinated calix[4]arene tetrahydroxamate, selectivity to extract Fe^{3+} from metal mixtures on

cellulose paper has been monitored using atomic absorption analysis (**Figure 5**). Further examples of where targeted metal ions in a matrix, present as unwanted contaminants or as valuable metals to be recovered, are selectively complexed and removed by such macrocyclic extractants dissolved in supercritical CO_2 are likely in the future.

Future Developments

Molecular recognition ligands for metal extraction are likely in the future to be cage-like and pre-organized to provide the preferred symmetry of the targeted metal ion. Higher selectivities of extraction for cations and anions can be expected, by reagents which subsequently release the guest under an applied stimulus. Molecular recognition speciation, allowing preferential extraction of individual oxidation and chemical species, will receive more attention. In chemical analysis, the incorporation of molecular recognition into miniaturized extraction devices or layers followed by detection will be further examples of the powerful role of designed molecular recognition reagents in inorganic extraction.

Introduction

‘Killing two birds with one stone’ is a common expression that captures the essence of multiresidue methods of analysis. Multiresidue methods are almost always more efficient than separate single analyte methods for multiple analytes. However, a possible drawback of multiresidue methods that cover a wide polarity range or diversity of analytes is a potential loss of selectivity for individual analytes. The use of high efficiency analytical separation techniques and/or very selective detectors can compensate for a lack of selectivity in preceding steps, but as a general rule, a greater degree of selectivity leads to higher quality results. Multiresidue methods often involve a balancing act between the analytical scope of the method and the quality of the results for all analytes. It is sometimes difficult ‘to have your cake and eat it, too’.

Residues

In general, residues consist of synthetically derived chemicals that are not intended to occur in the sample, but may be present at trace concentrations as a by-product of a preliminary process related to the sample, or as a separate process altogether. Residues may be inorganic or organic, but inorganic compounds are generally analysed separately from organics. Multielemental analysis measures the natural occurrence of elements as well as any residues that may occur in the sample. Microorganisms and dirt may also be considered residues according to some definitions, but their analysis requires different techniques from organic compounds and they will not be considered further in this discussion. In the case of organic chemicals, many natural components are capable of being analysed in the same approach as the residue method, but these compounds are usually termed interferences, and great effort is often spent trying selectively to remove or avoid them (however, other chemists may be very interested in these matrix interferants).

The most common type of multiresidue application is the analysis of organic chemical contaminants in food and environmental samples. There are instances

when a residue is intended, such as a fungicide designed to extend product life, but for the large majority of situations, residues are not desired in the sample. Residues may consist of pesticides, drugs, industrial by-products and/or other pollutants. Within each of these categories are subcategories known as classes of analyte. For example, classes of insecticides include organophosphorus (OP), organochlorine (OC), carbamate, pyrethroid, and others; classes of pollutants include volatile organic compounds (VOC), polycyclic aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCB) alkylphenol ethoxylates (APE) and others; and veterinary drugs include antibiotics (β -lactams, aminoglycosides and tetracyclines), antibacterials (nitrofurans, fluoroquinolones and sulfonamides), and anthelmintics (benzimidazoles, avermectins and milbemycins). Thus, multiresidue methods may be single-class or multiclass depending on the number of analytes and classes covered by the analytical scope of the method.

A few existing multiresidue methods may be used to analyse more than one type of residue (e.g. pesticides and industrial pollutants), but most applications generally require the analysis of a single residue category. Analytical needs do exist that would entail the monitoring of all types of residues in some sample matrices (e.g. certain foods), but different methods are usually conducted for the separate analysis of the different residue types. It is difficult enough to develop and perform multiclass, multiresidue methods, and very few multi-type, multiclass, multiresidue methods have been attempted. However, some overall analytical schemes may include a wide array of analyte types in the extraction procedure and then divide the extract into separate aliquots for different clean-up and analytical steps.

The Analytical Process

The analytical process goes through a series of steps which leads to the analytical results. Much like a chain that is only as strong as its weakest link, an analytical method is only as good as its weakest step. These steps consist of: (i) sample collection and handling; (ii) sample preparation (extraction, clean-up); (iii) analyte determination (analytical separation, detection); and (iv) reporting of results.

The primary consideration that must be addressed independently of the analytical steps, however, is the need for the data. The analytical method should be tailored to meet the minimum needs in terms of the scope of analytes to be detected, desired limits of detection (LOD) and acceptable precision and accuracy of the results. In many cases, the data needs will

require the best possible results for as many analytes as possible. However, no analytical method can detect all possible analytes in the same procedure, and all laboratories are constrained by available personnel, space, instrumentation and other resources. Thus, the analytes must be prioritized according to importance and weighed against the cost and availability of analytical methods for their detection. The analytical chemist considers the most efficient overall approach to determine the analytes of interest that meets the acceptable data quality requirements and fits within the laboratory budget. This process may involve trade-offs between the quality of results for a particular analyte balanced against the quality of results for one or more other analytes.

The first step in the analytical process involves sample collection and handling. Unless representative samples are collected of the appropriate matrix and the samples are treated properly to avoid losses of analytes or potential contamination, then the results may not provide the information necessary to meet the needs for the analysis. In fact, a false sense of security in misleading results is often the outcome unless each step in the analytical process is carefully considered and controlled. For example, excellent recoveries and reproducibilities may be achieved for the analysis of several OP insecticides in liver tissue, but nearly all OPs partition into fat tissue in animals, and very few appear in the liver. If the purpose of the analysis is to determine animal exposure to OPs and assess risk to humans, then fat tissue should be sampled, not liver. Otherwise, the analysis may accomplish nothing of real significance.

Extraction

Once the appropriate sample has been collected and handled properly, the next sequential step in the analytical process is the sample preparation procedure which is the subject of this article – *extraction*. Extraction is the separation of the analyte from the matrix. A few techniques, such as direct analysis of chemicals in liquids, may avoid the extraction step, but in most cases, the analytes must also be concentrated prior to analysis, which often necessitates an extraction process. The post-extraction steps in the analytical process may include clean-up of extracts and an analytical separation, but some sample preparation techniques incorporate clean-up and analyte separation into the extraction procedure. In other cases, the final analyte detection step may not require extra clean-up or analytical separation steps, but usually the price to pay for an approach that avoids clean-up steps is reduced ruggedness and higher instrument maintenance.

The type of extraction step that is used for a particular matrix depends on the nature of the matrix and analytes. Fundamentally, typical samples consist of solids, liquids and gases, or combinations thereof. Solids are usually not reasonably extracted with solids, and gases may not be extracted with gases (unless a solid membrane is placed between them), but all other combinations of liquid–solid, solid–gas, liquid–liquid and liquid–gas extractions are common in extraction techniques; supercritical fluids have also become a useful medium for extraction processes. With modern extraction techniques and the number of different solvents available, the control of pressure and temperature in the separation process has provided an essentially limitless number of possible separation conditions for the chemist to employ.

Extractions Involving Gases

For gaseous samples, the extraction process nearly always involves passing large volumes of sample through a solid phase or liquid trap. In solid-phase systems, the analytes are adsorbed on to the particle surfaces, and in liquids the analytes are partitioned into the liquid. In the case of low temperature trapping, the analytes may simply condense on to the cold surfaces. For the most volatile analytes, a combination of condensation and adsorption may be conducted by maintaining low temperature of an adsorptive surface. The analytes are concentrated in the trapping medium and may undergo clean-up or be directly analysed in a chromatographic system. The most common approach is probably to use active materials, such as Tenax, polyurethane foam, octadecylsilyl-derivatized silica, polymer resins, or a variety of other materials to adsorb the analytes.

The use of liquid trapping by bubbling the gas through a liquid is another easy approach to extracting air-borne substances, but evaporative losses of the liquid, greater temperature limitations and less convenience generally make large volume liquid trapping a less common approach. However, liquid coatings that are useful in gas chromatography (GC) are also useful at trapping analytes from gaseous samples. It is not uncommon to perform direct collection of gases from the atmosphere at the head of a GC column kept at relatively low temperature (typically -50°C to 50°C). The chemist must be careful, however, not to expose the column to temperatures outside its range of operation. Once the sample has been extracted/collected on the column, injection occurs by simply beginning the oven temperature programme to perform separation and analysis. Purge-and-trap techniques are another way of accomplishing this without introducing air into the GC system.

Thermal Desorption

Thermal desorption is an extraction technique which utilizes a flowing gas to extract a small heated solid or liquid sample. This process occurs during injection in GC systems and, in some cases, the approach is useful to separate thermally the analyte from the matrix for direct analysis in a flowing gas stream. The approach is not used widely in direct sample analysis, even for stable volatile and semivolatile analytes for a variety of practical reasons. For example, analyte–matrix interactions may be too strong in some cases, or matrix interferences may be too great.

Certain analytes are more prone to degradation during thermal desorption and, in multiresidue methods, these analytes may be deemed too important to sacrifice. Another potential pitfall may be that the sample size is too small to achieve the desired LOD. Thus, a liquid concentration step may be needed to increase the injected relative sample size, but then clean-up is usually required. Otherwise, thermal desorption can lead to a very rugged approach for sample introduction in GC analysis because the selectivity of the extraction matches the selectivity of the analysis. Unlike liquid sample introduction, nonvolatile components in the extract are not introduced into the GC column and the life of the chromatographic system is extended.

Solid-Phase Microextraction (SPME)

In the late 1980s, Pawliszyn and his group at the University of Waterloo in Canada invented a technique dubbed SPME, which conveniently takes advantage of the absorption and desorption processes between gases, liquids and solids. An SPME device is a small fibre rod that has been coated with a solid or liquid phase and which is contained in a pen-like sleeve. The coated fibre is exposed to the gaseous or liquid sample and then retracted into the sleeve for brief storage. Analysis may involve thermal desorption of the fibre in a GC injection port or solvent elution of the analytes from the fibre coating into a liquid chromatographic (LC) system.

SPME is applicable to extraction of liquid samples, but it has been most noteworthy for its effectiveness in the extraction of gases. In fact, one of its modes of operation for sampling liquids is to place the fibre in the headspace above the liquid sample in an enclosed volume. The analyte will eventually partition into the headspace and then into the coating on the fibre which can be desorbed into a chromatographic system for analysis.

The major advantage of SPME is ease of use. Other advantages include low cost and avoidance of hazardous solvents. At this time, only a few fibre coatings

are available, and this has limited the selectivity of SPME, but more coatings are expected to become available. The most common coating is polydimethylsiloxane (PDMS), which is also a common phase in GC columns.

Extractions Involving Only Liquids

Liquid-Liquid Extraction (LLE)

Water extraction is a common application for multi-residue methods. Water generally contains fewer matrix interferences than solid matrices and large volumes may often be extracted to decrease LOD. Before the widespread introduction of convenient solid-phase extraction (SPE) cartridges, LLE was the method of choice for extraction of water pollutants. Dichloromethane (DCM) is the most common solvent for extraction in LLE of water because: (i) it is only slightly miscible with water, (ii) it extracts an acceptably wide range of nonpolar analytes; (iii) it possesses a low boiling point to speed evaporation/concentration steps; and (iv) it is heavier than water and thus exists as the lower phase during partitioning in a separatory funnel or LLE glassware. Of course, other immiscible solvents are also used in LLE.

Traditionally, continuous LLE is conducted using specialized glassware which passes redistilled DCM through the water for an extended period of time (16–24 h). The extract collects with the DCM in a boiling flask where the DCM is removed by distillation. Otherwise, either manual or mechanical shaking is used to speed the extraction process (at the cost of more solvent volume and effort). In most cases, sample volume is limited to 1 L by the practical nature of the extraction process and size of the glassware. SPE has virtually displaced

LLE in water methods due to its greater versatility, convenience, solvent reduction and sample volume capacity.

Extractions Involving Liquids and Solids

The most common application in chemical residue analysis concerns the extraction of a solid sample using a liquid. A variety of liquid solvents are readily available to provide a medium for easy homogenization in a blending device. **Table 1** lists key properties of common liquids used in multiresidue methods. These parameters indicate the relative polarity of the solvent, volatility and miscibility with other liquids. In extraction processes, the tenet that like dissolves like (and conversely, opposites do *not* attract) is the primary consideration in choosing the extraction solvent. For example, hexane often provides a selective extraction for nonpolar analytes, and toluene may provide more selectivity for aromatic analytes. Practical considerations involving ease of evaporation, cost, safety and hazardous waste disposal also play a role in the selection of the extraction solvent. In situations involving acidic/basic analytes, pH is often the most critical property in the extraction and buffered aqueous solvents are often necessary. Another important consideration is the stability of the analytes in the extraction medium.

Soxhlet Extraction

In this technique, the sample is mixed with a dispersant and/or drying agent and placed in a permeable paper thimble. The extraction thimble is placed in a glass apparatus which is exposed to the extraction solvent. Fresh solvent enters the extraction section

Table 1 Selected properties of common solvents used in extractions

Solvent	Polarity index	Dielectric constant ^a	Boiling point (°C)	Viscosity (mN s ⁻¹ m ⁻²)	Density ^b (g mL ⁻¹)	Solubility in water (%w/w)
Acetone	5.1	20.7	56.2	0.337	0.791	100
Acetonitrile	5.8	37.5	81.6	0.375	0.786	100
Cyclohexane	0.2	2.02	80.7	0.980	0.779	0.01
Dichloromethane	3.1	9.08	40.7	0.449	1.326	1.6
Diethyl ether	2.8	4.34	34.6	0.245	0.713	6.89
Ethanol	5.2	24.55	78.4	1.08	0.789	100
Ethyl acetate	4.4	6.02	77.2	0.455	0.901	8.7
Hexane	0.0	1.89	69.0	0.313	0.659	0.001
Iso-octane	—	1.94	99.2	0.504	0.692	—
Methanol	5.1	32.70	64.6	0.544	0.791	100
Toulene	2.4	2.57	110.8	0.587	0.866	0.051
Water	9.0	78.30	100.0	0.890	0.998	—

^aAt 25°C.

^bAt 20°C.

from the distillation section of the apparatus. When the solvent reaches a certain level, the extract siphons into a boiling flask where the extracted components are concentrated. The solvent is boiled and redistilled to fall back into the region where the sample is contained. In this way, the Soxhlet glassware is designed to repetitively conduct a number of extractions of the matrix with fresh (redistilled) solvent each time. This process is rather time-consuming (up to 16–24 h) to achieve adequate extraction efficiencies and takes up a great deal of glassware and laboratory space. Automated Soxhlet instruments have been introduced, but the Soxhlet approach is frequently regarded in modern laboratories as archaic.

Blending and Sonication

Blending the sample with the solvent is also an old-fashioned approach, but it is very fast, convenient and inexpensive. Thus, the use of blenders, choppers, shakers, probes and other mixing devices is not likely to disappear even as newer instrumental techniques are being introduced. In the case of matrices such as clay soils that tightly retain certain analytes, sonication using a high energy probe is an alternative method that can break matrix–analyte interactions. However, due to the higher energy input involved, sonication has a greater potential for degrading analytes than simple blending, but the approach can be useful for stable analytes.

Microwave-assisted Extraction (MAE)

MAE is a technique used in the 1990s for the extraction of organic residues in solid samples (microwave digestion has been used in the analysis of metals for several years). The approach simply involves placing the sample with the solvent in specialized containers and heating the solvent using microwave energy. The extraction process is more rapid than Soxhlet, and reduces solvent consumption, but it is more complicated and time-consuming than blending. As in the case of sonication, MAE may overcome retention of the analyte by the matrix, but analyte degradation can be a problem at higher temperatures in certain applications.

The selection of solvent, microwave energy applied and extraction time are the main parameters controlled in MAE. The user should use proper extraction vessels and equipment in MAE, because very high pressures can be generated and explosions may result if appropriate precautions are not taken. MAE instruments are available that conduct batch extractions to increase sample throughput, which is an advantage over automated instruments in other techniques that perform sequential extractions.

Pressurized Liquid Extraction (PLE)

PLE is another time-saving and solvent-reducing approach that was developed in the mid-1990s. The instrumental approach generally involves first dispersing the sample with an inert material (e.g. drying agent or sand) and placing the mixed sample in an extraction vessel. The general approach consists of introducing the solvent into the vessel followed by heating the vessel and a static extraction step (no flow). After this 0.5–20 min step, flow is initiated (dynamic extraction step) and the extract is collected in a vial. The process may be repeated if necessary to increase analyte recoveries. Although increased temperature is not a necessity in PLE, higher temperature is usually used to speed the extraction and break analyte–matrix interactions.

The order of importance of parameters for an application in PLE (and extraction in general) is typically: (1) solvent; (2) temperature; (3) time; (4) repetitions; (5) pressure. The same types of solvents can be used in PLE as in traditional approaches, but relatively viscous solvents, such as ethanol and water, can be difficult to permeate through the sample even at high pressures. Also, highly acidic and basic conditions can be damaging to instrument components, which limits the use of PLE in certain applications. The properties of solvents can change dramatically at different temperatures and pressures (the boiling point at room temperature is commonly exceeded in PLE and MAE), thus it may be possible to replace potentially more hazardous solvents with more benign solvents. Unfortunately, physicochemical properties of many common solvents are not yet known at the elevated temperatures and pressures possible in PLE and MAE.

Solid-Phase Extraction

SPE, sometimes referred to as liquid–solid extraction, is a popular technique for the isolation and separation of analytes from a liquid matrix. SPE columns, packed with small quantities of various chromatographic sorbents, are commercially available. SPE columns may contain polar sorbents such as silica, Florisil or alumina for normal-phase separations, and nonpolar bonded silica phases or polymers for reversed-phase separations. One of the most widely used types of SPE columns is packed with nonpolar octadecylsilyl-derivatized silica, or C_{18} . When liquids such as water, plasma and in some cases, milk, are eluted through C_{18} SPE columns, nonpolar organic compounds such as certain pesticides, drugs or industrial pollutants will be adsorbed onto the column. These adsorbed analytes can be later eluted from the column with a relatively small amount of solvent.

SPE discs containing C_{18} are widely used for the isolation of contaminants from water. Large volumes (litres) of water can be fairly rapidly eluted through the discs, and organic compounds, such as OC pesticides, PCBs and PAHs will be retained. These trapped organic compounds can then be eluted from the SPE discs with organic solvents. In many cases, the choice of solvent, pH and SPE phase provides clean-up of matrix components during the extraction process.

Matrix Solid-phase Dispersion (MSPD)

MSPD is an extraction technique that entails mixing a sample of tissue or milk with an SPE sorbent. Stephen Barker and his group at Louisiana State University first developed the concept in the late 1980s. Typically, a small quantity (0.5 g) of liver, muscle, fat or milk is homogeneously dispersed with 2 g of C_{18} silica in a mortar and pestle. The C_{18} silica will disrupt the cells and disperse the contents over a large surface area, thereby exposing the entire sample to the extraction process. This homogeneous dispersion is then placed in a column, and the various components of the dispersion can be eluted from the column with a range of solvents. For example, lipids or fats can first be eluted from the column with hexane, while drugs, which are more polar, can be eluted with more polar solvents such as ethyl acetate and/or methanol. Thus, extraction and clean-up can be performed in a convenient procedure. Disadvantages of MSPD include the small sample size and potentially high cost of the solid-phase material.

Extractions Involving Supercritical Fluids

Supercritical Fluid Extraction (SFE)

SFE is an instrumental approach not unlike PLE, except a supercritical fluid is used as the extraction solvent rather than a liquid. SFE and PLE employ the same procedures for preparing samples and loading extraction vessels, and the same concepts of static and dynamic extractions are also pertinent. SFE typically requires higher pressure than PLE to maintain supercritical conditions and, for this reason, SFE usually requires a restrictor to better control flow and pressure of the extraction fluid. CO_2 is by far the most common solvent used in SFE due to its relatively low critical point (73 atm and $31^\circ C$), extraction properties, availability, gaseous natural state and safety.

A major advantage of SFE over liquid-based methods is that the extraction solvent becomes a gas after extraction and the analytes are conveniently concentrated in the collecting medium (solid-phase

trap or liquid). Liquid extraction methods nearly always require a concentration step after extraction. Another key advantage of SFE is that the density of the supercritical fluid and other physicochemical properties can be dramatically altered through control of temperature and pressure. This permits a somewhat higher degree of selectivity and versatility in the extraction process without having to use different solvents. In some cases, SFE can eliminate post-extraction clean-up steps, or at least make clean-up using SPE exceptionally convenient by using the SPE sorbent as a trapping medium in SFE. Due to its many practical advantages, SFE may be considered the first choice for extraction if it is able to meet the needs of the application.

However, SFE also has several disadvantages which have delayed the widespread implementation of the approach. The higher selectivity of SFE limits the range of analytes that can be extracted under the same conditions. Furthermore, SFE can have difficulty in overcoming analyte-matrix interactions in certain applications (soils in particular). Organic solvents (and water), often called modifiers in SFE, are sometimes added to the supercritical fluid to increase the polarity range of the extraction process and to help overcome analyte retention in the matrix. Other problems with SFE include the high cost of automated instruments, relatively small sample sizes and more involved method development process. SFE has been demonstrated to be effective in the extraction of a variety of residues from a variety of matrices, but it remains to be seen if the technique can overcome its drawbacks and become more widely implemented.

Conclusions

The analytical range of the overall analysis cannot exceed the analytical range of the extraction process, and in the case of multiresidue methods it is not uncommon to have a wide polarity range of analytes. For this reason, the use of rather exhaustive extraction conditions has been the traditional approach in multiresidue methods. The cost of a wide scope of analytes is often reduced selectivity, solvent-consuming and longer extractions, and additional clean-up of extracts. Ideally, however, the selectivity of the extraction process should match the polarity range of the targeted analytes, and no further clean-up would be required prior to analysis. Modern techniques may permit the realization of the ideal extraction process which is fast, automated, precise, efficient and safe. Furthermore, the variety of solvents and solid-phase sorbents, in combination with temperature and pressure control of modern instruments, can give the

chemist the ability to achieve the desired selectivity in a single, convenient extraction procedure.

Due to the additional parameters of temperature and pressure that modern instrumental techniques provide, it has become more difficult to compartmentalize extraction techniques based on whether the extraction fluid is a dense gas, liquid, supercritical fluid, or combination thereof. Strictly speaking, pressurized fluid extraction PFE includes all types of pressurized extractions independent of the solvent's state of matter. Subcategories of PFE include SFE and PLE, but instrument companies have confused the terminology by marketing PLE as accelerated solvent extraction (ASETM) and enhanced solvent extraction (ESE). Other scientists have developed other terms to describe extraction techniques, such as enhanced fluidity extraction, which connotes a mixture of gas, liquid and/or supercritical fluid, and subcritical water extraction, which is meant to represent PLE using water at high temperatures. However, the unifying principles of extraction are the same no matter what instrument-makers or scientists may call a particular approach.

High-Speed Countercurrent Chromatography

A. Marston and K. Hostettmann, Institut de Pharmacognosie et Phytochimie, Lausanne University, Switzerland

Copyright © 2000 Academic Press

In high speed countercurrent chromatography (HSCCC) a sample is partitioned between two non-miscible liquid phases. One phase is held stationary by a centrifugal force (applied by spinning the separation element at high speed), while the second phase is pumped through the apparatus, hence the alternative term for the process centrifugal partition chromatography (CPC).

Unlike high performance liquid chromatography (HPLC), in which the stationary phase occupies 5–7% and the mobile phase about 75% of the column, the relative proportions in HSCCC are 50–75% for the stationary phase and 20–50% for the mobile phase. As a consequence, large sample loads are possible with HSCCC. Another important advantage of the absence of a solid support is that irreversible adsorption is avoided. There is total recovery of the injected sample and tailing is minimized. HSCCC is thus of special importance for the separation of sensitive and easily degraded samples. Although the efficiency of HSCCC separations is lower than that encountered in HPLC, the optimization of selectivity is the great advantage offered by the former technique.

The potential of HSCCC is further shown by the possibility of applying gradients for separations.

Solvent proportions can be changed during a chromatographic run. Furthermore, solvent elution can be reversed in the course of a separation by changing over stationary and mobile phases. Consequently, one of the characteristics of HSCCC is its extreme flexibility.

Most applications of HSCCC have been performed on two types of instrument. The first category, namely rotating coil instruments, consists of a polytetrafluoroethylene tube (column) wrapped around a spool. The spool is rotated around a central axis in such a way that it describes a planetary motion. Alternatively, hydrostatic equilibrium instruments can be employed. These have either cartridges or discs arranged around a central axis. The separation column, in effect, consists of a series of cells in the cartridges or discs.

Preparative Applications

HSCCC is becoming a routine preparative technique in both industrial and university laboratories. Sample sizes ranging from milligrams to grams (and even kilograms in specialized instruments) can be successfully chromatographed. An extensive range of separations by HSCCC has been published (see Further Reading).

Aqueous and nonaqueous solvent systems are used and the separation of compounds with a wide range of polarities is possible. Two-phase solvents are chosen according to the hydrophobicity of the sample. For polar compounds, *n*-butanol can be employed (e.g. ethyl acetate–butanol–water or chloroform–butanol–water systems), for moderately hydrophobic compounds chloroform (e.g. chloroform–methanol–water) solvent systems, and for more hydrophobic compounds, *n*-hexane (e.g. *n*-hexane–ethyl acetate–methanol–water) solvent systems. Some of the more frequently used solvent systems are shown in Table 1.

A number of representative separations by HSCCC are presented here, in order to give an idea of the possibilities available, together with the chromatographic conditions employed.

Plant-derived Natural Products

Flavonoids Many HSCCC separations of natural products involve polyphenols. The reason for this fact is that there is a tendency to ‘tail’ or even to adsorb irreversibly on conventional chromatographic supports (silica gel, polyamide etc.). This problem does not occur with all-liquid separation techniques and quantitative recovery of injected sample is achieved.

Separations of flavonoid aglycones and flavonoid glycosides have been performed mainly with chloro-

Table 1 Frequently used solvent systems for HSCCC

Sample	Solvent system
Polar	CHCl ₃ –MeOH– <i>n</i> -BuOH–H ₂ O 7 : 6 : 3 : 4
	<i>n</i> -BuOH– <i>n</i> -PrOH–H ₂ O 4 : 1 : 5
	<i>n</i> -BuOH– <i>n</i> -PrOH–H ₂ O 2 : 1 : 3
	EtOAc– <i>n</i> -BuOH–H ₂ O 3 : 2 : 5
Moderately polar	CHCl ₃ –MeOH–H ₂ O 4 : 3 : 2
	CHCl ₃ –MeOH–H ₂ O 5 : 6 : 4
	CHCl ₃ –MeOH–H ₂ O 10 : 10 : 6
	CHCl ₃ –MeOH–H ₂ O 13 : 7 : 8
	CHCl ₃ –MeOH–H ₂ O 7 : 13 : 8
Apolar	<i>n</i> -Hexane–EtOAc–MeOH–H ₂ O 10 : 5 : 5 : 1
	<i>n</i> -Hexane–CH ₃ CN–MeOH 8 : 5 : 2
	<i>n</i> -Hexane–CH ₃ CN–CH ₂ Cl ₂ 10 : 7 : 3

form–methanol–water or chloroform–methanol–propanol–water systems.

The time required for a particular separation can be reduced by incorporating reversed-phase (RP) operation into the procedure. Figure 1 shows the situation for the flavanone hesperitin (1) and the flavonols kaempferol (2) and quercetin (3). When eluting with the upper phase (mobile phase), the most polar component eluted first and the time for complete separation is over 8 h. Reversing the elution mode and changing to the lower phase as mobile phase at 70 min leads to completion of the separation in just over 2 h.

Alternatively, gradient operation can be used to speed up HSCCC. By pumping simultaneously the upper and lower phases of the two-phase solvent system by separate pumps, the proportions of the phases are changed in the coil during separation. In the example shown in Figure 2, the coil (capacity 360 mL) of the chromatograph was initially filled with equivalent amounts of upper and lower phases of the solvent used in Figure 1. The flavonoid mixture was then injected. By pumping upper phase at 4 mL min⁻¹ and lower phase at 1 mL min⁻¹ through the apparatus, the content of the lower phase in the coil was increased from 180 to 340 mL over 3 h. The separation time of the three flavonoids was thus reduced by 5 h, when compared with normal operation.

Xanthenes This is another class of polyphenols to which liquid–liquid chromatography has successfully been applied. Extensive use of HSCCC was made for the separation of xanthenes from a plant, *Hypericum roeperanum* (Guttiferae), from Zimbabwe. A dichloromethane extract of the roots gave a fraction (363 mg) rich in xanthenes after initial chromatography. Separation of the individual xanthenes from this

Figure 1 HSCCC separation of hesperetin (**1**), kaempferol (**2**) and quercetin (**3**) by normal and reversed-phase solvent elution. Instrument: multilayer countercurrent chromatograph (PC Inc.). Solvent system: CHCl_3 -MeOH- H_2O 5 : 6 : 4. Detection: 254 nm. (A) Upper phase as mobile phase; flow rate 3 mL min^{-1} ; rotational speed 700 rpm. (B) Upper phase as mobile phase to 70 min, then lower phase as mobile phase; flow rate 3 mL min^{-1} ; rotational speed 700 rpm. Copyright 1990, John Wiley and Sons Limited.)

fraction by other methods, including semipreparative HPLC, proved very difficult. However, HSCCC gave six fractions which, after final purification steps

Figure 2 Gradient elution for the separation of flavonoids **1-3**. Instrument: multilayer countercurrent chromatograph (PC Inc.). Solvent system: CHCl_3 -MeOH- H_2O 5 : 6 : 4. Composition of mobile phase: upper phase at 4 mL min^{-1} , lower phase at 1 mL min^{-1} . (Reproduced with permission from Slacanian I, Marston A and Hostettmann K. (1989) Modifications to a high-speed countercurrent chromatograph for improved separation capability. *Journal of Chromatography* 482: 234-239. Copyright 1989, Elsevier Science.)

provided eight xanthenes. For the HSCCC separation, the solvent hexane-EtOAc-MeOH- H_2O 1 : 1 : 1 : 1 was employed, with the upper phase as the mobile phase. One of the new xanthenes isolated, 5-O-dimethyl-paxanthonin (**4**), could only be satisfactorily separated by HSCCC.

Chalcone derivatives A further example of the separation of polyphenols by HSCCC is provided by the isolation of chalcone derivatives **5-9** from *Brackenridgea zanguibarica*, a tree found in central Africa and belonging to the Ochnaceae family. This application of HSCCC also illustrates that large amounts of crude plant extract can potentially be handled.

Direct fractionation of 20 g of a methanol extract of the yellow bark layer from the tree is possible with the solvent system cyclohexane-ethyl acetate-methanol-water 8 : 8 : 6 : 6 (upper layer as mobile phase). The extract was dissolved in 20 mL of each phase and

introduced via a 60 mL sample loop. The separation column (660 mL) was first filled with 50% of each phase and then eluted with mobile phase. When steady run conditions had been achieved, the sample was injected. Seven fractions were obtained (A–G; Figure 3), three of these giving the antifungal polyphenols 5–8. Compound 5 crystallized from fraction

B, while compounds 6–8 were purified by a final low pressure liquid chromatography step on a C_{18} support. A novel, inactive, spiro derivative (9) was isolated from fraction E after low pressure liquid chromatography on a C_{18} stationary phase.

As can be seen, no more than two separation steps were required for each polyphenol isolated.

Figure 3 Thin-layer chromatography monitoring (solvent: lower phase of CHCl_3 – MeOH – H_2O 2 : 2 : 1) of fractions from the CCC-1000 HSCCC separation of *Brackenridgea zanguebarica* stem bark methanol extract. Solvent system: cyclohexane– EtOAc – MeOH – H_2O 8 : 8 : 6 : 6 (upper phase as mobile phase). Flow rate: 3 mL min^{-1} . Rotational speed: 1000 rpm. Detection: 254 nm. Sample size: 20 g.

Phenylpropanoids and coumarins It is possible to isolate natural products by HSCCC alone, as exemplified by the purification of phenylpropanoids and a furanocoumarin from a dichloromethane extract of the leaves of *Diplolophium buchanani* (Apiaceae). Initial fractionation gave semipure products (Figure 4). A subsequent liquid-liquid step, using a different nonaqueous solvent system in each case, gave pure myristicin (10, using hexane-*t*-butyl methyl ether-acetonitrile 5 : 1 : 5; upper layer as mobile phase) and a mixture of elemicin (11) and *trans*-isoelemicin (12) (using heptane-acetonitrile-methanol 6 : 3 : 1; upper layer as mobile phase). The furanocoumarin oxypeucedanin (13) was obtained by simple crystallization of the corresponding HSCCC

fraction. All four isolated compounds had both anti-fungal and larvicidal activities.

Lignans Initial fractionation of insecticidal neolignans from *Magnolia virginiana* (Magnoliaceae) by HSCCC was better, less expensive and more efficient than traditional open-column or more recent flash chromatographic methods. A hexane extract of the leaves was chromatographed with the lower layer of the solvent system hexane-acetonitrile-ethyl acetate-water 8 : 7 : 5 : 1 as mobile phase. This solvent contained only a small proportion of water to provide compatibility with the very lipophilic extract. Subsequent purification of the fractions provided a biphenyl ether (14) and two biphenyls (15, 16), which were not only insecticidal to *Aedes aegypti* (the vector of yellow fever) but also fungicidal, bactericidal and toxic to brine shrimp.

During the investigation of anti-human immunodeficiency virus type 1 lignans from creosote bush, *Larrea tridentata* (Zygophyllaceae), a cross-axis coil planet centrifuge was employed with aqueous phases containing sodium chloride, e.g. hexane-ethyl acetate-methanol-0.5% NaCl 6 : 4 : 5 : 5. The presence of salt reduced emulsification and gave improved stationary-phase retention.

Tannins Tannins include a wide variety of phenolic compounds, ranging from single glycosides of gallic

Figure 4 HSCCC initial fractionation on a CCC-1000 instrument of a dichloromethane extract of *Diplolophium buchanani* leaves. Solvent system: hexane-EtOAc-MeOH-H₂O 10 : 5 : 5 : 1 (upper phase as mobile phase). Flow rate 3 mL min⁻¹. Rotational speed: 1000 rpm. Detection: 254 nm. Sample size: 1.7 g.

acid to complex condensed and polymerized derivatives of catechin, epicatechin and related compounds. Their separation poses special problems since there is often irreversible adsorption and even hydrolysis on solid supports. Preparative HPLC is accompanied by sample loss and deterioration or contamination of the column. HSCCC has proved to be an ideal technique for the resolution of these particular problems.

Among the examples of successful separations performed on cartridge instruments is the resolution of two diastereomers, castalgin (**17**) and vescalagin (**18**), which differ only in the configuration of a single hydroxyl group. They were extracted from *Lythrum anceps* (Lythraceae) leaves and chromatographed with the solvent system *n*-butanol-*n*-propanol-water (4 : 1 : 5), using the upper phase as the mobile phase.

The same solvent system was used to obtain a trimeric (nobotanin J; molecular weight 2764) and a tetrameric (nobotanin K; molecular weight 3742) hydrolysable tannin from the leaves of *Heterocentron roseum* (Melastomataceae). The isolation procedure involved chromatography on Toyopearl HW-40 (methanol-acetone-water gradient). Final purification of the two tannins was on an instrument with 12 cartridges (total capacity 240 mL; 700 rpm; flow rate 3 mL min⁻¹).

Monoterpene glycosides Among the examples of monoterpene glycosides that have been separated by HSCCC are two secoiridoid glycosides from the South American plant *Halenia campanulata* (Gentianaceae). Size exclusion chromatography of a crude methanol extract of the plant on Sephadex LH-20, followed by separation by HSCCC (1000 rpm) with the solvent system CHCl₃-MeOH-H₂O 9 : 12 : 8 (lower phase as mobile phase; flow rate 3 mL min⁻¹) gave the two glycosides (**19**, **20**). Their separation is possible by HSCCC, despite the fact that they only differ in their configuration at C₇.

Triterpene glycosides Liquid-liquid chromatography is particularly suitable for the separation of highly polar compounds. Triterpene glycosides enter into this category and many successful isolations have

19 $R_1 = \text{OCH}_3$, $R_2 = \text{H}$

20 $R_1 = \text{H}$, $R_2 = \text{OCH}_3$

been performed using HSCCC either alone or in combination with other chromatographic methods. The direct separation of pure saponins from the crude methanol extract of *Hedera helix* (Araliaceae) berries has proved possible by this method. The extract was first partitioned between *n*-butanol and water. The *n*-butanol fraction was subjected to HSCCC, eluting with the lower layer of the solvent system $\text{CHCl}_3\text{-MeOH-H}_2\text{O}$ 7 : 13 : 8. Elution was monitored by thin-layer chromatography and gravimetry. Molluscicidal saponins 21–24, with hederagenin as aglycone, were separated within 2 h by this technique (Figure 5).

Alkaloids The utility of CPC in separating alkaloids from gummy or tarry matrices has been shown in the preparative separation of pyrrolizidine alkaloids from different plant sources. After classical alkaloid extraction procedures, batches of up to 800 mg of extract could be chromatographed on a rotating coil apparatus (380 mL capacity). Potassium phosphate buffer (0.2 mol L^{-1}) at an appropriate pH was used as stationary phase, while the mobile phase was chloroform. With the buffered stationary phase, good solute resolution was achieved since structurally similar pyrrolizidine alkaloids differ in their pKa values.

HSCCC has been employed for the separation of the antitumour drug, camptothecin (25). From sources such as *Nothapodytes foetida* (Icacinaeae), camptothecin is often mixed with 9-methoxycamptothecin (26). These can be easily separated with the solvent systems $\text{CHCl}_3\text{-CCl}_4\text{-MeOH-H}_2\text{O}$ 2 : 2 : 3 : 1 or $\text{CH}_2\text{Cl}_2\text{-MeOH-H}_2\text{O}$ 5 : 3 : 1. The low solubility of the samples poses a problem with traditional chromatographic techniques. However, for the HSCCC separation, 500 mg of sample can be dissolved

Figure 5 Separation of a methanol extract of *Hedera helix* berries on a Sanki CPC instrument. Solvent system: $\text{CHCl}_3\text{-MeOH-H}_2\text{O}$ 7 : 13 : 8 (lower phase as mobile phase). Flow rate 1.5 mL min^{-1} . Rotational speed: 700 rpm. Sample size: 100 mg.

in 70 mL lower phase and 10 mL upper phase (i.e. a large volume) for injection via a sample loop.

25 R=H (Camptothecin)
26 R=OCH₃ (9-Methoxycamptothecin)

Repetitive sample injections are possible for the separation of close-running compounds on rotating coil instruments. This has been shown for the separation of vincamine (27) and vincine (28) from *Vinca minor* (Apocynaceae). After 20 successive injections (at 42 min intervals), each of 1.7 mg sample mixture, 16.5 mg of 27 and 14 mg of 28 were obtained on a 230 mL rotating coil instrument. The solvent system was *n*-hexane-ethanol-water (6 : 5 : 5; lower phase as mobile phase). The resolution of the HSCCC system was not changed when the instrument was shut down overnight and restarted the next day with the same stationary phase in the column.

27 R=H (Vincamine)
28 R=OCH₃ (Vincine)

Marine Natural Products

The mild conditions achieved with HSCCC and the rapidity of the method are ideal for the separation of delicate marine natural products. Attempts at purification of antitumour ecteinascidins from the tunicate *Ecteinascidia turbinata*, for example, by normal-phase or RP chromatography leads to extensive loss of activity. HSCCC, however, proved to be an effective means of separating these light- and acid-sensitive alkaloids.

The pyrroloquinoline alkaloids isobatzellines A–C have been isolated from a *Batzella* sponge. They exhibited *in vitro* cytotoxicity against the P-388 leukaemia cell line and antifungal activity against *Candida albicans*. HSCCC with a rotating coil apparatus was used in their purification, following extraction and solvent partitioning. Elution was performed with the upper phase of the solvent system heptane–chloroform–methanol–water (2 : 7 : 6 : 3).

The nonaqueous solvent system heptane (or hexane)–dichloromethane–acetonitrile (10 : 3 : 7) has been applied to the separation of a variety of marine natural products, including a long chain methoxylamine pyridine, xestamine A (29), isolated from the sponge *Xestospongia wiedenmayeri*.

Antibiotics

Since its inception, HSCCC has been associated with the field of antibiotics. Liquid–liquid partition techniques are particularly suitable for their separation because bioactive metabolites are often produced in small amounts and have to be removed from other secondary metabolites and nonmetabolized media ingredients. Antibiotics are normally biosynthesized as mixtures of closely related congeners and many are labile molecules, thus requiring mild separation techniques with a high resolution.

To illustrate the applications of HSCCC to the separation of antibiotics, one example is provided by the sporavidins, which are water-soluble basic glycoside antibiotics with complex structures. These are unstable under basic conditions and exist as mixtures of closely related compounds. A sample comprising six sporavidins was resolved on a rotating coil countercurrent instrument (total capacity 325 mL; 800 rpm). Selection of the solvent system was based on partition coefficient data from chloroform–methanol–water, chloroform–ethanol–methanol–water and *n*-butanol–diethyl ether–water mixtures. After HPLC analysis, the final system adopted was *n*-butanol–diethyl ether–water (5 : 2 : 6). Sample was introduced by the so-called sandwich technique, in which sample was injected after filling with stationary phase and before mobile-phase elution. The six components were separated within 3.5 h, employing a total elution volume of 500 mL.

Streptomyces lusitanus produces the hydroquinone derivative **30** (cyanocycline C), which is extremely unstable and cannot be purified by semipreparative HPLC. However, isolation of this antibacterial compound was successfully performed on a rotating coil apparatus with the solvent system CHCl_3 -MeOH-iPrOH-H₂O 3 : 10 : 10 : 10.

Analytical Applications

Reducing the radius of revolution of a rotating coil and increasing the speed of rotation have produced highly efficient HSCCC systems with an effective analytical capability. Operational speeds lie between 2000 and 4000 rpm and the tube bore is less than 1 mm i.d. Efficient separations of micro-quantities of samples in a short time are thus possible. In general, the observed resolution and speed are comparable to those of HPLC. However, it is unlikely that HSCCC will displace HPLC for purely analytical applications. By comparison with analytical HPLC, the major advantage of HSCCC is that it is always possible to reverse the elution mode – this is useful for complex samples with a wide range of polarity. The other important use of analytical HSCCC is in the rapid selection of suitable solvent systems for scale-up to preparative applications.

The instruments available typically have a single rotating coil, with a total capacity of 5–40 mL. Flow rates are directly related to the selected solvent system and must be adapted in order to minimize back-pressure and leakage of the stationary phase. Although instruments are commercially available, many applications have been performed on prototype equipment.

While applications of analytical HSCCC to natural products are not numerous, many different classes of compounds have been separated: alkaloids, anthraquinones, coumarins, flavonoids, lignans, terpenoids and macrolides.

For example, the separation of a mixture of vincamine (**27**), the major alkaloid of *Vinca minor* (Apocynaceae) and vincine (11-methoxyvincamine) (**28**), has been performed by analytical HSCCC in hexane-ethanol-water (6 : 5 : 5) with a 0.85 mm i.d.

multilayer coil. Comparison of the separation with results obtained from analytical RP-HPLC showed that both methods gave baseline resolution, but it was possible to observe a small peak just preceding the vincine peak in analytical HSCCC which was not resolved by RP-HPLC. Analysis of the sample by HSCCC-mass spectrometry showed that the minor compound was probably an isomer of vincine.

A crude flavonoid mixture obtained from the ethanolic extract of the fruits of sea buckthorn (*Hippophae rhamnoides*, Elaeaginaceae) has been successfully separated with an analytical HSCCC instrument. The separation of a 3 mg mixture with chloroform-ethanol-water (4 : 3 : 2) was complete within 15 min when the mobile lower phase was pumped at a flow rate of 5 mL min⁻¹ (rotation speed 1800 rpm). The five main components of the fruit extract were resolved (including isorhamnetin, the principal flavonoid) within 8 min, a time scale wholly comparable to analytical HPLC separations. The instrument used has a 0.85 mm i.d. coil, with a 2.5 cm radius of revolution and a capacity of 8 mL.

Conclusion

The advantages of HSCCC favour a much wider use of this technique in the future: the absence of a solid chromatographic support avoids irreversible adsorption of samples; economics are favourable, as the consumption of solvent is up to 10 times less than conventional chromatographic techniques. Other features, such as the use of step and continuous gradients and the possibility of RP operation, add to the flexibility of the method. Very high sample loading is possible and large quantities of crude plant extracts can be injected without causing contamination problems. HSCCC, however, cannot be called a competitor to preparative-scale HPLC but it is rather a complementary technique. This complementarity can also be exploited when other chromatographic techniques fail to separate a given sample: HSCCC can be tried since its selectivity may be different.

It is still necessary to make improvements on the mechanical side. A variety of instruments are available but some are not yet reliable enough. Once larger scale production is underway, this sort of problem will be eliminated and the full potential of HSCCC will be realized.

Chemical investigation of plant constituents is strongly linked to the use of liquid chromatography (LC) at both the analytical and preparative level. Indeed, most of the secondary metabolites can be effi-

ciently separated or isolated by different liquid chromatographic techniques. The plant extracts are generally screened by different bioassays and submitted to fractionation by chromatography. The fractions obtained are further tested for their biological activities. This process is repeated until the isolation of a pure active constituent, which is finally identified by spectroscopic methods (bioactivity guided isolation; Figure 1).

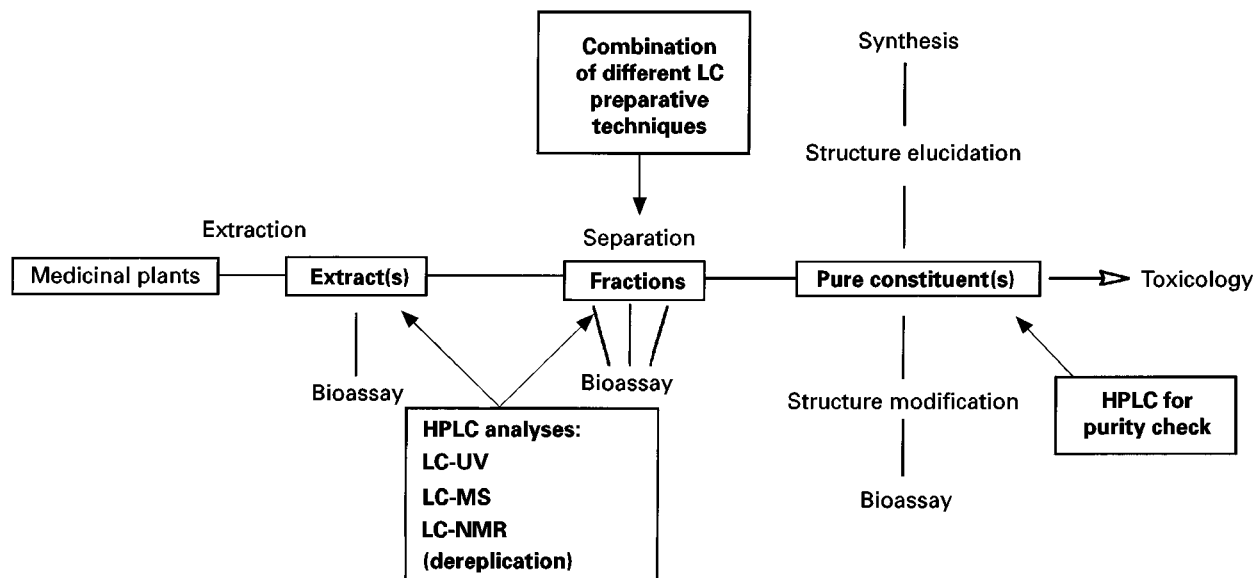

Figure 1 Procedure for obtaining the active principles from plants. LC techniques are used at the analytical and preparative level during the whole isolation procedure. HPLC hyphenated techniques play an important role in the early recognition of well-known compounds in the extract prior to isolation.

Generally the plant material is extracted by solvents of increasing polarity. This extraction step is very important because it allows a first rough fractionation of the plant constituents. Initial extraction with low polarity solvents yields the more lipophilic components, while alcoholic solvents give a larger spectrum of apolar and polar material. The plant extracts are usually very complex mixtures which contain hundreds or thousands of different constituents. Separation of all these constituents with a single chromatographic technique is often difficult to achieve. Thin-layer chromatography (TLC) and high performance liquid chromatography (HPLC) are the most commonly used techniques for a rapid check of the chemical composition of these extracts. If the isolation of a given constituent is required, a scale-up of the analytical separation conditions to preparative chromatography techniques is needed. These preparative techniques are generally open-column chromatography, low pressure LC (LPLC), medium pressure LC (MPLC) and semi-preparative HPLC. When irreversible adsorption problems or denaturation of natural products occur, countercurrent chromatography (CCC) techniques such as centrifugal partition chromatography (CPC) are preferred.

Analytical Techniques

High Performance Liquid Chromatography

Of all the LC chromatography techniques used in the analysis of plants, HPLC is probably the most useful and versatile. HPLC is used routinely in phytochemistry to pilot the preparative isolation of natural products (optimization of the experimental conditions, checking of the different fractions throughout the separation) and to control the final purity of the isolated compounds. For chemotaxonomic purposes, the botanical relationships between different species can be shown by chromatographic comparison of their chemical composition. Comparison of chromatograms, used as fingerprints, between authentic samples and unknowns permits identification of the unknown material and/or the search for adulteration.

HPLC of complex mixtures such as crude extracts is usually carried out on reversed-phase columns. For the separation of the different constituents, acetonitrile–water or methanol–water gradients are applied. Linear gradients are generally used but in the case of a very complex separation, a succession of isocratic and gradient steps may be necessary. For the suppression of tailing due to polyphenolic constituents, modifiers such as trifluoroacetic acid or acetic

acid are added, while for the separation of basic products such as alkaloids, amines or NH_4OH can be used. Crude extracts or fractions are usually injected without any sample preparation, but solid-phase extraction (SPE) prepurification or derivatization (usually to enhance the UV chromophore) can be performed in certain cases. The sample is preferably dissolved in the eluent but when solubility problems occur, as is often the case with plant extracts, stronger solvents such as tetrahydrofuran are used. When working with 4 mm i.d. columns, 50–200 μg of extract can be injected. In most cases, the separation is usually followed by UV detection because a majority of natural products possess UV chromophores. However, for the detection of constituents without a UV chromophore such as sugars, other techniques such as refractive index (RI), light scattering (LS) or electrochemical detection (ECD) are necessary.

A typical HPLC-UV chromatogram of the crude methanol extract of the roots of the African plant *Chironia krebsii* (Gentianaceae) is shown in Figure 2. The separation was achieved by applying a linear acetonitrile–water gradient on an RP-18 column. A good separation of the three main classes of constituents found in the plant was achieved.

HPLC Hyphenated Techniques

In many applications, it may be necessary not only to detect but also to identify compounds in extracts. With conventional detection methods such as UV, the identity of peaks can be confirmed only from their retention times, by comparison with authentic samples. In order to get more information on the metabolites of interest, there is a need for a multiple detection system offering the possibility of taking advantage of both chromatography as a separation method and spectroscopy techniques as detection and identification methods. HPLC has thus been coupled to various sophisticated detectors such as UV photodiode array detectors (LC-UV-DAD), mass spectrometers (LC-MS) or, more recently, to nuclear magnetic resonance instruments (LC-NMR).

When searching plant extracts for compounds with interesting properties, a multidimensional approach to their chromatographic analysis is of great significance. By combining HPLC online with UV, MS and NMR, a large amount of preliminary information can be obtained about the constituents of an extract before their isolation (Figure 1). In the case of polyphenols, for example, UV spectra recorded online give useful complementary information (type of chromophore or pattern of substitution) to that obtained with LC-MS and already provide a precise assignment of the peak of interest. When these data are not sufficient, LC-NMR can give a useful

Figure 2 HPLC-UV analysis of the methanolic extract of the root of *Chironia krebsii* (Gentianaceae). HPLC: column, RP-18 NovaPak (4 μ m, 150 \times 3.9 mm i.d.); gradient, MeCN-H₂O (0.1% TFA) 5 : 95 \rightarrow 65 : 35 in 50 min (1 mL min⁻¹).

complement for a full structural identification online. This preliminary LC chemical screening avoids the useless isolation of known constituents and concentrates the search only on the compounds of potential further interest.

This approach is illustrated by the following example: a Gentianaceous plant, *Swertia calycina*, presenting interesting antifungal activities, was studied by LC-UV, LC-MS and LC-NMR. The LC-UV analysis of the dichloromethane extract was quite simple and exhibited three main peaks. The LC-UV spectra of these peaks permitted a first rapid online recognition of the various types of constituents of the extract. The LC-MS provided molecular weight information for each of these compounds (Figure 3).

These online data, together with chemotaxonomical considerations, allowed the identification of a xanthone (3) and a secoiridoid (1) in this plant. However, the structure of compound (2) could not be completely ascertained by LC-UV-MS alone, because its UV spectrum was characteristic for a quinonic chromophore and no compound of this type has been reported in the Gentianaceae family. The LC-MS of (2) exhibited a protonated $[M + H]^+$ ion at m/z 189, indicating a molecular weight of 188 amu. The LC-NMR analysis of the extract gave well resolved ¹H-NMR online spectra for the three major compounds. For the unknown (2), the online ¹H-NMR spectrum revealed the presence of a methoxyl group together with a quinonic ring proton while four other aromatic protons appeared at lower field (Figure 4). These online data were in good agreement with those of *O*-methyl lawsone, a known naphthoquinone. This type of compound has, however, never been reported in the Gentianaceae family.

Preparative Techniques

Preparative-scale separation is one of the most important operations carried out in a natural products laboratory. It is often tedious and time-consuming, especially when the mixture to be separated is complex. The nature of the separation problem varies considerably from the isolation of small quantities (mg or less), for structure determination purposes, to the isolation of very much larger amounts (hundreds of mg to kg quantities), for comprehensive biological testing or even for production of therapeutic agents.

The most important preparative techniques which have found application in the isolation and purification of natural products are listed in Table 1. A distinction has to be made between techniques using a solid stationary phase or a liquid fixed on an inert solid support and all-liquid partition techniques. For all these techniques, the use of solvents such as acetone or in some cases chloroform is inadvisable because in their presence natural products may undergo transformations.

Flash Chromatography/Open-column Chromatography

Open-column chromatography and flash chromatography are the most popular techniques for natural product isolation. Flash chromatography is a preparative air-driven liquid chromatographic technique with moderate resolution. It has the advantage over conventional open-column chromatography of minimizing sample loss and the risk of decomposition of natural products, due to the fast elution of the sample. These two techniques allow the use of various column sizes and permit the introduction of

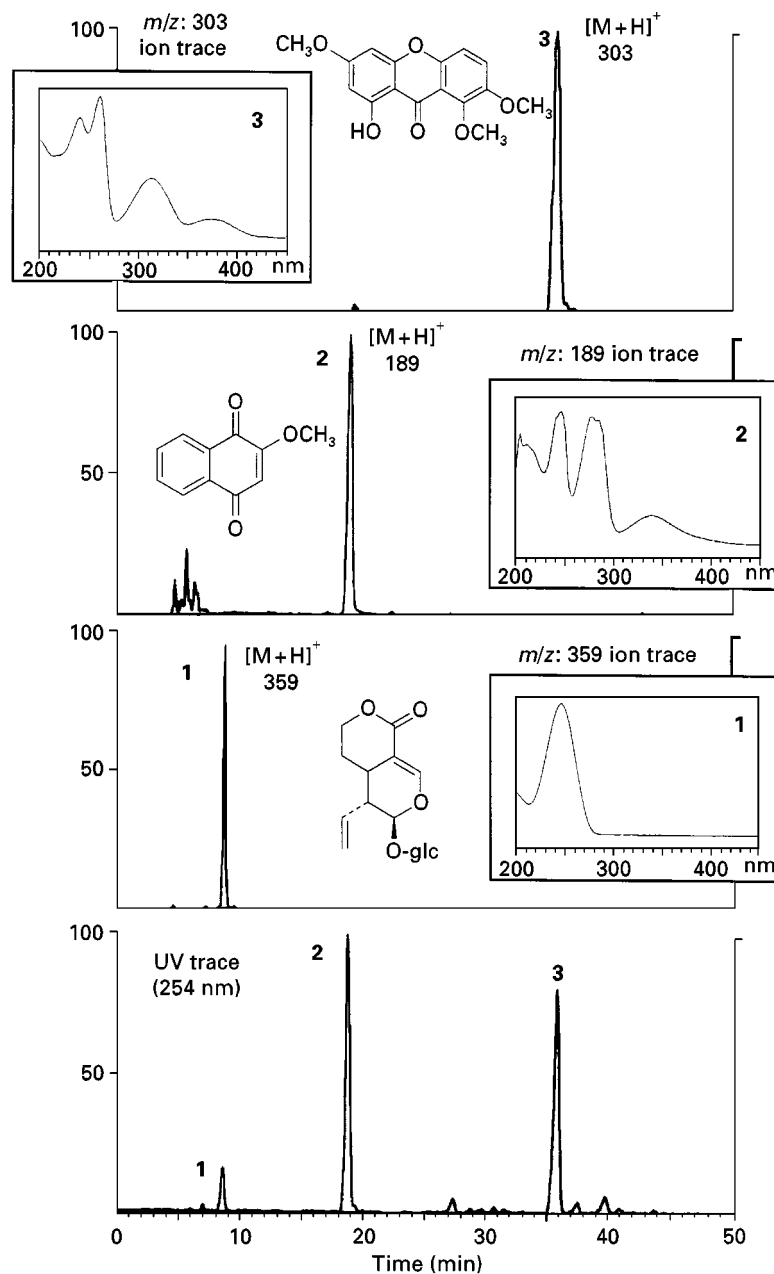

Figure 3 LC-UV and LC-thermospray (TSP)-MS analyses of the crude CH_2Cl_2 extract of *Swertia calycina* (Gentianaceae). For each major peak, the single ion LC-MS traces of the protonated molecular ions $[\text{M} + \text{H}]^+$ are displayed, together with the UV spectra obtained online.

mg to g quantities of sample. They are generally used with silica gel supports. As a rule of thumb, for natural product applications, around 30 mg sample loading per g of 50–200 μm support is feasible. When used only for filtration (first fractionation step of a crude plant extract), silica gel chromatography can be performed under overloaded conditions and quantities up to 100 mg g^{-1} of support can be loaded.

These techniques can be used at different steps in the isolation process of natural products. They are mostly well adapted to the separation of nonpolar to medium polarity plant extracts. In order to find the appropriate solvent system, preliminary TLC analyses are performed and the plate is sprayed with different reagents in order to detect the natural products of interest. For a given product, solvent systems producing R_F values between 0.2 and 0.3 are

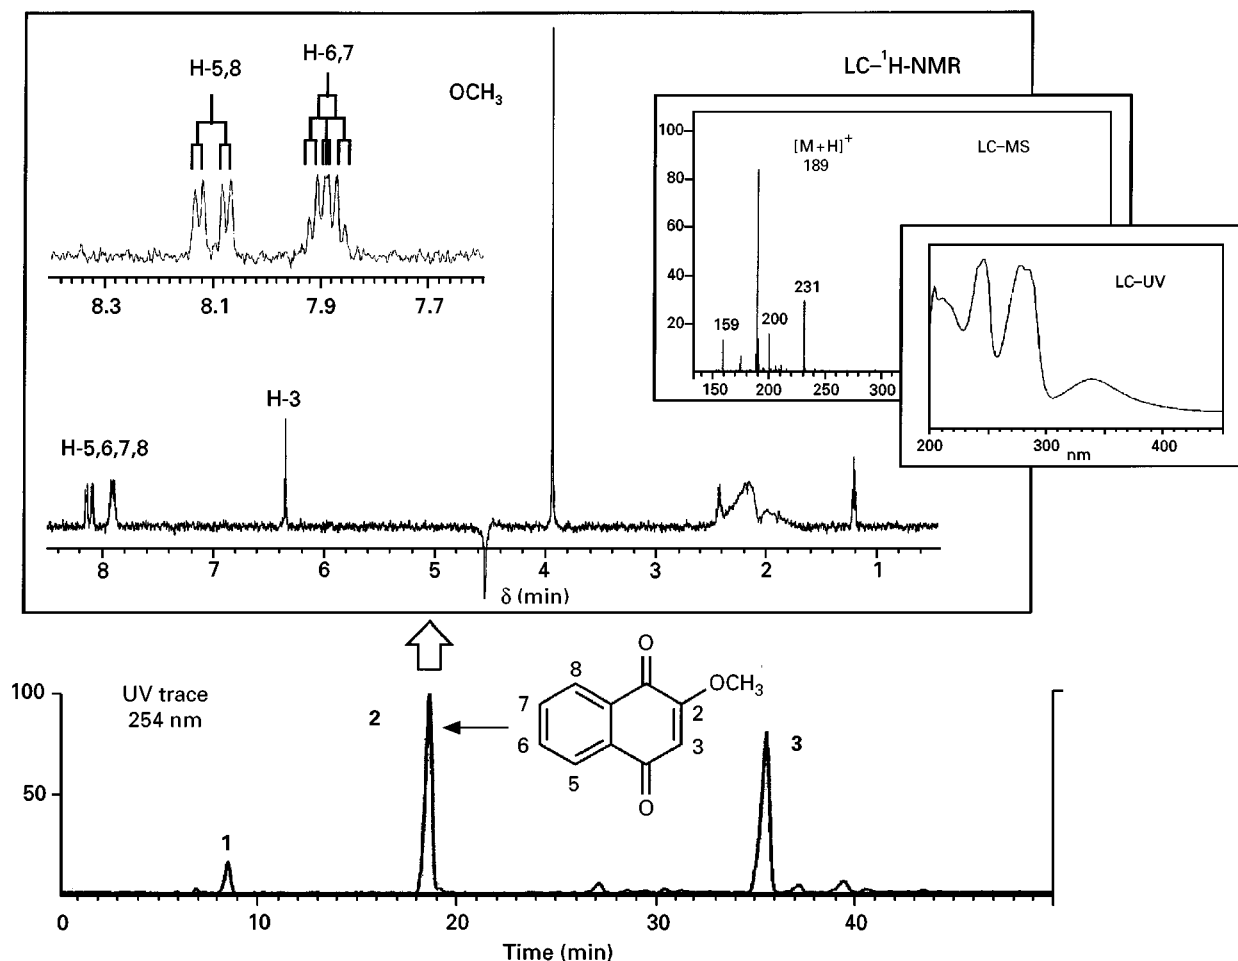

Figure 4 Summary of all the spectroscopic data obtained online by LC-UV, LC-MS and LC-NMR for the naphthoquinone (**2**) in the dichloromethane extract of *Swertia calycina* (Gentianaceae).

usually optimum for scale-up. When flash and open-column chromatography are used as first fractionation steps of crude plant extracts, solvent systems of increasing polarity are often employed. The fractions are checked by TLC at the outlet of the column and when compounds of a given polarity are eluted, the

solvent system is changed for a more polar one. This allows compounds of different polarities to be efficiently separated.

A typical step gradient solvent system for the separation of a dichloromethane extract by flash chromatography on silica gel is: chloroform-

Table 1 Preparative separation methods for plant constituents

Type	Technique	Abbreviation

	Medium pressure LC	MPLC
	High performance LC	HPLC
Liquid-liquid chromatography	Droplet countercurrent chromatography	DCCC
	Centrifugal partition chromatography	CPC

petroleum spirit (80:20), then pure chloroform, chloroform-methanol (80:20) and finally pure methanol for eluting the polar constituents.

Preparative Liquid Chromatography

Because of the complexity of the chemical composition of crude plant extracts, open-column chromatography or flash chromatography techniques alone often do not provide sufficient resolution for the isolation of pure natural products. The introduction of pressurized liquid chromatography in natural product chemistry has allowed the use of silica gel of smaller particle size and of bonded phases such as RP-8, RP-18 and diol, thus giving more versatility and better resolution.

Depending on the sample size and the resolution to be achieved, three techniques are generally used for phytochemical applications: LPLC, MPLC and semipreparative HPLC. Polar natural products such as glycosidic derivatives can mainly be separated on RP-8 or RP-18 bonded phases while compounds of intermediate polarity such as polyphenol aglycones, polyacetylenes and sesquiterpenes can be resolved on silica gel supports (Table 2).

Low and Medium Pressure Chromatography

LPLC makes use of columns containing packings of *c.* 40–60 μm , allowing high flow rates up to a pressure of 10 bar. Prepacked columns with various sizes and supports are available. MPLC accommodates much larger sample loads (100 mg–100 g) than LPLC (10 mg–1 g) and is designed to be operated at higher pressure (*c.* 5–40 bar). MPLC uses refillable columns of various sizes. Supports with particle sizes ranging from 15 to 200 μm can be used. MPLC is more versatile than LPLC but the basic operation of the two techniques is similar.

The chromatographic conditions for these techniques are selected by HPLC or by TLC. The

selectivity of the eluent is first optimized and then the composition of the mobile phase is adjusted to suit the preparative conditions. Retention factors (*k*) between 1 and 5 or R_F values < 0.4 are appropriate. Different representative solvent systems used for the separation of various classes of natural products are given in Table 2.

In some cases, similar resolution can be obtained by both LPLC or MPLC and analytical HPLC. This is of importance for the transposition of conditions from analytical to preparative level. It is illustrated here by the separation of iridoids and a phenylpropane glycoside from the root of *Sesamum angolense* (Pedaliaceae), a plant reputed to have antihemorrhagic properties in African traditional medicine. Analytical HPLC of the relevant fractions is shown in Figure 5A and 5B. Baseline separation of phlomiol (4) and puchelloside-I (5) was possible with methanol-water (10:90). Verbascoside (6) was, however, only eluted with 32% methanol. These analytical conditions could be applied directly to a preparative separation on a Lobar LPLC column by performing a step-gradient elution from 10% to 32% methanol.

Following a similar procedure, several xanthone glycosides (7–12) from *Halenia corniculata* (Gentianaceae) were successfully isolated from an enriched fraction by MPLC in a single isocratic run (Figure 6).

Semipreparative HPLC

While analytical HPLC is useful for obtaining information about sample mixtures and does not rely on their recovery, the aim of semipreparative HPLC is to isolate pure substances. Compared to the other column LC techniques, HPLC can handle very small particle sizes (5–30 μm) which provide a large gain in separation efficiency. In phytochemical investigations, this technique is often used for final purification steps for a small number of compounds which are

Table 2 Representative solvent systems used for LPLC or MPLC

Substance class	Support	Eluent
Polyacetylenes	SiO ₂	Toluene-EtOAc (85 : 15)
Flavonoid aglycones	SiO ₂	C ₆ H ₁₄ -EtOAc, CHCl ₃ -MeOH
	DIOL	CHCl ₃ -MeOH-HOAc (950 : 50 : 1)
Flavonoid glycosides	RP-8	MeOH-H ₂ O gradient
Phenylpropanoid glycosides	RP-18	MeOH-H ₂ O gradient
Chromenes	SiO ₂	CHCl ₃ -C ₆ H ₁₄ -MeOH
Sesquiterpenes	SiO ₂	C ₆ H ₁₄ -EtOAc
Diterpenes	RP-18	MeOH-H ₂ O (1 : 1)
Triterpenes	RP-8	MeOH-H ₂ O (4 : 1)
Iridoid glycosides	RP-18	MeOH-H ₂ O gradient
Alkaloids	RP-8	MeOH-0.02 mol L ⁻¹ NH ₄ OAc (3 : 2)

Figure 5 Isolation of iridoids from *Sesamum angolense*. (A) Analytical HPLC: column, LiChrosorb RP-8; eluent, MeOH-H₂O 10 : 90; detection, 254 nm. (B) Analytical HPLC: column, LiChrosorb RP-8 eluent, MeOH-H₂O 32 : 68; detection, 254 nm. (C) Preparative separation: column, Lobar RP-8 (310 × 25 mm i.d.); eluent, step gradient MeOH-H₂O 10 : 90 and 32 : 68; sample, 130 mg; detection, 254 nm.

difficult to separate. The loading capacity of the column is usually rather small (1–100 mg) and the isolation of a pure natural product often requires multiple injections of a given prepurified fraction. The number of applications of this technique to natural product isolation is very large.

Figure 7 shows the separation of closely related antifungal chromenes from *Hypericum revolutum* (Guttiferae) by semipreparative HPLC. The petroleum ether extract of the leaves and twigs after flash chromatography and LPLC on silica gel, gave an active fraction which appeared homogeneous by TLC. However, analytical HPLC on an RP-18 column showed the presence of two homologues (**13** and **14**). Since chromenes degrade in the presence of acid, forming the corresponding dichromenes, no acid was used in eluent for semipreparative separation. A total of 120 mg was separated by repetitive injections.

Centrifugal Partition Chromatography

The use of CCC represents an interesting complementary approach to LC on solid supports. This technique is an all-liquid method without the presence of a solid support and thus has the advantage over other liquid chromatographic methods of avoid-

ing irreversible adsorption of sample, allowing a quantitative recovery and minimizing the risk of sample denaturation. These points are extremely important when labile or polar natural products have to be isolated. Among the different countercurrent liquid chromatography techniques, CPC is probably the most popular technique because of its speed and ease of use. The choice of the solvent system can be guided by TLC and for rotating coils the best R_F range is 0.1–0.4. According to the type of instrument used – single coil, multiple coil or cartridge – the sample size ranges from 10 mg to 10 g. Selected examples of solvent systems used for the separation of various classes of natural products are given in **Table 3**.

In order to illustrate this approach, the separation of the active anthranoid pigments of *Psorospermum febrifugum* (Guttiferae), an African medicinal plant that exhibits strong growth inhibition of cancer cells and antimalarial activity, is shown in **Figure 8**. The lipophilic root bark extract of this plant was first separated by flash chromatography and LPLC but resulted in considerable material losses, owing to irreversible adsorption on the supports. However, in a single CPC step, three pure compounds (**15**, **16** and **17**) and a mixture of a fourth anthranoid pigment

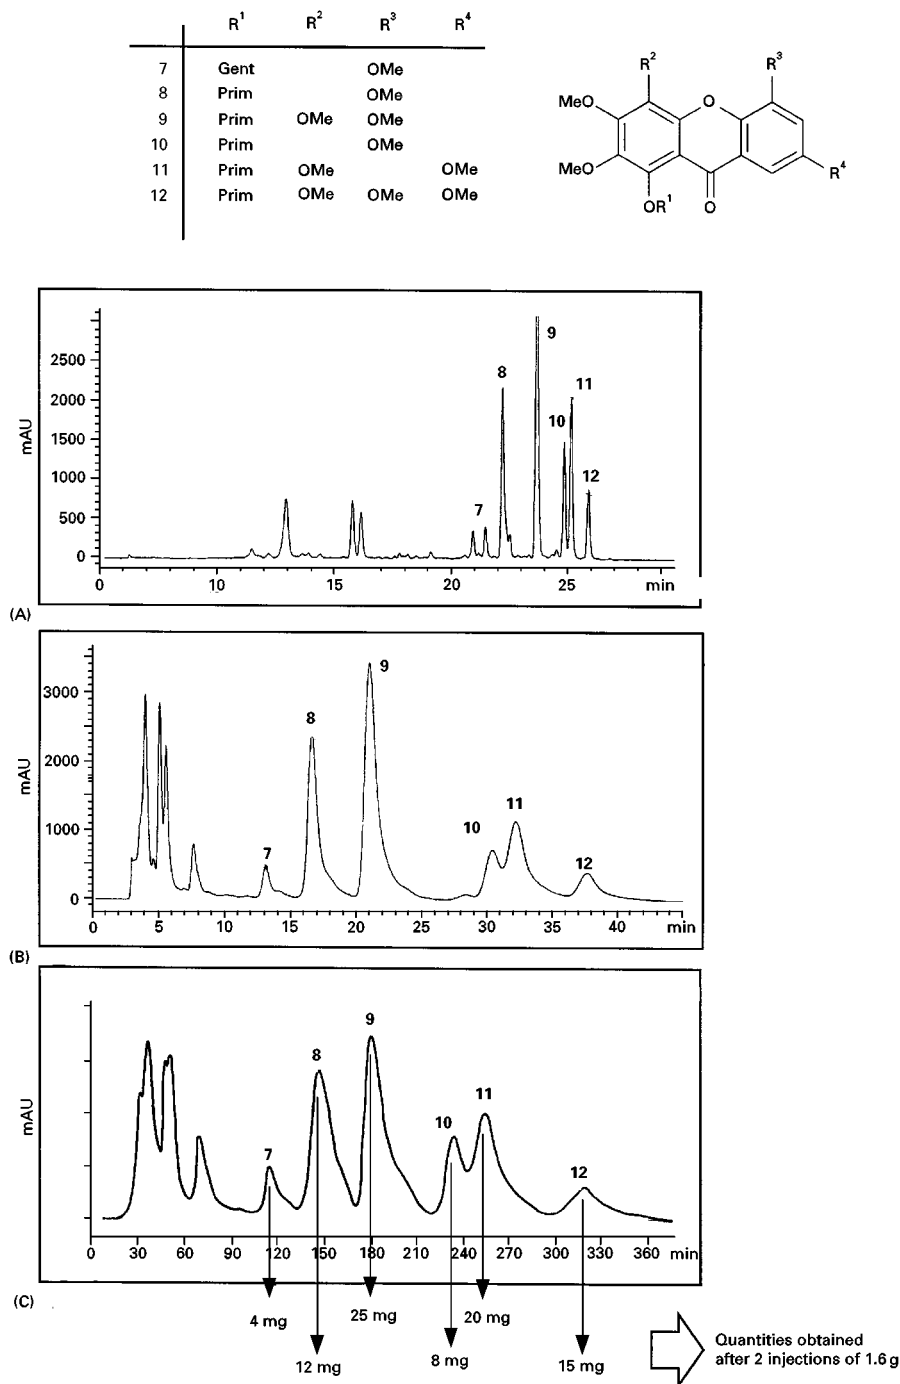

Figure 6 HPLC-MPLC transposition for the isolation of xanthone glycosides from an enriched fraction of *Halenia corniculata* (Gentianaceae) after separation by size exclusion chromatography on Sephadex LH-20 of the methanolic extract. (A) HPLC-gradient. Conditions: column: NovaPak RP-18 (3.9 × 150 mm); H₂O–MeCN; 5–65% MeCN in 50 min; 1 mL min⁻¹. (B) HPLC-isocratic. Conditions: column: LiChroCart; Lichrosorb RP-18 (7 μm); 4 × 250 mm; H₂O–MeOH (60 : 40); 1 mL min⁻¹. (C) MPLC-isocratic. Conditions: column: MPLC home-packed Lichrosorb Rp-18 (15–25 μm); 12 × 460 mm; H₂O–MeOH (60 : 40); 3 mL min⁻¹; 12 bar. Sample size 300 mg.

(18) with an unidentified constituent (19) were obtained without loss of product. A nonaqueous solvent system was used for the separation, which could be scaled up to a 500 mg sample size.

Combination of Methods

No single liquid chromatographic separation method is able to solve all separation problems and moreover

Figure 7 Separation of antifungal chromenes from *Hypericum revolutum* (Guttiferae). (A) Analytical HPLC: column, LiChrosorb RP-18 (250 × 4.6 mm i.d.); solvent, MeOH-H₂O 80 : 20; flow, 1.5 mL min⁻¹; detection, 254 nm. (B) Semipreparative HPLC: column, μ-Bondapak RP-18 (300 × 7.8 mm i.d.); solvent MeOH-H₂O 67 : 37; flow, 5 mL min⁻¹; detection, 254 nm.

it is very common to find multistep chromatographic operations for the isolation of pure natural products. Although it is possible to obtain a pure compound by a one- or two-step procedure,

a combination of techniques is normally required. Of course there are many different ways of putting together all the possible separation techniques, but in reality the choice of strategy is limited

Figure 8 CPC separation of a light petroleum ether extract of *Psorospermum febrifugum* (Guttiferae) root bark. Solvent, *n*-C₆H₁₄-MeCN-MeOH (40 : 25 : 10, mobile phase = upper phase); flow, 5.5 mL min⁻¹; rotational speed, 1500 rpm; sample, 100 mg; detection, 254 nm.

Table 3 Representative solvent systems used for CPC separations

Substance class	Eluent
Flavonoids	CHCl ₃ -MeOH-H ₂ O 4 : 3 : 2
Xanthenes	Petrol ether-EtOAc-MeOH-H ₂ O 1 : 1 : 1 : 1
Tannins	<i>n</i> BuOH- <i>n</i> PrOH-H ₂ O 4 : 1 : 5 <i>n</i> BuOH- <i>n</i> PrOH-H ₂ O 2 : 1 : 3
Saponins	CHCl ₃ -MeOH- <i>n</i> PrOH-H ₂ O 5 : 6 : 1 : 4 CHCl ₃ -MeOH- <i>i</i> BuOH-H ₂ O 7 : 6 : 3 : 4 CHCl ₃ -MeOH-H ₂ O 7 : 13 : 8
Polyacetylenes	Hexane-MeCN-TBME 10 : 10 : 1
Aporphine alkaloids	CHCl ₃ -MeOH-0.5% HOAc 5 : 5 : 3

by a number of constraints: the extraction method, the complexity of the extract, the sample preparation, the polarity, the stability, the solubility, the sample size and the complementarity of the separation techniques.

When choosing a separation strategy, it is often useful to pick steps which differ as much as possible in selectivity. During an isolation procedure, the scale of the operation decreases: as the purity of the product increases, there is a corresponding diminution of sample quantity. This implies that the initial fractionation steps are those which can separate large

Figure 9 Strategy for the isolation of various aromatic constituents from *Inulanthera nuda* (Asteraceae). Conditions: 1, CHCl₃-MeOH-H₂O-*i*-PrOH; 2, RP-18, MeOH-H₂O (1 : 9); 3, Sephadex LH-20, MeOH-H₂O (1 : 1); 4, RP-18, MeOH-H₂O (1 : 4); 5, RP-18, MeCN-H₂O (7 : 43).

amounts of material, e.g. column chromatography using relatively cheap stationary phases (silica, alumina, polyamide or XAD ion exchange resins), flash chromatography or CCC. Size exclusion chromatography (SEC) is also becoming increasingly popular as a first purification step. Subsequent chromatographic steps on smaller quantities can be performed with more expensive column packings and equipment. Semipreparative HPLC is often reserved for final purification.

The combination of different preparative chromatography techniques for the isolation of various aromatic compounds from *Inulathera nuda* (Asteraceae) is presented in Figure 9. A first liquid–liquid partition of the methanolic extract, dissolved in water, gave an enriched butanol extract which was further separated by CPC, affording 13 fractions. One of these fractions yielded (20) after recrystallization while the other constituents were further separated by MPLC or SEC. The final purification of flavonoid glycoside (25), for example, required a combination of SEC on Sephadex LH-20, followed by MPLC and semipreparative HPLC.

Conclusions

The introduction of modern liquid chromatographic methods has revolutionized the science of separation of natural products of plant origin. These new methods allow faster separations and facilitate the resolution of complex mixtures. As shown, techniques such as HPLC can be used both at the analytical and preparative level. At the analytical level and in combination with sophisticated detectors, structural information can be obtained online, while on the preparative scale closely related compounds can be successfully isolated.

The actual separation method or methods depend(s) on a number of factors relevant to the separation problem, but a judicious choice of strategy enables most targets to be reached. New methods and improvements are continually being introduced, with the result that the number of combinations available is steadily expanding, hopefully leading to a progressive simplification of the ever more complex separation problems that are being undertaken.

Liquid Chromatography–Nuclear Magnetic Resonance

B. Schneider, Max Planck Institute for Chemical Ecology, Jena, Germany

Copyright © 2000 Academic Press

Hyphenation of chromatographic and spectroscopic methods is important in analytical chemistry and is of great value in modern natural product analysis. Gas chromatography–mass spectrometry (GC-MS) has been used for many years to analyse volatile compounds and derivatives of nonvolatile natural products. The development of liquid chromatogra-

phy–mass spectrometry (LC-MS) extended the scope of MS coupling techniques to allow analysis of non-volatile compounds without derivatization. Nuclear magnetic resonance (NMR) is less sensitive than MS but represents the most informative and most universal analytical technique for natural products. Thus, using a NMR spectrometer in coupling methods does not simply mean adding another detector but represents a new dimension in analytical natural product chemistry.

The combination of NMR and chromatographic, or electrophoretic, separation methods was made

possible by the introduction of high field spectrometers, with an increased dynamic receiver range, the development of suitable continuous-flow cell probes and solvent suppression techniques. High performance liquid chromatography (HPLC)-NMR was first described by Watanabe in 1979 and it is now an established method in the field of natural product research. A number of examples, mainly of plant natural products, are reviewed in this article, demonstrating the advantages and limitation of HPLC-NMR.

Methodology

Sample Preparation

As sensitivity of HPLC-NMR is currently in the microgram or even nanogram scale, the amount of tissue investigated can be dramatically reduced as compared with that required for conventional isolation of natural products. Small scale extractions using 0.5–1 g of dried plant tissue have been described as being sufficient to record HPLC- ^1H NMR spectra with an excellent signal-to-noise ratio. Natural products which are present in living tissue in only trace amounts (pg g^{-1} tissue) are now amenable to NMR analysis without isolation, either directly in the crude extract, or after employing simple work-up steps.

The procedures for sample preparation are essentially the same as those for normal analytical HPLC. Since extracts of biological tissues are normally complex mixtures of various substances covering a broad range of polarity, including both lipophilic and hydrophilic components, pre-purification or fractionation of the crude extract can often improve the chromatographic resolution. Enrichment of the desired natural product prevents overloading of the column by unwanted components and enhances the concentration of analytes above the detection limit. Due to the use of a NMR spectrometer as detector, deuterated solvents are strongly recommended for injecting the analyte into the chromatographic system.

HPLC

There are only a few special requirements for HPLC combined online with NMR. A pulsation-free HPLC pump to provide proper gradient formation and efficient solvent mixing should be used. The first detector cell (usually UV), which in HPLC-NMR is no longer at the end of the process, should be as small as possible to reduce peak broadening to a minimum. In general, reversed-phase chromatography is used for most HPLC-NMR applications in natural product

chemistry. Water and protonated organic solvents cause resonances in the NMR spectrum. These eluent signals might overlap with those of the analyte and thus prevent adequate spectrum evaluation. To minimize the intensity of solvent resonances, and to improve the detection limit, deuterated solvents are utilized. In practice, fully deuterated water (99% D_2O) is used in combination with nondeuterated HPLC-NMR-grade acetonitrile or methanol. The phenomenon of peak broadening, often occurring in longer isocratic HPLC runs, reduces the fraction of the peak transferred to the flow cell. To compensate for this broadening, solvent gradients are recommended for elution. Addition of trifluoroacetic acid or phosphoric acid also contributes to peak focusing and does not cause additional signals in the ^1H NMR spectrum. Due to the implicit requirements of NMR methodology (solvent suppression, lock solvent), reversed-phase gradients cannot begin below a minimum concentration of 1% of the organic component and are not useful when exceeding about 95%. Flow rates between 0.6 and 1.0 mL min^{-1} , usually employed in analytical HPLC, are also convenient under HPLC-NMR conditions. However, adaptation of flow rate to the particular HPLC-NMR mode (continuous-flow, stopped flow) is required. Recent developments, allowing the use of microbore and capillary columns, which require lower flow rates and consume smaller amounts of solvents, permit the economical use of completely deuterated eluents. In general, the highest sample amount possible should be injected to reduce measuring time. Even column overloading, and partial peak overlap in the UV trace, may be acceptable to some extent because only a fraction of the desired peak is located in the active volume of the flow cell during spectrum acquisition. It is important to note that the quality of chromatographic separation determines the success of the NMR measurement and, thus, should be executed as carefully as possible.

NMR

HPLC-NMR probes do not make use of conventional removable NMR tubes but contain a continuous-flow cell, fitted to the HPLC via a polyetheretherketone (PEEK) transfer capillary. The capillary connection should be as short as possible, otherwise the stray field of the NMR magnet has to be considered. As a compromise, the HPLC is usually positioned slightly outside the 5 mT line (corresponding to about 1.5 m for a 500 MHz magnet) of the stray field. A valve interface between the HPLC detector and the NMR probe allows selection of different modes, like continuous-flow, stopped-flow and storage

mode. The active volume of the flow cells is between 40 and 240 μL in size. In continuous-flow mode, the detector volume and the flow rate determine the residence time of the sample in the flow cell and thus have a significant impact on sensitivity. Capillary flow cells with a detection volume in the order of 50–900 nL have been developed for microbore and capillary HPLC. Since there is no sample rotation it is possible to fit the radiofrequency coils directly on the glass body of the flow cell. This arrangement affords an optimal filling factor and, consequently, results in extraordinarily high sensitivity of the HPLC-NMR probes.

Commercially available HPLC-NMR probes are designed as inverse detection probes and, therefore, are most efficient for acquiring ^1H NMR spectra. Figure 1 shows ^1H NMR spectra recorded in MeCN- D_2O with and without solvent suppression. In the nonsuppressed spectrum only the eluent signals are visible. To visualize the resonances of the analyte, suppression of the solvent signals is necessary. This can be accomplished by presaturation or by the 'water suppression enhanced through T1 effects' (WET) sequence. WET is more efficient in con-

tinuous-flow measurement because it requires shorter delays in comparison with the presaturation technique. However, even most efficiently suppressed solvent signals cover a certain part of the spectrum and may overlay some of the resonances of the analyte. This general drawback of HPLC-NMR can be reduced by running the same sample again in another eluent system having different chemical shift values, e.g. using acetonitrile (δ 2.0)- D_2O in the first and methanol (δ 3.2)- D_2O in a second run. The sensitivity of HPLC-NMR significantly depends on the operation mode and a number of further factors discussed above and by other authors. For the stopped-flow technique, which is the most sensitive mode, the detection limit in routine analysis (500 MHz; 120 μL flow cell) is below 1 μg in reasonable times. Using a capillary column and a nanolitre flow cell, the detection limit is now in the nanogram range. The stopped-flow technique is also suitable for acquiring homonuclear correlation spectra (COSY, TOCSY, NOESY and ROESY) of samples below 10 μg . Moreover, gradient-assisted inverse-detected heteronuclear correlation spectroscopy (GHSQC and GHMBC)

Figure 1 Stopped-flow HPLC- ^1H NMR spectra of an aromatic natural product measured in MeCN- D_2O . Spectrum (A), which was acquired without solvent suppression, exhibits the large signal of nondeuterated MeCN, small satellites of MeCN and the signal of HDO. Resonances of the analyte are not visible. Spectrum (B) was acquired using solvent suppression by double pre-saturation of MeCN and HDO. Spectrum (C) is an enlargement of (B), showing the well-resolved resonances in the aromatic part of the spectrum.

is also possible under HPLC-NMR conditions. The measurement in stopped-flow mode requires an accurate determination of the transfer time between the first detector, usually an UV or diode array detector, and the active volume of the flow cell. This is to ensure that the HPLC pump stops just at the moment when the top of the peak is in the magnet. Synchronization of HPLC and NMR is also required in fully automated mode that enables measurement of several peaks without further interaction of the operator.

The continuous-flow mode is much less sensitive than the stopped-flow technique but provides the opportunity to scan an extract rapidly for interesting natural products. Since the NMR resonances of the solvent depend on the composition ratio of the eluent, gradient elution requires continuous adaptation of the solvent suppression frequency to the moving signal. This suppression frequency is determined for each increment by the so-called scout scan prior to the WET sequence. In continuous-flow spectra the retention times (y axis) are plotted versus the chemical shifts (x axis). The extraction of traces from these unusual two-dimensional spectra yield one-dimensional ^1H spectra of the desired increment that can collectively be outlined as stacked plots.

Applications

Identification of Natural Products

An increasing number of applications of HPLC-NMR are devoted to the identification and structure elucidation of natural products. The main part of these investigations covers plant natural products as novel biologically active components for pharmacological and agricultural preparations. The aims and methodology of a number of these investigations are discussed in the following paragraphs. **Table 1** summarizes the classes of plant natural products and the plant families that have been analysed by hyphenated HPLC-NMR techniques.

Extracts equivalent to 250 mg of dried leaves of *Zaluzania grayana* (Asteraceae) were used for HPLC separation with direct measurement of ^1H NMR spectra in the online mode. Overlapping peaks could be separated more efficiently by the stopped-flow mode, collected in a sampling unit and analysed later by ^1H and 2D COSY measurements. These investigations provided information on the structure of two known and a novel sesquiterpene lactone of taxonomic relevance. Using a microsampling technique, glandular trichomes from the leaf surface of *Scalesia* species (Asteraceae) were collected. A sample combined from several species of the genus was used for

online HPLC-NMR analysis. Flavones and sesquiterpene lactones were identified by comparison with spectra of authentic reference compounds or literature data.

Unstable and structurally closely related bitter acids from dried female flowers of *Humulus lupulus* were extracted by supercritical carbon dioxide and analysed by HPLC-NMR in the stopped-flow mode without any degradation. Using an acetonitrile- D_2O eluent containing H_3PO_4 , well-resolved spectra of α - and β -hop acids were obtained despite column overloading (2.5 mg of extract was loaded on to an analytical reversed-phase column).

The online analysis of a CH_2Cl_2 extract of *Swertia calycina* (Gentianaceae) provided ^1H NMR spectra of all major constituents. Extraction of single traces from the 2D plot allowed a precise assignment of their specific resonances. Approximately $0.05\ \mu\text{mol}$ per peak was needed to obtain a ^1H NMR spectrum in the online mode using a 500 MHz NMR instrument. To improve the quality of the ^1H spectra and to measure a 2D COSY spectrum of one of the components, sweroside, the same extract was investigated in the stopped-flow mode. The detection limit for a ^1H NMR spectrum could be lowered by a factor of about 100 under stopped-flow conditions but longer acquisition times were required in comparison with the continuous-flow mode. In the case of the more complex methanol extract of another Gentianaceae species, *Gentiana ottonis*, clear ^1H NMR spectra of secoiridoids, flavones and xanthenes were only obtained in the stopped-flow mode. LC-UV and LC-MS data were also needed for full identification of compounds from both species.

Complementary HPLC-NMR and HPLC-MS studies were also performed on crude extracts and bioactive fractions from *Monetes engleri*. On-flow experiments indicated two major prenylated flavanone components in the CH_2Cl_2 extract of this plant but did not monitor minor components. A bioactive fraction obtained by medium pressure liquid chromatography (MPLC), containing these components, was subjected to stopped-flow HPLC-NMR analysis. ^1H NMR, 1D TOCSY, 2D NOESY and gradient-enhanced inverse ^1H , ^{13}C correlation experiments (GHSQC, GHMBC; **Figure 2**) were recorded from the enriched sample in a total acquisition time of 9.6 h. The WET sequence was used to suppress the eluent signals of the residual HDO resonance, the resonances of MeCN and its two ^{13}C satellites, and those of the propionitrile impurities of MeCN. The constitution of monotesone A, a new prenylated flavanone, was elucidated online using the strategy described. However, determination of the absolute configuration was only possible after isolation.

^a Combined sample of several species of the genus; ^b and other *Senecio* species.

Figure 2 GHMBC spectrum of a prenylated flavanone acquired under HPLC-NMR conditions in 6 h 20 min. 1 mg of fraction injected. Reprinted with permission from Garo E, Wolfender JL, Hostettman K *et al.* (1998) Prenylated flavonones from *Monofes egleri*: on-line structure elucidation by LC/UV/NMR. *Helvetica Chimica Acta* 81: 754.

HPLC-NMR was shown as being the method of choice to assign the structure of a rapidly isomerizing dimeric secoiridoid glucoside carrying a (*Z*)-*p*-coumaroyl unit found in aerial parts of *Lisianthium seemannii* (Gentianaceae). The stopped-flow ^1H NMR spectrum of this unstable isomer was very similar to that measured for the isomerization product, as far as the monoterpene and glycosidic parts of the molecule were concerned. However, the resonances corresponding to the coumaroyl moieties exhibited signals of an (*E*)-double bond for the stable isomer and (*Z*)-double bond for the unstable one.

Less polar fractions of *Vernonia fastigiata* (Asteraceae) were investigated under continuous-flow conditions. In order to obtain information about signals hidden by suppressed peaks of the MeCN- D_2O eluent, HPLC-NMR spectra were measured a second time in MeOH- D_2O . The combination of both complementary spectra allowed the assignment of all proton resonances of the corresponding sesquiterpene lactones in just two HPLC-NMR runs (Figure 3). 2D COSY spectra of selected compounds from the more polar fractions were measured in the stopped-flow mode. 2D NOESY and a 1D selective NOESY have been employed to clarify stereochemical features. Due to the selective excitation technique in the 1D NOESY, no solvent suppression was required. A similar array of methods was reported for HPLC-NMR

investigations on active triterpenoid saponines from *Terminalia macroptera* (Combretaceae).

An example of how natural products were identified by simply using HPLC- ^1H NMR was described for anthraquinones from hairy root cultures of *Rubia tinctorum* (Rubiaceae). First, the HPLC- ^1H NMR spectrum of a known anthraquinone, lucidine, was identified by comparison with an authentic standard and was then used to assign the structures of lucidin glycosides for which no reference compounds were available.

Partially purified extracts of *Taxus baccata* (Taxaceae) leaves were used in another example. Despite incomplete chromatographic separation, identification of two isomeric taxanes was clearly possible. Pre-purified extracts of only 0.5 mg air-dried needles of further *Taxus* species, *T. canadensis*, *T. chinensis* var. *mairei*, and *T. \times media* cv. *Hicksii*, were subjected to stopped-flow HPLC-NMR by ^1H and 2D TOCSY analysis. Taxol[®] and several other neutral and basic taxanes were identified by means of comparison with spectra of reference compounds or were deduced from related compounds. Due to the use of different solvents in HPLC-NMR and conventional NMR spectroscopy, differences of chemical shifts have to be considered. Comparing spectra measured by HPLC-NMR in MeCN- D_2O with that of the same compound measured under conventional conditions in deuteriochloroform indicated that chem-

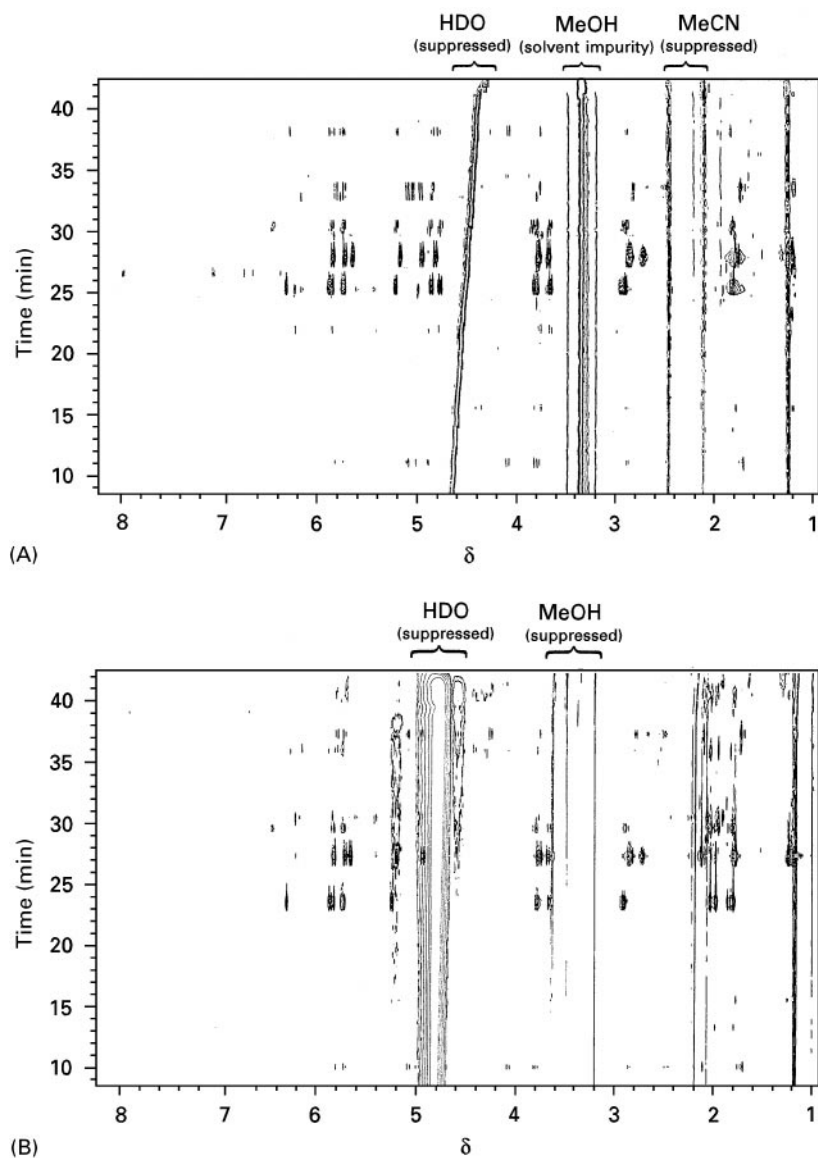

Figure 3 Comparison of 2D online HPLC-NMR plots of an extract of *Vernonia fastigiata* in (A) MeCN-D₂O and (B) MeOH-D₂O. Complementary HPLC-NMR eluents were used in order to provide information on signals hidden by suppressed resonances of each solvent. Adapted with permission from Vogler B, Conrad J, Hiller W, Klaiber I, Roos G and Sandor P (1998) Can LC-NMR serve as a tool for natural products elucidation? In: Schreier P, Herderich M, Humpf HU and Schwab W (eds) *Natural Product Analysis*, p. 143. Braunschweig/Wiesbaden: Vieweg.

ical shift differences did not exceed 0.2 p.p.m. However, due to the fact that some resonances were shifted upfield and others downfield, some signals appeared interchanged in sequence.

A series of HPLC-NMR analyses have been carried out at 600 MHz on naphthylisoquinolines from two plant families, the Diocophyllaceae and the Ancistrocladaceae. ¹H spectra extracted from the pseudo-2D continuous-flow diagram obtained under isocratic HPLC conditions using crude leaf extracts of *Ancistrocladus guineënsis* showed the typical signal pattern of naphthylisoquinolines. An optimized nonlinear

HPLC gradient was used for stopped-flow NMR analysis of a known alkaloid and two further closely related compounds. A 2D TOCSY of the HPLC fraction containing both compounds allowed the proton assignment of these isomers in a single NMR experiment. **Figure 4** shows 2D ROESY spectra of naphthylisoquinolines, the first example of the use of HPLC-NMR hyphenation to predict relative configuration. *Triphyophyllum peltatum* was analysed similarly. The major alkaloid of that species, dioncophylline A, was identified by ¹H, 2D TOCSY and 2D ROESY spectra. Additionally, two minor components

(A) Peak eluting at $t_R = 21.05$ min exhibits a correlation between ^3H and ^1H . (B) Peak eluting at $t_R = 21.60$ min shows a correlation between ^3H and ^1Me . Reproduced with permission from Bringmann G, Günther C, Schlauer J. *et al.* (1998) HPLC-NMR on-line coupling including the ROESY technique: direct characterization of naphthylisoquinoline alkaloids in crude plant extracts. *Analytical Chemistry* 70: 2805.

were identified in the same plant using an array of analytical methods, including HPLC-NMR. The constitution and relative configuration of new naphthylisoquinoline alkaloids from *Ancistrocladus likoko*, with a 5,8' coupling pattern, were also elucidated by application of 2D TOCSY and 2D ROESY experiments in the stopped-flow HPLC-NMR mode. Naphthylisoquinolines were also detected by online and stopped-flow HPLC-NMR techniques in *Dioncophyllum thollonii* (Dioncophyllaceae). Moreover, chromatographically unresolved diastereomeric tetralones with slightly different retention times were measured in a time-slice experiment. ^1H spectra were acquired in the stopped-flow mode at different positions of the chromatographic peak, and the diastereomers were distinguished by comparison of ^1H spectra of slices of pure and mixed components. The constitution and relative configuration of an isoquinoline and a naphthylisoquinoline from crude extracts of *Habropetalum dawei* (Dioncophyllaceae) were established by combined application of HPLC-NMR and HPLC-electrospray ionization (ESI)-MS-MS. Additional combinations with subsequent stopped-flow HPLC-circular dichroism (CD) experiments allowed deduction of the absolute configuration of these new metabolites.

While most HPLC-NMR studies make use of the stopped-flow option, either alone or after preliminary continuous-flow experiments, a variety of natural products from *Orophea enneandra* (Annonaceae) have been tentatively characterized by means of the continuous-flow technique without a subsequent stopped-flow run. Column overloading (2 mg) did not prevent proper separation of the components. The structures of three lignanes were identified by reference to literature data. In the cases of a tocopherol derivative and an unstable polyacetylene, targeted isolation and structure elucidation by complementary coupling techniques and conventional analytical methods were necessary.

A variety of lignanes were also identified from extracts of *Torreya jackii* (Taxaceae). Some of them were completely characterized by stopped-flow HPLC- ^1H NMR while in other examples isolation was required to confirm the structures by conventional NMR spectroscopy. After HPLC-NMR measurements, individual lignanes were collected and subjected to MS, which was considered to be an indispensable tool for complete structure assignment.

A study on *Senecio vulgaris* (Asteraceae) has allowed identification of a variety of pyrrolizidine

alkaloids and differentiation of certain isomeric macrocyclic diesters of that type. These compounds adopt *cis-trans* configurations and are not distinguishable by LC-MS. This example demonstrated again that complementary measurements in MeCN-D₂O and MeOH-D₂O are necessary to observe all resonances. Information obtained from the continuous-flow ¹H spectrum (24 scans per increment; column overloading by 3 mg of extract) were shown to be comparable to those from a corresponding stopped-flow spectrum.

Online and stopped-flow HPLC-NMR analysis of two minor isomeric meroterpenoid naphthoquinones from *Cordia linnaei* (Boraginaceae) yielded ¹H NMR spectra exhibiting identical signals in the aromatic region. Differences were only found in methyl signals when MeCN-D₂O and MeOH-D₂O were used as complementary HPLC-NMR eluents. One of the isomers, cordiaquinone C, carried a senecioic acid moiety while the other, being a new compound, was found to contain a tigloyl substituent instead.

Extracts of *Anigozanthos flavidus* (Haemodraceae), a plant family accumulating phenylphenalenones and stilbenes in the roots, were investigated using stopped-flow HPLC-NMR. Comparison with spectra of references and literature data was used to differentiate between known and novel compounds. A number of known compounds were identified without isolation, while others had to be isolated, especially when possessing regions poor in hydrogen atoms.

Biosynthetic Applications

HPLC-NMR has been used in biosynthetic and enzymatic investigations of secondary plant products. Michellamines, representing dimeric naphthylisoquinoline alkaloids highly active against HIV, were formed biosynthetically by oxidative coupling of their inactive korupensamine monomers. This dimerization was catalysed by peroxidase preparations from three *Ancistrocladus* species (Ancistrocladaceae) and from *Triphyophyllum peltatum* (Dioncophyllaceae). The peroxidase was partially purified from *Ancistrocladus heyneanus* and characterized in more detail. The exclusive formation of a michellamine from its monomeric korupensamine precursor, shown in Figure 5, was confirmed by HPLC-MS and stopped-flow HPLC-¹H NMR experiments.

Details of the phenylpropanoid metabolism preceding later steps of the biosynthesis of phenylphenalenones from *Anigozanthos preissii* (Haemodraceae) were elucidated by Schmitt and Schneider using the stopped-flow HPLC-NMR technique. Incorporation of dihydrophenylpropanoids into phenylpropanoids in root cultures of that plant was

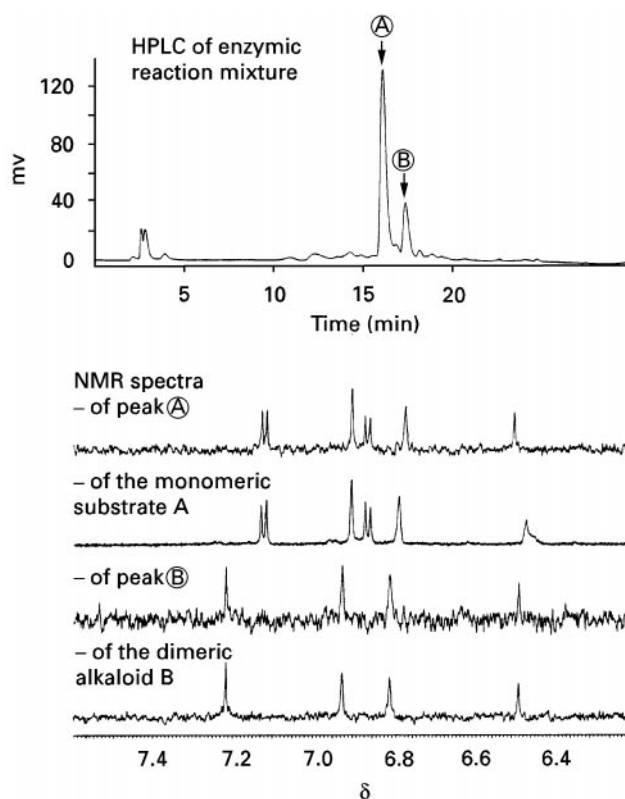

Figure 5 Stopped-flow HPLC-¹H NMR experiment confirming exclusive formation of a dimeric naphthylisoquinoline **B** from monomer **A** in the coupling reaction catalysed by peroxidase purified from *Ancistrocladus heyneanus*. Adapted with permission from Schlauer J, Rückert M, Herderich M *et al.* (1998) Characterization of enzymes from *Ancistrocladus* (Ancistrocladaceae) and *Triphyophyllum* (Dioncophyllaceae) catalyzing oxidative coupling of naphthylisoquinoline alkaloids. *Archives of Biochemistry and Biophysics* 350: 87.

proved by the coupling pattern in the HPLC-¹H NMR spectrum of *p*-coumaric acid biosynthesized from [2-¹³C]dihydrocinnamic acid (Figure 6). A number of simple phenolics, which are supposed to be formed from phenylpropanoids, were also detected in these experiments by HPLC-¹H NMR spectroscopy in the stopped-flow mode.

Applications Related to Natural Products

In areas related to natural product research, Careri and Mangia have reviewed the analysis of natural food components by HPLC-NMR. Lindon *et al.* have published an overview on HPLC-NMR in biomedical applications, and a small number of investigations have shown that the analysis of amino acids and peptide mixtures is also possible by HPLC-NMR.

The first HPLC-NMR analysis of biological macromolecules, published by Rückert *et al.*, utilized the combination of ion exchange chromatographic

Figure 6 Stopped-flow HPLC- ^1H NMR experiment confirming biosynthetic incorporation of ^{13}C label into C-2 of *p*-coumaric acid. ^1H NMR spectra of (A) $[2\text{-}^{13}\text{C}]p$ -coumaric acid resulting from treatment of *Anigozanthos preissii* root cultures with $[2\text{-}^{13}\text{C}]$ dihydrocinnamic acid and (B) nonlabelled reference.

separation with ^1H , 2D TOCSY and 2D NOESY spectroscopy to characterize small proteins in mixture. The authors expect that HPLC-NMR at very high field (750 and 800 MHz) and further enhancements in sensitivity should permit online experiments and heteronuclear 2D and 3D stopped-flow experiments in the future.

Summary and Future Developments

HPLC-NMR coupling has been developed into a valuable tool for natural product analysis. In general, the online technique is used to provide a rapid overview of the major components occurring in plants and other sources of natural products. The more sensitive stopped-flow method allows the detection and structure assignment of even minor components and enables the use of various homo- and heteronuclear correlation NMR experiments. However, unambiguous structure assignment of novel compounds of unexpected structural types requires information from other analytical methods, especially MS. Complete structure elucidation, together with stereochemical information, by multiple online com-

binations including NMR is possible but currently is rather the exception. Rapid development in analytical chemistry is expected to overcome present limitations of HPLC-NMR. The future scenario in a natural product laboratory could be an automated characterization of sources of natural products, starting with extraction and separation, followed by hyphenated instrumental analysis and finally computational structure elucidation. Additional combination with biological screening could avoid isolation of inactive compounds.

HPLC-NMR is an excellent approach to search for novel biologically active structures to be tested as new medicinal and agricultural agents, to identify known compounds without isolation, and to avoid unwanted re-isolation of known constituents from living organisms. Due to the large amount of structural information provided by NMR spectroscopy, its combination with HPLC and further spectroscopic techniques is also suitable when searching for new sources of rare natural products, for clarification of uncertain chemotaxonomic relationships and distribution of secondary compounds in various tissues. The introduction and routine application of capillary HPLC

and innovative fused capillary nanolitre flow cells in NMR probes, and further development in cryoprobe technology along with the use of improved processing procedures, will continue to enhance the sensitivity of HPLC-NMR coupling. As a microanalytical method, HPLC-NMR allows the detection of various groups of natural compounds and other biomolecules in the nanogram or even picogram range and, therefore, can contribute to the solution of problems of biochemical, physiological and chemoecological research.

Supercritical Fluid Chromatography

E. D. Morgan, Keele University, Staffordshire, UK

Copyright © 2000 Academic Press

The mild elution temperatures and the wide range of molecular masses it can accommodate makes supercritical fluid chromatography (SFC) particularly applicable to natural products. It is becoming the preferred method for the separation of enantiomers, and is especially useful for combined or hyphenated techniques. It forms a link between liquid chromatography (LC) and chromatography (GC), it has capabilities between the two and shares the instrumental set-ups of both, so both capillary column and packed column applications are recorded here.

The advantages and disadvantages of the method are debated elsewhere, but some of its strong points are indicated here. In all, 99% of supercritical fluid applications use supercritical carbon dioxide, since it has the great advantage that it is a nontoxic, non-flammable, pure, cheap mobile phase that presents no disposal problems. The greatest usefulness of SFC comes in connection with supercritical fluid extraction, which has received much attention for the isolation of natural products. If a substance can be extracted from plant or animal material with a supercritical fluid and some of the extract can be diverted to an online SFC, the course of the extraction can be followed very easily. Many of the applications of SFC recorded for natural products are of this type. The

greatest disadvantage of supercritical carbon dioxide is its relatively nonpolar nature. In its solvent powers, it resembles hexane at lower pressures, becoming slightly more polar at higher pressure. The polarity of the fluid can be increased by the addition of a small proportion of a highly polar organic solvent, miscible with the supercritical CO₂. This is most commonly methanol. The solubility of water in supercritical CO₂ is too low to be of much use to increase the polarity (but see below). The proportion of the so-called modifier solvent can range from 1 to 25%, but the critical point of the mixed fluid increases with the proportion of organic liquid and the advantages mentioned in this paragraph are steadily eroded with increasing proportion of modifier. In the chromatography of natural products, therefore, SFC is most useful for products of low polarity, such as terpenes, lipids and essential oils.

Free fatty acids, methyl esters, mono-, di-, and triglycerides can all be separated by SFC methods. The technique is particularly useful for triglycerides. Because triglycerides lack a useful UV absorption for high performance liquid chromatography (HPLC) and are at the limit of volatility for GC, they are not easy to separate and quantify without conversion to methyl esters. Using SFC with capillary columns and a flame ionization detector, they can be analysed directly. For capillary column determination of free fatty acids in an ethanol extract of *Sabal serrulata* two alternatives have been proposed: derivatization of the carboxyl group and saturating the CO₂ with water. Both methods produce a drastic improvement in resolution. Hydroxy acids are too polar for direct determination, and the separation of triglycerides is improved by the addition of a little methanol or acetonitrile, which then is detrimental to the use of a flame detector. It is possible to convert free carboxylic acids to their methyl esters in a flow-through system with CO₂ containing 10 mol% methanol at 80°C over a cation exchange resin in the H form. Capillary columns with a flame ionization detector have been used to separate the fatty acids and alcohols from hydrolysis of jojoba oil. The unhydrolysed portion of the wax esters could also be seen in the chromatogram. Wool wax alcohols from hydrogenated lanolin have been examined similarly. Using a microextractor, the triglycerides of a single cotton seed kernel were extracted by supercritical fluid extraction (SFE) and linked directly to SFC for analysis. In a rare example of application to insects, the same microcell (at 45°C and 20.2 MPa or 200 atm) has been used to extract the cuticular hydrocarbons and waxes from the cuticle of a dried fruit beetle *Carcophilus hemipterus*, which were then separated by capillary SFC. The results, probably

not optimized, were not as good as normally obtained by GC. Prostaglandins have been separated on a capillary column at 100°C with a CO₂ density gradient.

Staby and Mollerup have produced a comprehensive review of the separation and chromatography of fish oil constituents with supercritical fluids. These include triglycerides, free fatty acids, methyl and ethyl esters, cholesterol, α -tocopherol, phospholipids and squalene. The review is particularly directed towards pilot plant separations. Another review by Borch-Jensen and Mollerup in 1997 compared chromatographic systems for natural products like fats, seeds, oils and tissues.

The less polar steroids are usefully separated by SFC. Eleven steroids, including testosterone, oestrone, oestradiol, oestriol, cortisone and hydrocortisone, can be separated in less than 2 min with 6.1% methanol in CO₂ on a cyanopropyl HPLC column. Even bile acid conjugates (e.g. glycocholic acid and taurocholic acid) can be subjected to SFC. The ecdysteroids (insect moulting hormones, with a polyhydroxycholesterol structure) have been separated on packed columns under very similar conditions. Boronic ester derivatives of a diol functional group in some ecdysteroids improve selectivity for that group. The ecdysteroids, which have a strong UV chromophore, are also found in many plants of diverse type, and extracts of plants can be very quickly scanned for the presence of so-called phytoecdysteroids. With the coupling of a mass spectrometer to the SFC column, separation and identification of phytoecdysteroids can be performed in a matter of minutes.

Capillary SFC has been used to analyse the terpenes of some aromatic plants and the results compared with those obtainable by GC. Thyme (*Thymus vulgaris*) gave the same information as GC; for peppermint (*Mentha × piperita*) and basil (*Ocimum basilicum*) the separation is much better by GC but SFC quantification is more reliable. The monoterpenes of lemon peel oil have been examined on a packed SFC column. Using two different silica columns (Nucleosil 100 and Spherisorb Si) linked in series with SFC Fourier transform infrared (FTIR; see later) eight sesquiterpenes (longicyclene, longifolene, aromadendrene, ledene, valencene, *cis*- and *trans*-calamenene and humulene) have been separated and identified, as have five sesquiterpenes from copaiba balsam and ylang-ylang oil under similar conditions.

Carotenes, with their strong visible and UV chromospheres, are ideal subjects for SFC. In spite of their low polarity, there are frequent reports that addition of a very small amount of an organic modifier improves selectivity. Vitamin A can exist in five pairs of *cis-trans* isomers which can be separated at

temperatures below 50°C, so avoiding any fear of isomerization.

More Polar Compounds

As already indicated, many examples of SFC of natural products are found where extraction with a supercritical fluid (SFE) and chromatography are coupled. A classic SFC separation, performed in 1982, was the separation of caffeine, theophylline and theobromine with CO₂-methanol. The pungent phenolic oil of ginger (*Zingiber rhizoma*) has been analysed for [6]-gingerol (see structure), [8]-gingerol and [10]-gingerol. SFE-SFC has been used in the extraction of ginkgolides (oxidized diterpenes from the leaves of *Ginkgo biloba*), paclitaxel (the antitumour agent Taxol) from *Taxus brevifolia*, and the anti-malarial artemisinin and its precursor artemisinic acid from *Artemisia annua*. The chromatography of artemisinin was carried out on both a capillary column with CO₂ (and 3% methanol) and a flame detector and on an aminopropyl packed column with a CO₂-methanol gradient (17.18 MPa and 40°C) and an evaporative light-scattering detector. The packed column method was faster: both compounds were eluted in 7 min as against 25 min by the capillary method. Paclitaxel has a strong UV absorption, but the ginkgolides do not, so the evaporative light-scattering detector is very helpful. Ginkgolide A has a molecular formula C₂₀H₂₄O₉, ginkgolide B C₂₀H₂₄O₁₀, paclitaxel C₄₇H₅₁NO₁₄, and artemisinin C₁₅H₂₂O₅, which shows that highly functionalized compounds can be suitable for SFC.

Limonoids from hexane extracts of the plants *Aphanamixis polystacha*, *Harpephyllum caffrum* and *Entandrophragma deveoyii* have been ana-

lysed by capillary SFC. A liquid crystal-modified polysiloxane phase that discriminated molecular shape was used in a capillary column to separate triterpene acids, including geometric isomers, from *Disoxylum pectigrewianum*. The natural insecticide azadirachtin (see structure) is usually analysed by reversed-phase HPLC, but because the extract obtained from Neem seeds usually contains a lot of less polar contaminants, including triglyceride oil, the column has to be flushed with pure methanol or acetonitrile at the end of each run, and total cycling time can be of the order of 1 h. With packed column SFC, using an aminopropyl silica or cyanopropyl silica column and CO₂-methanol (24 : 1, v/v) mobile phase at 20.6 MPa (3000 psi or 207 bar) at 55°C and at a flow rate of 2 mL min⁻¹, the oily impurities are eluted in the solvent front, good resolution and good peak shape are obtained, and the cycle time is about 20 min (Figure 1). The example illustrates how SFC in the right situation can have marked advantages over other chromatographic methods.

The cannabinoids and their metabolic products have been examined on capillary columns. SFC is perhaps not the most useful way to examine alkaloids, but a number of separations have been made. Six opium alkaloids (narcotine, papaverine, thebaine, ethylmorphine, codeine and morphine) have been separated from poppy straw on an aminopropyl column with CO₂-methanol-methylamine-water. Seven ergot alkaloids were separated from *Claviceps purpurea* and eight pyrrolizidine alkaloids from *Senecio anonymus*.

Flavonoids from citrus fruits that contain several methoxy groups (hexa- and heptamethoxyflavone, tangeretin, nobiletin, sinensetin and others) were separated on a silica column with CO₂-methanol.

Figure 1 SFC chromatogram of an extract of triterpenoids from the seeds of *Azadirachta indica*, on a Spherisorb cyanopropyl column (150 × 4.6 mm i.d.) of 5 μm particle size, flow rate 2 cm³ min⁻¹ of CO₂-methanol (94 : 6) at 3000 psi (20.7 MPa) and 50°C with UV detection at 217 nm. Compounds are: A, nimbin; B, salannin; C, 6-desacetylsalannin; D, 3-desacetylnimbin; E, 3-tigloylazadirachtol; F, 3-acetyl-1-tigloylazadirachtinin; G, azadirachtin. Unpublished results of A.P. Jarvis and E.D. Morgan.

Figure 2 SFC of monosaccharides on Zorbax TMS column (250 × 4.6 mm i.d.), flow rate 5 cm³ min⁻¹ of CO₂-modifier (80:20, v/v) at 200 bar (20 MPa) and 60°C. The modifier was methanol-water-triethylamine (91.5:8.0:0.5, v/v). Compounds in order of elution are D-ribose, m-erythrose, D-xylose, xylitol, L-sorbose, D-mannose, D-glucose and mannitol. (Reproduced with permission from Salvador A, Herbreteau B, Lafoose M and Dreux M (1997) Subcritical fluid chromatography of monosaccharides and polyols using silica and trimethylsilyl columns. *Journal of Chromatography A* 785: 195.)

A number of monosaccharides, polyols and glycolipids have been separated on silica and trimethylsilyl-bonded silica under subcritical conditions (41°C, 200 bar, and CO₂-methanol 80:20, or a modifier of methanol with 4% or 8% water; Figure 2).

An extensive review (in French) by Lubke cites 207 references on the advantages of SFC for the analysis of natural products.

At the time of writing there is increasing interest in the use of subcritical water at 100–200°C as a mobile phase with divinylbenzene polymer columns for the chromatography of highly polar compounds like alcohols, phenols, amino acids and flavones. Clearly any compounds to be analysed must be stable to hydrolysis, as must the stationary phase. As temperature and pressure increase, water becomes less polar – at 200°C it is rather nonpolar – so by controlling these conditions a fluid phase of intermediate polarity similar to the water-methanol mixtures used in HPLC can be achieved.

Chiral Separations

Another advantage of SFC is in the separation of enantiomers. Chiral separations can be carried out at lower temperatures (often with greater efficiency than by GC on the same phases), and on larger molecules than with GC and with improved resolution over HPLC. The subject is still at a very early stage of development, with new discriminator phases appearing rapidly. If insufficient resolution is obtained under supercritical conditions, some investigators recommend subambient (and consequently subcritical) conditions. Separations have included the plant hormone abscisic acid (see structure), benzoin, ephedrine, mandelic acid, tropic acid (Figure 3), underivatized amino acids and their derivatives. For the separations shown in Figure 3, the composition of the mobile phase had the largest effect on retention, peak shape and enantioselectivity, with temperature the second most important influence. Tyrosine and tryptophan enantiomers are separated under subcritical conditions on a Chirobiotic T phase at 30°C and 200 bar isocratically with 40% modifier (methanol-water-glycerol, 92.8:7.0:0.2 v/v) in CO₂ with 0.1% triethylamine and 0.1% trifluoroacetic acid. Enantioseparations of five lignans were carried out on polyWhelk-O between 0°C and –42°C with 5–15% methanol in CO₂ with α values from 1.28 to 1.44. The potential of chiral separations of less volatile pheromones unsuitable for GC has not yet been explored.

Hyphenated Methods

All the predictable couplings of SFC to spectroscopic methods have been tried. SFC-FTIR has been used to look for isomerized fatty acids in the triglycerides of partially hydrogenated soya bean oil and in the free fatty acids after hydrolysis using a flow-through FTIR cell. SFC is more easily coupled to a mass spectrometer than HPLC, therefore many examples of SFC-mass spectrometry (MS) can be

found. The spectra resemble chemical ionization spectra, with prominent M^+ or $M + 1$ ions. Alkaloids of *Securidaca longipendunculata* have been separated by SFC-MS and SFC-MS-MS with a moving belt. Thermospray in the electron ionization mode with an SFC gradient was used for the indole alkaloids of *Catharanthus roseus* to identify 60 compounds. By SFC-UV 10 major alkaloids and 30–40 minor compounds were detected in the extract. A few antibiotics, including penicillin, cyclosporin, tetracyclin, oxytetracyclin and mitomycin C have been determined, in some cases after extraction from

blood. Ecdysteroid spectra can be varied by the operating conditions to give additional ions for $M-H_2O$, $M-2H_2O$, etc.

There are a number of examples of direct coupling between SFC and proton nuclear magnetic resonance (NMR) spectrometers. CO_2 has the great advantage of being transparent and only a small proportion of CD_3OD may be required. For polar compounds, subcritical D_2O can be used (see discussion above); it is both transparent and does not generate a very high pressure. The vapour pressure of water at $200^\circ C$ is only 1.55 MPa (225 psi or 15.5 bar). Resolution of

Figure 3 Separation of the enantiomers of mandelic acid on (A) Chiralpak OD (3,5-dimethylphenylcarbamate derivative of cellulose coated on $10\ \mu m$ silica gel) and (B) Chiralpak AD (3,5-dimethylphenylcarbamate derivative of amylose coated on $10\ \mu m$ silica gel). Both columns were $250 \times 4.6\ mm$ i.d., at flow rate $2\ cm^3\ min^{-1}$ of CO_2 -methanol containing 0.1% triethylamine and 0.1% trifluoroacetic acid and programmed from 5% modifier (5 min) to 30% at $5\%\ min^{-1}$ at 200 bar (20 MPa) and $30^\circ C$. Figure 4 A stopped-flow ^1H NMR spectrum at 400 MHz of piperine extracted from pepper with supercritical CO_2 at $0.5\text{ cm}^3\text{ min}^{-1}$. Pressure was 294 bar (29.4 MPa), and temperature 44°C . (Reproduced with permission from Albert, 1997.)

the NMR spectra under continuous flow approaches the quality of conventional spectra. SFC-NMR has been applied to vitamins and a range of natural products, including extracts of coffee, hops and pepper (Figure 4). Two problems are, firstly, the dependence of NMR signals on pressure, and secondly, the increased spin-lattice relaxation times in a supercritical fluid.

Mycotoxins from *Fusarium roseum* culture extracts have been studied with a combination of SFC-UV and SFC-MS. Some experiments have been conducted with SFE-SFC-NMR-MS and we can expect to see more of such techniques and the hyphens extended.

Future Directions

SFC will not replace GC or HPLC, but predictions are dangerous. We already see new ideas coming forward, such as subcritical cryoseparations and use of superheated water as the mobile phase, that will extend its potential. In the field of polymers, surface active compounds are being used to render growing polymers soluble in supercritical CO_2 . The advantages of SFC are such that we can expect every opportunity to be seized to extend its possibilities, particularly in the areas of chiral separations and hyphenated methods.

Supercritical Fluid Extraction

E. D. Morgan, University of Keele,
Staffordshire, UK

Copyright © 2000 Academic Press

There are two interesting points of the phase diagram of a pure substance: the triple point, where solid, liquid and gas are all in equilibrium, and the critical point, at which liquid and gas phases cease to have separate existence. At temperatures and pressures beyond the critical point there exists only the supercritical phase, with properties between those of a gas and a liquid, varying with conditions. For example, at high pressures a supercritical fluid has solubility and density properties close to those of the liquid, but with greater diffusibility and lower viscosity. High diffusibility and low viscosity improve mass transfer and so help to decrease extraction time. All this would be of only academic or research interest, were it not that one substance, carbon dioxide, which is cheap, readily available in a pure state, and non-toxic, has a readily accessible critical point (31.1°C, and 72.9 atm, 73.8 bar, 1071 psi, or 7.38 MPa). The density of supercritical carbon dioxide at various

values of temperature and pressure is given in Figure 1. Its vaporization on release of pressure avoids the step of concentrating a liquid solution after extraction.

The possibilities of using supercritical carbon dioxide as an extraction fluid were recognized first in industry in the 1950s and 1960s. It entered the laboratory in the 1980s at the same time pumps and control equipment were developed for supercritical fluid chromatography (SFC). Since then supercritical fluid extraction (SFE) has been explored with a wide variety of materials, and is generally recognized as a possible alternative to chlorinated or other toxic solvents for extraction of organic substances. There is no close competitor for carbon dioxide as a supercritical fluid for extraction. Other substances with easily accessible critical points are either too expensive (xenon), toxic (ammonia, nitrous oxide), flammable (ethane, pentane) or corrosive (ammonia). Extraction may be described as static (under pressure without flow of the supercritical fluid) or dynamic (the supercritical fluid flowing through the material to be extracted). Dynamic extraction is more common, but it can be preceded by a period of static extraction.

Figure 1 A plot of carbon dioxide density against pressure and temperature above the critical point. 10 bar = 1 MPa. Horizontal arrows represent constant densities of 0.4, 0.6 and 0.8. Fatty acids are extracted only above 0.4 g mL⁻¹, triglycerides above 0.6 g mL⁻¹. Reproduced with permission from Gere DR and Derrico EM (1994) *LC.GC International* 7: 325.

The subject roughly divides itself into two aspects: commercial-scale separation of valuable products (e.g. vitamins, drugs, flavours, fragrances, pigments) and laboratory-scale extraction for research or analysis of components. Bevan and Marshall have considered the design of large scale extractors. There are a number of commercial extractors available for small scale work. They usually have six or more chambers so that extractions can be carried out on several samples simultaneously or consecutively. Pressure can be maintained and controlled by an electronic valve or by use of a fixed restrictor, such as a length of silica capillary. After release of the pressure the extract can be collected on a solid adsorbant or the CO₂ bubbled through a solvent. Precautions have to be taken to prevent loss of material as an aerosol.

It is possible to build an extractor at modest cost. The chief needs are high pressure pumps (one for the CO₂, another for the modifier (if used, see below), a cooler for the CO₂, since it is pumped as a liquid, an old gas chromatography (GC) oven to maintain the desired temperature of the extraction, some empty high performance liquid chromatography (HPLC) columns for extraction chambers, a pressure gauge and some means of controlling and releasing the pressure. The simplest solution for this is a length of about 30–50 cm of silica capillary. Whatever the purpose of the extraction, it can be convenient to couple the equipment to a chromatographic system to monitor the course of extraction. Most convenient is on-line SFC. The composition of the extract can be sampled periodically by inserting a switching valve leading to the chromatograph. GC linked to the extraction is also much used, particularly for the extraction of essential oils and fragrances. The chromatograph can in turn be linked to a mass spectrometer. Now there is no end to the complexity of equipment that can be linked to the extraction. Albert has particularly explored the linking of SFE to nuclear magnetic resonance (NMR) spectroscopy, and gives examples that include natural products.

The solubility properties of supercritical CO₂ are close to those of hexane (polarity increases slightly with pressure), so its chief disadvantage is poor solubility for more polar substances. To extract lipids, the density needs to be above 0.4 g mL⁻¹ (see Figure 1),

for triglycerides it should be above 0.6 g mL⁻¹. The best way to improve solubility (if increasing pressure is not convenient) is to add a small proportion (5–10%) of a polar organic solvent, such as methanol. The organic solvent in this context is commonly called a modifier. The plant, animal or other material from which substances are being extracted is often called the matrix. The solubility of water in supercritical CO₂ is very low (0.4 mol% at 8.0 MPa, rising to 0.8 mol% of water at 20.0 MPa), but there are a number of examples where water has been used as a modifier for extraction of more polar compounds. The polarity of water drops remarkably as it approaches its critical point.

An early landmark in SFE was the commercial extraction of caffeine from coffee with CO₂. Caffeine is a relatively polar compound, so its extraction with the very apolar CO₂ is surprising. Hops and spices followed closely.

Lipids

Lipids from plant and animal sources are obvious targets for SFE, both on a commercial scale and as an analytical method in the laboratory. There are many reports of its use to extract fish oils (particularly to obtain concentrates of polyunsaturated acid glycerides), dairy products and seed oils. In many cases attempts are recorded to make selective extraction of valuable minor substances accompanying the oil, such as tocopherols, carotenes or sterols. The content of tocopherols is said to be significantly higher from rapeseed and soybeans by SFE. One can find examples of SFE of natural products in the reviews by Bevan and Marshall and by Jarvis and Morgan. The lipids of rapeseed and soybeans were extracted with CO₂ alone and with added propane or nitrous oxide. In another case, oil from a fungus *Mortierella ramanianae* was extracted with CO₂, N₂O, CHF₃ and SF₆. Extraction was best at 60°C and 157–295 bar with N₂O, followed by CO₂, CHF₃ and SF₆. Addition of 20% ethanol greatly increased the solubility of the oil and decreased its acidity. Some examples are listed in **Table 1** with some of the conditions used for the extraction, although in most cases a range of differing conditions were explored. Unfortunately, there is a scarcity of information directly comparing efficiency of SFE with solvent extraction.

1 Bixin

Table 1 Examples of extraction of lipids with conditions used

Extracted	Matrix	Temperature (°C)	Pressure (MPa)	Additional information ^a
Bixin (1)	<i>Bixa orellana</i> (annatto)	40	60.62	4% Acetonitrile with 0.05% trifluoroacetic acid, yield 0.27%
Carotenes	<i>Daucus carota</i> (carrots)	40	60.6	5% CHCl ₃ 92.7%, 1 h
Carotenes	<i>Mauritia flexuosa</i> (buriti fruit)	40–55	30	80%
Carotenes and lutein	Leaf protein concentrate	40	30	
Fatty acid methyl esters	Fish oil	40	8.0	20 min
γ -Linolenic acid	<i>Oenothera paradoxa</i> (evening primrose) seed	40–60	20–70	30 min, 95%
Phospholipids	Rape seed (Canola)	70	55.2	10% EtOH
Phytosterols	Seed, corn oil, margarine			
Sterols	Egg yolk	45	17.7	a ^b , 1 h
Tocopherols	<i>Hordeum vulgare</i> (barley)	40	23.69	1 h, 4.38%, density 0.921
Triglycerides	Rapeseed, soybeans	20–40	25	a
Triglycerides	Ground rapeseed, linseed meal	90	34.3	
Triglycerides	Sunflower	42–80	15.2–35.4	20% EtOH

^aHigh percentages refer to total content, usually compared to that obtainable by solvent extraction; low percentages refer to total extracted as a percentage of total mass.

^bYield comparable to solvent extraction.

Glycolipids and phospholipids are less easily extracted and usually require the addition of methanol as modifier. Sterols and sterol esters are more difficult to extract than triglycerides, but have also been explored. By stepwise increases of pressure, the concentration of phytosterols in soybean extract increased 30 times, from corn fibre by 12 times and from corn bran by 37 times. Methods are available for the analytical determination of sterols in animal skin, meat and fat. SFE is particularly useful for unstable compounds such as γ -linolenic acid and carotenes. The latter have been extracted from leaf protein concentrates and carrots (see Table 1). Figure 2 shows a chromatogram of a carotene extract obtained from carrots. The content of tocopherols is greater in the oil of rapeseed and soybeans extracted by SFE than by solvent extraction. Fluorometric and electrochemical detectors with HPLC have been used to follow the extraction.

Lanolin has been extracted from wool using 20% acetone as modifier, giving comparable results to dichloromethane Soxhlet extraction, but it gave a cleaner product (less mineral salts and protein).

Essential Oils

Essential oils are an obvious target for SFE (Table 2), and this is probably the area that has received most attention in recent years, judging by the number of publications. Many compounds in essential oils are either highly unsaturated or subject to thermal or oxidative degradation, so that SFE offers a clear

advantage for them. One complication is that many plant oils have been obtained by steam distillation, which extracts the monoterpenes but leaves most of the sesquiterpenes behind. SFE removes monoterpenes and sesquiterpenes together, so that the composition and odour of the SFE product may be distinctly different. When the price paid for a

Figure 2 HPLC chromatogram of the SFE extract of carrots collected at 40°C and 50.5 MPa for 1 h with a flow rate of 600–750 mL min⁻¹ of CO₂. 1, α -carotene; 2, β -carotene. β -Phellandrene, <i>p</i> -cymene, cryptone, spathulenol and 86 others	<i>Eucalyptus camaldulensis</i>			
Limonene, fenchone, methylchavicol, anethole	<i>Foeniculum vulgare</i> (fennel)	31–35	8.0–8.4	10.0%
Anethole	<i>Illicium verum</i> (star anis)	80		Density 0.35, 90% pure
Olive oil aroma (hexanal, 2-hexenal, hexanol, 3-hexenol and others)	Olive oil and olives	40–45	7.7–11.5	Static 1–5 min, dynamic 30 min
Essential oil (limonene)	Orange peel	20–50	8–28	Optimum for limonene (99.5%) 35°, 12.5 MPa; optimum for linalool, 35°, 8.0 MPa
Kavain, yangonin, methysticin and derivatives	<i>Piper methysticum</i> (kava)			
Essential oil	<i>Piper nigrum</i> (black pepper)	30–50	15–30	
Carnosic acid	<i>Rosmarinus officinalis</i> (rosemary)	37–47	10–16	
Eugenol, eugenol acetate, α - and β -caryophyllenes	<i>Syzygium aromaticum</i> (clove buds)	50	24	
Tanshinone IIA	<i>Salvia miltiorrhiza</i> (bunge)	60	24.5	0–10% MeOH
Pyrazines	<i>Theobroma cacao</i> (cocoa beans)	60	20.0	2% MeOH, 20 min

product depends upon odour, or content, this is important. Cedarwood oil obtained by SFE is closer in aroma to the original wood than steam-distilled oil. A disadvantage of SFE is that, at higher pressure, leaf waxes, which are not extracted by steam, are extracted as well. Freshly cut peppermint and spearmint plants extracted with supercritical and subcritical CO₂ (temperature 24–43°C) gave oils similar to that from steam distillation. A comparative study of essential oils and wax from lavender showed that the SFE extract contained three times as much linalyl acetate as the steam distillate; presumably the lower content was caused by hydrolysis. In the citrus industry it is reported that removing terpenes from citrus oil avoids oxidation to undesired products, while an

SFE product can be used to re-blend to give new flavour. SFE of rosemary leaves for 10 min gave similar yield to that of 4 h sonication with CH₂Cl₂ (Table 2). There is interest in the antioxidants obtainable from rosemary and sage, obtainable by a two-stage SFE extraction of the essential oil followed by the antioxidants. In a study of extraction of orange peel, the dried peel should be reduced to 2 mm particles for rapid extraction. For particles of 0.3 mm, 75% of the total oil was extracted with a ratio of 6 kg of CO₂ per kg of orange peel. In a study of effect of different modifiers on the SFE of lemongrass oil, GC-mass spectrometry (GC-MS) indicated a different profile of monoterpenes depending upon the modifier.

Flavours and Fragrances

The subject of flavours and fragrances overlaps with essential oils (Table 2). The mild conditions used for SFE with CO₂ can provide an accurate representation of the taste, colour and odour of natural substances found in herbs, spices, beverages and foods. Many studies have been of an analytical nature, to compare products obtained by different processes, to compare plant materials for quality, or to find the essential source of the desirable odour, as for example in the cases of coffee and olive oil. A brewed coffee aroma as similar as possible to the original brewed coffee has been obtained by SFE, monitored by smelling the product. Attempts have been made also to extract the aroma of virgin olive oil, from the oil and the olives, trap it on Tenax and analyse the product by GC-MS. SFE of cocoa beans with GC-MS analysis of the extract was used to assess the effect of storage on quality of the beans. Some alkylpyrazines were reduced after storage. There have been a number of studies of clove oil, none of which have reported a distinctly different yield between SFE and distillation methods. In many reports the yield is slightly lower by SFE. Hops have been the subject of study to produce bitter extracts for the brewing industry. The optimum conditions for an extract for the beer bitterness and aroma have been developed. Extraction of the leaves of hops gave no bitter extract. By adjusting the conditions the flavour of roasted peanuts could be collected without extracting the oil (Table 2).

Extraction of fennel seeds gave a higher yield by SFE (10.0%) than steam distillation (3.0%), about the same as extraction with hexane (10.6%), and less than ethanol extraction (15.4%), but the SFE and distilled products had a much more intense odour and taste than the solvent extracts. Cumin seed oil by SFE contained valuable components which would be thermally degraded by steam distillation. In the case of onion flavour oil SFE and liquid CO₂ extracts had the flavour of fresh onions, while the steam distillation solvent-extracted oil had a cooked onion flavour. The flavour of Emmentaler cheese during ripening has been followed by SFE and GC-MS, but further fractionation was needed because of the dominance of fatty acids, in order to analyse the less abundant alcohol, carbonyl and lactone aroma compounds. Guaca or quemadora (*Splilanthus americana*), with a slightly burning and numbing taste, is used in South American cooking. Comparison of steam-distilled and SFE extracts of leaves, stem and flowers showed significant differences (Figure 3). Eighty-eight compounds were identified in the extracts.

Saffron is such an expensive spice, that it is very liable to fraudulent imitation. The most important aroma compound, safranal (2), has been studied by isotope analysis. Synthetic safranal can easily be distinguished from the natural by ¹³C-isotope content. SFE gave a cleaner and faster method of obtaining an extract of volatiles than solvent extraction, but there was some isotopic fractionation depending upon extraction yield.

Medicinal Compounds and Alkaloids

There are many medicinal compounds in plants that are targets for SFE, but many of these are more polar substances and are therefore more difficult to extract efficiently. The conditions must be explored for each example at our present state of knowledge (Table 3). Feverfew (*Tanacetum parthenium*) is much in demand as a herbal remedy and other worthless dried plants of similar appearance are frequently sold as feverfew. The value of the plant can be checked by SFE with CO₂ for the content of parthenolide (4), the active ingredient. Artemisinin (5) is an antimalarial present in *Artemisia annua*. Texanes and baccatins have been extracted from ground needles and seeds of *Taxus* spp. with 3% ethanol modifier; ethyl acetate, methanol, dichloromethane and diethyl ether have all been used as modifier for this purpose. In all cases waxy materials are co-extracted, so hexane solvent extraction was used first

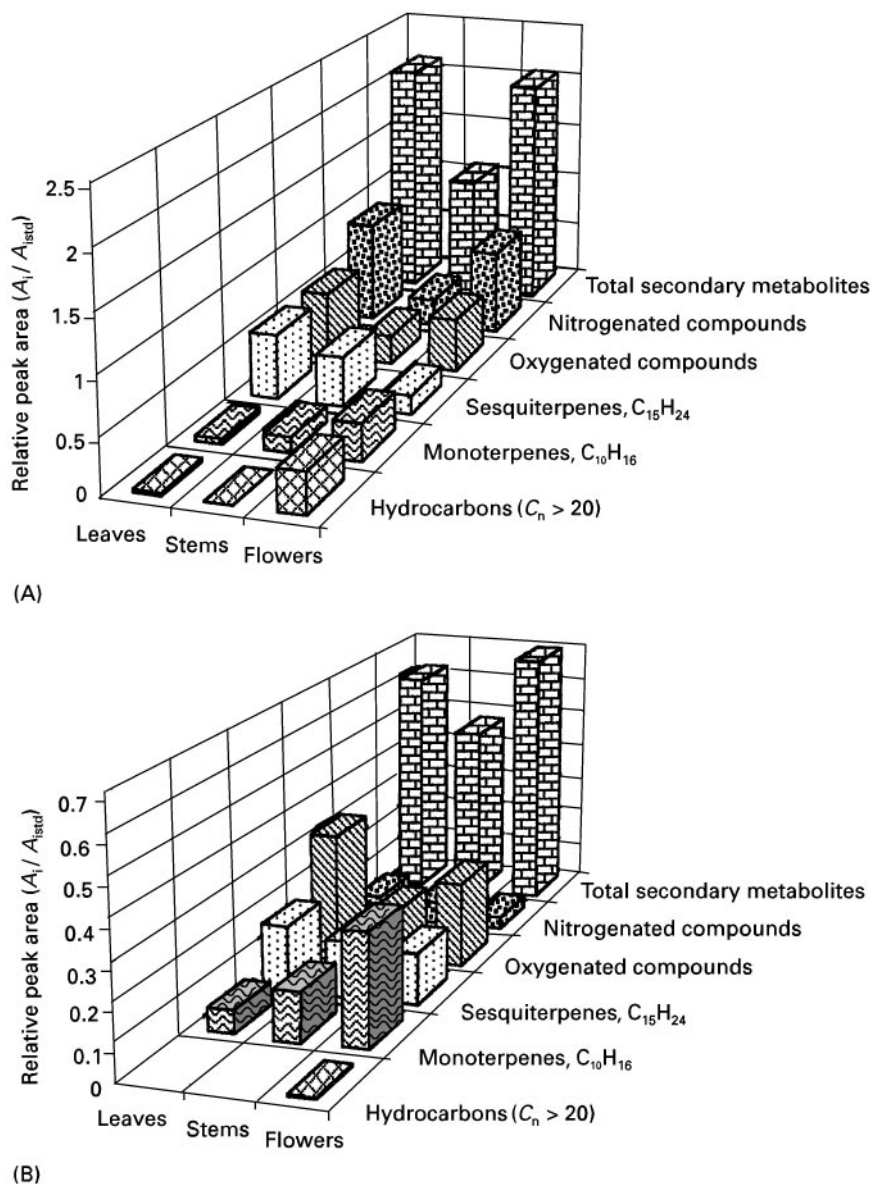

Figure 3 The composition of extracts obtained from different parts of the plant *Spilanthes americana* by (A) SFE and (B) simultaneous steam distillation–extraction. (Reproduced from Stashenko EE, Puertas MA and Combariza MY (1996) *Journal of Chromatography A* 752: 223 with permission from Elsevier Science.)

5 Artemisinin

to remove the waxes and then SFE was applied for the precursors of paclitaxel (taxol). Ginkgolides and bilobalides are extractable from *Ginkgo biloba* with 10% methanol added. There is a report of SFE of medicinal plants being directly coupled to a uteronic bioassay on abdominal muscle to discover possible substances to induce uterine contraction.

The bark of *Magnolia officinalis* is used in Chinese medicine for a number of purposes. A major active compound is magnolol (6), a neolignin. SFE was compared with solvent extraction with phyto-sols, a series of new nonchlorinated fluorocarbon

Table 3 Examples of extraction of medicinal compounds, alkaloids and polar compounds with conditions used

Extracted	Matrix	Temperature (°C)	Pressure (MPa)	Additional information
Atractylon (8)	<i>Atractyloides</i> rhizomes	40	10	2 mL min ⁻¹ , 20 s
Bile acids	Bovine bile	70	22	15% MeOH, 20 min, 88% recovery
Cedrelone (9)	<i>Cedrela toona</i>	40	40.0	30 min static, 40 min dynamic, 0.6 g sample wetted with 40 μL MeOH
Pyrethrins	<i>Chrysanthemum cinerariaefolium</i>	40	8.3	Most extracted in 3 h
Uterine contractants	<i>Clivia miniata</i> , <i>Ekebergia capensis</i> , <i>Grewia occidentalis</i> , <i>Asclepias fruticosa</i>		20–40	
Podophyllotoxin (6)	<i>Dysosma pleiantha</i> roots	40–80	13.6–34.0	With MeOH added, yield 95%
Phenols	Olive leaves	100	33.4	CO ₂ density 0.70, 10% MeOH, total 2 mL min ⁻¹ , 140 min
Glycosylated flavonoids	<i>Passiflora edulis</i> (passion fruit leaves)	75	10.1	15% MeOH, 5 min, 1.75%
Schisandrols, schisandrins (lignans)	<i>Schisandra chinensis</i>	40–80	13.6–34.0	80% of that from MeOH extraction
Flavonoids	<i>Scutellariae radix</i>	50	20.0	CO ₂ –MeOH–H ₂ O 20:2:0.9
Isoflavones	Soybean products	50	60	20% EtOH, 1 h, 93%
Theobromine, caffeine, cocoa butter	<i>Theobroma cacao</i> (cocoa)	40–90	8.0–30	EtOH modifier

solvents of varying polarity. SFE with 10% added methanol gave the highest yield of magnolol (1.86%), and phytosol A gave the lowest (0.78%). Digoxin can be obtained from *Digitalis lanata* leaves by SFE, but the process is not very selective and various strategies have been tried to improve selectivity, including use of trifluoromethane and tetrafluoroethane as extractives, but no one alternative had a clear advantage.

The antiviral compound podophyllotoxin (**7**) from *Dysosma pleiantha* and atractylon (**8**) from the oriental drug *Atractyloides* rhizome illustrate further the types of separations that have achieved. Atractylon, an oxidatively unstable compound, was extracted analytically in 20 s with a recovery 30% higher than by solvent extraction. The phototoxic furocoumarins (psoralen and derivatives) were extracted analytically from the vegetable celariac (*Apium graveolens*) by SFE, Soxhlet extraction with ethanol and sonication

with chloroform. SFE gave higher extractions (Figure 4).

Polar Compounds

The wide range of polar compounds of interest as natural products is a greater challenge to the power of

**6** Magnolol**7** Podophyllotoxin**8** Atractylon

9 Cedrolone

SFE. The success obtained varies considerably, and our understanding of the physical process of diffusion, cell wall penetration, rate of dissolution and solubility are too rudimentary to make predictions. Attempts to extract the tetranortriterpenoid azadirachtin ($C_{35}H_{44}O_{16}$) from neem (*Azadirachta indica*) seeds with or without added methanol did not give as high a yield as methanol solvent extraction. Attempts to remove triglyceride oil from the seeds first by selecting extraction conditions were not successful. Trichothecene mycotoxins at p.p.m. levels in wheat have been extracted for analytical purposes and determined online by chemical ionization-mass spectrometry (CI-MS).

McHugh and Krukoniš have discussed the decaffeination of coffee extracts. The removal of nicotine from tobacco and snuff has also been achieved, chiefly for analysis. Some lignans and coumarins with lower numbers of hydroxyl groups

can be extracted. Hydroxypinoresorcinol was extracted from *Fraxinus japonica* and other *Fraxinus* species using CO_2 with water modifier. The extraction of lignans by SFE from *Forsythia* species was as good as solvent extraction with refluxing hexane or ethanol. SFE gave better extraction of flavanones and xanthones from the root bark of the Osage orange (*Maclura pomifera*), provided 20% methanol was used as modifier, than liquid extraction, and in much shorter time. An unusual example is the determination of the alkaloids berberine and palmatine in *Phellodendri* cortex using ion pair SFE. The ion-pairing agent was dioctyl sodium sulfosuccinate, with 10% methanol as the modifier. The extraction required only 10 min. Microcystins, toxic peptides, have been extracted from cyanobacteria with a ternary mixture of 90% CO_2 , 9.5% acetic acid and 0.5% water. Even the particulate material from hardwood smoke has been examined (the principal substances identified by GC-MS were guaiacol and syringol derivatives).

Where cost is mentioned, SFE is in many cases admitted to cost more at present than Soxhlet extraction, but some studies suggest that costs can be reduced with proper experiment design, even for poorly soluble natural products.

Looking Ahead

SFE is firmly established as an industrial process for the isolation of a small number of natural products. Patents exist for a larger number of examples. As new industrial plant is bought into operation, and old

Figure 4 Comparison of extraction of three phototoxic furocoumarins from celeriac (*Apium graveolens*) by SFE (open columns), Soxhlet extraction (ethanol: filled columns) and sonication with chloroform (hatched columns). equipment removed, the number of examples will increase. Essential oils are going that way quickly. For polar substances, the published work shows that each material has to be examined to find the best conditions. It is difficult to assess how many natural products are being routinely extracted in this way, but the steady output of papers indicates continuing interest. As the chlorinated solvents are withdrawn, we can expect to see the use of SFE increase strongly. There is a ready market for some cheaper and less elaborate extraction equipment to meet this growing demand.

Introduction

The use of thin-layer chromatography (TLC) for the analysis of plant extracts began in the 1960s, with the work of Stahl and Randerath. The continuing use, and further development of TLC in plant analysis is justified because of its rapidity and because of the availability of a number of different sorbents. TLC is also useful in plant analysis because it is possible to work on crude extracts, which is not the case with other analytical methods. In plant analysis, derivatization methods serve to increase sensitivity and selectivity in addition to providing evidence concerning the quality of the separation. A selection of the most important derivatization/detection methods are given in **Table 1**. As well as these advantages, TLC is very economical and can be employed for routine use because the consumption of solvent is very low, and it is possible to analyse numerous samples on the same plate. The literature on plant analysis by TLC is very extensive, with the most important contributions being those of Stahl, Randerath, Fried and Sherma, Harbone, and Wagner, who is our main reference on this topic. Most TLC

studies are listed in the different pharmacopoeias of the world, as reported by Wagner. The classes of plant compounds separated by TLC covered in this article are as follows:

- Alkaloids
- Glycosides: flavonoids, coumarins, anthocyanins, ginkgolides, anthraquinone glycosides, cardiac glycosides
- Saponins
- Essential oils
- Cannabinoids
- Valepotriates
- Bitter principles

Alkaloids

Most plant alkaloids are tertiary amines; others contain primary, secondary, or quaternary nitrogen (**Figures 1–4**). The basicity of individual alkaloids varies considerably; depending on which of the four types is represented. The pK_b values lie in a range 10–12 for weak bases like purines to 3–7 for stronger bases like opium alkaloids. These factors must be borne in mind for extraction, and also for derivatization. The sample sizes applied to the TLC plate must be calculated, according to the average alkaloid content of the specific extracts. The majority of workers

Table 1 Detection methods and spray reagents

Acetic anhydride	10 mL acetic anhydride, heated at 150°C for about 30 min and then inspected in UV light (365 nm)	Ginkgolides
Anisaldehyde-sulfuric acid	0.5 mL anisaldehyde with 10 mL glacial acetic acid, 85 mL methanol and 5 mL concentrated sulfuric acid, in that order. Spray and heat at 100°C for 5–10 min. Then evaluated in visible light or UV 365 nm; conservation limited, not usable when the reagent is red-violet	Terpenoids, propylpropanoids, saponins, anthocyanins
Antimony(III) chloride (SbCl ₃)	20% solution of antimony chloride in chloroform, or ethanol sprayed and then heated for 5–6 min at 110°C	Cardiac glycosides, saponins
Chloramine-trichloroacetic acid	10 mL freshly prepared 3% aqueous chloramine T solution with 40 mL 25% ethanolic trichloroacetic acid, sprayed, then heated at 100°C for 5–10 min then evaluated in UV light (365 nm)	Cardiac glycosides
Dinitrophenylhydrazine	0.1 g, 2,4-dinitrophenylhydrazine in 100 mL methanol, followed by addition of 1 mL 36% hydrochloric acid; evaluation immediately in visible light	Ketones, aldehydes
Dragendorff (Munier-Macheboeuf) reagent	Solution A: 0.85 g basic bismuth nitrate in 10 mL glacial acetic acid and 40 mL water under heating. Solution B: 8 g potassium iodide in 30 mL water. Stock solutions A + B are mixed	Alkaloids
Dragendorff, followed by sodium nitrite	After spraying with Dragendorff, the plate is sprayed with 10% aqueous sodium nitrite. The coloured zones are brown	Alkaloids
Dragendorff (with hydrochloric acid)	5 g bismuth carbonate in 50 mL H ₂ O, then 10 mL hydrochloric acid and add 25 g potassium iodide, complete with water to 100 mL. The spray reagent is obtained by dilution of 1 mL in 25 mL HCN	Alkaloids, purines (caffeine, theobromine, theophylline)
Fast blue	Fast blue salt B in 100 mL. Spray then look in visible light. A second solution can be sprayed using 10% ethanolic acid, followed by inspection in visible light	Cannabinoids
Iodine	About 10 g solid iodine is spread in a chromatographic tank; the plate is placed into the tank and exposed to iodine vapour, yellow-brown zones are detected in visible light	Compounds with conjugated double bonds
Iodine-chloroform	0.5 g iodine in 100 mL chloroform; after spraying, the plate is warmed at 70°C during 5 min, the plate is evaluated after 20 min in visible or UV light (365 nm)	Ipecacuanha alkaloids
Iodine-hydrochloric acid	Solution A: 1 g potassium iodide and 1 g iodine in 100 mL ethanol. Solution B: 25 mL 25% HCl with 25 mL ethanol. Spray the plate with 5 mL of A followed by 5 mL of B	Purines
Iodoplatinate	0.3 g hydrogen hexachloroplatinate hydrate in 100 mL water with 100 mL 6% potassium iodide solution	Alkaloids (blue-violet)
Iron(III) chloride (FeCl ₃) Kedde reagent	10% in aqueous solution evaluation in visible light 5 mL freshly prepared 3% ethanolic 3,5-dinitrobenzoic acid with 5 mL 2 mol L ⁻¹ NaOH	Polyphenols Cardenolides
Liebermann reagent	5 mL acetic anhydride and 5 mL concentrated sulfuric acid is added carefully to 50 mL absolute ethanol, while cooling in ice. This agent must be freshly prepared. The plate is warmed at 100°C, 5–10 min and then inspected in UV light (365 nm)	Triterpenes, steroids (saponins)
Marquis reagent	3 mL formaldehyde in 100 mL concentrated sulfuric acid; evaluation in visible light	Morphine, codeine, thebaine
Neu (NP/PEG)	1% methanolic diphenylboric acid β -ethylaminoester (diphenylboryloxyethylamine, NP) followed by 5% ethanolic polyethylene glycol-4000 (PEG)	Flavonoids, anthocyanins

Table 1 Continued

Nitric acid (HNO ₃ concentrate) for alkaloids	After spraying the plate is heated 15 min at 120°C	Ajmaline, brucine
Nitric acid (HNO ₃) + KOH	After spraying, the plate is heated 15 min at 120°C. Then sprayed with 10% ethanolic KOH reagent. Red brown in visible light yellow-brown, brown fluorescence with UV light (365 nm)	Anthracenosides, sennosides
Phosphomolybdic acid reagent	20% ethanolic solution of phosphomolybdic acid spraying then heating at 100°C for 5 min	Essential oils
Potassium hydroxide (KOH) (Borntraeger reagent)	5% or 10% ethanolic potassium hydroxide. In visible light, anthraquinones coloured red; anthrones yellow in UV light (365 nm). Coumarins blue in UV light (365 nm)	Anthracenosides, coumarins
Vanillin-hydrochloric acid	1% in ethanol followed by 3 mL concentrated HCl. In visible light, heating 5 min at 100°C intensifies colours	Essential oils
Vanillin-phosphoric acid	1 g vanillin in 100 mL of 50% phosphoric acid. Heat 10–20 min at 120°C	Essential oils
Vanillin-sulfuric acid	1 g vanillin in 100 mL ethanol then add 2 mL of concentrated H ₂ SO ₄ . The plate is sprayed and heated at 100°C (10 min)	Essential oils
Van Urk reagent	0.2 g 4-dimethylaminobenzaldehyde in a cooled mixture of 35 mL water and 65 mL concentrated sulfuric acid. Then add 0.15 mL of a 10% aqueous iron(III) chloride solution	Indolic alkaloids, ergot alkaloids

use silica gel 60 F254 precoated TLC plates but aluminium oxide is also suitable. Many mobile phase systems contain chloroform, the eluting power of which may be decreased by addition of cyclohexane or increased by acetone, ethanol or methanol. The mobile phase is often made alkaline by the addition of ammonia or diethylamine to the less polar solvents but diethylamine is not easy to remove before spraying. The most commonly employed eluents are chloroform-methanol (90:10) and chloroform-diethylamine (90:10). It is also possible to use a screening system, suitable for the major alkaloids of most drugs employing a solvent mixture of toluene-ethyl acetate-diethylamine (70:20:10).

The detection of alkaloids is possible by quenching UV light at 254 nm and at 365 nm and by two main spray reagents Dragendorff and iodoplatinate (see Table 1). The chromatographic systems used for plant alkaloids and also the derivatization techniques used for identification are given in Table 2.

Glycosides

Glycosides are compounds that yield one or more sugars upon hydrolysis. Among the products of hydrolysis, the non-sugar components of the glycosides are known as aglycones. The classification of glycosides is a difficult matter and here the therapeutic use has been chosen.

Flavonoids

The flavonol glycosides and their aglycones are generally termed flavonoids. A large number of differ-

ent flavonoids are known to occur in nature, and these yellow pigments are widely distributed throughout the higher plants. The main constituents of flavonoid drugs are 2-phenyl- γ -benzopyrones. The various structural types of flavonoids differ in the degree of oxidation of the C ring. Most of these compounds are present in drugs as monoglycosides or diglycosides. It is possible to classify flavonoids into flavonols, flavones, flavanons, flavanols and flavanolignans in relation to substituents and the presence of double bonds (Figure 5).

There are numerous plants containing flavonoids and there are also numerous flavonoids and so here only the main plants and compounds are cited in Table 3.

Before TLC is possible, extracts of the plant must be made, and a general method for the extraction of flavonoids is as follows: 1 g of the powdered plant material is extracted with 10 mL methanol for 5 min at 60°C and then filtered. The methanolic extract is then analysed by TLC. When the plant contains lipids it is often necessary to use hexane to defat the powder prior to methanolic extraction and TLC. It is also worth noting that when analysing flavonoids, it is often better to examine the aglycones present in hydrolysed plant extracts. Having obtained a suitable extract, it is then possible to separate the various components using TLC and a variety of chromatographic systems have been devised for this purpose.

It is possible to screen flavonoids on silica gel TLC plates with the following solvent: ethyl acetate-formic acid-glacial acetic acid-water (100:11:11:26).

Figure 1 Alkaloids: indoles.

Quinoline/isoquinoline

Pyrrolizidine

Tropane

Figure 2 Alkaloids: quinoline/isoquinoline, pyrrolizidine and tropane.

With addition of methyl ethyl ketone (MEK) to give the solvent ethyl acetate–formic acid–glacial acetic acid–MEK–water (50 : 7 : 3 : 30 : 10) it is possible to separate rutin and vitexine-2-O-rhamnoside. Numer-

ous other eluents are also used, such as chloroform–acetone–formic acid (75 : 16.5 : 8.5) for flavanolignans of milk thistle (*Silybum marianum*) and amentoflavone from black haw (*Viburnum*

Tropolone**Quinolizidine****Purines**

Theophylline	CH ₃	H

Figure 3 Alkaloids: tropolone, quinolizidine and purines.

prunifolium). Chloroform–ethyl acetate (60 : 40) has been used for the flavonoid aglycones of orthosiphon (*Orthosiphon aristatus*).

Flavonoid aglycones In addition, the following eluents can be used to separate the aglycones of flavonoids: benzene–pyridine–formic acid (72 : 18 : 10) and toluene–ethyl formate–formic acid (50 : 40 : 10). Toluene–dioxane–glacial acetic acid (90 : 25 : 4) and a further list of suitable sorbents and solvent systems for flavonoids and their aglycones is given in **Table 4**.

Flavonoids can be detected on TLC plates containing a fluorescent indicator because they cause fluorescence quenching when irradiated with UV light at 254 nm, or 365 nm depending on the structural type. Flavonoids also show dark yellow, green or blue fluorescence, which is intensified and changed by the use of various spray reagents. With the spray reagent diphenylboryloxyethanolamine/polyethylene glycol (NP/PEG), flavonoids and biflavonoids give yellow–orange and green fluorescence when irradiated at 365 nm. Acetic acid reagent gives various blue fluorescent zones after heating.

Figure 4 Miscellaneous alkaloids.

Coumarins

Coumarins are derivatives of benzo- α -pyrones (Figure 6).

- *Simple coumarins* consist of coumarin and compounds substituted with OH in umbelliferon, or OCH_3 in scopoletin, and both present in tonka beans (*Coumarouna odorata*), woodruff (*Asperula odorata*) and melilot (*Melilotus officinalis*) or in position C6- and C7-scopoletin which is common in Solanaceae C5 and C8 like fraxin, isofraxidin, fraxetin three compounds of ash bark (*Fraxinus excelsior*).

- *Complex coumarins* belong to two families of plants, the Solanaceae and especially the Apiaceae. C-prenylated coumarins like umbelliprenin are found in angelica root (*Angelica archangelica*). The furanocoumarins possess a furan ring fused at C6 and C7 like psoralen from rue (*Ruta graveolens*), imperatorin, bergapten in ammi (*Ammi majus*), angelica and burnet root (*Pimpinella major*), or a furan ring fused at C7-C8 like angelicin in angelica. Pyranocoumarins have an additional pyran ring at C7-C8, for example visnadin, samidin from ammi (Figure 6).

Table 2 Alkaloids

Group	Eluents	Reagents	Compounds
Quinoline/isoquinoline			
Cinchona (bark): <i>Cinchona</i> sp., <i>Cinchona succirubra</i> , <i>Cinchona ledgeriana</i>	Chloroform–acetone– methanol–ammonia (60 : 20 : 20 : 10) Chloroform diethylamine (90 : 10) Toluene–ethyl acetate–diethylamine (70 : 20 : 10)	10% ethanol H ₂ SO ₄ , then UV 365 nm 10% H ₂ SO ₄ or 10% HCOOH, then iodoplatinate	Quinine, quinidine, strong fluorescence Quinine, quinidine cinchonine, cinchonidine main alkaloids, dihydrocompounds and epiquinine basis give coloration; pink to blue with iodoplatinate
Opium (<i>Opium</i>)	Toluene–acetone–ethanol– ammonia (45 : 45 : 7 : 3) Cyclohexane–ethylenediamine (80 : 20) Chloroform–acetone– diethylamine (50 : 40 : 10) Chloroform–methanol (90 : 10) Toluene–ethyl acetate–diethylamine (70 : 20 : 10)	Dragendorff and NaNO ₂ Iodoplatinate Marquis reagent NP/PEG, then UV 365 nm	Morphine, codeine, noscapine, papaverine thebaine; all major alkaloids give orange–brown coloration Pink coloration with papaverine, noscapine, thebaine Blue with morphine and codeine Violet for codeine and morphine Except codeine, the main alkaloids give a blue fluorescence
Ipecac (<i>Cephaelis ipecacuanha</i>)	Toluene–ethyl acetate– diethylamine (70 : 20 : 10)	UV 365 nm Iodine reagent Dragendorff	Cepheline, emetine, fluorescence light blue Cepheline, bright blue emetine yellow–white The major alkaloids give orange–brown coloration
Celandine (<i>Chelidonium majus</i>)	Propanol–water–formic acid (90 : 9 : 1)	UV 365 nm Dragendorff	Bright yellow fluorescence of coptisine, sanguinarine; weak yellow–green for chelidonine, chelerytrine Brown. Not stable with main alkaloids
Pyrrolizidine			
Golden senecio (<i>Senecio vulgaris</i>)	Chloroform–methanol– ammonia–pentane (82 : 14 : 2.6 : 20) Acetone–methanol–ammonia (40 : 30 : 20)	UV 254 nm	Senecionine, Senecionine <i>N</i> -oxide, agmatine
Tropane			
Belladonna (<i>Atropa belladonna</i>), Thorn apple (<i>Datura stramonium</i>), Henbane (<i>Hyoscyamus niger</i>)	Toluene–ethyl acetate– diethylamine (70 : 20 : 10) Acetone–water–ammonia (90 : 7 : 3)	Dragendorff Iodoplatinate	Scopolamine, (–)-hyoscyamine or atropine
Tropolone			
Meadow saffron (<i>Colchicum autumnale</i>)	Chloroform–methanol (95 : 5) Benzene–ethyl acetate– diethylamine–methanol–water (15 : 12 : 3 : 6 : 12) Chloroform–acetone– diethylamine (80 : 10 : 10)	UV light (254 nm) Dragendorff, 10% ethanol Hydrochloric acid gives a yellow coloration	Colchicine, demecolcine, 3-demethylcolchicine

Table 2 Continued

Group	Eluents	Reagents	Compounds
Indole alkaloids			
Rauwolfia: <i>Rauwolfia</i> sp., <i>Rauwolfia vomitoria</i> , <i>Rauwolfia serpentina</i>	Toluene–ethyl acetate–diethylamine (70 : 20 : 10) Heptane–methyl ethyl ketone–methanol (53 : 34 : 8) Cyclohexane–diethyl ether (60 : 40)	UV 254 nm Dragendorff (orange–brown) Nitric acid	Ajmaline: prominent quenching All alkaloids, ajmaline, serpentine, rescinnamine, rauwolficine give orange colours Ajmaline give red colour
Catharanthus leaves (<i>Catharanthus</i> sp.)	Ethyl acetate–ethanol–benzene–ammonia (100 : 5 : 5 : 3) Chloroform–methanol (90 : 10) two dimensional: direction 1, ethyl acetate–methanol (80 : 20); direction 2, dichloromethane–methanol (12 : 1)	Dragendorff	Vinblastine, vincristine, vindoline Catharanthine, and other minor alkaloids give a brown coloration
Yohimbe bark (<i>Pausinystalia yohimbe</i>)	Toluene–ethyl acetate–diethylamine (70 : 20 : 10)	UV 365 nm Dragendorff	Yohimbine (blue fluorescence) Yohimbine, pseudoyohimbine, coryantheine (orange zones)
Ergot (<i>Claviceps purpurea</i>)	Toluene–ethyl acetate–diethylamine (70 : 20 : 10) Toluene–chloroform–ethanol (28.5 : 57 : 14.5)	Van Urk	Ergocristine, ergotamine, ergometrine give blue zone
Common periwinkle leaves (<i>Vinca minor</i>)	Ethyl acetate–methanol (90 : 10)	UV 254 nm Dragendorff	Vincamine, vincaminine, vincamajine, vincine give blue–green fluorescence Weak brown, with major alkaloids
Nux vomica (<i>Strychnos nux vomica</i>) Ignatius beans (<i>Strychnos ignatii</i>)	Toluene–ethyl acetate–diethylamine (70 : 20 : 10)	UV 254 nm Dragendorff Iodoplatinate Nitric acid	Strychnine, brucine give strong blue fluorescence Brown for brucine, strychnine and minor orange–brown zones for pseudostrychnine, and α, β -colubrines for nux vomica Blue zones with brucine and strychnine Brucine give a red colour
Syrian rue (<i>Peganum harmana</i>)	Chloroform–acetone–diethylamine (50 : 40 : 10) Chloroform–methanol–ammonia 10% (80 : 40 : 1.5)	UV 365 nm	Harmanol, harmaline, harmine, harmone, harmon, give a strong blue fluorescence
Miscellaneous alkaloids			
Aconite (<i>Aconitum napellus</i>)	Ether–chloroform–ammonia (25 : 10 : 1) Cyclohexane–ethyl acetate–ethylenediamine (80 : 10 : 10) Hexane–chloroform (60 : 40) Chloroform–methanol (80 : 20)	UV 254 nm Dragendorff NaNO ₂	Aconitine, mesaconitine, hypoaconitine, give orange colours

Table 2 Continued

Group	Eluents	Reagents	Compounds
Barberry (<i>Berberis vulgaris</i>)	n-Butanol–formic acid–water (90 : 1 : 9)	Dragendorff	Berberine, protoberberine, jateorrhizine, palmitine give orange colours
	n-Butanol–ethyl acetate–formic acid–water (30 : 50 : 10 : 10)	Without treatment	Berberine, yellow in visible light
Hydrastis (<i>Hydrastis canadensis</i>)	(See barberry, <i>Berberis vulgaris</i>)	UV: hydrastine, blue–white fluorescence with Dragendorff	Berberine, hydrastine
Boldo (<i>Peumus boldus</i>)	Toluene–ethyl acetate (93 : 7)	Dragendorff	Aporphinic alkaloids, boldine
Tobacco (<i>Nicotiana tabacum</i>)	Toluene–ethyl acetate–diethylamine (70 : 20 : 10)	UV for nicotine, Dragendorff	Nicotine, nornicotine, anabasine, give red–orange colours
Desert tea (ma huang) (<i>Ephedra</i> sp.)	Toluene–chloroform–ethanol (28.5 : 47 : 14.5)	Ninhydrin (violet–red for ephedrine)	Ephedrine, norephedrine, pseudoephedrine give orange colours
Quinolizidine			
Lupines (<i>Lupinus</i> sp.)	Chloroform–methanol ammonia (85 : 14 : 7)	UV and iodine vapours, Dragendorff	Lupanine, sparteine, cytisine, <i>N</i> -methylcytisine,
Broom tops (<i>Sarothamnus</i> sp.)	Chloroform–methanol (80 : 20) Cyclohexane–diethylamine (70 : 30) Toluene–acetone–ethanol–ammonia (30 : 40 : 12 : 4) Cyclohexane–dichloromethane–diethylamine (40 : 40 : 20)	Iodoplatinate Heating the plate to 100°C, then UV 254 nm Note: quantification by densitometry (565 nm) after derivatization by Dragendorff	hydroxylupanine, matrine Fluorescence blue
Purines			
Coffee (<i>Coffea</i> sp.)	Ethyl acetate–methanol–water (100 : 13.5 : 10)	UV light (254 nm)	Fluorescence quenching for caffeine, theobromine,
Thea (<i>Thea sinensis</i>)	Ethyl acetate–formic acid–glacial acetic acid–water (100 : 11 : 11 : 26)	Dragendorff, acidic iodine–hydrochloric acid reagent	theophylline range coloration Dark brown coloration
Cocoa (<i>Theobroma cacao</i>)			
Kola nuts (<i>Kola nitida</i>)			
Mate (<i>Ilex paraguayensis</i>)			
Guarana (<i>Paullinia cupana</i>)			

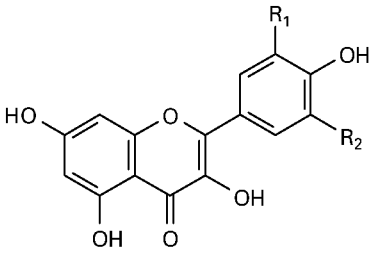

For analysis by TLC, it is necessary to first prepare an extract and for this 1 g is extracted with 10 mL methanol for 30 min under reflux on a water bath. After filtration the solution is evaporated to about 1 mL before application to the plate. For separation on silica gel TLC plates, the following eluents are used: toluene–ether (10 : 10; saturated with 10% acetic acid) – this eluent is used for coumarin/aglycones; and ethyl acetate–formic acid–glacial acetic acid–water (10 : 11 : 11 : 26) for glycosides. Following chromatography, the coumarins can be detected by irradiation with UV light as there is distinct fluorescence quenching for all coumarins at 254 nm and 365 nm. Simple coumarins give blue or blue green fluorescence, and furano and pyranocoumarins yellow, brown, blue, or blue–green fluorescence. The non-substituted chromones show less intense fluorescence: visnagin (pale blue);

khellin (yellow brown). They can also be detected by using spray reagents and these include NP/PEG and KOH.

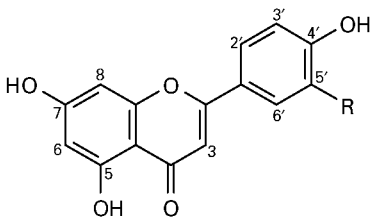

Anthocyanins

Anthocyanins are the most significant group of coloured substances in plants; they are responsible for the pink, mauve, red, violet, and blue colours of flowers and other plant parts. They are present in plants as glycosides of flavylum salts in petals and leaves. In the fruits of higher plants, they are mostly present as glycosides of hydroxylated 2-phenylbenzopyrylium (Figure 7). Anthocyanins found in numerous plants used therapeutically include the following: hibiscus (*Hibiscus sabdariffa*) (hibiscin); corn flowers (*Centaurea cyanus*) (cyanin; pelargonin); common mallow (*Malva sylvestris*) (malvin

and delphinidin glycosides); hollyhock (*Althea rosea*) (delphinidin-3-glycoside, malvidin-3-glycoside); bilberry (*Vaccinium myrtillus*) (delphinidin-3-glycoside = myrtillin A).

For analysis, anthocyanins must be extracted from plants with solvents containing acetic or hydrochloric acid. Plants are extracted for 15 min with methanol–HCl 25% (9 : 1) and the filtrates are subsequently used for chromatography. For TLC on silica gel, the following eluents are commonly used: ethyl acetate–glacial acetic acid–formic acid–water (100 : 11 : 11 : 26); and n-butanol–glacial acetic acid–water (40 : 10 : 20 or 40 : 10 : 50). Because these compounds are coloured, detection is possible visually without the need for chemical treatment or the developed TLC plates can be sprayed with anisaldehyde–H₂SO₄ reagent.

Anthraquinone glycosides

A number of glycosides with aglycones related to anthracene are present in such drugs as cascara (*Cascara sagrada*), aloes (*Aloe* sp.), alder buckhorn (*Rhamnus frangula*), rhubarb (*Rheum officinalis*) and senna (*Cassia senna*). These drugs are employed as cathartics. On hydrolysis, the glycosides yield aglycones which are di-, tri-, or tetrahydroxy-anthraquinones or derivatives of these compounds (Figure 8). The anthraquinones possess phenolic

groups on C1 and C8 and keto groups on C9 and C10; in the anthrones and anthranol, only C9 carries an oxygen function. Most compounds in this group are present in the plant as O-glycosides. In the O- and C-glycosides, the only sugars found are glucose, rhamnose and apiose.

Prior to TLC, the powdered plant material is extracted for 5 min with methanol (1 g of plant in 100 mL) then filtered. It is necessary to hydrolyse the extract to characterize the aglycones and for this 1 g of powder plant is heated under reflux with X mL 7.5% hydrochloric acid for 15 min. After cooling, the mixture is extracted by shaking with X mL of chloroform or ether. The organic phase is then taken and concentrated to about 1 mL, and then used for TLC. Chromatography is performed on silica gel precoated plates with light petroleum–ethyl acetate–formic acid (75 : 25 : 1) or ethyl acetate–methanol–water (100 : 13.5 : 10) for all anthracene drug extracts except for senna. In this case, n-propanol–ethyl acetate–water–glacial acetic acid (40 : 40 : 29 : 1) is used.

For the non-laxative dehydroanthrones of St John's wort (*Hypericum perforatum*) (Figure 8), TLC is performed with the eluent toluene–ethyl formate–formic acid (50 : 40 : 10).

Following TLC, all anthracene derivatives can be readily detected because they quench fluorescence

when irradiated at UV 254 nm and give yellow or red-brown fluorescence. Different specific reagents are also used for detection (see the Appendix). Thus anthraquinone appears red in the visible after spraying with KOH. With NP/PEG, anthrones and anthranones give intense yellow fluorescence when irradiated at 365 nm. For the characterization of sennosides, the TLC plate is sprayed with HNO₃ and then heated for 10 min at 120°C. Before spraying with ethanolic KOH, these appear brown-red in UV 365 nm and brown in visible light. Hypericin gives red fluorescence when irradiated at 365 nm.

Cardiac glycosides

There are some steroids present in nature, known as the cardiac glycosides, which are characterized by the highly specific and powerful action that they exert upon cardiac muscle. These steroids occur as glycosides with sugars in the 3-position of the steroid nucleus. The steroid aglycones or genins are of two types, either a cardenolide or a bufadienolide.

The steroids are structurally derived from the tetracyclic 10,13-dimethylcyclopentanoperhydrophenanthrene ring system. They possess a γ -lactone ring for the cardenolide or a δ -lactone ring for the bufadienolide attached in the position at C17. The sugar residues are derived from deoxy- and/or C3-O-methylated sugars, and they are linked glycosidically by the C3-OH groups of the steroid aglycones (Figure 9). The main plants containing cardenolides are white foxglove (*Digitalis lanata*), red foxglove (*Digitalis purpurea*), oleander (*Nerium oleander*), strophanthus (*Strophanthus gratus*; *Strophanthus kombe*), adonis (*Adonis vernalis*) and lily of the valley (*Convallaria majalis*). The main plants containing bufadienolides

are hellebores (*Helleborus* sp.) and squill (*Urginea maritima*).

For analysis, 1–10 g of powered plant is extracted by heating for 15 min under reflux with 20 mL 50% ethanol, with the addition of 10 mL 10% lead(II) acetate solution. After cooling and filtration, the solution is extracted twice with 15 mL dichloromethane. The combined lower organic phases are then filtered over anhydrous sodium sulfate and evaporated to dryness. The residue is dissolved in 1 mL of dichloromethane-ethanol (1 : 1) and the solution obtained is used for chromatography.

The TLC of the cardiac glycosides is accomplished on silica gel with the following solvents: ethyl acetate-methanol-water (100 : 13.5 : 10) or (81 : 11 : 8) and ethyl acetate-methanol-ethanol-water (81 : 11 : 4 : 8); and the lower phase of chloroform-methanol-water (35 : 25 : 10) for Hellebore bufadienolides.

The separated analytes can be detected under UV light at 254 nm as there is weak fluorescence quenching for cardenolides which is more distinct for bufadienolides. Spray reagents for detection include antimony chloride in chloroform and heating at 100°C, chloramine T, sulfuric acid and Kedde reagent (see the Appendix).

Saponins

The formation of persistent foams during the extraction or concentration of plant extracts indicates the presence of saponins. The saponins are mainly triterpene derivatives, with similar amounts of steroid present. The most important plants are described in Table 5. Ginseng roots (*Panax ginseng*) contain triterpene glycosides: the ginsenosides a, b, c, d, e, f,

<i>Plants</i>	<i>Eluents</i>	<i>Reagents</i>	<i>Compounds</i>
Ginseng roots (<i>Panax ginseng</i>)	Chloroform-methanol-water (70 : 30 : 40) Butanol-ethyl acetate-water (40 : 10 : 10)	Vanillin-phosphoric acid gives red zones in the visible and red; fluorescence in UV 365 nm Sulfuric acid then heated 110°C, 7 min	Triterpene glycosides, ginsenosides Rx (x = a, b ₁ , b ₂ , d, e, f, g ₁ , h) Derived from dammarane (protopanaxatriol, panaxadiol)
Eleutherococque roots (<i>Eleutherococcus senticosus</i>)	1,2-Dichloroethane-ethanol-methanol-water (65 : 22 : 22 : 7)	Vanillin-sulfuric acid detection at UV 285 nm	Triterpenes: eleutherosides
Liquorice roots (<i>Glycyrrhiza glabra</i>)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8) Ethyl acetate-ethanol-water-ammonia (65 : 25 : 9 : 1)	Anisaldehyde-sulfuric acid	Saponosids: glycyrrhizin, glycyrrhizic acid Aglycone: glycyrrhetic acid
Milkwort roots (<i>Polygala senega</i>)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8)	Anisaldehyde-sulfuric acid: five red saponin zones	Triterpene ester saponins = senegenins
Red soapwood (<i>Saponaria officinalis</i>)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8)	Anisaldehyde-sulfuric acid give six violet zones and one brown band	Triterpene saponins derived from gypsogenin (quillaic acid)
Butcher's broom (<i>Ruscus aculeatus</i>)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8)	Anisaldehyde-sulfuric acid: six to eight yellow or green bands	Steroid saponins = neoruscogenin glycosides Aglycones: ruscogenin and neoruscogenin
Sarsapilla (<i>Smilax</i> sp.)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8)	Anisaldehyde-sulfuric acid: six yellow-brown saponins	Steroid saponins: smilax saponin, spirostanol-saponin Aglycones: sarsapogenin and its isomer smilagenin
Indian pennywort (<i>Centella asiatica</i>)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8)	Anisaldehyde-sulfuric acid: violet-blue in fluorescence. Brown-violet zone	Esters saponins Madecassoside, a mixture of asiaticoside A and B
Soap bark (<i>Quillaja saponaria</i>)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8)	Anisaldehyde-sulfuric acid: brown-to-violet zones	Quillaja saponins constitute a mixture of hydroxy gypsogenins
Horse chestnut seeds (<i>Aesculus hippocastanum</i>)	Chloroform-glacial acetic acid-methanol-water (60 : 32 : 12 : 8) Propanol-ethyl acetate-water (40 : 30 : 30)	Anisaldehyde-sulfuric acid gives main blue-violet-black of aescins Iron(III) chloride at UV 540 nm	Pentacyclic triterpene glycosides, aescine, aescinol <i>β</i> -Aescine

and soap bark (*Quillaja saponaria*) quillaja saponins (Figure 10).

Steroid saponins are present in Butcher's broom (*Ruscus aculeatus*) like ruscogenin and *Sarsaparilla smilax* sp. smilax saponins.

In order to obtain a suitable sample for TLC the plant powder is extracted by heating for 10 min under reflux with 10 mL of 70% ethanol. After filtration

and evaporation, this solution is used for TLC. Ginseng radix is extracted with 90% ethanol under the same conditions.

Chromatographic solvents for the separation of these compounds on silica gel include chloroform-glacial acetic acid-methanol-water (64 : 32 : 12 : 8) which is suitable for separation of numerous saponin mixtures. For ginsenosides

chloroform–methanol–water (70 : 34 : 4) is used whilst ethyl acetate–ethanol–water–ammonia (65 : 25 : 9 : 1) is useful for glycyrrhetic acid.

Once separated, the various analytes can be seen by inspection under UV light at 254 or 365 nm for glycyrrhizin and glycyrrhetic acid. Spraying with vanillin–sulfuric acid reagent gives a range of colours for the saponins in the visible spectrum mainly blue, blue–violet and sometimes red and yellow–brown zones. The anisaldehyde–sulfuric acid reagent gives the same colours as vanillin. Vanillin–phosphoric acid reagent with ginsenosides gives red–violet colours in the visible spectrum, and reddish or blue fluorescence when viewed under UV light at 365 nm.

Essential Oils

Essential oils are the odorous principles found in various plant parts (Table 6) because they evaporate when exposed to the air at room temperature, they are called ‘volatile oils’, ‘ethereal oils’ or ‘essential oils’; the last term is applied since volatile oils represent the ‘essences’ or odoriferous constituent of the plants. Odorous principles consist either of (a) terpenes, i.e. alcohols (borneol, geraniol, linalool, menthol), aldehydes (anisaldehyde, citral), ketones (carvone, fenchone, menthone, thujone), esters (bornyl acetate, linalyl acetate, menthyl acetate oxides, 1,8-cineole) or (b) phenylpropane derivatives i.e. anethole, apiole, eugenol and safrole (Figure 11). Es-

Figure 10 Saponins.

Figure 10 Continued.

essential oils are soluble in ethanol and toluene and are mostly obtained by steam distillation of plant material.

For the preparation of extracts, a micro-steam distillation method is used to obtain the essential oil; a standard method is described in some pharmacopoeias. The essential oil is recovered in toluene or xylene and constitutes the sample to be analysed by TLC, but it is also possible to isolate it with hexane, ether or acetone.

Silica gel is the most widely used sorbent for the essential oils, with solvents such as benzene or toluene, chloroform, methylene chloride ethyl acetate for development. Because of its toxicity, however, benzene can no longer be recommended as a solvent for TLC. The eluent toluene-ethyl acetate (93 : 7) is suitable for the analysis and comparison of all of the important essential oils. Different eluents can be employed in special cases, e.g. toluene (*Pimpinella*

Table 6 Essential oils

<i>Plant family</i>	<i>Plants</i>	<i>Main compounds</i>	<i>Colour with vanillin-sulfuric acid</i>

anisum), chloroform (*Melissa officinalis*), methylene chloride (*Pimpinella*, *Juniperus*, *Lavandula*, *Rosmarinus*, and *Salvia*), toluene-ethyl acetate-

(*Eucalyptus*, *Mentha*), chloroform-toluene (75 : 25) for *Thymus vulgaris* and *Chamomilla recutita* (Table 2).

Figure 11 Essential oils.

Under UV light at 254 nm, compounds containing at least two conjugated double bonds quench fluorescence and appear as dark zones against the light-green fluorescent background of the TLC plate. This is the case for the derivatives of phenylpropane (anethole, safrole, apiol, myristicin, eugenol) and compounds such as thymol. The spraying reagents that can be used for the essential oils are (see Appendix) anisaldehyde-sulfuric acid, which gives blue, green, red and brown coloration, and phosphomolybdic acid, which gives uniform blue zones on a yellow background. However, the reagent most widely used for these compounds is vanillin-sulfuric acid which gives a range of different colours (Table 6).

Cannabinoids

The cannabinoids are found in Indian hemp (marihuana; *Cannabis sativa* var. *indica*) (Figure 12). The cannabinoids are benzopyran derivatives but only $\Delta^9,10$ -tetrahydrocannabinol (THC) shows hallucinogenic activity. The type and quantity of the constituents present in the plant depends on the geographical origin and climatic conditions. Marihuana is the flowering or seed-carrying, dried branch tips of the female plant. Hashish is the resin from the leaves and flower of the female plant. The most important cannabinoids are cannabidiol, cannabidiol acid, cannabinol, and Δ^9 -THC.

For chromatography, the powdered plant material is extracted with chloroform or hexane and separation can be performed on silica gel TLC plates with hexane-diethyl ether (80 : 20) or hexane-dioxane (90 : 10).

The cannabinoids can be detected by irradiation under UV (254-nm) light as they show fluorescence quenching. With the Fast blue reagent the cannabinoids form violet-red, orange-red or carmine zones; standard thymol gives an orange zone.

Valepotriates

The main active constituents of these drugs, the valepotriates are triesters of a terpenoid, trihydric alcohol. This alcohol has the structure of an iridoid cyclopentanopyran with an attached epoxide ring. Valepotriates are present in valerian rhizome (*Valeriana officinalis*). The drug is extracted with dichloromethane at 60°C then filtered and evaporated to dryness. The chromatographic system is silica gel with toluene-ethyl acetate (75 : 25) or n-hexane-methyl ethyl ketone (80 : 20) as eluents. Under UV light (254 nm) they give a yellow fluorescence and in the visible region with the dinitrophenylhydrazine reagent, after heating, green-grey or blue zones appear. The valepotriates characterized in this way are valtrate, isovaltrate, and acevaltrate.

Bitter Principles

The bitter principles are other compounds in plants which can be characterized by TLC. Plants with bitter principles include gentian, hops, condurango, artichoke and bryony root. Most of them possess a terpenoid structure and can be characterized in TLC with ethyl acetate-methanol-water (77 : 15 : 8) and then derivatization with vanillin-sulfuric reagent. However, these compounds are less important

Figure 12 Cannabinoids.

than the compounds mentioned elsewhere in this chapter.

Conclusion

TLC has many advantages for the analysis of herbal products, especially phytopharmaceuticals, for the identification of plants and the quantification of certain marker substances. Planar chromatography has advantages because it allows a parallel evaluation and comparison of multiple samples. In addition, various chromatographic separation systems can be combined with a multitude of specific and non-specific derivatizing agents. Even in samples having complex matrixes such as the pharmaceutical preparations of extracts of plants, sample preparation can be kept simple because of the use of the stationary phase for only one analysis. Unlike column chromatography, contamination of the chromatographic system by carryover cannot occur. In many instances the chemical composition of the herb is not completely known and for many plants, there are often no established methods of analysis available so that a rapid screening technique like TLC is very valuable. Constituents of herbals that belong to very different classes of chemical compounds can often create difficulties in detection, but with this in mind, TLC can offer many advantages.

NEUROTOXINS: CHROMATOGRAPHY

K. J. James and A. Furey, Cork Institute of Technology, Cork, Ireland

Copyright © 2000 Academic Press

Chromatography has had a major impact on the discovery and detection of potent, naturally occurring neurotoxins. The neurotoxins discussed in this article were selected because they significantly impact on human health as a result of intoxications from bites and stings or the consumption of contaminated food and water. Many of these toxins target receptors that have implications for the development of potential therapeutic agents. In the neurotoxin topics that have

been highlighted here, the role of chromatography in toxin discovery, purification and analysis is emphasized.

Neurotoxins from Marine and Freshwater Algae

It was only in the latter part of the 20th century that scientists appreciated that certain species of microalgae can cause sporadic toxic events that can lead to serious illness, with occasional deaths, in humans as well as farmed and domestic animals. When high populations of toxin-producing microalgae occur

Table 1 Representative neurotoxins that are found in microalgae and marine food

Toxin	Toxin potency, $LD_{50} \mu\text{g kg}^{-1}$	Poisoning syndrome	Food type	Typical LC method
Saxitoxin	3	Paralytic shellfish poisoning (PSP)	Shellfish, freshwaters	LC-FL
Azaspiracids	140–200	Azaspiracid poisoning (AZP)	Shellfish	LC-MS
Anatoxin-a	200	'Very fast death factor'	Freshwaters	LC-UV, LC-FL
Anatoxin-a(s)	20	–	Freshwaters	LC-MS
Tetrodotoxin	8	Puffer fish poisoning	Puffer fish, crabs	LC-FL
Brevetoxin-a	95	Neurological shellfish poisoning (NSP)	Shellfish	LC-UV
Ciguatoxin	0.45	Ciguatera	Finfish	LC-MS

LD_{50} , lethal dose at 50% mortality, for 14–20 g mouse, when delivered intraperitoneally (IP).

they are termed harmful algal blooms (HABs) and there is compelling evidence to suggest that there is a global increase in the frequency of such events. Molluscs are the marine animals most susceptible to this toxicity, especially the filter-feeding varieties such as mussels, clams, scallops and oysters, which accumulate these toxins to hazardous concentrations. However, potent neurotoxins can also occur in finfish, toxins can accumulate in food plants, while skin absorption of toxins from bacteria is also possible. The comparative potencies of the main neurotoxins that are found in microalgae and marine food are shown in **Table 1**. Their high toxicities, together with the worldwide occurrence of these toxins, have led to a requirement for sensitive analytical methods for their determination. Ciguatoxin is a lipid-soluble toxin and occurs in the flesh of finfish in tropical and subtropical waters. It exerts its effect by activating voltage-dependent sodium channels, producing both gastrointestinal and neurological symptoms with occasional fatalities. Other neurotoxins that act on sodium channels include (1) tetrodotoxin, first discovered in puffer fish, (2) saxitoxin, responsible for paralytic shellfish poisoning (PSP) and (3) brevetoxins, responsible for neurological shellfish poisoning (NSP). A new human toxic syndrome, azaspiracid shellfish poisoning (AZP), which is caused by the consumption of mussels, has recently been identified in Europe. Cyanobacteria (blue-green algae) can produce both hepatotoxins and neurotoxins and represent a serious hazard because of their contamination of freshwater lakes and reservoirs used by animals and for human consumption. Anatoxin-a is the most common neurotoxin in freshwaters but PSP toxins have also been reported. Chromatography continues to play an important role, not only in the discovery of neurotoxins, but also in the development of analytical methods that are used for their quantitative determination for regulatory control and for forensic investigation of intoxications. Highly sensi-

tive chromatographic detection methods, especially using fluorescence (liquid chromatography–fluorescence, LC-FL) and mass spectrometry (liquid chromatography–mass spectrometry, LC-MS), have been particularly important and have been critical for the identification of the microalgae responsible for producing specific neurotoxins.

Neurotoxins from Cyanobacteria (Blue-Green Algae)

There have been reports since the 19th century of animal mortalities associated with drinking water contaminated by cyanobacteria. These phenomena have occurred throughout the world and have been attributed to both hepatotoxic microcystins and to neurotoxins which are produced by some species of cyanobacteria. There are three classes of neurotoxins that are commonly found in cyanobacteria: (1) saxitoxin and analogues, (2) anatoxin-a(s), (3) anatoxin-a and analogues. These compounds are shown in **Figures 1–3**.

Saxitoxin and analogues The most spectacular neurotoxic event due to cyanobacteria occurred in Australia in 1991 when a toxic bloom in the Darling river resulted in the deaths of 1600 sheep and other animals. These intoxications were attributed mainly to neurotoxins belonging to the saxitoxin group, which were previously identified as PSP toxins. These toxins are discussed elsewhere. The investigation of

**Figure 1** Saxitoxin.

Figure 2 (A) Anatoxin-a(s), m/z 253.1; (B) fragment ion, m/z 143.1.

these events relied heavily on the application of the fluorimetric high performance liquid chromatography (HPLC) method (LC-FL) for saxitoxins, developed by Oshima. This method uses paired ion reagents with three sets of isocratic reversed-phase chromatographic conditions to separate 18 analogues, which are detected by post-column oxidation and form highly fluorescent products. In addition to the PSP toxins that have previously been identified in shellfish, a number of new PSP analogues have recently been isolated from cyanobacteria.

Anatoxin-a(s) Anatoxin-a(s) is a unique organophosphate toxin and it is a potent cholinesterase inhibitor. This neurotoxin has been identified in cyanobacteria in North America and in Europe where it has been fatal to dogs and birds. However, this toxin is difficult to detect as the chromatographic sensitivity using ultraviolet light (LC-UV) is very poor and it is probably more widespread in nature than has so far been discovered. Anatoxin-a(s) is unstable, particularly at slightly basic pH, but has been determined using fast atom bombardment-mass spectrometry (FAB-MS). However, even a 'soft' ionization tech-

nique such as electrospray LC-MS produces mainly the fragment ion at m/z 143.1 (Figure 2B), due to loss of the phosphate moiety. Fortunately, this ion is sufficiently characteristic to allow the screening of water and algae samples for the presence of anatoxin-a(s).

Anatoxin-a and analogues Anatoxin-a (Figure 3A, R = CH₃) was the first cyanobacterial toxin to be structurally elucidated and it is a potent nicotinic agonist which acts as a depolarizing neuromuscular blocking agent. Typical symptoms in animals include muscle fasciculations, gasping and convulsions, with death due to respiratory arrest within minutes after drinking contaminated water. In fact, fatalities to animals, including cattle and dogs, were so rapid that before the identification of anatoxin-a this toxin was referred to as 'very fast death factor'. A related toxin, homoanatoxin-a (Figure 3A, R = C₂H₅), was isolated recently in Norway.

Several chromatographic methods are available for the analysis of anatoxin-a in cyanobacterial bloom material, including LC-UV and LC-MS using electrospray ionization. Derivatizations of anatoxins, followed by gas chromatography (GC) with electron capture or MS detection have also been successful. A highly sensitive LC-FL method has been developed by the authors for the determination of anatoxin-a, using derivatization with 4-fluoro-7-nitro-2,1,3-benzoxadiazole (NBD-F). This has been applied to the analysis of the anatoxins and their degradation products, the dihydro (Figure 3B) and epoxy (Figure 3C) analogues, which result from the reduction or oxidation of the alkene moiety. These degradation products are not detected by the commonly used LC-UV method as they do not have the α,β -unsaturated ketone that is present in the parent toxins.

The determination of anatoxin-a in raw waters poses greater analytical problems mainly due to the low natural concentration of this toxin. However, Harada has developed an efficient solid-phase extraction (SPE) procedure in which anatoxin-a and analogues are efficiently extracted from water using a weak cation exchange phase. After trapping the anatoxins on the SPE cartridge, which is washed with methanol-water, they are readily eluted using acidic methanol since they are basic compounds. All of these anatoxins can be derivatized by reaction with NBD-F (Figure 4), at room temperature for several minutes, to produce highly fluorescent products that are readily separated using isocratic reversed-phase LC-FL. A typical chromatogram showing the separation of the NBD derivatives of anatoxin-a, homoanatoxin-a and their degradation products is shown in Figure 5A. The detection limit for anatoxin-a

Figure 3 (A) Anatoxin-a (R = CH₃), homoanatoxin-a (R = CH₂CH₃); (B) dihydroanatoxin-a (R = CH₃), dihydrohomoanatoxin-a (R = CH₂CH₃); (C) epoxyanatoxin-a (R = CH₃), epoxyhomoanatoxin-a (R = CH₂CH₃).

Figure 4 Reaction of anatoxin-a with NBD-F to produce a fluorescent product.

is 0.02 ng mL^{-1} , which allows this method to be applied to the routine monitoring of water supplies as well as for the forensic investigation of toxic incidents. This method was used to investigate the deaths of two dogs near Lough Derg, Ireland, two weeks after the event. Figure 5B shows a chromatogram from the investigation in which the dihydroanatoxin-a isomers are separated and are present in higher levels than anatoxin-a. Frequently, the detection of dihydroanatoxins in old samples may be the only evidence to implicate anatoxins in an intoxication event as anatoxin-a is unstable and readily decomposes at basic pH and in light.

Azaspiracid Poisoning (AZP) – A New Human Toxic Syndrome

Azaspiracid (formerly KT-3) is a marine toxin responsible for a new toxic syndrome, AZP. The first confirmed occurrence of this toxicity was in November 1995 in the Netherlands when at least eight people reported severe illness after the consumption of cultured mussels from the west coast of Ireland (Killary Harbour). Although human symptoms, which included vomiting, severe diarrhoea and stomach cramps, were similar to diarrhetic shellfish poisoning (DSP), only insignificant levels of DSP toxins were detected using LC-FL. The isolation of the major toxin was difficult, which is typical when dealing with a complex matrix such as shellfish tissue, and relied on the use of a variety of preparative chromatographic phases, as described by Satake and co-workers. Starting with 20 kg of mussel meat, the extract from several solvent extraction procedures was first subjected to adsorption chromatography using silica, followed by gel permeation chromatography. Next, carboxymethyl (CM) and diethylaminoethyl (DEAE) weak ion exchange phases were used and the final purification again used gel permeation to give 2 mg of azaspiracid.

Azaspiracid is characterized by a trispiro assembly and an azaspiro ring moiety that is unique in nature (Figure 6). In 1997 azaspiracid was again responsible

for a toxic incident, which occurred in Arranmore Island, Ireland, with more than 12 local human intoxications. There have been several other reported incidents, in Italy and France, and two analogues of azaspiracid have also been isolated, namely methylazaspiracid (AZ-2) and demethylazaspiracid (AZ-3). There have only been limited toxicological studies of azaspiracids. Mice administered high doses of azaspiracid died after short periods, showing neurotoxic symptoms, while morphopathological studies showed that the target organs are the liver, spleen and digestive tract.

Azaspiracids, like most other shellfish toxins, are produced by dinoflagellates but the causative organism is as yet unknown. However, unlike other types of shellfish toxicity, natural depuration of azaspiracids is very slow and toxins can persist in shellfish for as long as eight months. The development of analytical methods to determine azaspiracids in seafood is therefore a priority research topic and LC-MS has proved invaluable for the monitoring and management of toxic outbreaks. Figure 7 shows the chromatograms obtained from a crude extract from mussels using electrospray ion-trap mass spectrometry, without using any clean-up procedure. To achieve further confirmation of toxin identity, liquid chromatography–collision-induced dissociation–mass spectrometry (LC-CID-MS), with a collision energy of 40%, gave a characteristic fragmentation due to sequential loss of water molecules, as shown in Figure 8.

Venoms from Snakes and Spiders

Neurotoxic Peptides

More than 90% of the snake venoms produced by mambas, cobras and tiger snakes (which all belong to the family *Elapidae*), contain small protein molecules that are responsible for a wide range of toxicological and pharmacological activities. The complex mixtures of polypeptides that are present in most snake

(B) Chromatogram obtained using a water sample from Lough Derg, Ireland, showing the presence of NBD derivatized anatoxins. This water contained anatoxin-a ($2.1 \mu\text{g L}^{-1}$), dihydroanatoxin-a isomer 1 ($49 \mu\text{g L}^{-1}$) and dihydroanatoxin-a isomer 2 ($1.6 \mu\text{g L}^{-1}$). HPLC conditions: $5 \mu\text{m}$ Prodigy C_{18} column ($250 \times 3.2 \text{ mm}$); temperature, 35°C ; mobile phase, acetonitrile–water (45 : 55, v/v); flow rate, 0.5 mL min^{-1} ; fluorescence detection, λ_{ex} 470 nm, λ_{em} 530 nm.

venoms can be generally divided into neurotoxins and cardiotoxins (6000–10 000 amu), together with phospholipases A_2 (*c.* 13 000 amu) and larger enzymes. Often, the toxic effects of these peptides

result from a synergistic effect of the polypeptides rather than from a high intrinsic toxicity of individual compounds, and they have attracted interest for their potential therapeutic applications.

Figure 6 Azaspiracid (AZ-1, $R_1 = H$, $R_2 = Me$), methylazaspiracid (AZ-2, $R_1 = R_2 = Me$), demethylazaspiracid (AZ-3, $R_1 = R_2 = H$).

The analysis of snake venoms has traditionally relied on chromatographic separations using gel filtration and ion exchange phases, with protein size determined using methods such as sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE). Subsequent sequencing of the amino acids in the isolated proteins can be carried out by automated Edman degradation with a gas phase microsequencer.

Using these techniques, the isolation of 28 peptides from the venom of the black mamba snake has been reported, most of which are structurally related cationic peptides, called dendrodotoxins, with similar activities. However, the application of capillary electrophoresis–electrospray ionization–mass spectrometry (CE-ESI-MS) has been shown to be a particularly effective technique for the separation and analysis of such complex mixtures of small proteins as are found in these venoms. A problem that is often encountered when separating basic peptides is the retention of a net positive charge that leads to peak broadening due to the sorption of analytes to the negatively charged column wall. Several column wall derivatizing reagents have been reported to minimize this problem and it has been shown by Tomer and co-workers that when CE is carried out using a fused silica column derivatized with 3-aminopropyltrimethoxysilane (APS), the charge on the capillary wall becomes positive. Excess negative ions in solution drive the electroosmotic flow from a high negative potential to ground, and positively charged analyte ions are repelled by the column wall. ESI-MS is particularly useful for the analysis of large protein analytes, as these become multiply charged. The m/z

Chromatographic conditions: C_{18} Luna column ($5 \mu\text{m}$, $250 \times 3.2 \text{ mm}$, Phenomenex); 25°C ; acetonitrile–water (70 : 30) containing 0.50% TFA; Flow rate 0.2 mL min^{-1} .

Figure 8 Mass spectrum obtained by LC-CID-MS of azaspiracid at 40% collision energy showing fragment ions for $[M + H - H_2O]^+$ and $[M + H - 2H_2O]^+$ at m/z 824.5 and 806.4, respectively.

ratio (determined by the mass spectrometer) is consequently reduced, which permits the determination of higher charged large molecules using spectrometers with significantly lower mass ranges. For example, the CE-ESI-MS analysis of the black mamba snake venom showed two dominant ions in the spectrum at m/z 1020 and 1090 which were related to the $[M + 7H]^{7+}$ and $[M + 6H]^{6+}$ ions of toxin 1 (7133.5 amu), previously shown to be the predominant dendrotoxin.

Acylpolyamine Neurotoxins from Spider Venoms

The tendency among humans to avoid contact with spiders is attributed, in part, to the ability of some species to deliver potent venoms. This venomous capability is used largely to paralyze or kill prey, particularly insects, but also affects a wide range of invertebrate and vertebrate animals. Neurotoxins are important as tools in neurochemical research and to investigate the functioning of neural receptors and ion channel modulators. Chemical studies on spider venoms have been hampered by the fact that many proteins, polypeptides and polyamines are often present in samples that are difficult to acquire in sufficient quantities. Special interest has been shown in acylpolyamines, low molecular weight toxins from spiders that antagonize specific glutamate receptors, since there are few other examples of this activity. Neural functions affected include memory and motor control and these toxins are important in studies to design potential therapeutic agents.

Acylpolyamines were first discovered in the 1980s and some examples are shown in **Figure 9**. They contain an aromatic ring connected to chains containing amide and amine moieties with some also incorporating amino acids, particularly arginine. The lengths of the polyamine chains vary considerably, as they can contain from 7 to 43 atoms, and they are linked to various phenol or indole rings. Examples of toxins with a dihydroxybenzene ring include NSTX-3 (Figure 9A-2, X = C) and JSTX-3 (Figure 9A-3, X = C).

Several chromatographic techniques have been applied to separate these complex mixtures, which can contain as many as 50 acylpolyamines in a single spider venom sample. Preparative HPLC can be used directly to separate toxins in an aqueous extract of spider venom using photodiode-array UV detection. However, tandem LC, combining UV detection with on-line fluorescence detection, following reaction with *o*-phthalaldehyde (OPA), has proved valuable for the detection of minor components. For these separations, a linear gradient of water (containing 0.1% trifluoroacetic acid), for example 5–60% acetonitrile, can be used for reversed-phase chromatography. Fractions containing active constituents typically require up to three further preparative LC steps, with both ion exchange and octadecylsilica (ODS) columns, to purify toxins to homogeneity. Bioassays of fractions to detect toxin activity are also frequently used in these studies and an example is the assay of histamine release from rat peritoneal

Figure 9 Structures of acylpolyamine toxins from spiders.

mast cells. Toxin identification requires NMR and/or hydrolysis of toxins to amino acids and amines, but for structural confirmation of very small quantities of toxins synthesis has also been employed.

In recent years, major advances have been made possible by the use of μ -column LC with FAB-MS. **Figure 10** shows the two-dimensional MS chromatogram from a spider venom extract obtained using on-line μ -column LC-FAB-MS. The acylpolyamines in this venom have an arginine terminal group with structures similar to those in Figure 9A–2A, –2B and –2C. Further structural information can be obtained

using collision-induced dissociation (CID) tandem mass spectrometry (MS-MS) which is often sufficient for the full structural elucidation of these toxins. The aromatic ring in each toxin is readily identified from the strong MS signal because fragmentation at the carbon adjacent to the ring produces ions of m/z 107 (phenol), 123 (dihydroxybenzene), 130 (indole) or 146 (hydroxyindole), as illustrated in Figure 9B. From such studies, over 40 acylpolyamines have been identified in a crude spider venom extract. A combination of LC-MS and matrix-assisted laser desorption/ionization (MALDI) MS has emerged as

Figure 10 Two-dimensional MS chromatogram display of protonated molecular ions $[M + H]^+$ obtained from spider venom (*Nephilengys cruenta*) extracts using on-line μ -column LC-FAB-MS. (Reproduced with permission from Palma MS *et al.* (1997) *Natural Toxins* 5: 47.)

a powerful technique for the analysis of small samples of venom containing complex mixtures of these toxins.

NICKEL AND COBALT ORES: FLOTATION

G. V. Rao, Regional Research Laboratory, Council of Scientific and Industrial Research, Bhubaneswar, India

Copyright © 2000 Academic Press

Introduction

Most of the world's nickel is extracted from the mineral pentlandite, $(\text{Ni, Fe})_9\text{S}_8$, which frequently occurs in ores containing predominantly pyrrhotite and various non-sulfides, some of which contain magnesium (Table 1). The nickel content in such sulfide ores is generally low (0.2–3%) and varies from place to place in the same deposit. The low nickel content of the present-day nickel sulfide ores renders them unsuitable for either direct smelting or hydrometallurgical extraction, thus requiring beneficiation.

The usual method of nickel extraction from sulfide ores is through the production of nickel matte after enriching the nickel content of the ore. This is commonly carried out by magnetic separation, flotation, or a combination of both after the ore is comminuted to below 200 μm in size. The enrichment depends upon the degree of rejection of the other sulfide and non-sulfide gangue. The maximum grade of nickel achieved by flotation is around 28% Ni.

Problems Associated with Sulfide Mineral Flotation

The main problem encountered is selectivity of pyrrhotite and also in some cases chalcopyrite during flotation. A clean and satisfactory separation of pentlandite from pyrrhotite by flotation is difficult in practice since pyrrhotite typically contains intergrown inclusions of pentlandite as well as nickel in solid solution. In fact pyrrhotite often contains 0.5–1% Ni that cannot be separated by physical methods. The common occurrence of both monoclinic (magnetic) and the hexagonal (nonmagnetic) forms of pyrrhotite in association with pentlandite also poses problems. Another type of alteration which adversely affects flotation recoveries is that tochilinite has flotation properties similar to that of pyrrhotite. As a consequence it either reports to the flotation tailings, thereby decreasing the nickel recovery, or, if it is effectively floated, a significant amount of pyrrhotite accompanies it, diluting the nickel grade in the concentrate.

There is a distinct difference in silicate mineralogy between types of host rock, which have their own problems with respect to rejection of gangue by

flotation. Talc and other naturally hydrophobic magnesia-bearing minerals have a tendency to float with sulfides, resulting in a concentrate exceptionally high in magnesia. The presence of magnesia causes viscosity problems in the slag during smelting. Magnesia also promotes conditions favourable to hetero-coagulation of minerals, especially fine sulfides with coarse gangue minerals, thus leading to nickel loss.

Flotation Practice in Nickel Sulfide Deposits

Nickel sulfide minerals such as pentlandite can, in general, be separated from their gangue by flotation using a thiol group of collectors like xanthates and alkyl dithiophosphates in the presence of variety of activators, depressants and dispersants. Since nickel sulfides contain other sulfides such as pyrrhotite, pentlandite and chalcopyrite, the enrichment of nickel is generally carried out by two methods:

1. production of bulk concentrate containing all sulfides together as smelter feed;
2. production of bulk chalcopyrite–pentlandite concentrate by preferentially depressing the pyrrhotite followed by selective flotation of chalcopyrite and pentlandite.

Although bulk flotation of all sulfides is relatively simple the presence of pyrrhotite, which contains minor amounts of nickel but substantial amounts of sulfur (Table 2), causes excessive sulfur dioxide emissions during smelting of the concentrate.

Since most of the sulfur contained in the flotation concentrate is emitted from pyrrhotite, the rejection of pyrrhotite is important, especially in Canada, owing to stringent limits imposed on SO_2 emissions from smelters in that country. The pyrrhotite from the Canadian ores in the Sudbury region occurs in two crystallographic forms having distinct characteristics. The monoclinic pyrrhotite, being magnetic, can be partly rejected by magnetic separation, while the hexagonal pyrrhotite is separated by flotation.

Pyrrhotite is known to float poorly in alkaline media; therefore the general practice is to selectively float pentlandite from pyrrhotite, by maintaining a highly alkaline pH with cyanide as depressant and using thiols like xanthates or dithiophosphates as collectors. Although it is possible to reject significant

Table 1 Principal nickel and nickeliferous minerals in nickel sulfide deposits

<i>Secondary</i>		
Pyrite	FeS ₂	Up to 12
Marcasite	FeS ₂	Up to 6
Smythite	Fe _{3.25} S ₄	Up to 5
Tochilinite	6Fe _{0.9} S·5(Mg,Fe)(OH) ₂	Up to 5
Magnetite	Fe ₃ O ₄	Up to 1

(Reprinted with permission from The Minerals, Metals and Materials Society (TMS).)

amounts of pyrrhotite in this way, the concomitant pentlandite losses into flotation tailings are highly unsatisfactory, in addition to the problem of water contamination due to cyanide.

A typical example of a nickel sulfide plant operating with highly floatable talcose gangue is at Trojan mine in Zimbabwe. The Zimbabwean sulfide deposits contain very low grades of nickel (0.6%) and copper (0.04–0.4%). The easily floatable non-sulfide minerals dilute the grade of the concentrate and also result in nickel losses into the tailings. This problem can be overcome by using depressants like carboxymethylcellulose (CMC) and guar gum deriva-

tives, although their cost accounts for as much as 60% of the reagent cost incurred in the plant.

Developments in Flotation

Flotation of Nickel Sulfide Minerals

Collectorless flotation It is known that chalcopyrite and pyrrhotite can be floated without collectors at electrode potentials of +400 mV and +50 mV respectively, and pyrite does not float even at +700 mV. The underlying mechanism causing hydrophobicity, although obscure, is attributed to surface oxidation, formation of elemental sulfur and partial dissolution of mineral surface, leaving a sulfur-rich layer.

Collectorless flotation studies on three lean nickel sulfide ores, from Outokumpu Finnmines Oy (Enonkoski (0.31% Ni and 0.14% Cu), Vammala (0.9% Ni and 0.45% Cu) and Hitura (0.32% Ni and 0.11% Cu)), ground in steel and ceramic mills at a pH range of 3–12 using polypropylene ether as frother revealed interesting details.

The pentlandite, chalcopyrite and pyrrhotite from Enonkoski ore ground in a steel mill floated easily without a collector at low pH values of 3–5 (Figure 1). The floatability of these three minerals was improved when the same ore was ground in a ceramic mill (Figure 2). This suggests that collectorless flotation in acidic pH can be adopted as a low-cost pre-concentration phase to obtain a bulk sulfide concentrate.

Effect of sulfur dioxide It is possible to effectively separate Cu–Ni ores from pyrrhotite gangue in the absence of a collector, but with SO₂ and an effective complexing agent such as diethylenetriamine (DETA) and a frother. The depressant action of SO₂, which is greatly enhanced in the presence of DETA, does not affect the recovery of chalcopyrite. Figure 3 shows that 93% of chalcopyrite can be recovered in 12 min in the presence of SO₂, but the co-recovery of 12% pentlandite and 23%

Table 2 Distribution of Ni and S in sulfide ores

Ore source	Nickel distribution (%)		Sulfur distribution (%)		
	Pentlandite	Pyrrhotite	Pentlandite	Chalcopyrite	Pyrrhotite

pyrrhotite makes the grade unacceptable. The overall recovery of pentlandite and pyrrhotite could be restricted to 4.1% and 2.5% respectively by introducing DETA in combination with SO₂ (Figure 4).

The differential separation of pentlandite and pyrrhotite from the resulting flotation tailings with sodium isobutyl xanthate collector and Dow froth -250 can also be achieved in the presence of SO₂ and DETA. By using 1.4 kg SO₂ per tonne of ore in combination with 300 g DETA per tonne a concentrate with an overall pentlandite recovery of about 89% could be produced, while restricting pyrrhotite recovery to less than 12.5% (Figure 5).

Problems due to process water The difficulty of selective depression of pyrrhotite at Canadian plants was found to be due to the process water containing heavy metal ions such as Ni²⁺, Cu²⁺, Ag²⁺, which were causing the inadvertent activation. By using a small amount of DETA the separation effi-

ency was greatly improved (Figure 6); however, the depressing effect is more effective when the ore is oxidized.

The activation products formed on pyrrhotite may be sulfides of Ni, Cu and Ag, which are usually insoluble under reducing conditions. When the mineral is oxidized, the activation products convert to oxides, increasing the solubility in the presence of DETA and thus causing its depression.

Effect of pulp potential Pentlandite can be floated selectively from pyrrhotite by maintaining the pulp

pH at a sufficiently alkaline value and with minimal quantities of collector. Careful grinding and classification are essential for retrieving the coarse pentlandite while restricting the entry of pyrrhotite into the concentrate. Interestingly, the influence of pulp potential on flotation recovery of pentlandite and pyrrhotite is virtually the same (Figure 7), and the possibility of achieving satisfactory selective flotation from such mineral mixtures by means of differential pulp potential can be ruled out.

Recovery of Valuable Slimes

By High Intensity Conditioning

The recovery of valuable metal being lost in slimes is of paramount importance. It has been estimated that recovering 15% of the metal lost in the less than 10 μ m fines in Canada would increase revenue by approximately \$100 m.

High intensity conditioning of slimes in the presence of collector and frother substantially improves the flotation kinetics of pentlandite slimes. The floatability of fine particles by high intensity conditioning, however, largely depends on the nature of the ore and the power input per unit volume of pulp treated. Maximum recoveries are obtained at a power input exceeding 1.5 kWh m⁻³ of pulp. High intensity conditioning of slurry adopted at the Trojan mill in Zimbabwe has improved nickel recoveries by 2-4%, owing to the increased flotation response of oxidized and tarnished nickel-bearing sulfides.

Depression and Activation by Slimy Gangue Minerals

Many hydrophobic silicate minerals such as talc, chlorite, kaolinite and serpentinite activate other minerals by forming slime coatings. It is also known that the serpentine slimes, containing chrysotile and

lizardite, form slime coatings on unoxidized pentlandite and such coatings depress nickel flotation. The formation of these slime coatings is directly related to the magnitude and sign of surface charges of the slimes and sulfide particles.

Crysotile is known to depress nickel sulfide more than lizardite. Addition of small amounts of chrysotile to the flotation pulp (0.05 g L^{-1}) dramatically decreases pentlandite flotation recovery, from 90% to 5%.

Dispersion of Slime Coatings

The reagents generally known to modify the slime surface charge and reduce their adverse influence on pentlandite flotation are dextrin, sodium pyrophosphate, sodium silicate, sodium carbonate, guar gum and CMC. Among these reagents CMC has been found to be the best, despite the high concentration required (more than 2 kg t^{-1}). CMC treatment of an Australian ore containing a number of magnesium silicate minerals improved the flotation rate of pentlandite when using amyl xanthate as a collector. The carbonate ions derived from soda ash enhanced dispersion in the pulp, while CMC facilitated the removal of slime particles from pentlandite, thereby allowing the xanthate to coat the surface. The pentlandite fines flotation was found to be improved with either soda ash or CMC but the synergistic effect of both proved beneficial for intermediate sizes.

Effect of Saline Water

The extent of slime coating is related to the zeta potential, being greatest when slime and particles have a high zeta potential of opposite sign. The zeta potential of the particles can be decreased by increasing the concentration of counterions. A highly saline pulp produces a high concentration of counterions, Na^+ , and Cl^- , which influence the slime dispersion, besides enhancing hydrophobicity due to modification of the hydration layer around the mineral particles and air bubbles.

In the presence of 10% saline solution, fine nickel sulfide flotation is promoted, whereas flotation with 1 kg t^{-1} CMC does not result in upgrading the nickel sulfides. Flotation tests on the whole feed and cyclone overflow of a transition ore, from Western Australia, in saline pulp gave better results (Figure 8) than the addition of 1 kg t^{-1} of CMC.

Separation of Nickel from High Nickel Matte

The separation of chalcocite (Cu_2S) and heazlewoodite (Ni_3S_2) from high nickel matte can be

Figure 8 Comparison of dispersant regimes on nickel recovery from cyclone overflow material with CMC and NaCl. (Reprinted from Wellham *et al.* (1992) with permission from Elsevier Science.)

achieved by maintaining the proper pH and pulp potential while using xanthates as collectors. The flotation recovery of Cu_2S and Ni_3S_2 has been studied by adjusting the oxidation-reduction potential of the flotation pulp with $(\text{NH}_4)_2\text{S}_2\text{O}_8$ and KMnO_4 . The recovery of Ni_3S_2 is almost zero either at pH 8.5 where $E_h > 500 \text{ mV}$ or at pH 11.2 with $E_h > 400 \text{ mV}$, whereas the potential has little effect on Cu_2S at pH 8.5. The depression of Ni_3S_2 can be improved by employing $\text{Ca}(\text{ClO})_2$, as modifier of potential, and Ca^{2+} ions. As the potential of Ni_3S_2 is increased, with increase in dosage of $\text{Ca}(\text{ClO})_2$ the recovery decreased, but the potential appears to have little effect on the flotation behaviour of Cu_2S (Figure 9).

Figure 9 Flotation recovery of Cu_2S and Ni_3S_2 and E_h as a function of $\text{Ca}(\text{ClO})_2$ in the presence of a mixture of butyl xanthate and ethyl xanthate ($10^{-4} \text{ mol L}^{-1}$). (Reprinted with permission from International Academic Press.)

Lateritic Nickel Resources

Lateritic nickel resources are formed when peridotite, an igneous rock comprising predominantly the mineral olivine, which contains around 0.25% Ni, are exposed to prolonged and intense chemical weathering. During such prolonged weathering, the magnesium and silica are leached out of the rock to leave a residue rich in ferric oxide, nickel and other minor constituents such as aluminium and chromium. The type of weathering which dissolves silica and metallic elements from rocks to produce limonite and silicate nickel ores occurs most frequently in tropical climates with a high rainfall, and with decomposing vegetable matter to provide organic acids and carbon dioxide in the ground water.

Lateritic nickel deposits are classified on the basis of differences in the essential make-up of the profiles. The differences between limonitic and silicate minerals influence the methods by which they are treated for nickel recovery.

Developments in Laterite Flotation

Flotation studies on an ore from New Caledonia with a variety of collectors did not give any substantial upgrading with appreciable recoveries (Table 3). Laboratory investigations on garnierite samples from the Pomalaa mine, Indonesia, indicated that by using sodium oleate in combination with a chelating reagent like dimethylglyoxime or α -diphenylglyoxime the flotability of garnierite could be markedly increased at high pH. Between pH 11 and 12 stable nickel chelate complexes are believed to be formed, causing maximum flotability (Figure 10). However,

Figure 10 Effect of pH on the floatability of garnierite using dimethylglyoxime (DMGO) or α -diphenylglyoxime (DPGO) as chelating reagents along with sodium oleate. (Reprinted from Nakahiro Y, Saburi H and Wakamatsu T (1987) Fundamental study on the flotation of garnierite using chelating reagents and anionic collectors. *International Journal of Mineral Processing* 19: 69–76 with permission from Elsevier Science.)

other anionic collectors like mercaptobenzothiazole and sodium diethyldithiocarbamate show no favourable effects on garnierite collection even when the same chelating reagents are used in combination.

Treatment of Limonitic Ores

In India, substantial quantities of nickel-bearing lateritic material containing 0.5% Ni are available at Sukinda, Orissa, which is the country's largest chromite deposit. During chromite mining, nearly 10 t of

waste overburden, containing on average 0.5% Ni, 0.02% Co and 25% Fe, are currently being rejected for every tonne of chromite mined. The nickel in such waste materials is found to be in association with goethite, which is the predominant iron mineral and tends to become enriched in the fines along with iron.

Flotation of goethite has been attempted to enrich nickel in proportion to iron enrichment. The nickel could be enriched to above 1.1% Ni with around 75% recovery at pH between 3.5 and 5 on a variety of samples studied by using a commercial grade (SPS 430) anionic petroleum sulfonate collector. The flotation response of the lateritic nickel-bearing iron with different collectors and their mixtures can be seen in Figures 11 and 12. The flow chart suggested for enriching nickel to above 1.1% from lean lateritic chromite overburden is given in Figure 13.

The pertinent details concerning the flotation response of a variety of samples drawn from a wide cross-section of the overburden dumps, including scrubbing, are given in Table 4.

Cobalt

Cobalt is present in many rocks, soils and sea water in very low concentration and exploitable deposits occur only in a few places. As a result cobalt-containing ores are not mined primarily for their cobalt content, but rather cobalt is produced as a by-product, particularly from the production of copper, nickel, silver, gold, lead and zinc. The cobalt minerals which are exploited mostly for their recovery as by-products are given in Table 5.

The only beneficiation plant put up exclusively to recover cobalt is in Morocco, treating the complex cobalt-bearing ores from the Bou-Azzer deposit. The principal ores at Bou-Azzer are skutterudite and

erythrine. The specific gravity of these cobalt-bearing minerals being high (5.7–6.8), they are recovered first by gravity concentration followed by flotation of the middlings of the gravity circuit and the fines using amyl xanthate collector subsequent to activation with sodium sulfide and copper sulfate. A mixed cobalt concentrate containing 10% Co can be obtained by combination of gravity and flotation from a feed containing 0.9% Co.

Cobaltite can be separated from pyrite, chalcopyrite and pyrrhotite by initial separation of chalcopyrite, followed by an acidic bulk flotation of all the remaining sulfides using amyl xanthate. Pyrite and pyrrhotite are subsequently floated by depressing the cobaltite with monocalcium aryl sulfonate. Another known flotation separation of cobaltite, from a similar ore containing the same type of minerals, is by direct flotation of all the sulfides other than cobaltite at mildly alkaline pH followed by flotation of cobaltite from tailings with ethyl xanthate at acidic pH after activation with copper sulfate.

By utilizing nitrosonaphthol-based collectors, the flotation of two oxide minerals – erythrite ($\text{Co}_3(\text{AsO}_4)_2 \cdot 8\text{H}_2\text{O}$) and smolyaninovite (Co_3Ni ,

$\text{Ca,Mg}_3(\text{Fe,Al})_2(\text{AsO}_4)_4 \cdot 11\text{H}_2\text{O}$ – and a sulfide mineral – arsenosulfide cobaltite (CoAsS) – could be improved.

The flotation response of cobaltite (CoAsS) from Mount Cobalt with nitrosophthol indicated an optimum response between pH 8 to 9 (Figure 14) whereas its flotation response with xanthates is known to be best at pH 4–4.5.

The flotation results obtained with xanthate and nitrosophthol can be seen in Table 6. Nitrosophthol collectors are found to be pH-dependent

and specific for cobalt-bearing minerals. The availability of cobalt ions on or near the mineral surface may be the determining factor for the selectivity of nitrosophthol collectors. Alkyl group attachment on to the naphthalene ring increases the hydrophobicity of the cobalt-bearing minerals on to which these compounds adsorb, thereby increasing the collecting capability of nitrosophthol, but at the expense of selectivity.

A combination of xanthates and nitrosophthol collectors is suitable for the recovery of cobalt sulfide

deposits that are partly oxidized, whereas nitrosonaphthol collector alone is effective for oxide cobalt deposits.

Conclusions

The nickel extraction process is dictated by the mineralogical assemblage of the ore. Pyrrhotite rejection has been of no real importance in many mills treating sulfide ores except in countries having strict restrictions on SO₂ emission. Pyrrhotite rejection from pentlandite is not very satisfactory in the plants adopting differential flotation, but recent investigations indicate the possibility of employing SO₂ and DETA besides adopting starvation flotation. The problems often encountered in sulfide flotation are the fast floating magnesia-bearing minerals and coatings of crysotile and lizardite. Such problems can be addressed successfully by adding soda ash, CMC or sodium chloride. Plants where SO₂ emissions are not

a problem can adopt collectorless flotation at acidic pH as a cost-effective pre-concentration process. New flotation reagents like nitrosonaphthol can be adopted in circuits containing oxidized sulfide ores.

There seems little prospect of upgrading nickel from oxide ores since the nickel values are finely dispersed. Marginal upgrading is possible by using dioxime collectors. In view of the contemporary technological practices being followed elsewhere in the world and the Ni content of ores utilized by such processes, flotation of limonitic ores with anionic collectors like petroleum sulfonates is likely to play

Table 5 Principal cobalt minerals

Mineral	Formula	Cobalt content (%)

a vital role in raising the nickel content to above 1.1% from lean limonitic deposits abundantly available in various tropical zones. Processing such flotation concentrate by hydrometallurgical routes needs to be explored.

Cobalt minerals are generally recovered as by-products during the extraction of zinc, copper, nickel, silver etc. Flotation of cobalt sulfide ores can be best achieved at acidic pH (~ 4) with xanthate collectors and at pH of about 7.5 for oxide ores with nitrosonaphthol chelating reagents, while their mixture is recommended for oxidized sulfide ores.

NOVEL INORGANIC MATERIALS: ION EXCHANGE

D. J. Jones, Université Montpellier,
Montpellier, France

Copyright © 2000 Academic Press

Introduction

The modification of open-structured solids by ion exchange is a versatile and powerful synthetic route to new compounds. These may be either novel inorganic phases that cannot be prepared directly using high temperature ceramic routes, or composite systems incorporating an additional organic or inorganic component. In both cases the methods used are part of *chimie douce*, a rare example of a scientific French term that has penetrated into common international usage.

From both a conceptual and a practical point of view, it is useful to distinguish those solids that, by the arrangement of their constituent atoms in space, form a rigid, open-structured network and that readily undergo ion exchange reactions only to within the limit of the size constraint of the window openings of the structure, and those in which the framework is made up of two-dimensional layers that may be prised apart if sufficient energy can be provided to overcome the van der Waals or hydrogen bonding interactions. Typical examples of the former are provided by microporous zeolites, such as zeolite A, while smectite clays, such as montmorillonite, exemplify the latter. Here, as in layered oxides, phosphates and other classes of bidimensional solids, the structure adapts itself depending on the incoming molecule, and the variable parameter represented by the interlayer spacing allows an enormous variety of species to be ion exchanged or intercalated. While more classically, ion exchange or intercalation was a single-step process, much recent work is characterized by the development and use of pre-expansion or exfoliation techniques, and reprecipitation of the dispersed layers in the presence of the desired intercalant ion, molecule or polymer. These methods have significantly broadened the range of new nanocomposite materials that can be prepared, which display properties including second harmonic generation (in the case of intercalation of dyes), chiral recognition, electronic conductivity (in the case of ion exchange of electroactive molecules or polymers), protonic conductivity, micro- and meso-porosity for catalysis and sorption, etc.

The term 'intercalation' will be used in its strictest sense here, to mean the topotactic and reversible insertion of a guest species into a host layered compound; this term has been more generally applied to host matrices of any dimensionality.

Host-Structures for Ion Exchange Reactions

To a first approximation, solids of fixed pore size are three-dimensional structures. In zeolites, and zeotypes with ultralarge pores and having alumino- or gallo-phosphate framework compositions, the window frames to the pores are composed of tetrahedrally coordinated atoms, the number of which defines the size of the entry aperture. Zeolite and zeotype molecular sieves are characterized by their high crystallinity and narrow pore size distribution dominantly in the micropore range, i.e. pore diameter below 2 nm, but more recently extending up into the low mesopore region. Charge imbalance created, in the simplest cases, by inclusion of aluminium in a silica framework, is counterbalanced by intrapore cations, and the Si/Al ratio therefore defines the number of exchangeable ions, or ion exchange capacity, usually expressed as the number of milliequivalents (of exchangeable ion) per gram (of ion exchanger). While the modification of zeolites and zeotypes is a starting point for new inorganic syntheses, zeolite ion exchange properties have long been exploited for water softening in detergents and their Brønsted acidity has been used by the petroleum industry in fluid catalytic cracking and other processes.

This enormous historical use and the economical necessity to crack progressively heavier fractions provided the impetus for the synthesis of ion exchanging materials having a pore size reaching more firmly into the mesopore range, and the plethora of activity associated with all aspects of surfactant-assisted syntheses of mesoporous solids attests to the significance of the discovery of this liquid crystal templating, or cooperative nucleation approach. If the surface acidity has since proved to be disappointing, the narrow and controllable mesopore distribution readily attainable using these routes represents a major advance with applications in many fields. Of the hexagonal, cubic and lamellar phases known, only the ion exchange capacity and unidimensional channels of

the first have been used in the synthesis of composite new materials. Potential host structures for modification by ion exchange include the macroporous silicates or aluminio- (zircono, titano-, etc.) silicates formed, for example, by sol-gel routes. However, these are generally amorphous compounds, and this article will be restricted to crystalline host matrices.

Compounds that crystallize in a layered arrangement have no permanent porosity, and the structures adapt in at least one dimension – that perpendicular to the stacking axis of the layers – on ion exchange or intercalation. Layer-structured crystals can be divided into those having neutral layers, which have no ion exchange properties and in which the driving force for any intercalation reaction is an electron transfer process, and those with either positively or negatively charged layers, which are anion and cation exchangers, respectively. The best-known anion exchangers are the layered double hydroxides $[M_1^{II} - x M_x^{III}(\text{OH})_2]^{x+} [X_{x/m}^{m-} \cdot n\text{H}_2\text{O}]^{x-}$ and hydroxy double salts $M^II M^III(\text{OH})_3 X$, where X is an exchangeable anion, such as OAc^- , Br^- , CO_3^{2-} , etc. In the first of these, charge imbalance in the parent brucite, $\text{Mg}(\text{OH})_2$, crystal structure is induced by partial substitution of M^{II} by M^{III} and X occupies the interlayer region. The situation is different in the series based on the botallackite structure $\text{Cu}_2(\text{OH})_3\text{Br}$, as the anion forms part of the coordination sphere of the metal atoms, and its replacement may involve a dissolution–reprecipitation mechanism. Layered silicates (e.g. smectite clays), layered niobate or titanate perovskite structures, layered silicic acids (magadiite, kenyaite, etc.), layered sulfates and phosphates are all known cation exchangers. These may be prepared directly in their hydrogen form, as is the case with α -metal(IV) hydrogen phosphates, or in a form containing an interlayer alkali metal ion, readily exchanged for the proton in acidic solutions. These are solid acids and may display, in addition to the catalytic properties already referred to above in the context of zeolite host matrices, high, water-assisted protonic conductivity. Indeed, ion exchange with inorganic layered matrices can be perceived in the more general framework of ion transfer/transport and ionic mobility.

This section would not be complete without mentioning two additional important classes of ion exchanging materials, which find their place quite naturally between those two extremes of three- and two-dimensionality described above. In one class a permanently porous structure is formed from a layered structure by pillaring, in which process some of the initial ion exchange capacity is retained, and in the other, a layered solid is formed from an initially three-dimensional framework by the clustering of

structural defects induced by ion exchange. These two classes will be discussed in greater detail below.

Synthesis of Metastable Microporous Layered or Framework Materials

The classical approach to the synthesis of many solid state compounds is to mix individual elements or simple solid compounds together and fire them at elevated temperature. Here, the diffusion of atomic/ionic species through reactants and products controls product formation. Nonclassical routes to the preparation of inorganic solids, including the full range of solution chemistry, sol-gel chemistry, insertion and intercalation chemistry techniques of synthesis, have gained increasing importance because they offer alternative means by which both classical materials and novel compositions may be prepared. Of particular interest in the present context is the use of topochemical pathways whereby a solid prepared by high temperature ceramic methods is the precursor for a thermodynamically unstable but kinetically stable phase. This usually involves the extraction or insertion of a mobile species from/into a rigid framework, either by ion exchange or a redox process.

Often, the mobile species is an alkali metal ion. The material takes on industrial importance in the particular case of lithium, with the potential and actual use of lithium insertion compounds as electrodes in lithium batteries, in particular for portable electronic devices and for electric vehicles. For example, the spinel form of manganese dioxide known as λ - MnO_2 cannot be obtained directly by classical methods, nor is it stable at high temperatures, but it is prepared by extraction of lithium either chemically or electrochemically from its lithiated congener LiMn_2O_4 . Generally, in order to maintain charge balance, this process occurs with oxidation of Mn^{III} in the mixed valence ($\text{Mn}^{III}/\text{Mn}^{IV}$) precursor to give λ - Mn^{IV}O_2 . This oxidative extraction can provide cell voltages of c. 4 V. X-ray absorption spectroscopy (near-edge and fine structure) have provided much information on the changes in oxidation state and accompanying local structural modifications induced by the loss of the Jahn–Teller ion Mn^{III} and resulting increase in local symmetry. Lithium-rich spinel manganates $\text{Li}_{1+x}\text{Mn}_{2-x}\text{O}_4$, with $0 < x < 0.33$, are also known. In these materials lithium occupies octahedral sites left vacant by the lower manganese content and electrical neutrality is achieved by an increase of the average oxidation state from 3.5 in LiMn_2O_4 to 4 in $\text{Li}_{1.33}\text{Mn}_{1.67}\text{O}_4$. Oxidative removal is no longer possible, and ion exchange with protons occurs when lithium is removed chemically in acid solution. The octahedral sites vacated by manganese, and not occu-

pied by lithium in the acid exchanged samples, result in lamellar-type lattice defects in the spinel structure in which weakly bound water could be trapped. There is no direct synthetic route to either protonated or nonprotonated λ - MnO_2 .

Indeed, for obvious reasons, high temperature routes often preclude the formation of hydroxylated or hydrated inorganic compounds. Amongst others, protonated dicalcium triniobate $\text{HCa}_2\text{Nb}_3\text{O}_{10}$ and the trititanate $\text{H}_2\text{Ti}_3\text{O}_7$ are simply prepared in acid solution by ion exchange of potassium and lithium, respectively. The materials formed are solid acids, with important implications for eventual proton conductivity or catalytic activity; other modifications may be imposed depending on the dimensionality of the solid. Thus $\text{HCa}_2\text{Nb}_3\text{O}_{10}$ can be further derivatized by acid–base reaction with alkylamines, and by pillaring. These last aspects will be further developed below. The so-called γ -form of zirconium phosphate, $\gamma\text{-ZrPO}_4(\text{H}_2\text{PO}_4) \cdot 2\text{H}_2\text{O}(\gamma\text{-ZrP})$, is metastable with respect to the α -form, $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, and protonated $\gamma\text{-ZrP}$ can only be obtained via ion exchange in acid solution of sodium or ammonium ions in the corresponding precursor prepared at 80–180°C from zirconyl chloride, sodium or ammonium hydrogen phosphates, and phosphoric or hydrochloric acid.

Other possibilities are opened up when the topotactic step is followed by dehydroxylation–condensation. An interesting example is provided by a particular form of titanium dioxide that can be prepared from potassium tetratitanate, $\text{K}_2\text{Ti}_4\text{O}_9$. The latter is formed at 950°C, but is hygroscopic and sensitive to acid hydrolysis. In water, potassium ions are eliminated:

and, when $x = 2$, thermolysis at 500°C yields $\text{TiO}_2(\text{B})$, where the index B indicates the structural relationship to the bronze Na_xTiO_2 (Wadsley bronze). When $x = 1$, then the octatitanate is formed, $\text{K}_2\text{Ti}_8\text{O}_{17}$. The structure of this is identical to that of the potassium richer phase $\text{K}_3\text{Ti}_8\text{O}_{17}$ (Watts bronze), which can be prepared by a classical high temperature route. This is illustrated in Figure 1.

Rather than extraction, a starting compound can also be modified by further insertion of a mobile species. Thus, in addition to the removal of lithium from LiMn_2O_4 described above, lithium may be further reversibly inserted with reduction of Mn^{IV} to give $\text{Li}_2\text{Mn}_2\text{O}_4$. This intercalation can be performed electrochemically, at an average voltage of 3 V, or chemically, using butyllithium or lithium iodide. From

Figure 1 Soft chemical route from dipotassium tetratitanate to a form of titania [$\text{TiO}_2(\text{B})$] and dipotassium octatitanate.

a structural point of view, the local distortions around Jahn–Teller Mn^{III} ions in octahedral sites are no longer suppressed by the presence of non–Jahn–Teller Mn^{IV} , and the unit cell becomes increasingly tetragonally distorted due to cooperative elongation of the J–T $\text{Mn}^{\text{III}}\text{O}_6$ octahedra along the c -axis of the crystal. Although the tetragonal structure is crystallographically different from the precursor cubic structure, they are related in that the linkage of edge-sharing MnO_6 octahedra in the three-dimensional $[\text{Mn}_2\text{O}_4]$ spinel sublattice is conserved.

Use of Ion Exchange and Intercalation for the Synthesis of Materials with New Compositions

The modifications of open-structured two- or three-dimensional hosts by ion exchange with functionalized organic (monomeric, polymeric), inorganic (simple ions, inorganic complexes, polynuclear ions) or organometallic species to give nanocomposite

solids of new composition and tailored structure is an increasingly powerful route to materials displaying a range of enhanced or induced physical (mechanical, optical, electrical, magnetic, textural) or chemical (catalytic, molecular or chiral recognition) properties. Of these, perhaps most attention has been given over recent years in two areas, that of the insertion, or formation *in situ*, of polymers or extended aggregates in the interlayer or intrapore regions of inorganic hosts, and that of the synthesis of pillared layered solids.

Molecular Recognition

The separation of enantiomers on a preparative, rather than analytical, scale is an increasingly important objective, in particular for the pharmaceutical industry. Ion exchanging, microporous solids represent one route currently being explored for the separation of chiral molecules, either making use of a chiral inorganic solid or by modifying the host structure by ion exchange in a first stage such that it recognizes, and becomes specific for, the uptake of one enantiomer from a racemic solution. This is an exciting area of study that deserves to receive much attention in the future.

Intercalated Polymers and Extended Aggregates

During the 1990s considerable interest has focused on the association of ion exchanging host matrices and polymers (or extended aggregates), inspired from both fundamental and more applied viewpoints. As well as being considered to be model systems for interface studies, such constrained environments are expected to enforce a higher degree of polymer ordering, and be conducive to the isolation of polymer chains. Polymer-inorganic host nanocomposites can be discussed, *inter alia*, in relation to the nature of the property induced or enhanced. Currently, two important areas can be distinguished corresponding to materials displaying either mechanical or electrical (ionic, electronic) properties. For example, unprecedented mechanical properties of nylon-clay nanocomposites have been observed, involving a doubling of the tensile modulus and strength, and an increase of the heat distortion temperature by up to 100°C. On intercalation of polymer electrolytes, typically poly(ethylene oxide) (PEO), into a host structure, the oxyethylene units replace water in the coordination sphere of interlayer Li^+ or Na^+ ions and the normally soluble polymer is heterogenized and protected from chemical aggression. Thermal stability is improved, and the materials display good ionic conductivity over a broader temperature range than PEO-salt electrolytes. The association of host matrices with

electroactive polyaniline, polypyrrole and organic metals such as tetrathiafulvalene provide an original source of electronically conducting materials and has inspired research directed at building devices from molecular assemblies. In addition, it can be predicted that in the future, matrices occluding chromophore aggregates will play a role in the field of second harmonic generation; however, as yet the number of examples of nanocomposite solids displaying nonlinear optical properties is limited.

Inorganic host structure-polymer (or aggregate) nanocomposites can also be discussed in relation to the synthetic method used to intercalate or form the polymer *in situ*. From a conceptual point of view the simplest, direct ion exchange, has been used to insert hydrophilic polymers such as PEO, poly(ethylene-imine) (PEI), poly(ethylene glycol) (PEG), poly(phosphazene), gelatin, lysozyme and protamine from solution into layered solids including montmorillonite, fluorohectorite, divanadium pentoxide, transition metal phosphorus trichalcogenides and zirconium phosphate. This strategy requires a compatible polymer-host solvent system. An alternative related method lies in the use of direct intercalation from polymer melts in which the solid polymer (polystyrene, polyamides, polyesters, polycarbonate) and the inorganic matrix are heated to above the softening point of the polymer. The hydrophobicity of the polymer and of the interlayer environment is a key experimental factor, and the latter can be modified prior to intercalation from the melt, e.g. by ion exchange of interlayer Na^+ , etc., for surfactant ions. The intercalated organic-inorganic hybrids formed have an interlayer separation of 1–3 nm, but another, rarer, situation exists when the miscibility of the inorganic and organic systems is high, in which the layered host is exfoliated and individual layers are separated by 10–15 nm. Third, in the absence of any exchange reaction with the host solid, a phase-separated composite is formed, where packets of nonmodified host matrix are embedded in a polymer matrix (Figure 2).

Other synthetic routes make use of ion exchange with a monomer and *in situ* polymerization in the interlayer or intrapore region. Here, distinction can be made between the polymerization of assembled monomers and a redox intercalative polymerization. In the former, monomer species bearing reactive groups that might be, for example, acetylenic, nitrile, functionalized aromatic molecules or condensable moieties, are ion exchanged in a first stage into the inorganic host. In the case of a layered host structure, the charged surface leads to a particular orientation of the monomer units that may favour a given polymerization pathway in the subsequent polymerization

Figure 2 Schematic representation of the continuum in inorganic layered host structures and polymer arrangements between (A) phase-separated regime; (B) intercalated polymer; and (C) polymer dispersion of exfoliated inorganic layers.

step induced thermally, radiatively or chemically. Thus cation exchange of aminocaproic acid into montmorillonite or zirconium phosphate, or anion exchange from acrylic acid into layered double hydroxides, lead to nylon-6 and to polyacrylate, respectively, as the monomers are condensed and water is split off when the temperature is raised to *c.* 200°C. Propargylamine ($\text{HC}\equiv\text{CCH}_2\text{NH}_2$) and dipropargylamine [$\text{HC}\equiv\text{CCH}_2(\text{NH})_2$] readily intercalate with proton transfer into metal(IV) phosphates, and γ -radiation or thermal treatment under inert atmosphere produces polymers of polyacetylenic character. ^{13}C NMR is of particular utility, as a probe spectroscopic technique for the interlayer region, in following the loss of monomer and identifying the nature of the polymer formed. An interesting example is provided by ion exchange of *p*-xylylene- α -dimethylsulfoxonium for Li^+ or Na^+ in M_xMoO_3 . On thermal treatment at 100–250°C, dimethylsulfide is eliminated and interlayer poly(*p*-phenylenevinylene) generated. Chemical oxidation (atmospheric oxygen, ammonium peroxide, etc.) has also been used to initiate the polymerization process, e.g. of anilinium in zeolite-Y, mordenite and ordered mesoporous aluminosilicate MCM-41, and of methyl methacrylate in montmorillonite.

The polymer intercalate may also serve as a precursor phase; a potentially important development lies in the use of clay-polymer intercalation nanocomposites as precursors for graphite films. Such template carbonization uses the inorganic matrix to orient the organic species as it evolves from the ion exchanged monomer to a polymer to a carbon. Destruction of the template and subsequent heat treatment leads to flexible graphite films.

Intercalative polymerization can occur when the matrix has electron transfer properties. These may be inherent to the host solid, as in FeOCl , V_2O_5 , etc., or may be conferred on a redox-inactive matrix by ion exchange with appropriate transition metal ions. Thus following ion exchange of Cu^{2+} or Fe^{3+} into mordenite, zeolite-Y, montmorillonite, zirconium phosphate, ordered mesoporous aluminosilicate MCM-41, etc., electron donor molecules such as aniline (Figure 3) and pyrrole are oxidized, ion exchanged and undergo polymerization concomitantly, and the metal ion is reduced and, in some cases, eliminated as electrically neutral colloidal particles. Electroactive molecules such as tetrathiafulvalene (TTF) have also been assembled in γ -zirconium phosphate using this same approach.

TTF provides an example of an electron donor molecule that can only be inserted in an ion

Figure 3 Schematic diagram showing layers of (A) $\gamma\text{-ZrPO}_4 \cdot \text{HPO}_4 \cdot (\text{anilinium})$, (B) $\gamma\text{-ZrPO}_4 \cdot \text{HPO}_4 \cdot (\text{PANI})$.

exchanging matrix if oxidized. Indeed, from the point of view of associated electrical properties, partial oxidation of TTF is required. These two conditions have been combined recently by oxidizing TTF with bromine to $\text{TTF}^{0.72+}$, which can then be ion exchanged with species used to pre-expand the interlayer region in host α - and γ -ZrP. The TTF units do not lie parallel to the plane of the phosphate layers and, although not a polymer system, they are nevertheless stacked into extended aggregates and provide the π -orbital overlap necessary for conduction.

Pillared Layered Solids

Reference was made above to the requirement by the petroleum industry during the 1970s for acid catalysts of pore size in the mesopore region, distinctly greater than that of the zeolites available at that time. Although templated routes to larger pore zeolites had not yet been successful, the modification of

preformed layered solids by ‘pillaring’ was to give rise to a new area of chemistry and a new type of porous solid. The calculated surface area of a two-dimensional solid is high, $960 \text{ m}^2 \text{ g}^{-1}$ for example for α -zirconium phosphate, although nitrogen BET (Brunauer, Emmett, Teller) measurements indicate a surface area of *c.* $5 \text{ m}^2 \text{ g}^{-1}$ only. To render at least part of the surface area accessible, the layers must be permanently separated using inorganic spacers introduced by ion exchange or intercalation. To consolidate the structure and liberate interlayer regions occupied by organic moieties, hydroxyl groups or water, the expanded phase is then treated thermally or chemically (Scheme 1 and Figure 4).

The presence of inorganic species acting as pillars and interacting strongly with the layers gives rise to thermally stable materials of high surface area (BET surface areas typically between 150 and $400 \text{ m}^2 \text{ g}^{-1}$) and pore volume accessible for adsorption and separation, catalysis and ion exchange. An important area

Scheme 1 Formation of a pillared compound from a layered solid.

Figure 4 Synthesis of pillared layered structures by ion exchange and grafting from (A) swelling matrices and (B) host structures of high layer charge density.

represented by metal phosphonates is beyond the scope of this article by virtue of the synthetic routes to this class of pillared solid.

The extent of uptake of the pillar precursor species, a direct result of the ion exchange capacity of the host matrix, is a key parameter influencing the ultimate textural properties of the pillared solid, since it con-

trols the lateral spacing of the pillars. Indeed, the synthesis of porous solids from higher layer charge density solids was only achieved some 15 years after the first results published on smectite clays. In addition, the layer charge density of smectite clays is sufficiently low that they swell spontaneously in water and the ion exchange of generally bulky, polynuclear inorganic ions still occurs readily. In contrast, for non-clay substrates of higher layer charge density a pre-expansion or exfoliation step is the general rule. This is summarized in **Table 1**.

A further requirement is that the pillaring species should be regularly arranged in the interlayer region, in order to generate a solid of narrow pore size distribution. While this regular distribution is achieved at the precursor stage by the registry between host and guest ions, sintering of the metal oxide particle on thermal treatment and degradation of the host structure itself both contribute to producing a broader – and frequently bimodal (spanning the micro- and small meso-pore range) – pore size distribution than is characteristic, say, of zeolites. Additional criteria for the matrix are therefore that it must be sufficiently rigid that it does not collapse in regions between the pillars on dehydration and that the layer charges must be uniformly distributed. In this respect, synthetic clays and non-clay substrates have received particular attention recently since, in addition, these provide the possibility of varying the layer charge density, e.g. by changing the Si/Al ratio or by partially replacing sites for ion exchange with nonexchangeable groups. Nevertheless, when the host matrix has small platelet diameter or when it undergoes an exfoliation stage in the synthesis, reassembly of the layers following ion exchange with the pillaring solution can lead to the situation where edge-to-face stacking predominates ('house-of-cards' arrangement), which has more developed mesoporosity (**Figure 5**).

Most of the two-dimensional matrices mentioned above have been used as a starting point for pillared

Table 1 Comparison of properties of smectite clays and nonswelling host lattices and consequences on the formation of porous, and not just cross-linked, layered solids

<i>Smectite clays</i>	<i>Non-clay substrates</i>
Low layer charge density	High layer charge density
Spontaneously swell in water	No spontaneous swelling in water; exfoliation (infrequent) under defined conditions not necessarily compatible with existence of polynuclear inorganic species
Pillaring by direct ion exchange with aqueous solution of polynuclear inorganic pillaring species	No direct intercalation → must pre-expand and then ion-exchange, e.g. butylamine/ Al_3^{+}
Inserted species are well spaced	Crowded interlayer

Figure 5 (A) House-of-cards arrangement of the layers of a pillared solid where flocculation after delamination has led to predominant edge-to-face stacking. (B) regular pillared solid with predominant edge-to-edge stacking morphology.

layered structures. A broad spectrum of pillaring species exists based on polynuclear metal hydroxo or oxo complex ions obtained by the hydrolysis of metal salts, such as the aluminium Keggin ion $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$, their gallium and iron analogues, and heteronuclear combinations. These include aluminium Keggin ion modified by the addition of rare earth ions, $[Cr_3(OH)_4(H_2O)_9]^{5+}$, $[Zr(OH)_8(H_2O)]^{8+}$, metal chloride cluster ions $[M_6Cl_{12}]^{2+}$, $M = Nb, Ta$, organometallic oligomers, e.g. $[H_2N(CH_2)_3Si_{1.5}]_8$, silicon tris(acetylacetonate), positively charged colloidal particles of titania or silica and, in the case of cationic layers, polyoxometallate ions. The variety of pillaring ions and layered hosts available provides enormous flexibility for creating numerous chemical combinations. This opportunity arises precisely because the route to pillared solids is via ion exchange, which allows variety in framework chemical and atom concentrations not yet attainable in other porous solids, in particular in the family of M41S mesoporous silicates. However, in large part because of the low degree of crystallinity of pillared layered solids, little direct structural information is available using X-ray diffraction and the relationship between structure and properties remains to be explored. Furthermore, in the case of complex polynuclear ions, the dominant species in solution may not be the same as that stabilized in the interlayer region. Local structural information around the metal atoms of the layer and the pillaring species can be obtained using magic angle spinning nuclear magnetic resonance (MAS-NMR) and X-ray absorption spectroscopies.

Some of the ion exchange capacity used in assembling the pillaring species is regenerated during the

calcination stage. This retained ion exchange capacity is important, since it provides the opportunity for a Brønsted acidity additional to the Lewis acidity generally conferred by the inorganic oxide particles forming the pillars. It can be exploited to further modify the chemical composition of the solids, and so tailor them for a particular application, in particular in catalysis. In addition, pillared layered solids can be seen as a new type of confining matrix for the organization and quantization of polymers and metal clusters or sulfides, and pillared materials derivatized in this way have been termed nano/nanocomposites.

Finally, mention should be made of a new development in a related area making use of sol-gel and intercalation chemistry, and surfactant-directed synthesis. Porous clay heterostructures are formed by reacting cationic surfactant exchanged fluorohectorite, vermiculite or rectorite with neutral amine/tetraethoxysilane to give a structure in which silica-lined cavities impart permanent porosity to the interlayer region.

THE NUCLEAR INDUSTRY: ION EXCHANGE

J. Lehto, University of Helsinki, Helsinki, Finland

Copyright © 2000 Academic Press

Introduction

Ion exchange is used in nearly all phases of the nuclear fuel cycle beginning in the early stages of uranium ore treatment where ion exchange is one of the major processes used: uranium is removed from ore leach liquors using anion exchange resins.

At nuclear power plants, ordinary organic ion exchange resins are mainly used for the removal of ionic and particulate contaminants from the primary circuit, condensate and fuel storage pond waters. Ion exchange resins are also used for the solidification of low- and medium-activity nuclear waste solutions. The number of applications of selective inorganic ion exchangers in the separation of radionuclides from nuclear waste solutions has been increasing since the mid-1980s.

In nuclear fuel reprocessing plants, the main separation method is solvent extraction. Ion ex-

change is, however, used for the solidification of low- and medium-activity waste solutions, as well as for the partitioning of radioactive elements for further use.

This article reviews all the most important areas of the utilization of ion exchangers in the nuclear power industry. Special attention is paid to ion exchange processes, which involve radionuclide removal functions, and to new developments in selective ion exchange materials.

Ion Exchange Materials Used in the Nuclear Industry

Nuclear Grade Ion Exchange Resins

Organic ion exchangers used at nuclear power plants are based on conventional poly(styrene-divinylbenzene) resins with sulfonic acid ($-\text{SO}_3^-$) and quaternary ammonium ($-\text{N}(\text{CH}_3)_3^+$) functional groups for cations and anions, respectively. Nuclear grade resins,

NUCLEIC ACIDS

Centrifugation

A. Marziali, University of British Columbia, Vancouver, Canada

Copyright © 2000 Academic Press

Introduction

Centrifugation has been applied to nucleic acid isolation and purification through numerous protocols which, at some level, contain elements of one or more of three basic techniques: isopycnic or density equilibrium separation, phenol-chloroform extraction, and differential precipitation. Even if we consider only the protocols that are in current use, numerous variations on these appear in the literature. These variations result from the intended use of the product, the required purity from specific contaminants, the cost and throughput goals of the technique, and often the author's personal preferences. This article will make no attempt to cover all variations but will instead illustrate by example the basic forms of centrifuge-based techniques for nucleic acid separation as they are presently used. A rough guide to these three basic techniques and their applications is contained in Table 1. Each of these will subsequently be described separately.

Recent demands imposed on nucleic acid purifications by large scale DNA sequencing operations have led to the development, and increased use of filtration-based purification methods for high throughput separations. Though the cost of the filter membranes required for these separations is much higher than the cost of centrifugation, the throughput and ease of automation of the membrane based methods make them preferable in many situations. Recent developments in automation of centrifugation, discussed in the last section of this article, may reverse this trend.

Isopycnic Separations

General Principle

Isopycnic separations rely on the balancing of the buoyant and centrifugal forces acting on a submerged sample during centrifugation. When a sample of density ρ_s and effective volume V is placed in a medium of density ρ_m in the presence of a centrifugal field a , the sample feels an upward buoyant force $F_b = \rho_m Va$, and an opposing centrifugal force $F_c = \rho_s Va$. Consequently, the sample will move 'up' toward the rotation axis if $\rho_s < \rho_m$ and 'down' if $\rho_s > \rho_m$. This motion terminates when the sample reaches the boundary of the medium or when it enters a region of the medium where $\rho_s = \rho_m$. Based on this principle, if a sample container is filled with a medium whose density increases gradually in the downward direction, a sample injected in this medium will migrate to the region of the medium that matches the sample density (provided such a region exists). This location is known as the isopycnic point of the sample.

Samples may therefore be separated based on their densities provided a medium is found that can be formed into a density gradient and whose density range includes that of the sample. One of the criteria in the selection of separation media for a specific sample is to ensure that this condition is met.

After a substantial migration period (often over a day), the sample fractions of different densities can be observed as bands within the medium. Extraction of these bands is performed by puncturing the centrifuge tube with a hypodermic needle and withdrawing the desired band. The resolution provided by this method is a function of the separation medium and the relative density difference in the fractions to be separated.

In the case of nucleic acids, RNA and DNA exhibit very different densities in aqueous solutions and therefore can be separated. Cesium salt solutions are typically used as the separation medium since in

Table 1 Three common methods of nucleic acid separation employing centrifugation

<i>Separation type</i>	<i>Application</i>
Isopycnic centrifugation: Gradients of cesium salts –	High purity, low throughput DNA purification. Separation of DNA, RNA, and DNA–RNA hybrids. Separation of DNA by conformation. Plasmid DNA purification. Nucleic acid separation by base composition
Non-ionic media gradients – (Metrazimide, Nycodenz)	High purity RNA purification
Phenol–chloroform extraction	Separation of nucleic acids from proteins
Differential precipitation	Concentration of nucleic acids, removal of some salts. High throughput, medium purity nucleic acid purification

a centrifugal acceleration field they spontaneously form into a density gradient whose range can include that of DNA. RNA typically exhibits higher density than the maximum cesium gradient density and pellets at the bottom of the centrifuge tube. DNA may also be fractionated according to a number of variables which affect its buoyant density. Single stranded DNA and double stranded DNA differ in their degree of hydration and therefore exhibit different buoyancies, allowing them to be separated into two different bands in Cs_2SO_4 (or NaI) gradients. Also, the base composition (G + C content) of DNA linearly affects its buoyancy allowing separation of DNA from different organisms, and, in some cases, even separation of DNA from different regions of the same eukaryotic genome (Figure 1).

The addition of intercalating molecules such as ethidium bromide to the gradient may be used to separate DNA based on its conformation. Linear and relaxed circular DNA allow a larger amount of ethidium bromide to intercalate than supercoiled DNA, leading to decreased density and band separation. In the example described below, this result is used to separate supercoiled plasmid DNA from genomic and nicked circular plasmid DNA.

Separation of RNA is difficult to perform in cesium salt solutions because of its density and tendency to form a precipitate. Consequently, separation of RNA is now performed in nonionic media such as Metrazimide and Nycodenz. Table 2 lists some commonly used density gradient media and their associated use.

A common example of the use of cesium chloride gradients is illustrated in the isolation of plasmid DNA. Note that this is an abbreviated protocol: the

references at the end of this article should be consulted for further details.

Phenol Extraction for Separating DNA/Proteins

A common method for separating nucleic acids from proteins is extraction by phenol or phenol:chloroform. In this technique, solutions containing protein and nucleic acids are combined with an equal part of phenol or phenol:chloroform and mixed into an emulsion. Since phenol and chloroform are solvents for denatured proteins while nucleic acids are soluble in the aqueous phase, centrifugation of the phases results in separation of nucleic acids from proteins. In some cases, multiple extractions may be required and may be followed by extractions in pure chloroform and by ethanol precipitation depending on the required purity of the nucleic acid sample. A simple example of this technique is the purification of DNA from M13 bacteriophage for purposes of DNA sequencing. An abbreviated protocol is given in Figure 2.

Differential Precipitation Methods

Ethanol or Isopropanol Precipitation

Perhaps the simplest way to concentrate nucleic acids by centrifugation is precipitation in ethanol or isopropanol solutions. This technique takes advantage of the fact that nucleic acids can form a solid precipitate in these solutions when their negative charge is neutralized by the presence of monovalent cations. A common example of this is ethanol precipitation of DNA in which an aqueous DNA sample is mixed with ethanol and a small amount of salt (often sodium acetate). After incubation, a solid precipitate of the sodium salt of DNA is formed which can be centrifuged into a pellet. Repeated washing of this pellet with 70%–80% ethanol solutions helps remove residual salts.

Though ethanol precipitation is not useful in separating nucleic acids from many contaminants, this form of purification is the final step in many nucleic acid purification schemes as it tends to both concentrate the nucleic acid and remove any remaining salts or contaminants used in previous separations and extractions. In some cases, salt contaminants already present in the sample can be used to aid precipitation without further addition of sodium acetate (or other salts). The simplicity of this protocol has made it a cornerstone of high throughput nucleic acid purification. Table 3 is a rough guide to the choice of salt used in the precipitation.

Figure 1 Plasmid DNA purification by CsCl – Ethidium bromide continuous gradient.

Precipitation of nucleic acids from buffers containing high concentrations of EDTA or phosphate ions may result in co-precipitation of these substances. Also, precipitation of small nucleic acid strands (< 100 nucleotides) may be improved by the addition of carriers such as glycogen, by the addition of MgCl_2 , or by increased duration and speed of the

centrifugation ($100\,000 \times \text{g}$, 1–2 hours). Centrifugations for nucleic acid precipitations are typically carried out at $0\text{--}4^\circ\text{C}$, though for substantial concentrations ($> 40 \text{ ng } \mu\text{L}^{-1}$) of long strands (such as DNA template for sequencing) incubation and centrifugation can also be carried out at room temperature.

The generic protocol shown in **Figure 3** is an example of ethanol precipitation for final concentration of DNA from a plasmid or M13 preparation.

Discarding of the ethanol supernatant is a common source of problems during precipitations performed in microtitre plates for two reasons. First of all, the pellet is not tightly bound to the sample plate as the centrifugation can only be performed at $3500 \times \text{g}$. Secondly, the ethanol is usually removed by inverting the entire microtitre plate and gently shaking or tapping it on a bench. Not surprisingly, inexperienced manual execution of this step can lead to loss of the DNA pellets with the ethanol.

Table 2 Some density gradient media commonly used for nucleic acid separation

Separation medium	Application
CsCl	Isolation of plasmid DNA. Separation of DNA by conformation. Separation of DNA by base composition
NaI	Separation of single vs. double stranded DNA
Metrizamide, Nycodenz	Fractionation of RNA

Figure 2 M13 DNA purification by phenol:chloroform extraction.

After the initial precipitation, the pellet can be resuspended in TE buffer to the desired concentration, or, if particularly low salt concentration is

Table 3 Salt solutions used for nucleic acid precipitation

Salt	Final concentration	Advantage/application
Ammonium acetate	2.0–2.5 M	Reduces co-precipitation of dNTPs
Lithium chloride	0.8 M	Works with high concentrations of ethanol (as used in RNA precipitation)
Sodium chloride	0.2 M	Allows SDS to remain soluble in ethanol Used with samples containing SDS
Sodium acetate	0.3 M	Used for routine RNA and DNA precipitations

desired in the final product, a further ethanol wash can be performed. This is done by washing the pellet in 70% ethanol and centrifuging for a further five minutes before again discarding the ethanol.

Isopropanol may be used in place of ethanol. In this case, only one volume of isopropanol should be used per volume of DNA solution. This is usually less desirable as residual isopropanol is more difficult to remove and more likely to cause coprecipitation of salts.

Precipitation of RNA is performed as for DNA except that 2.5 to 3 volumes of ethanol should be used per volume of RNA solution.

Plasmid Preparations by Differential Precipitation

Another form of differential precipitation is commonly used for the separation of small nucleic

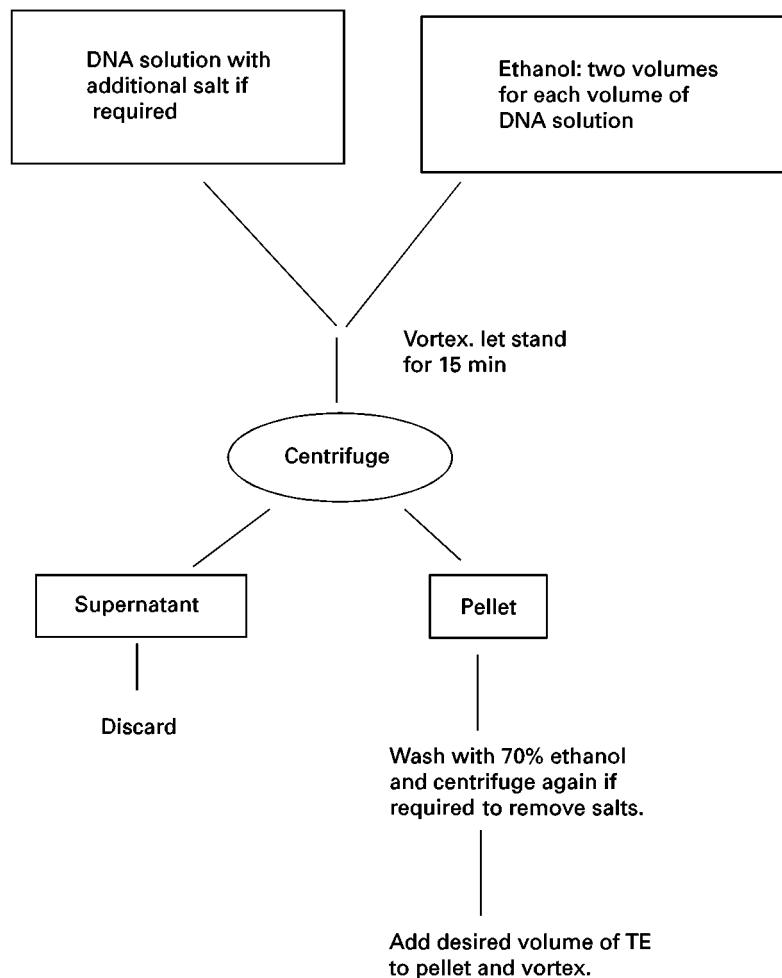

Figure 3 Ethanol precipitation of DNA.

acid molecules such as plasmid DNA from genomic DNA, RNA and protein contaminants. One example of this technique is the frequently used alkaline lysis preparation for the purification of plasmid DNA from *E. coli*. The technique takes advantage of the fact that the large genomic DNA strands from lysed bacterial cells will precipitate much more easily than the smaller plasmid molecules. Consequently, a mixture can be generated in which the genomic DNA can be pelleted, allowing the plasmid DNA to be extracted with the supernatant. The generic technique is shown in **Figure 4**.

Nucleic Acid Separation at High Throughput

Present and future efforts in the development of novel nucleic acid purification methods are likely to be aimed at satisfying the demand for inexpensive and high speed purification of a large number of

samples simultaneously. This is particularly true in applications related to large scale DNA sequencing and analysis. Currently, large-scale sequencing labs are expanding their operations to reach sequencing rates of 50 000 to 100 000 DNA samples per day. Though density gradient separations such as CsCl have historically provided the highest purity DNA, they are far too laborious to be employed at this rate. Furthermore, because of the inherently parallel operation in these cases, any DNA purification schemes must be compatible with standard microtitre plate formats.

Large scale operations have therefore depended largely on a variety of simpler purification methods including membrane purifications, magnetic bead separations, and precipitation based separations. The first two of these rely on preferential binding of the desired nucleic acid to a membrane such as glass fibre, or to a slurry of beads which can be isolated magnetically. Both these methods are easily scaled to highly parallel operation through the use of conventional

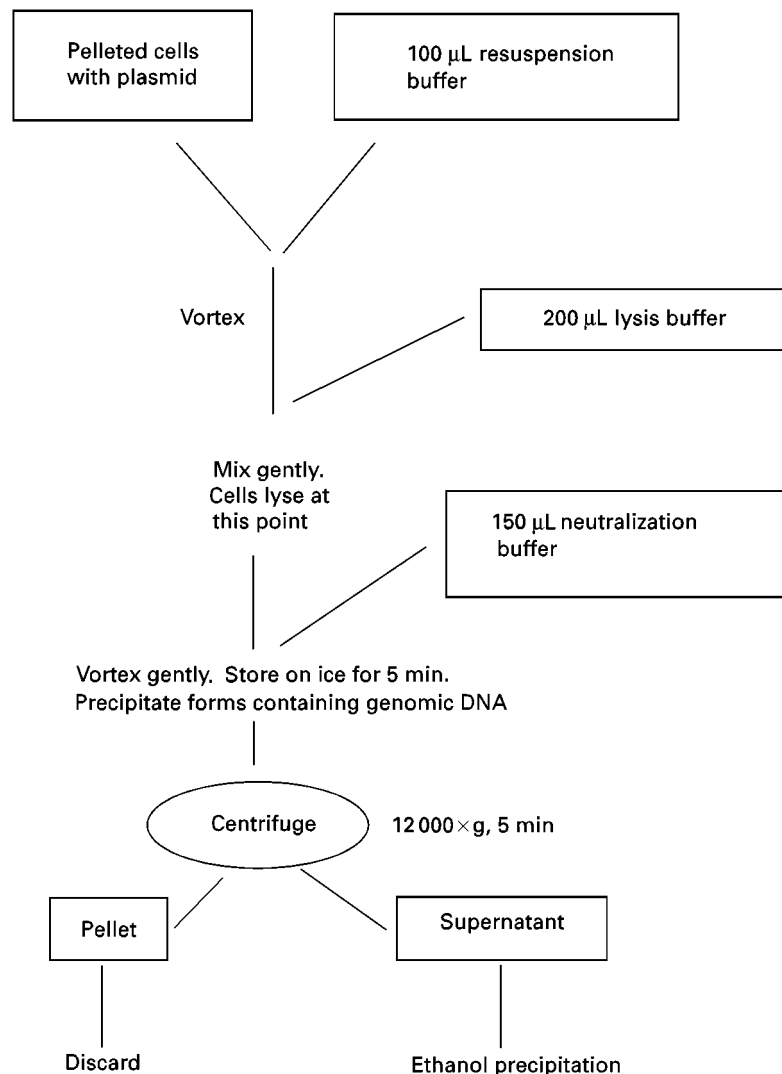

Figure 4 Plasmid purification by differential precipitation.

microtitre plates (for bead separations) and microtitre membrane plates (now available with up to 384 sample wells per plate). Furthermore these two methods are easily automated, and numerous instruments now exist that can perform filter membrane or magnetic bead based separations with very little labour cost and at high throughput. The only drawback to these methods has typically been the cost associated with either the magnetic beads or the disposable filter membranes.

Precipitation based purification methods, though inherently less expensive because of the lack of disposables involved, have been somewhat harder to adapt to large scale operation because of the human effort required to set-up and operate a conventional centrifuge. Though centrifugation of high density microtitre plates is routinely performed, unat-

tended automation of this process has been avoided until recently, and many large sequencing labs simply rely on manual execution of centrifuge based protocols.

Automation of Nucleic Acid Separation by Centrifugation

Two methods for performing high throughput automated centrifugation have emerged which allow the construction of automated instruments for performing centrifugation-based purification protocols.

Automated, indexing centrifuges The first of these methods is based on automation of centrifugation in the same fashion as it is performed manually. This involves simply automating the placing and removal of sample plates or tubes in and out of a standard

centrifuge. The difficulty involved with this method is that standard centrifuge rotors are not designed to stop at a repeatable indexed orientation. Consequently, the robotic arm which places and removes the samples from the samples from the centrifuge, cannot know the location of the samples at the end of a run.

The solution to this problem is to index the rotor position by means of an electronic sensor or a mechanical stop. One example of this type of solution is a plasmid preparation instrument developed at the Lawrence Berkeley National Laboratory (LBNL). This instrument consists of a robotic gantry equipped with a pipetting and gripping tool which can access a work surface that includes an indexing centrifuge. To prepare the centrifuge for robotic access, a pneumatic actuator opens the lid while another actuator is extended to interfere with tabs attached to the rotating rotor shaft. These tabs, when pressed against this actuator, define a well-indexed position for the rotor buckets. To ensure contact between these tabs and the actuator, the rotor is turned by an external friction coupling which can slip once the tab is in contact with the actuator. With the rotor positioned in this fashion, the robotic tool can reliably enter the centrifuge and locate the rotor bucket or sample plate.

With an instrument of this type, plasmid purification at the rate of 192 samples in 2.5–4 h can be performed. Final DNA purification occurs by ethanol precipitation, automated within the centrifuge described.

Similar methods have been used to automate centrifugation in other instruments including the commercially available Autogen 740 and Autogen 850 instruments. These instruments also contain automated centrifuges and are capable of various DNA and RNA purifications at rates up to 48 samples per 4–6 h.

Miniature, arrayable centrifuges A second approach to automation of centrifugation for high throughput DNA purifications has recently been developed at the Stanford DNA Sequencing and Technology Center. The goal of this approach is to remove the inherent radial acceleration limit ($\sim 3500 \times g$) imposed on microtitre plate centrifugation by the structural weakness of the sample plate. It is because of this strength limit that centrifugation of DNA samples in microtitre plates typically requires 20–30 min per separation. By centrifuging the samples directly within a reusable, high strength rotor, accelerations of over $20\,000 \times g$ can be reached, substantially decreasing pelleting times. To implement this at high throughput, a large number of small rotors operating in parallel is required.

Figure 5 (See Colour Plate 108) Titanium belt driven and air driven rotors used in the arrayable flow-through centrifuge. A penny is shown for scale.

The Stanford group's implementation of this concept consists of blocks of 96 individual, high speed rotors, arrayed on the same spacing as a standard 96 well microtitre plate. The rotors (Figure 5) can be spun at up to 70 000 rpm in both directions about their central axis by means of either compressed air or a motor driven belt.

In the belt driven version of the device, all 96 rotors turn simultaneously at identical rotation speeds, thus ensuring protocol uniformity across all samples. The rotors are manufactured from titanium, and are washable and reusable. The inner cross section of these rotors is wider in the middle (axially) than at the ends, thus guaranteeing that pellets will form in a specific area away from the inlet and outlet. The general principle of operation is as follows (Figure 6).

Figure 6 Principle of operation of arrayable flow-through centrifuge: (A) Sample is injected through the upper axial orifice into the spinning rotor. The centrifugal field instantly presses the sample against the inside wall of the rotor preventing it from exiting through the bottom orifice. (B) Rapid spinning of the rotor separates sample phases – any solid precipitate is pressed into the widest part of the rotor. (C) The rotor is stopped and the supernatant drips out the bottom orifice. The pellet can be re-suspended by injecting a small amount (100 μ L) of buffer into the rotor and agitating the rotor through repeated clockwise and counterclockwise accelerations. This procedure can also be used to clean the rotor and prepare it for the next sample to be separated.

The small size of this flow-through centrifuge allows highly parallel operation, smaller sedimentation drift distances, and high angular velocities. These high velocities in turn translate to large sedimentation forces which, coupled with the short drift distance, lead to much shorter separation times than a conventional microtitre plate centrifuge. Calculations based on *E. coli* sedimentation indicate a 40 fold decrease in pelleting time over a conventional centrifuge.

Applications of this technology to nucleic acid separation are being exploited primarily in the area of plasmid DNA purification for sequencing purposes. Instruments are being constructed based on this technology which should be capable of purifying over 500 plasmid DNA samples from cell cultures within one hour using an alkaline lysis protocol. In this protocol, two separations are required, one to clear the cell lysate, followed by ethanol precipitation to collect the DNA. With this protocol in mind, a multi-stage version of this flow-through centrifuge system (where the supernatant from one array of rotors drips into the input of a second array) is being developed at Stanford.

Introduction

The recent explosion of information from recombinant DNA technology and the human genome initiative has come about in response to a number of key technological advances. These include the discovery and characterization of restriction endonucleases, the development of plasmid and phage vectors, and the creation of high throughput DNA sequencing methodologies. Less dramatic, but no less important, has been the development and refinement of protocols for extracting, purifying, and characterizing the various nucleic acids from complex biological mixtures. The present chapter reviews these procedures with particular emphasis on the unique characteristics and methodological constraints involved in dealing with deoxyribonucleic acid (DNA) vs. ribonucleic acid (RNA).

Figure 1 establishes the experimental hurdles to the isolation of purified nucleic acids. A eukaryotic cell contains a variety of biological macromolecules of

which the genetic material (nucleic acids) represents a minor component. The investigator is therefore faced with the daunting task of separating proteins, lipids, and nucleic acids from each other. Indeed, many applications require fractionating the genetic material into DNA and RNA and even subfractionating the RNA into ribosomal and messenger RNA species. These last two tasks are complicated by the fact that chromosomal DNA is a fragile, double-stranded molecule of very high molecular weight (3 billion total base pairs). RNA, on the other hand, while much smaller (75–10 000 nucleotides), is a single-stranded molecule that is exquisitely sensitive to enzymatic degradation. Fortunately, each biological fraction within a cell bears unique biophysical characteristics (charge, lipophilicity, chemical makeup, etc.) and these characteristics provide convenient mechanisms for resolving the macromolecules from one another.

In general, various nucleic acid isolations follow a common procedure. Cells, tissues, or organs are homogenized under conditions designed to protect the nucleic acid integrity, while simultaneously disrupting other macromolecules. This is followed by a relatively simple organic extraction (phenol-based) and selective precipitation from ethanol. The resulting preparations are then characterized by

Figure 1 The technical hurdles in isolating nucleic acids from an animal cell. The cell is composed of a complex mixture of macromolecules (proteins, lipids, carbohydrates and nucleic acids) present in a number of different compartments. This is also true of the nucleic acids, where DNA is predominantly housed in the nucleus (with a small proportion of mitochondrial genes present within these organelles). The DNA is packaged in a complex mixture of nucleic acid and protein. The messenger RNA is present in the cytoplasm as free nucleic acid, as well as mRNA bound to soluble and membrane-bound ribosomes. The ribosomes themselves are composed of proteins and the structural ribosomal RNA molecules (18S and 28S rRNAs). Finally, the lysosomes are specialized organelles that sequester degradative enzymes from the rest of the cellular contents. The experimental challenge is therefore to disrupt the cell (while inactivating the degradative enzymes) and extract pure nucleic acids from the complex mixture of diverse macromolecules.

spectrophotometric and size fractionation methodologies (gel electrophoresis).

Organic (Phenol-Based) Extraction and Ethanol Precipitation

Before turning our attention to the peculiarities and specifics of DNA versus RNA isolation, we will consider two common features of nucleic acid isolation in general, namely, organic extraction with phenol-based solutions and the precipitation of nucleic acids with ethanol. A fundamental observation was made over 40 years ago that a simple organic extraction can resolve nucleic acids from nearly all other cellular macromolecules. Notably, mixing an aqueous homogenate of cells/tissues with phenol results in the extraction of the hydrophobic lipids into the organic phase and the denaturation, partial extraction and precipitation of protein. Therefore, if such an aqueous-organic emulsion is resolved – generally by low speed centrifugation – three specific compartments will be generated. The heavy, organic phase will be found at the bottom, the aqueous phase (containing the nucleic acids) will be found at the top, and a precipitate of insoluble protein will be found in a thin interface between the disparate solutions. This very simple approach has become a mainstay of the mod-

ern molecular biology laboratory and permits the economical and efficient preparation of nucleic acids.

Several modifications of the approach have been made in the years since that initial observation. First, it was found that inclusion of an equal volume of chloroform (CHCl_3) improves phase separation of the aqueous and organic compartments. Moreover, it ‘drives’ residual water from the phenol phase, thus limiting reductions in the volume of the aqueous phase. Finally, inclusion of small amounts of isoamyl alcohol reduces or prevents foaming of the solution during emulsion. As a result, many common protocols require the use of PCI (phenol-chloroform-isoamyl alcohol), in a 25:24:1 ratio, for the extraction of nucleic acids from complex mixtures.

Once nucleic acids (both DNA and RNA) have been resolved from other macromolecules, they frequently need to be concentrated prior to further experimental manipulation. This can be readily accomplished by ethanol precipitation. The addition of high concentrations of monovalent cations to a solution of nucleic acid polymers neutralizes their phosphate backbone. These large macromolecules are then only barely maintained in solution. Keep in mind that even small tRNA molecules (75 nucleotides) are

25 000 Da in size; eukaryotic chromosomes, on the other hand, are on the order of 50 billion Da. The subsequent addition of ethanol to such a solution produces structural transitions in the nucleic acids, with their subsequent precipitation from solution. The precipitates are collected by centrifugation and then washed with ethanol to dissolve the salt and the preparation is then redissolved in a buffer of choice. Most monovalent cations are suitable for the precipitation, although sodium acetate, ammonium acetate and sodium chloride are used, in that order of preference. As will be discussed, there are specialized applications in which lithium is used in the selective precipitation of RNA. Typically, the salt concentration of a solution is raised to ≥ 0.3 M and two volumes of ethanol added (to raise the final ethanol concentration to 67%). Following a varying period of precipitation (depending on the specific application), the DNA or RNA is collected, extracted with 75%, salt-free ethanol and then used.

DNA Purification

DNA can be isolated from whole blood, and from virtually any tissue or collection of cells. Selecting which protocol best suits one's needs will be dependent upon three basic criteria: (1) the starting material (both the biological source and the amount); (2) the desired size of the resultant DNA; and (3) the quantity of DNA needed. With almost any starting material, if the end-point application can accommodate chromosomal DNA that has been sheared somewhat, the investigator has the greatest flexibility in the selection of methodologies. In addition, as a result of the explosion in molecular biology-related research and development over the last 10–15 years, there are numerous kits available through companies such as Promega and Qiagen that supply reagents and complete protocols for purifying DNA. There are also reagents that allow the researcher to isolate RNA, DNA and proteins from the same starting material. In this section, we discuss the general principles involved in DNA extraction and briefly describe some of the more popular commercially available reagents

Genomic DNA (Mammalian)

To begin a DNA purification, if the starting material is whole blood or cultured cells, the first step is to concentrate the cells. This is accomplished by rinsing the cells in an appropriate buffer, followed by centrifugation and removal of the liquid phase. For tissue preparations, those that have been snap frozen (in liquid nitrogen) can either be ground to a fine powder while still frozen using a mortar and pestle,

or disrupted using any of a number of manual or mechanical homogenization devices. The desired size of the resultant DNA and the tenacity of the tissue type determines if relatively mild (e.g. Teflon to glass, hand-held homogenizers) or more severe (mechanical homogenizers such as the Brinkman Polytron) devices are required. The goal of this first step of the isolation is to disrupt cell-cell interactions and to produce some cell lysis. The next step, independent of the starting material, is the release of the intercellular contents from the structures that maintain internal compartmentalization (e.g. nuclear membranes). Once the cells have been homogenized, final lysis is typically accomplished by enzymatic digestion with proteinase K (a broad specificity serine protease) followed by extraction of the DNA in an equal volume of phenol. Interestingly, proteinase K is most active in high concentrations of detergent (typically sodium dodecyl sulfate, SDS) and elevated temperatures. Therefore, investigators generally need not worry about nucleases as a source of confounding activities because they are inactivated under these conditions.

Depending upon the purity and size of DNA required, subsequent extractions can be performed (with pooling of the aqueous phase each time) followed by dialysis (to recover high molecular weight DNA, e.g. > 200 kb) or by precipitation of the DNA with two volumes of ethanol. After several washings of the pellet with 70% ethanol, the dried DNA pellet can be resuspended in water or buffer and assessed spectrophotometrically for quantity and quality by determining its absorbance at 260 and 280 nm. DNA that is relatively free of contaminating proteins or phenol will have a ratio greater than 1.75.

There are now a number of reagents being marketed that allow for 'single-step' separation of DNA, RNA and protein (e.g. Tri Reagent, Molecular Research Center, Inc.; TRIzol, Gibco-BRL). The initial cell disruption phase is identical to what has already been described, with the caveat that the cells are resuspended (or homogenized) in a solution of phenol and guanidine thiocyanate. The homogenate from this resuspension is separated into phases by mixing with either bromochloropropane or chloroform. DNA is found almost exclusively at the interface between the liquid phases, while RNA is in the aqueous phase and proteins are in organic phase. These reagents provide a quick, convenient and reliable means to isolate nucleic acids from samples of nearly any origin.

The extraction of genomic DNA from plant cells and bacterial cells is nearly identical to what has already been described, with one exception. Both plant cells and some strains of bacteria are rich in

polysaccharides – compounds that must be effectively removed from preparations to ensure high quality DNA for cloning and sequencing. To accomplish this, following treatment of a cell preparation with detergent and proteinase K, the NaCl concentration is adjusted to 0.7 M and 1% cetyltrimethylammonium bromide (CTAB) is added to the cell lysate. This compound complexes with both polysaccharides and with residual proteins such that a chloroform extraction removes the polysaccharides, proteins, and cell debris. The high molecular weight DNA can then be precipitated from the supernatant with ethanol.

Plasmid DNA (Bacterial)

The cloning of a mammalian gene of interest into a bacterial plasmid vector, with subsequent amplification in bacterial cell culture and purification of this amplified plasmid DNA, has been a hallmark of molecular biology for 20 years. Isolation of plasmid DNA is a routine practice for any laboratory actively engaged in recombinant DNA research. The basic methodology has not changed significantly since the original alkaline lysis procedure was first described. Briefly, an overnight culture of bacterial cells, carrying a plasmid vector of interest, is first concentrated by centrifugation followed by aspiration of the growth medium. The cells are then resuspended in a Tris-EDTA buffer containing $100 \mu\text{g mL}^{-1}$ RNase A, lysed in a 0.2 M sodium hydroxide and 1% SDS solution, and neutralized with 1.3 M potassium acetate solution. After a centrifugation step, the cleared lysate is mixed with a DNA-binding resin. This can then be poured onto a minicolumn that traps the DNA/resin mixture upon application of a vacuum or upon centrifugation (by placing the minicolumn into a microfuge tube). The column is washed several times with a Tris-EDTA solution containing potassium acetate and 55% ethanol and the DNA is eluted from the column in either water or buffer (e.g. Tris-EDTA). DNA, prepared in this fashion, is suitable for enzymatic digestion, cloning, or sequence analysis. Quantification of plasmid DNA can be accomplished as described earlier in this section.

Following the extraction and purification of DNA, it is characterized in a variety of ways. It is quantified by measuring the absorbance at 260 nm. The extinction coefficient of pure DNA is approximately $1 \text{ OD}_{260}/50 \mu\text{g mL}^{-1}$. The structural integrity of the nucleic acid can be analysed by resolving the molecular weight species by agarose or polyacrylamide gel electrophoresis. The resolved nucleic acids can then be visualized with a fluorescent intercalating dye (e.g. ethidium bromide).

RNA Purification

It seems ironic that one of the key resources for the analysis of gene expression – the RNA – is exquisitely sensitive to degradative enzymes naturally found within the cells (the ribonucleases, RNases). Moreover, the human body produces robust levels of RNase within the secretions of the body as a barrier to external microorganisms. This is particularly true of the sweat, and nucleases are a ubiquitous problem on the fingers of an investigator. Finally, the most commonly-used enzyme, RNase A, is virtually impossible to ‘kill’. That is, it has been known for many years that RNase A can be boiled and disrupted but it spontaneously refolds into an active conformation and reestablishes its enzymatic activity. Therefore, the traditional means of sterilizing materials for an experiment – autoclaving – is largely ineffective in handling this problem. Efforts must be taken to start with no environmental contaminants and then treat the materials with very strong reagents to inactivate any adventitious contamination problems.

Homogenization in Chaotropic Agents

The secret of successfully isolating RNA is the rapid inactivation of degrading enzymes and the resolution of the nucleic acid. This is generally accomplished by disrupting the fresh tissues (or freshly frozen tissue) in a solution composed of a very strong chaotropic agent. The chemical of choice is a guanidinium salt (generally as an isothiocyanate salt). This is a very strong disruptive compound that is not oxidizing and so does no damage to the nucleic acid. Note that RNA is naturally single-stranded and so will be perturbed if its secondary structure is transiently disrupted. Referring again to Figure 1, The reader will see that in the intact cell, the degradative enzymes are sequestered from the RNA within the lysosomes. The problem is therefore to protect the nucleic acids from the enzymes during the extraction process. This is generally accomplished by disrupting the cells (whether fresh or still frozen) directly in the chaotropic agent. The key is to prevent any freezing–thawing cycles or other physical manipulations that will disrupt the subcellular organelles and release the degradative nucleases to attack the RNA. From this point on, the extraction is similar to isolation of DNA. Namely, the homogenate is extracted with phenol or PCI, the aqueous solution is extracted with chloroform to remove traces of phenol, and the nucleic acids are precipitated with monovalent cation and ethanol. One notable exception is the use of lithium salt instead of sodium or ammonium. In practice, lithium selectively precipitates RNA and so

aids in the removal of small amounts of DNA contamination.

The resulting purified RNA is once again quantified by measuring the absorbance at 260 nm (extinction coefficient of $1 \text{ OD}_{260}/40 \mu\text{g mL}^{-1}$) and the quality assessed by the $\text{OD}_{260}/\text{OD}_{280}$ ratio (pure RNA has a value ≥ 2.0). Following denaturing agarose gel electrophoresis, a typical cellular RNA preparation will present two prominent species representing the structural ribosomal RNAs (16S and 23S for prokaryotic cells; 18S and 28S for eukaryotic cells).

Isolation of Poly-A⁺ Containing RNA

For many purposes, an investigator will be interested only in the messenger RNA fraction, and because the structural ribosomal RNAs represent 98% or greater of the total, measures must be taken to purify the mRNA. This is accomplished by taking advantage of the fact that most (but not all) eukaryotic mRNA molecules are distinguished by the presence of a homopolymeric adenylate sequence at the extreme 3' end of the macromolecule (the poly A⁺ tail). This stretch of 100–200 residues acts to stabilize the mRNA; however, it also serves as a convenient mechanism for purifying this particular nucleic acid species. Most of the applications are predicated on an affinity column chromatography with oligo-deoxythymidine residues of between 12 and 18 nucleotides in length (oligo-dT₁₂₋₁₈). The poly A⁺ tail binds via complementary hydrogen bonding to the oligo-dT and the structural RNAs fail to hybridize and bind. Conditions are changed so as to disrupt the nucleic acid interactions and the mRNA is released (desorbed) from the affinity matrix. Note that almost all mRNA species contain a poly A⁺ tail and so this separation approach does not differentiate between specific mRNA species.

Summary/Future Directions

Nucleic acid extraction from biological samples was one of the enabling technologies in the development of molecular biology. It has remained largely un-

changed for the past 20 years and, in its present state, continues to be a mainstay of the field. Most of the common advances have been in the automation of the process and the creation of high throughput technical platforms. The challenge for the coming years will be the further refinement of these automated applications and the creation of solid-state systems. These approaches will involve the liberation of nucleic acids from the biological samples, capture of the specific chemical form (DNA or RNA) on a solid matrix, and the subsequent analysis of the nucleic acid in that physical environment without further manipulation. Regardless of these potential technical advances, however, the essential principles will remain unchanged and the separation of nucleic acids from complex mixtures of macromolecules will be a requisite step in the characterization of genomic systems.

Introduction

Investigations in nucleic acid biochemistry are directed toward a better understanding of how the chemical structure of nucleic acids correlated with their unique biological functions. This information

can then be used to gain a deeper insight into how cells normally regulate their metabolic activities, allows speculation on how they evolved their respective biological role(s), and potentially permits correlation of the altered structures of nucleic acids in abnormal or diseased states to biological function. An understanding of how cells behave normally and in the diseased state provides the basis for the development of rational therapeutics and improved diagnostic tools. Studies are now being undertaken in many laboratories on nucleic acid metabolites as cancer markers, and of chemical carcinogens and mutagens adducted to nucleic acids for assessment of human exposure to environmental insults. Methodological limitations have hampered the advancement and exploitation of using modified nucleosides and their signals in routine tests in clinical chemistry or as important determinant life molecules in biochemical research. The development of high resolution chromatographic methods for qualitative identification and quantitative measurement of an array of nucleosides and to obtain chemical *information on* nucleic acid components has been a challenge to analytical biochemists since the beginning of the 1960s and has evolved into a powerful tool since the mid-1980s.

Our laboratory has made extensive investigations on reversed-phase high performance liquid chromatography and ultraviolet-photodiode array detection (RP-HPLC-UV) nucleoside analysis and has developed comprehensive chromatographic methods and quantitative enzymatic RNA hydrolysis procedures. Sixty-seven known nucleosides can be identified and 31 ribonucleosides; six deoxynucleosides can be quantified directly in a single chromatographic run from an enzymatic hydrolysate of RNAs, DNAs, and in physiological fluids. In collaborative efforts with scientists across the world we have applied these methods in a number of interesting investigations. We briefly introduce RP-HPLC-UV for deoxynucleosides and ribonucleosides and place emphasis on applications in three areas:

1. RP-HPLC-UV methods for total nucleoside composition of RNAs and DNAs;
2. modified nucleosides as cancer markers and in normal metabolism; and
3. preparative isolation of unknown nucleosides in nucleic acids for structural characterization.

RP-HPLC of Nucleosides

Chromatography Information on HPLC instrumentation; chromatographic parameters for high resolution, high speed, and high sensitive separation of nucleosides; analytical and semipreparative enzy-

matic hydrolysis of nucleic acids; and clean-up procedures (ultrafiltration procedure and phenylboronate gel column clean-up) for ribonucleosides in physiological fluids have been presented in the literature (see 'Further Reading' section).

It is a challenge to the analytical biochemist to separate and measure such a large number of nucleosides simultaneously in a complex biological matrix. One of the major problems for nucleoside chromatography is to obtain the needed reference molecules so that the information for the essential qualitative and quantitative analytical references can be established. There are only about 20 modified ribonucleosides that can be obtained through commercial sources. We have standardized the chromatographic retention times, obtained RP-HPLC-UV spectra and determined the molar response factors for a large number of ribonucleosides. Scientists in their respective laboratories need to standardize and calibrate their analytical system for modified nucleoside analysis in a broad range of biological matrices. To overcome this limitation, we have selected three unfractionated transfer RNAs (tRNAs) – *Escherichia coli*, brewer's yeast, and calf liver – as reference sources of the nucleosides. Each of these tRNAs contain unique as well as common nucleosides and provide an array of modified nucleosides that are often encountered by researchers. Some minor differences in the modified nucleoside profile may be observed in these three tRNAs from different sources, especially for *E. coli* tRNAs. This problem can be resolved by using a reliable supplier or by standardization of a selected lot of tRNAs obtained in large quantity and of good homogeneity. **Figure 1** shows the 254 nm chromatograms from the high resolution separation of the nucleosides in the three reference tRNAs. The nucleoside peaks are identified by an assigned index number, which essentially corresponds to their respective elution order. **Table 1** gives the IUPAC names, one-letter symbol, and the index number of the nucleosides that have been determined by RP-HPLC-UV. Other ribonucleosides, which are not yet characterized by RP-HPLC-UV, are also included in this table. A total of 67 ribonucleosides have been chromatographically and spectrometrically characterized.

RP-HPLC-UV Methods for Total Nucleosides Composition of RNAs and DNAs

Nucleoside chromatography protocols for a broad array of RNAs and DNAs have been applied extensively. In general, RNA nucleoside chromatography

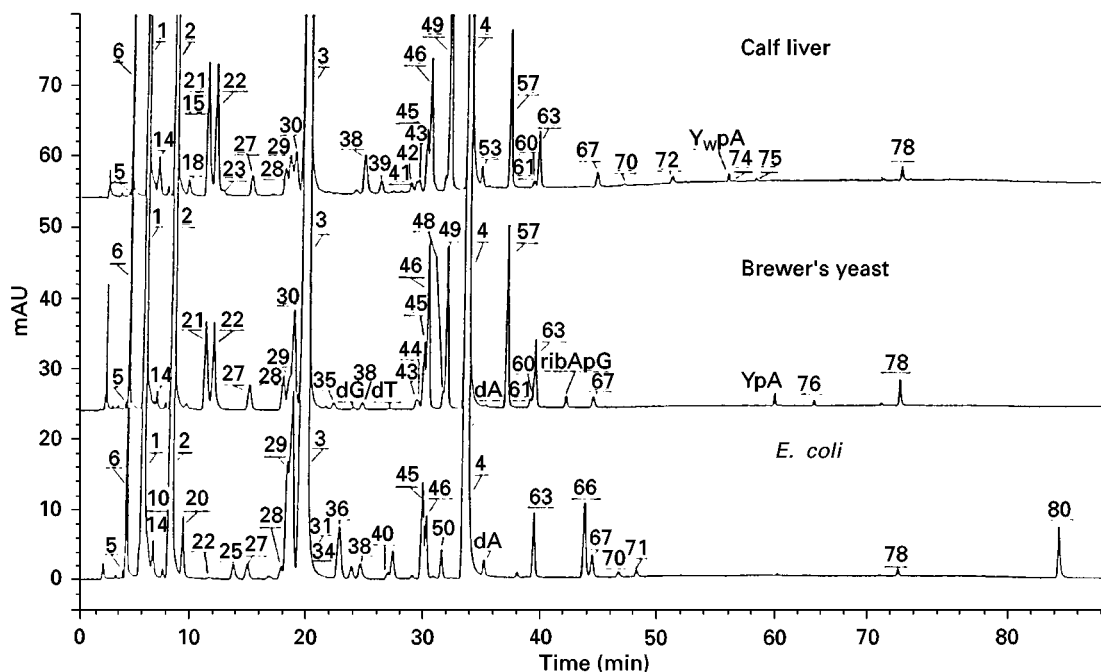

Figure 1 HPLC chromatography of reference nucleosides from unfractionated calf liver, brewer's yeast, and *E. coli* tRNAs.

requires emphasis on resolution and flexibility, and for DNA the emphasis is on accuracy and speed. There is also an ever-increasing need in biochemical analysis for high sensitivity. Recent progress in instrumentation and column technology has increased LC-UV sensitivity more than 10-fold so that low picograms of nucleosides can be quantitated routinely.

Unfractionated tRNA constitutes one of the most complicated mixtures of biopolymers known and high resolution is required for this analysis (Figure 1).

Isoacceptor tRNAs are usually available only in very small amounts (less than a few micrograms); however, an advantage with single-species tRNAs is that they are less complicated in composition. For analysis of single-species tRNAs, an intermediate resolution and higher sensitivity protocol (high speed) are generally used. An accurate identification and quantitation of the total nucleoside composition are very important in providing supplementary and confirmatory information in support of tRNA sequence studies. Figure 2 shows the separation of nucleosides in tRNA^{Leu} from bovine serum. Table 2 gives the comparison of quantitative results from five isoacceptor tRNAs obtained by RP-HPLC-UV and compared to sequence analysis. The lower m⁷G value is indicative of the instability of m⁷G at alkaline pH during enzymatic hydrolysis. It is of interest that differences of one residue number for uridine in tRNA^{Phe} and uridine and guanosine values in tRNA^{Val} were

observed from the two analytical methods. Table 3 gives the mol% values of all the nucleosides in four bovine isoaccepting tRNAs. These four tRNAs were isolated in Dr Gerard Keith's group at the Institute for Molecular and Cellular Biology (IBMC) in Strasbourg, France. Their sequences were not yet determined at the time of HPLC analysis. These mammalian tRNAs have considerably more modifications than the tRNAs from *E. coli* (Table 2) and two unknown modified nucleosides were observed in tRNA^{Leu}.

Ribosomal RNA Nucleoside Analysis

Ribosomal RNA (rRNA) is a high molecular weight RNA. In *E. coli* the 70S rRNA has a molecular weight of 2.75×10^6 amu and the small subunits, 16S rRNA and 23S rRNA, have 1542 and 4718 residues, respectively. Only 10 methylated nucleosides have been reported in the 16S and 23S rRNAs. To accomplish the chromatography of rRNA for composition analysis it is necessary to separate and measure one modified nucleoside residue in ca. 5000 nucleotides. This demands a high column capacity so that a large amount of sample (100 μ g or more) can be injected without loss of resolution. The high resolution and high speed chromatographic protocols described for tRNA nucleoside composition analysis all have adequate capacity to meet this requirement for rRNA

RP-HPLC so that the respective deoxy- and ribonucleoside are differentiated. RP-HPLC showed qualitative and quantitative differences of modification in both 16S rRNA and 23S rRNA as compared to the literature values. In 16S rRNA we found one additional residue of m⁵C, and m²G. Two nucleosides, Gm and m⁴Cm, were not found. From 23S rRNA, four additional residues of Ψ, two of m⁴C, one of m⁵C, two of m²G, and one of m²A, were found by RPLC. A number of other modifications as shown in Table 4 are in good agreement with the literature values.

Messenger RNA Nucleoside Analysis

Messenger RNAs from viral and eukaryotic cells contain a unique structure known as 'caps' that consist of an inverted 7-methylguanosine (m⁷ Guo) linked to

the penultimate nucleoside through a 5'-5' triphosphate bridge. These mRNAs usually have a very low amount of internal nucleoside modification (< 1/1000). A highly selective RP-HPLC-UV separation using a micro anion exchange column was developed for isolation of the cap structures to enhance the resolution and sensitivity of the separation and measurement.

Deoxynucleoside in DNAs

The determination of the molar composition of the major and modified deoxynucleosides in high molecular weight DNAs requires a high degree of accuracy and sensitivity. Modified nucleosides in the DNA such as 5-methyldeoxycytidine (m⁵dc) 6-methyldeoxyadenosine (m⁶dA) and 4-methyldeoxycytidine (m⁴dC) are normally present at 0.1 to 2 mol% level. Several separation systems were developed and used in our laboratory. The method that we use is dependent on the sample matrices (i.e. presence of RNA, deoxyinosine (dl), inosine (I), nucleobases, and other UV peaks) and amount of DNA sample available. An optimum amount of DNA is 10 μg. The best chromatographic system for the separation of deoxynucleosides is a two-buffer, single ramp gradient using a 150 × 4.6 mm Supelcosil® LC-18S column. With this column a complete separation can be achieved in less than 15 min. Dual wavelength quantitation and high quality data reduction software are essential for the analysis. The deoxynucleoside reference compounds obtained from commercial sources do not have the required purity to obtain the accuracy pair ratio, i.e. (dC + m⁵dC)/dG = 1.000 and dT/(dA + m⁶dA) = 1.000, from high molecular weight DNAs. Quantitation of the nucleoside composition of a large number of isolated DNA oligomer fragments and synthesized oligomers requires a high sensitivity. In this case, a 5 cm or 3 cm regular bore (3.9–4.6 mm) with 3 or 5 μm particle size columns used in an isocratic separation mode provides the separation in less than 10 min with a five-fold increase in sensitivity. Refer to the published HPLC protocols for quantitation of major and modified nucleosides in DNA. Precision and linearity of the method are presented in Tables 5 and 6. The high resolution separation of ribo- and deoxynucleosides is presented in Figure 5.

Modified Nucleosides as Cancer Markers and in Normal Metabolism

Borek stated that the hope of finding some unique metabolic products or unique components of malignant cells circulating in body fluids which can be

Figure 3 HPLC of nucleosides in *E. coli* 16S rRNA.

measured is as old as modern biochemistry. The term 'tumour marker' has been coined by Dr Morton K. Schwartz of the Sloan Kettering Institute for such a product. Before we consider whether we have fulfilled such a hope, we ought to define what a tumour marker should be. The requirements for an effective tumour marker are manifold; it ought to be specified for malignancy – it should provide a minimum of false-positives and false-negatives; it ought to indicate the extensiveness of the malignancy and it should preferably diminish or hopefully disappear after effective therapy.

At an international conference held in Vienna (1982) under the auspices of the Society for Early

Detection of Cancer, someone calculated that there were close to 90 reported different tumour markers. It can be stated, however, that unfortunately none of these putative tumour markers meet even partly the qualifications we have set above.

A problem is that most of the tumour markers in use today are proteins. Proteins are the peripheral end products of the molecular mechanisms of every cell. A mammalian cell is endowed with the capability of producing perhaps 10 000 or more different proteins. Unless we chance upon a protein which is either causal of a malignancy or which is a universally aberrant concomitant of malignant tissues, looking for protein products which will qualify as tumour

markers in terms of the requirements listed above is hopeless.

A promising marker is the tRNAs of tumour tissue. The finding of aberrant tRNA-methylating enzymes in tumour tissue prompted the study of the tRNAs themselves. Surprisingly, only a few of the tRNAs in

^aSee notes to Table 5.

the malignant tumour were found to be different in structure from those in the normal tissue counterpart. Dr Guy Dirheimer of Strasbourg isolated 18 different tumour-specific tRNAs and found modification on them different from those in normal counterparts. On the other hand, we have determined with the aid of Japanese colleagues that the primary sequence is the same. Perhaps to enable it to perform its many functions, tRNA is endowed with an extraordinarily complex structure. Its primary sequence consists of about 80 of the four major bases found in other RNAs: adenine, cytosine, guanine and uracil. In addition to these major bases, tRNA contains a large variety of modified bases that are unique to it. The modified bases increase in number with the complexity of the organism. Thus, for example, *E. coli* tRNA may contain only two or three, yeast tRNA may contain five or six, and mammalian tRNA may contain modified bases constituting as much as 20% of the total. It has also been shown that the tRNA methyltransferases are abnormally hyperactive in every malignant tissue. Borek found that the level of excretion of the nucleosides in urine when followed before, during, and after therapy in a malignancy that responds well to chemotherapy, that within five days of commencement of therapy in six patients with Burkitt's lymphoma, that the excretion levels in urine returned to normal and remained normal as long as the subjects were in remission.

There have been reports since the early 1950s that cancer patients excrete elevated levels of methylated purines and pyrimidines as well as other modified nucleosides. Ample evidence had indicated that increased tRNA methylase activity in neoplastic cells was a common and consistent finding, and increased excretion of modified bases in urine from cancer patients and tumour-bearing animals had also been reported. Methylation of the bases in tRNA had been

Figure 5 High resolution chromatography of ribonucleosides and deoxynucleosides.

found to occur after the macromolecule is formed, and of particular interest was that these methylated compounds were not reincorporated into the tRNA molecule but thought to be excreted intact. It has been suggested that the high turnover of a subpopulation of tRNA is the major reason for increased excretion of modified nucleosides by cancer patients. The measurement of modified ribonucleosides in body fluids as biological markers of cancer resulted largely from the studies of tRNAs by the late Dr Ernest Borek. In 1974, Dr Gordon Zubrod, then director of the National Cancer Institute (NCI), appreciated the possible value of this concept. A contract was awarded by the NCI to our laboratory at the University of Missouri to develop high resolution quantitative chromatographic methods of modified nucleosides for use in tumour marker studies. Under the leadership of Professor Charles W. Gehrke gas chromatographic and RP-HPLC-UV methods were developed for measuring modified nucleosides in urine. Later the method was further improved for measuring serum nucleosides. The RP-HPLC-UV method is far better than the gas chromatographic method for highly water-soluble nucleosides, and hence it was used in analysis for a majority of the clinical studies. **Figure 6** and **Figure 7** show the separations for ribonucleosides in human urine and serum from a patient with lung cancer and acute myelogenous leukaemia, respectively. **Figure 8** presents the recovery of nucleosides from spiked serum and normal serum.

Our research on tRNA catabolites in urine and serum has centred on analysis of the modified nucleosides following isolation of the nucleosides by

boronate gel affinity chromatography. Advances in the isolation, identification and measurement of modified nucleosides have been striking, and are now providing greater insights into the value of modified nucleosides as potential tumour markers in following the course of cancer and treatment. Numerous research groups in the USA, Europe, and Japan have studied modified nucleosides and their potential relationships to cancer. A comprehensive review was presented by Zumwalt *et al.* Trewyn and Grever have provided an excellent review of urinary nucleosides in patients with leukaemia. They reviewed the available literature and discussed laboratory analyses, including methods, reference values, and multivariate analyses; clinical studies covering nonmalignant disease and infection, acute leukaemia (childhood and adult) and chronic leukaemias. They concluded that measurement of urinary nucleoside excretion offers a potential tool for monitoring disease activity in patients with acute lymphoblastic leukaemia, chronic myelo-cytic leukaemia, and perhaps chronic lymphocytic leukaemia. They also point out that additional work is necessary in following serial determinations of nucleosides at frequent intervals in patients with different types of leukaemia to assess the true value of these compounds as an accurate monitor of disease activity within the individual patient. We initiated investigations to study the correlation of the levels of serum-modified ribonucleosides with clinical status of the patient. Longitudinal serum samples were collected from leukaemia, lymphoma, and lung cancer patients. Four modified nucleosides Ψ , m_2^2G , t^6A , and m^1I , were selected to study the relationship of their levels in serum versus the course

Figure 6 RP-HPLC-UV separations of nucleosides in (A) human urine and (B) serum from a lung cancer patient and a chromatogram for a morning and evening sample.

of disease. Serum pseudouridine levels showed a direct relationship to total RNA turnover. N^2,N^2 -Dimethylguanosine and N^6 -threoinocarbonyladenine, which are only found in tRNA, showed that their concentrations in serum reflects the state of tRNA catabolism. 1-Methylinosine is a very interesting modified nucleoside. The concentration of serum m^1I in the normal population is quite high ($65 \pm 21 \text{ nmol mL}^{-1}$) and is one of the commonly elevated nucleosides found in cancer patients.

The origin of serum 1-methylinosine is not completely clear at this time. It can be accounted for partially from direct tRNA turnover and deamination of m^1A by adenosine deaminase in serum. We also studied longitudinal collected normal serum samples and found that the four target nucleosides levels in serum are constant during one day (7.30 a.m., 12.00 noon and 5.00 p.m.), and over 14 days. For cancer patients we plotted the ratio of each nucleoside to the average concentration found from 94 normal subjects

as a percentage. The results of the longitudinal studies from one selected leukaemia patient, one lymphoma, and one with lung cancer are presented here. The modified nucleoside level from the respective patients over time are presented in Figure 9, Figure 10 and Figure 11. The patient description and correlation of clinical status and modified nucleoside levels are as follows.

Patient MP-K (Acute Myelogenous Leukaemia): Patient Description (Figure 9)

A 31-year-old white male smoker was admitted on 12 June 1991 with fever. Work-up showed severe leucocytoses, with increased white cell count up to 244 000. The patient went into pulmonary oedema; a bone marrow test was performed and leucopheresis started. Bone marrow showed acute myelogenous leukaemia. Chemotherapy and antibiotics were given. Sample collection was started 10 days after

Figure 7 RP-HPLC-UV separations of nucleosides from patient with acute myelogenous leukemia versus normal.

diagnosis. The patient recovered and on 2 July 1991 a bone marrow test was again done and there was no evidence of leukaemia. However, 2 weeks later a repeated bone marrow showed relapse of disease. Chemotherapy was again given on 18 July 1991. A bone marrow 2 weeks after treatment (day 38) showed persistent disease. In the meantime the patient developed appendicitis and surgery was performed but the patient died postoperatively.

Clinical status and modified nucleoside levels (Figure 9) We started collecting samples on this patient right after induction chemotherapy was given. A bone marrow test done by the time sample no. 2

was drawn showed no evidence of leukaemia. However, there was already a slight increase in modified nucleoside levels. Relapse of the disease was clinically suspected and confirmed by bone marrow and there was a marked increase in all modified nucleoside levels. Reinduction chemotherapy was given and correspondingly there was a decrease in levels of modified nucleosides. A bone marrow test was performed at day 38 of the study, which showed presence of leukaemic cells at a time when modified nucleoside levels were also increasing. From this date, a good clinical correlation of the level of markers increased with clinical deterioration of the patient.

Figure 8 Recovery of nucleosides from spiked and normal serum.

Figure 9 Serum-modified nucleoside levels as cancer biomarkers in patient with acute myelogenous leukaemia.

Patient MP-Y (Non-Hodgkin Lymphoma): Patient Description (Figure 10)

A 60-year-old white female smoker presented on 1 June 1991 with weakness in the lower extremities and magnetic resonance imaging (MRI) showed evidence of cord impression. Biopsy showed non-Hodgkin lymphoma, large cell type. Postoperatively the patient received radiation therapy. The patient was started on chemotherapy after assessment of disease. On physical examination she had axillary adenopathy and computed axial tomography (CAT) scan of the chest showed chest wall disease and a pleural effusion. CAT scan of the abdomen showed metastasis to the lumbar spine. Sample collection started on 20 September 1991 while the patient was on therapy. Evaluation of her disease showed response by physical examination (axillary lymph node decreased size), neurological examination improving and by CAT scan with decreased pleural fluid. CAT scan of the abdomen showed no evidence of disease. The patient continued the same regimen of chemotherapy. In February (day 140) the patient went into respiratory distress and increased pleural effusion was detected. However, cytology and bronchos-

copy found no evidence of lymphoma. Chemotherapy was continued as soon as the patient recovered. Shortly after the patient was again admitted to hospital with fever. The patient also complained of a chest wall mass that had been growing in the last few weeks. The patient died shortly after this from cardiorespiratory arrest before any treatment was given. Autopsy showed lymphoma.

Clinical status and modified nucleoside levels (Figure 10) By the time the patient was included in the study she was already on chemotherapy and clinically responding. Modified nucleoside levels were quite steady until day 175, when there was a gradual increase and a peak around day 250 of the study. Clinically the patient was having lung problems and an infiltrate and new pleural effusion by lymphoma was never documented; however, all four modified nucleoside levels increased to 250–350% of the normal control mean values. The modified nucleoside levels continued to increase and remained higher. The patient died from cardiorespiratory arrest. Lymphoma was later proved present by biopsy in the chest wall mass. There was a good clinical correlation of

Figure 10 Serum-modified nucleoside levels as cancer biomarkers in lymphoma patient.

the four serum modified nucleosides levels and lymphoma.

Patient LRH (Adenocarcinoma of the Lung): Patient Description (Figure 11)

A 58-year-old white male smoker presented in April 1993. Biopsy and MRI showed poorly differentiated adenocarcinoma of the lung with metastases to the adrenal gland (adrenal mass) and no pleural effusion. Chemotherapy was started on 26 May 1993. This patient was not responding to chemotherapy and his clinical status was gradually deteriorating. In October 1993 (week 23) the patient was in the end stage of the disease.

Clinical status and modified nucleoside levels (Figure 11) This patient was not responding to treatments. His clinical status was continually deteriorating. The progression of disease correlated with increased levels of modified nucleosides. When the disease reached the end stage, the levels of all four modified nucleosides were > 300% higher than the normal control mean values. In this case the modified

nucleoside levels clearly correlated with the progress of the disease.

Preparative Isolation of Unknown Nucleosides in Nucleic Acids for Structural Characterization

Knowledge of the chemical structure of nucleoside modifications in nucleic acids is essential for increasing our understanding of their chemical structure and biological function relationships. tRNA is one of the most heterogeneous biopolymers known. It not only has a variety of functions within the cell, but also contains a much larger proportion of modified nucleosides than other nucleic acids; more than 60 modified nucleosides have been characterized in tRNA. With our newly developed RP-HPLC-UV nucleoside chromatography methodology, providing its enhanced resolution and sensitivity, many new modified nucleosides have been detected and identified. As tRNA research investigations are conducted on more complex organisms it is highly likely that additional modified nucleosides will be discovered, as we have

Figure 11 Serum-modified nucleoside levels as cancer biomarkers in patient with adenocarcinoma of the lung.

observed many unidentified nucleosides in urine and serum. The information on modified nucleosides in human tRNAs is limited, and further investigation should be conducted.

For purification of specific tRNAs, various types of chromatographic and electrophoretic procedures have been used. Because of the complexity of the initial mixture, the first purification step is generally not for high selectivity but for high capacity. We therefore used the countercurrent distribution (CCD) method, which is mild and serves as a first preparation step with a high capacity. This CCD method has been adapted from Holley and Merrill and by Dirheimer and Ebel. This technique permits separation of quantities of tRNAs as high as 5–6 g.

In our research we introduced standard RPLC-UV methodologies for the analysis of nucleosides and nucleoside composition of RNAs, detailed the chromatographic protocols, developed the ‘nucleoside columns’, and gave the essential requirements needed in the HPLC instrumentation. Three optimized systems with particular emphasis placed on resolution, speed, and sensitivity are described. In addition, three unfractionated tRNAs were selected: *E. coli*, yeast, and calf liver as sources of ‘reference nucleosides’ to establish the performance of the

chromatography; also a quantitative enzymatic hydrolysis protocol to release exotically modified nucleosides from tRNAs was described. We have addressed the analytical characterization of nucleosides in nucleic acids, and chromatography and modification of nucleosides from the perspective of additional chromatographic methodologies for isolation of the nucleic acids, quantitative enzymatic hydrolysis, high resolution preparative HPLC, and affinity chromatography to obtain the pure single-species nucleosides for UV absorption spectroscopy and interfaced mass spectrometry identification. In addition, we described experiments on the determination of the structure–spectrum relationships, composition, and conformation using an array of advanced analytical techniques of HPLC-UV, FT-IR, nuclear magnetic resonance and mass spectrometry (MS), as well as structure–RP-HPLC retention relationships. In these studies, a consortium of scientists from different institutions have combined their expertise and present a comprehensive discussion of the isolation and analytical–structural characterization of tRNAs, oligonucleotides, and nucleosides in RNA and DNA. Two modified nucleosides, A* and G* in yeast initiator tRNA (initiator tRNA^{Met}) at positions 64 and 65 in the T-Ψ stem were identified as an unmodified

guanosine at position 65, and for A* as O- β -D-ribofuranosyl-(1''-2')-adenosine in position 64. We elucidated that the final structure for A* at position 64 in yeast initiator tRNA^{Met} was established as an O-ribofuranosyl-(1''-2')-adenosine-5''-phosphate linked by a 3'5'-phosphodiester bond to G at the position 65.

An unknown U* nucleoside in position 34 isolated from yeast mitochondrial tRNA^{Leu} was characterized as cmnm⁵U by HPLC-UV-MS.

Also, we have confirmed m³U, an unknown modified uridine, in the 16S colicin fragment from *E. coli* rRNA, and report the structural characterization of a catabolite in canine urine as 5-hydroxy-methylcytidine (om⁵C).

This report describes the 'research tools' we have developed and are using in analytical characterization of modified nucleosides and dinucleosides in RNAs and which will be of value to others in molecular biology investigations.

A good clinical correlation was observed in patient management using four cancer modified nucleoside biomarkers in following the course of disease and treatment.

Thin-Layer (Planar) Chromatography

J. J. Steinberg, Albert Einstein College of Medicine, Yeshiva University, New York, NY, USA

Introduction

Thin-layer (TLC; or planar chromatography) is well suited to the separation of nucleic acids. One of the

most important chromatographic systems for nucleic acids – ion exchange chromatography – received great impetus with the development of poly(ethylene imine)-HCl prepared cellulose (PEI), which became available in the early 1960s. The studies that followed laid the foundation for the analytical and preparative TLC of nucleic acids. Many types of plate are presently available for TLC, but most reports are limited to PEI-cellulose, ODS (octadecylsilica), and silica gel in simple one-dimensional systems.

Gel electrophoresis has diminished the need for TLC of large oligonucleotides and the inability to have stable thick (2 mm or more) chromatographic plates has diminished the development of preparative TLC. High performance liquid chromatography (HPLC) has become important for smaller oligomer separations, and especially important for preparative chromatography. TLC and HPLC together can serve for initial investigations, but usually require further analytical instrumentation or chemical characterization. Coupled UV and Fourier transform infrared (FTIR) have added to the power of chemical characterization by HPLC and these systems are now becoming available in TLC. HPLC, however, is limited when employing highly radioactive molecules as extensive cleaning and decontamination of the whole HPLC system is required. In the hands of expert experimentalists TLC offers outstanding flexibility that matches HPLC, with less labour and cost.

Sorbents

Considerations for sorbents are: physical and chemical properties, pore diameter, pore volume, surface area, particle size distribution and mean size. Adsorption is the main mode of chromatography employed. Weak physical interactions in TLC include van der Waals forces, dipole-dipole forces and hydrogen bonding. Cellulose ion exchange further employs polyethyleneimine ($-\text{CH}_2-\text{CH}_2-\text{NH}$)_n for more specific separations. Typically, polar solvents are employed for polar solutes with hydrophobic phases. Solvents are based on an elutropic classification with elution power increasing with polarity. The speed of elution also depends on the viscosity of the eluent.

Cellulose is used when ion exchange properties are not needed. It is most often used for the separation of sugars, amino acids and similar compounds. A popular sorbent for the separation of nucleic acid derivatives, it readily separates pyrimidines (higher R_F) from purines. Commercial grade microcrystalline cellulose (Avicel) has been used for the retention of guanine (base or nucleoside) in either acidic (HCl; formic acid) or basic (ammonia) solvents.

Diethylaminoethylcellulose (DEAE) has the functional group incorporated into the paper. It is an anion exchanger that is generally used to separate proteins and enzymes and similar materials, but is also used for nucleic acids, nucleotides, deoxynucleotides and nucleosides. Separation on DEAE-cellulose is not as sharp as on PEI-cellulose, but there is a considerable amount of information on the separation of nucleic acids on these layers.

There are many published tables that contrast TLC separations with various solvents and demonstrate the utility of cellulose in the relative retention of amino groups, regardless of purine/pyrimidine structure, in either acid (HCl, isobutyric acid) or ammonium hydroxide mixtures. The presence of ammonium carbonate (and to a lesser extent formate) affects purine/pyrimidine separations, with R_F values greater for pyrimidines.

ECTEOA is the abbreviation for the epichlorohydrin and triethanolamine groups that are combined with cellulose. DEAE-cellulose and ECTEOA-cellulose layers have about the same ability to resolve nucleic acid derivatives. ECTEOA-cellulose is especially useful for the separation of nucleic acids, nucleotides and nucleosides as an anion exchanger and is also good for the rapid separation of pyrimidines from purines.

ITLC (instant TLC) plates are glass microfibre sheets. The addition of silicic acid or silica gel gives the additional designation of SA or SG, respectively. Multiple solvent systems used with these plates allow the retention of adenine and its associated structures.

Silica gel has been used extensively, although it was not used in the early development of the TLC of nucleic acids. It is also used for the separation of amino acids and proteins. It is especially advantageous in separating pyrimidine from purines.

G is the designation for CaSO_4 binder (gypsum). Silica-G has been used to resolve pyridine nucleotides, uridine diphosphate (UDP) derivatives of hexosamines and acetylhexosamines. Silica-G is used for preparation of larger quantities of bases, nucleosides and many of their derivatives.

Reversed-phase (RP; ODS or C_{18}) performs essentially as silica gel. The opportunity of developing a strategy on RP-TLC and transferring it to a similar HPLC system is possible, but not always successful. The utilization for TLC of commonly available premixed HPLC solvents (methanol, acetonitrile, tetrahydrofuran, phosphates) is very convenient and allows information to be obtained quickly. RP-TLC, as opposed to its HPLC counterpart, cannot be as easily employed over a wide range of pH values.

Much of the knowledge of PEI-cellulose has come from the work of Randerath. This material has been

extensively studied and used in the separation of nucleic acid bases, nucleosides and nucleotides, with good separation and resolution. It has also been used for the separation of RNA and DNA hydrolysates, and for large scale preparations among other applications. It remains the most versatile paper for the separation of deoxynucleotide monophosphates (dNMP).

High performance (HP) TLC is constantly undergoing improvements; it offers smaller layers, more uniform and smaller sorbent particles, thinner layers and faster development. HPTLC can be utilized for nucleic acid identification, but is not commonly used. Typically, HPTLC offers quantities of product that are too small for identification by GC, FTIR or NMR.

Preparative TLC is a rapid technique where the analyte is streaked across a plate, and separation commences on a layer 1–5 mm thick. The nucleic acid of interest is scraped off the plate and eluted accordingly. Papers for centrifugal layer chromatography offer an alternative preparative technique. Chiralplates have had excellent results in separating enantiomers and halogenated compounds, and can also play a role in separation of nucleic acids.

Solvents

These are discussed in detail in the publications given in the Further Reading section. Tactically, an initial screen of unknowns or products on TLC is carried out as a preparation for the development of an HPLC method. This is helpful, and the rule of thumb is that 20 one-dimensional TLC runs with different solvents will determine the best eluent.

Directionality, including ascending, descending, two- and multi-dimensional, circular and drip chromatography have all been employed either to improve separations or to increase sample throughput. Automated anti-circular TLC systems where the solvent is applied at the periphery and flows inward toward the centre offer improved ability to examine fractions with R_F values near 1.

Results are essentially empirical, with advantages for most techniques based on analysis time for a specific set of analytes. Excellent reproducibility and success has been obtained with two- or multi-dimensional TLC, which greatly enhances the number of theoretical plates available, and hence the ultimate separation. Significant progress in gradient TLC will also impact on nucleic acid separations.

TLC has great flexibility – concentration, viscosity, polarity, pH, ionic strength, composition of gas phase and temperature are all important and controllable. Educated trial and error is not inappropriate to devel-

op initial TLC characterization of analytes. The strategy of many separation techniques emphasizes the chemical differential migration, e.g. hydroxyl, ammonium groups, of the various dNMPs with selective retention. The solvent affects all components of a mixture equally as a nonselective driving force. Further resolution of dNMPs from DNA can be accomplished by selective removal of particular compounds, or groups of compounds; to emphasize or diminish a specific dNMP we would consider competing with an analogue, e.g. deaza-dGMP for dGMP adducts, or depurinating to emphasize pyrimidines (see Figures 1 and 2). This strategy allows us to maintain simplicity in the solvent system.

In optimizing planar chromatography, computer programs exist that are very helpful in developing choices for solvents. Demixing remains a major problem in predicting retention and the ultimate experimental outcome. Again, 20 chromatograms are sufficient to define experimental variables for optimum resolution. Solvent selectivity has been discussed in terms of proton donation, acceptance or dipole interactions. Many mixtures of solvents exist, yet a reliable few can serve almost all purposes. We have listed the common solvents for TLC as a guide in Table 1.

Uniformity of Techniques

A general problem with TLC is the paucity of uniform guidelines that can direct investigators in different laboratories. Any serious investigator in TLC systems must establish rigorous and reproducible techniques. Few papers give in detail all the parameters necessary to reproduce successfully experimental TLC protocols. Much of this is pragmatic, especially given simple unidimensional systems where only one known chemical, with established controls, is confirmed. Most typically, these are pharmaceutical-based studies, which simply confirm one known pharmaceutical that conforms to the available control.

Success in characterizing true unknowns in complicated bi- or multidirectional systems (two-dimensional TLC) requires the publication and listing of uniform criteria. Attempts have been made to validate TLC techniques by directing attention to a number of concerns including R_F reproducibility, the role of the mobile phase, the stationary phase, the quality and quantification of zones, the method of elution and the estimation of spots. It is suggested that published TLC papers should attempt a more uniform approach to stating clearly experimental materials, methods and conditions. In view of the need for interlaboratory reproducibility, listed below are the

(A)

Figure 1 (A) Stylized representation of nucleic acid separations. (B) Normal enzymatic and ^{32}P -labelled digest of placental DNA.

chromatographic conditions necessary for the successful separation of dNMPs on PEI-cellulose:

1. Solvents (composition): first dimension, acetic acid (1.0 mol L^{-1} , pH 3.5 with NaOH); second dimension, $5.6 \text{ mol L}^{-1} (\text{NH}_4)_2\text{SO}_2$, $0.12 \text{ mol L}^{-1} \text{Na}_2\text{EDTA}$, $0.035 \text{ mol L}^{-1} (\text{NH}_4)\text{HSO}_4$ to pH 4.0. Stable over 2 weeks.
2. Layer (brand, grade): PEI-cellulose, Sigma.
 - Size, geometry: square, $200 \text{ mm} \times 200 \text{ mm}$.
 - Method of storage: refrigerator at 4°C .

- Preparation: no pre-run; constant room temperature and humidity.
 - Treatment: cool air-dried (dehumidified) during spotting.
 - Heterogeneity (R_F lower with thicker paper): $> 1\text{--}3\%$ variation over each TLC.
3. Developing tank (make, size): Sigma Inc; $275 \text{ mm} \times 275 \text{ mm} \times 75 \text{ mm}$ with lid.
 4. Application amount: $1.0\text{--}10.0 \mu\text{L}$ (or 20 000–100 000 CPM (counts per minute)).
 5. Drying (origin, plate, after first dimension): at 1 cm, 1 cm x, y axis; cold dryer.
 6. Direction of development: ascending, both dimensions.
 7. Distance of origin from solvent reservoir (closer for higher R_F): 1.0 cm.
 8. Depth of immersion: 5 mm.
 9. Volume of solvent in reservoir: 15 mL.
 10. Duration of development (h): first dimension, 4 h; second dimension, 15 h.
 11. Temperature: 17°C ; 50–60% humidity constant.
 12. Equilibrium humidity in tank: complete prior to TLC.
 13. Character of solvent front: observe as regular, linear.

Figure 2 DNA analogue-labelled digest: deaza-dAMP replacing dAMP.

14. Comparison of R_F versus R_X : consistency of chemical migration versus relative standard – less than 3% variability. All R_F values given as ' R_X ' with x, y coordinates. NB: Conversion of R_X to R_F requires all numbers divided by 19 cm. (If R_F values are given these are usually multiplied by 100 = hR_F .)

Most parameters in TLC are quantifiable, and all quantitative information should be listed. A greater attempt by investigators, reviewers and editors to adhere to these standards will increase both the likelihood of chromatographic success, its reproducibility, and sensitivity.

Sensitivity

In our 2D-TLC system for dNMPs we attempt to discover and analyse altered nucleic acids (adducts) or synthetic nucleic acids used as pharmaceuticals (analogues). The technique can ultimately detect one radioactive adduct per 10^8 nucleotides, which is as sensitive as any analytical system available. At this stage we radiolabel 0.2 μ g of DNA with 32 P to 6.0×10^6 DPM (disintegrations per minute). We assay from 2.0×10^4 to 1.0×10^6 DPM and can reliably detect as few as 50 DPM over background. This allows a mathematical minimum detection of one adduct per 10^5 – 10^8 nucleotides. Yet, many unique analytes can be detected at up to one per 10^8 – 10^{10} dNMP (as few as 25 DPM above background). An example of detectability can be seen by the complicated pattern of adducts formed by DNA in buffer remaining refrigerated for a prolonged period and obvious DNA reactivity with water and oxygen as noted by the proliferation of adducts at 72 h autoradiography. Furthermore, we have detected adduct incorporation when we have altered and 'contaminated' the dNMP reaction mixture pool with less than 1 nmol of a foreign dNMP during enzymatic incorporation (see Table 2). These lower values are within the range for detecting modifications by environmental, drug and ageing processes, e.g. methylated or deaminated dNMPs.

Reliability

Control dNMPs and DNA are run with every batch of samples. Experience with this technique shows that variations of R_F values ranging from 1 to 5% can be achieved in over 2000 analyses. The Ambis (computerized radioactive scanning of TLC) statistically correlates consistently with laser densitometry, but mean values can vary in densitometry by $\pm 6.5\%$ overall. There are also qualitative differences be-

tween densitometry and scintillation counting, specifically where densitometry is unable to account for all the 'spots' that it detects as a 'smear', though the human eye can easily distinguish borders, zones and spots. However, the Ambis is more successful in quantifying smear areas by counting smear CPM. A statistical analysis of Ambis data versus densitometry provides a correlation coefficient of 0.93, $p < 0.001$, $n = 23$ pairs, providing the formula: Ambis DPM = 62.4 (mm^2 area from densitometry) – 17 410. The Ambis is more successful in detecting dUMP (see Figure 3) and other less discrete dNMPs than densitometry. Yet densitometry shows up borders between migration patterns of close dNMPs better, especially methylated dNMPs. Other variations in CPM reflect quenching of radioactivity from the TLC plates. At low DPM, quenching blocks 90% of counts detectable, but at high DPM, quenching blocks only 50% of counts. These differences are mathematically quantifiable, and the formulae generated have high predictability. TLC data must be presented as quantitative and statistical values to further increase reliability of techniques, and correlate inter laboratory discrepancies.

Analyte Identification

The major ability to both elute and identify any nucleic acid resides in its functional groups and heterocyclic rings. Any approach to identification of unknown or modified nucleic acids should begin with characterizing functional groups, and subsequently using this information to improve separation. Furthermore, functional groups offer sites of chemical alteration and simple bench-top techniques, can confirm structure. tRNA has served as the primary impetus for developing accurate and reproducible techniques to separate methylated nucleosides. It is not possible to summarize in this article the literature that exists on the chemistry of nucleic acids.

In consideration of both choice of TLC paper and likely nucleic acid identification, a few observations apply. In general hydrophobic modifications and methylation decrease R_F , hydrophilic modifications, e.g. succinylations, increase R_F . Low versus high negative nucleic acid charges are alterable and dependent on TLC and solvent system. Other strategies may be first to react chemically with nucleic acids prior to chromatography.

Sugars such as pentose ring riboses and deoxyriboses react readily. The sugars are uncharged at physiological pH, and lose a proton at pH 12. The major advantage of the phosphodiester bond is that it is cleaved with extreme acid or alkali. The charge and number of the phosphates ultimately confer their

T1 = ascending development, 10 cm in 45 min; T2 = wang method; T3 = 12 cm development distance; T4 = ascending, saturated chamber; T5 = gradient elution, two-dimensional chromatography; T6 = room temperature 18–22°C, for two-dimensional, 11–13 cm, dry at 40°C, then 8–9 cm in the second direction.

Techniques for nucleotides:

T7 = 15 minutes development time, 8–10 cm; T8 = ECTEOLA-cellulose sprayed with 0.01 ammonium tetraborate (pH 9.0) and dried with 17 cm run, 2 h/closed tank; * = R_f rel to inorg. phosphate; T9 = closed tanks or open trays when two-dimensional development, 6 inches; T10 = 5–10 min; T11 = 50–60 min; T12 = stepwise development; S28–45 s, S29–6 min and S30 to 13 cm; T13 = gradient elution, two-dimensional; * = ref. rel to CMP.

Solvents:

S1 = H₂O; S2 = isobutyric acid/conc. ammonium hydroxide/water (33 : 1 : 16); S3 = 0.005 N HCl; S4 = saturated ammonium sulfate/1 N sodium acetate/isopropanol (40 : 9 : 1); S5 = isopropanol/water (9 : 1); S6 = 75 mL of 1.0 mol L⁻¹ NH₄HCO₃ in one chamber and 85 mL of 0.15 mol L⁻¹ NH₄HCO₃ in the second chamber; S7 = 75 mL of 2.0 mol L⁻¹ ammonium formate, pH 4.2, in one chamber and 85 mL of 0.2 mol L⁻¹ ammonium formate, pH 2.8, in the second chamber; S8 = isopropanol/HCl/H₂O (65 : 16.7 : 18.3 v/v); S9 = isobutyric acid/H₂O/25% NH₄OH (400 : 208 : 0.4 v/v); S10 = isopropanol/H₂O/concentrated (28%) NH₄OH (85 : 15 : 1.3); S11 = *n*-butanol/H₂O/formic acid (77 : 13 : 10); S12 = saturated (NH₄)₂SO₄/1 mol L⁻¹ sodium acetate/isopropanol (80 : 18 : 2); S13 = heptane/butanol/acetic acid (4 : 4 : 1), development time for 8 cm, 60 min; S14 = carbon tetrachloride/acetic acid/acetone (4 : 1 : 4); S15 = toluene/pyridine/ethylenechlorohydrin/0.8 N NH₄OH (5 : 1 : 5 : 3 : 3 v/v); S16 = 0.15 mol L⁻¹ sodium chloride; S17 = 0.01 N HCl; S18 = 95% ethanol/0.1 mol L⁻¹ ammonium tetraborate pH; S19 = 0.005 N HCl; S20 = isobutyric acid/concentrated ammonium hydroxide/water (33 : 1 : 16); S21 = 0.02 N HCl; S22 = 0.03 N HCl; S23 = 0.4 N HCl; S24 = *n*-butanol/acetone/acetic acid/5% ammonium hydroxide/water (4.5 : 1.5 : 1.5 : 1); S25 = *n*-butanol/acetone/acetic acid/5% ammonium hydroxide/water (3.5 : 2.5 : 1.5 : 1.5 : 1); S26 = *t*-amyl alcohol/alcohol/formic acid/water (3 : 2 : 1); S27 = saturated ammonium sulfate/1 mol L⁻¹ sodium acetate/isopropanol (80 : 18 : 2); S28 = 2 mol L⁻¹ LiCl; S29 = 1.0 mol L⁻¹ LiCl; S30 = 1.6 mol L⁻¹ LiCl; S31 = 75 mL of 1.0 mol L⁻¹ NH₄HCO₃ in one chamber and 85 mL of 0.15 mol L⁻¹ NH₄HCO₃ in the second chamber; S32 = 2 mol L⁻¹ ammonium formate, pH = 4.2 in one chamber and 85 mL of 0.2 N ammonium formate, pH = 2.8 in the second chamber.

Table 2 Purine/pyrimidine detection schema

<i>Moiety</i>	<i>Reagent/reaction</i>	<i>Result: nucleic acids</i>
Nucleoside mono-, di- and triphosphates	Ammonium molybdate–perchloric acid	Blue spots
Caffeine	Chloramine-ammonia	Rose-red coloured spots
Xanthine derivatives	Chlorine-ammonia	Xanthine derivatives – violet
Deoxyribonucleosides, deoxyribo-, mono-, di- and triphosphates	Cysteine–sulfuric acid	Purines – green fluorescence
Purines	Eosine–mercury chloride	Purines – red violet best seen under UV light
Purines	Mercuric acetate–diphenyl carbazole	'Shadows' on violet background (circle after appearance not stable)
Purines and pyrimidine bases	Mercuric nitrate–ammonium sulfide	Black spots
Oxidized pyridine nucleotides, adenine-containing compounds	Potassium cyanide	Oxidized pyridine nucleotides – fluorescent zones; adenine-containing compounds
Adenine, guanine, hypoxanthine, xanthine and derivatives from cytosine and derivatives from chloride, bromide and iodide from histidine	Silver nitrate–bromophenol blue	Adenine, guanine, hypoxanthine, xanthine, and derivatives – blue spots Cytosine and derivatives – royal blue; chloride, bromide, iodide – violet
Purines	Silver nitrate–sodium dichromate	Red spots
Sulfur derivatives of purines and pyrimidines	Thiocarbamide reaction	Green or blue spots
Guanine and xanthine and compounds from other naturally occurring purine and pyrimidine derivatives (except urate)	UV light + exposure to HCl	Dark spots against fluorescence of paper (except uric acid) guanine and xanthine exposed to HCl–strong fluorescence

mobility on chromatography. The monoester phosphate has two ionizable OH groups, and is in relative equilibrium at physiological pH.

Studies have been carried out on the lipophilic characteristics of xanthine and adenosine derivatives. These are potentially important for large classes of drugs, including chloroadenosine. Lipophilic characteristics can be studied with silicone-coated or C₁₈ TLC plates. Methanol/phosphate buffer, pH 7, with a methanol content ranging from 30 to 80% have been used. Equations have been obtained to allow maximum allowable separations of 44 purines.

Separation of hydroxy-2'-deoxyguanosine-3'-monophosphate is carried out in 1.5 mol L⁻¹ ammonium formate (pH 3.5), and then 0.4 mol L⁻¹ ammonium sulfate. Though good separation of C₈-hydroxy-dGMP is obtained, most dNMPs remain in the midline, with significant artefacts in the second dimension. Aside from ageing, metabolism of DES (the hormonal drug diethylstilbesterol) also forms C₈-hydroxy-dGMP.

Novel separations of anomeric α (pharmacological) purines can be carried out on copper acetate Chiral-plates with methanol/water/ACN and visualization under UV light.

Others use silica gel separations of noncyclic radioactive [³H] adenosine as neuromodulators, and only use one-dimensional separation. The solvents are various mixtures of butanol/ammonia/water/ acetic acid. Separation takes 3–4 h. Typical separations un-

equivocally demonstrate cAMP, inosine, adenosine and adenine. UV sensitivity is down to 5 nmol. Plant cytokinins (adenine) are separated on silica gel in ethanol/ammonium borate, butanol/ammonia or butanol/water. Measured ATP is obtainable from degraded meat via 5% cold perchloric acid on silica gel and isobutanol/ amyl alcohol/ethoxyethanol/ ammonia/water (mature solvents for 48 h).

Guanine can be separated from other nucleic acids on PEI-cellulose with triethylammonium bicarbonate (TEAB) 0.5 mol L⁻¹ pH 7.6. Good separation of cyclics, phosphates and nucleosides is evident. Cyclic purines are separated by PEI with ammonium acetate/hydroxide/ethanol eluent at pH 9.0 in one dimension, ascending from triphosphates to nucleobases. Cyclic purines are also separated with PEI in 0.4 mol L⁻¹ acetic acid, then 0.125 mol L⁻¹ LiCl. GTP is separated with PEI and Luciferase, water and then 1.4 mol L⁻¹ LiCl for 50 min. Assay is by scintillation counter.

Alkylated deoxyuracil separation is carried out with RPTLC in methanol/propanol/water/dichloroethane. Water/ethanol has greatest effects on longer chains. Here TLC demonstrates quantitative structure–activity relationships (QSAR).

Thymine dimer separation has been successful on silica gel with one-dimensional chloroform/methanol/water and two-dimensional ethyl acetate/propanol/water, then sprayed with cysteine/sulfuric acid. Separation is evident, but almost all in midline.

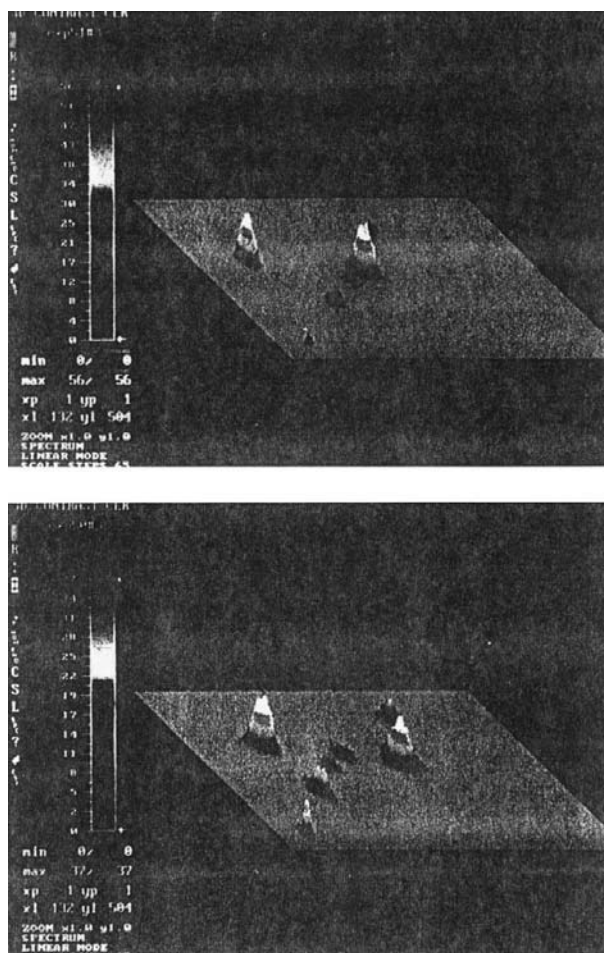

Figure 3 Three-dimensional ^{32}P computer reconstruction of DNA digest and DNA digest with chemically introduced dUMP.

Thymine dimers are also separable via cellulose and *n*-butanol/water, and 2D-ammonium sulfate/sodium acetate/propanol. Adhesive tape can be used to remove cellulose for scintillation counting.

'Bench-top' chemistry can be successfully employed for chemical identification of nucleic acids with derivatization by dimethylaminonaphthalene-5-sulfonyl chloride (DANS-Cl) formic acid (6%), acetate/ethanol/ammonium hydroxide, or ethyl acetate/ethanol/ammonium hydroxide used on a polyamide sheet. Also borohydride is used in post-labelling reduction [^3H].

Halogenated uracils can be separated on silica HPTLC plates. Solvents are chloroform/ethanol/water \pm acetate. As many as 27 pyrimidine analogues have been separated. Cellulose TLC and various combinations of butanol/ammonia/ethyl acetate/formic acid/sodium phosphate/propanol/isoamyl alcohol were used. New analogues are regularly discovered by 2D-TLC with PEI in isobutyric acid/water/ammonium hydroxide (first dimension) and ammonium

sulfate/isopropanol/sodium acetate (second dimension). Among these is 'pdJ', a nucleotide. Hydrazine is used to destroy other pyrimidine rings. These modified nucleotides are resistant to post-labelling.

Diol detection occurs with methyl red in ethanol, boric acid and acetone. These conditions are good for polar sugars; arabinosyl, ribosyl and deoxyribosyl are well handled with PEI in LiCl. Acyclonucleosides are powerful antiviral agents, e.g. acyclovir for herpes. These analogues lack one or more atoms on the pentofuranose ring. Separation strategies can be developed to take advantage of the alterations in the sugar.

Typical specimens from biological sources contain mixtures of purines and pyrimidines. Thin TLC layers (0.1 mm thick) give no elongated spots when used. The separations are fast (10 min) with good efficiency (5000 theoretical plates) at R_F values under 5.5 cm. Ammonium sulfate (0.2–5.0 mol L $^{-1}$) solutions are used as eluents; other salts (many less ionized than $(\text{NH}_2)_4\text{SO}_4$) contribute little. pH (borax, acetate, HCl, ammonium) contributes little to separations achieved with ammonium sulfate.

TLC has been used to separate nucleotides from cell culture. TLC gives high resolution, but low load capacity and cumbersome sample-handling procedures. CEL 300 plates and butanol/acetic/water or ethanol/ammonium acetate (pH 5) effect good separations. Colorimetric quantitation is possible with ninhydrin-cadmium. TLC is most effective for nucleotides of relative molecular mass below 4000. Plant viral RNA has been chromatographed with cellulose TLC with *n*-butyric/ammonia/water in one dimension, and ammonium sulfate/sodium acetate/isopropanol in the second. The system easily separates 2' versus 3' NMPs. Methylated RNA is separated by 2D-TLC on plates consisting of varying percentages of silica gel/cellulose with acetonitrile (ACN) ethyl acetate/propanol/butanol/water/ammonium hydroxide eluents. Many of these simpler systems line the NMPs in the midline. Pyrimidine/guanine dinucleotides are well separated on PEI with 0.8 LiCl/acetic acid.

An additional challenge to biomedical applications of TLC relates to the separations of cyclic nucleotides from noncyclic phosphates. Alumina TLC and ammonium acetate, pH adjusted with ammonium hydroxide, has been used to effect these separations. 3'-5'-cGMP uses borate impregnated silica in butanol/methanol/ethyl acetate/ammonium hydroxide. Cyclic pyridines/purines are separated on cation exchange layers, pretreated with HCl, as opposed to the popular anion (PEI) systems, with an eluent of 0.05 mol L $^{-1}$ oxalic acid.

The utility of gel electrophoresis for the separation of long chain oligonucleotides has relegated TLC to

smaller chain species. Intermediate chain oligonucleotides are readily handled by HPLC, but many smaller ones are not. This is the province of TLC. Silica gel TLC has been important in oligomer separations well up to decamers.

tRNA digests can be effectively separated, based on the nucleobase irrespective of adenines. PEI-cellulose in butanol/methanol/water, then formic acid in water, is used. For TLC that is salt-sensitive, PEI plates and 0.5% formic acid in an ascending fashion (occasionally using urea, which reduces smear) are worthwhile. 0.15 mol L^{-1} Li/formate, pH 3.0, achieves separations with as little as 5 DPM after 3 weeks autoradiography. In 2D-TLC systems, one can also add urea/formic acid/pyridine. 2D-TLC is carried out with 22% formic acid in the first dimension and with 0.1 mol L^{-1} formic + pyridine to pH 4.3 in the second dimension. Variation in TLC batches giving different binding capacities and relative primary, secondary and tertiary amine separation were observed but it was felt the results were internally consistent. The best pH is at 4.3, and investigators were successful up to 50 nucleotides.

Avicel cellulose can be used in 2D to 3D with isopropanol/ammonium hydroxide, isobutyric/ammonium hydroxide/EDTA, or ammonium acetate with detection by ethanol/scanning slit UV of the plates. Up to the C_{18} isomer were nicely resolved in a stepwise fashion. Silica gel and ammonium acetate separates up to the C_{12} isomer, and achieves good distinction.

Fingerprint Analyses

In practice all conceivable nucleic acids with altered moieties that form, whether from oxygen stress, aldehydes or other reactive species, cannot be immediately chemically defined on a routine basis. Most investigators in the field of nucleic acid adducts define a particular pattern that is specific to a chemical alteration, mutagen or carcinogen. In ageing research, these are designated 'indigenous' spots. One can employ as much specific chemical characterization as possible, but ultimately may rely on fingerprint analyses. Many of our published figures demonstrate examples of a fingerprint chromatogram (Figure 1).

Detectors and Instrumentation

The main detection techniques are colorimetry and visual inspection, zone elution (scraping) for HPLC, spectrometry and GC, or voltammetry, densitometry and radiochemical techniques. More recent methods include computerized radiochemical, laser densitometric and phosphoroimager techniques.

Identification of an unknown analyte requires R_F values that are reproducible to $\pm 3\%$. The geometry of the unknown must conform to the known, under the same chromatographic conditions. Co-chromatography of known and unknowns is always required.

Table 2 lists chromogenic reactions; a great deal of nucleic acid colorimetric information is available from published sources. Common reagents include mercuric acetate (purine and pyrimidines), Ehrlich reagent for *N*-carbamyl amino acids formed after alkali hydrolysis (NaOH), and Pauly reagent for imidazole rings.

Fluorescence remains a standard technique. TLC plates are impregnated with UV fluorescent material at 254 nm (typically zinc silicate). Upon exposure, the nucleic acids absorb at 254 nm and therefore quench, so that they appear black against a blue-green background of fluorescence. The errors in quantification by UV remain high (30%). Some scanning detectors employ UV, which can be applied to TLC plates and gives better quantitative data.

Sensitivity is enhanced by fluorescence techniques but typically these techniques require derivitization (pre- or post-chromatography), which is well described in nucleic acid chemistry.

Fourier transform infrared detection is available for TLC. Many papers had high IR absorbance and were inadequate for direct IR measurement. Papers are now available that allow direct measurement. GC is best employed in conjunction with zone elution, and certainly has application to nucleic acids, though lipids have been more extensively studied.

Mass spectrometry (MS) is readily applied to nucleic acids, but typically after zonal elution to avoid interfering solutes. Present developments in coupled MS-TLC must take into account the sorbent, solvent and analyte - which will not exceed 0.25% w/w based on sample and sorbent. The apparatus requires the ability to extract, elute or volatilize analyte directly from the TLC plate. These instruments will be a boon to the ability to detect and characterize analytes. Investigators have defined nucleic acid photoproducts, radical-induced products, those modified by xenobiotic biotransformation, new and naturally occurring nucleosides especially found in RNA, methylated bases and stable isotopes. Interfaces between MS and liquid chromatography systems have also been extensively investigated.

A large amount of data has been accumulated based on laser densitometry using autoradiographically developed X-ray film from 2D-TLC chromatograms that house the separation of radioactive dNMPs. The exposure times chosen give the ability to label unknowns at high counts, in as little as 2 h, but

typically runs take 24–72 h. Many runs of 96 h to weeks reveal groups of adducts that are reproducible, and many undescribed. Present densitometric techniques can range from a few minutes for unidimensional analyses to 2 h for complete analyses of a 20 cm × 20 cm autoradiogram. Comparison of techniques with direct scintillation counting – the other gold standard – approach r values of 0.99, and similarly correlate with the best quantifying techniques.

Scintillation Counting

The coupling of sensitive (25 DPM above background), rapid (15 min for a 20 cm × 20 cm plate) scintillation counting with computerization represents a major advance in TLC quantification. It allows *in situ* measurement of radioactivity and quantitative reconstruction of the nucleic acids in two or three dimensions. The ready ability to compare TLC plates, generate tables for comparison and rapidly apply statistical or analytical methods by computer is immense. This has revealed quantifiable relationships in nucleic acid and DNA chemistry that were previously quite complicated to examine.

Scintillation counting and densitometry both have very significant advantages and disadvantages. Clearly the ability to quantify a plate immediately after a run and drying makes scintillation counting the ‘first-look’ method. Yet densitometry allows one to examine, by eye, parts of the chromatogram that may be viewed as background by scintillation counting. These techniques are complementary and will be more extensively used in the future.

Phosphoroimager

Recently, sensitive, rapid phosphoroimagers have been made available that give excellent quantitative data. They employ phosphors able to capture radiation energy from various sources comparable to autoradiography in less than 8% of the time. They not only deliver standard R_F values, but also a mass of quantitative information. The better ability to subtract controls, carry out statistical analyses and enhance minute adducts may revolutionize adduct and analogue detection of nucleic acids.

Immunoassay

This technique, similar to Western blotting, allows colorimetric reactions to occur after binding by antibodies that recognize nucleic acid adducts, and subsequent recognition by enzyme-linked antibodies that cause colorimetric reactions with the application of the appropriate substrate. Little experience is at hand

on these techniques, but they increase the specificity of reaction adducts of interest.

Summary and Future Developments

Uniformity in approach is required in TLC chromatography. This article has highlighted information drawn from the wider nucleic acids literature and has referred the reader to new techniques that have been successful in the author’s laboratory. These will enhance nucleic acid TLC and the characterization of unknowns, especially where expensive equipment is not available. Greater quantification of data by methods that are now well accepted is needed. The TLC of nucleic acids still remains significantly underused, and it is hoped that this article has offered the investigator a ready source to follow for analytical investigations.

OCCUPATIONAL HYGIENE: GAS CHROMATOGRAPHY

M. Harper, University of Alabama at Birmingham, Birmingham, AL, USA

Copyright © 2000 Academic Press

Introduction

Industrial or occupational hygiene has been defined as the anticipation, recognition, evaluation and control of environmental factors or stresses arising in or from the workplace that may cause sickness, impaired health or significant discomfort. The factors causing stress encountered in the workplace are typically divided into 'physical' and 'chemical', although, increasingly, a biological component has been recognized as, for example, with infectious diseases.

Chemicals can occur as gases, vapours and mists and as solids in the form of dusts and fumes. Their hazard potential is related to their ability to react with or be absorbed by the skin or lungs. The physiological response to exposure is related to its frequency, duration and severity, the route of exposure, and the chemical make-up of the substance, as well as factors relating to individual susceptibility. Gases and vapours can cause problems in the lungs by irritation, or can be absorbed into the bloodstream to cause problems elsewhere in the body. While such absorption is most likely in the lungs, substantial uptake of vapour is also possible through the skin. Liquids and solids also may be absorbed through the skin with local irritation or systemic effects, while aerosols can be deposited in various regions of the pulmonary system. In the lungs, certain dusts cause problems associated with their physical characteristics, while others are soluble and may be absorbed. Very fine particles may also enter the body and be transported elsewhere. Liquid droplets may cause irritation or be absorbed. Absorption of any chemical into the body may cause acute or chronic health effects in organs or tissues distant from the site of absorption. The most important classes of chemicals are the permanent gases, organic chemicals, inorganic acids and the heavy metals. Exposure limits for these chemicals are published by government and other agencies.

Monitoring of the environment is required to determine the nature and quantity of chemicals present, and also to evaluate the effectiveness of control measures. Monitoring is typically carried out through sampling, either of the air being breathed, or of

surfaces which the skin or clothing may contact, or of the workers themselves through analysis of breath, blood or urine. Protocols have been established to standardize the methods of sampling and analysis. These methods are generally available, although they are often updated to meet the changing needs of hygiene investigations so that it is important to maintain a current awareness of the literature. Gas chromatography (GC) is one of a number of techniques used in the analysis of samples. It is used to separate the hazardous chemicals one from another, or from the matrix in which they are presented for analysis. GC is most often a laboratory analytical tool, but field-portable units are also available.

Factors in the Selection of Sampling and Analysis Methods

The ideal method would be specific, sensitive, and free from interference. In addition, it would provide real-time continuous output as well as time-integrated results. Finally, it would be simple and cheap to operate. It is rarely possible to satisfy all these criteria in currently available technology and compromise is often necessary.

Air Sampling

There is substantial variation of hazardous chemical concentration in both space and time. To obtain accurate information concerning the airborne dose to the worker, it is necessary to sample air from the 'breathing zone'. Personal monitors therefore require an inlet port or sensor close to the face. Temporal variability can be covered by taking a time-integrated sample. Regulated concentration limits normally are expressed in terms of 8-h (work-shift) averages, although short-term limits are also employed for compounds with more acute toxicity. The time period for short-term averaging is typically 15 min in the USA, although other periods (e.g. 30 min) may be in use elsewhere. In addition, some regulations call for ceiling limits that cannot be exceeded under any circumstances. Although time periods for ceiling limit determinations are not stated, implying an instantaneous warning, in practice all monitoring equipment involves some time lapse. Equipment used for short-term sampling is often used to monitor ceiling values.

The simplest method for taking an air sample is to trap the air in an inert container. The air can be analysed either in the laboratory or in a field-portable gas chromatograph, by direct injection using a gas-tight syringe or gas sampling loop. Alternatively the chemical content can be concentrated by secondary trapping using a sorbent-filled or cryogenically cooled trap, and then released by rapid heating. The containers used include glass syringes or bottles, bags made of various polymers (e.g. Tedlar®, Teflon®, Mylar®, Saran®) or metal containers (stainless steel that has been electropolished, treated by the SUMMA® process or lined with fused silica). However, all such containers are bulky, even though smaller canisters have been manufactured recently to hold 200–500 mL of air and which can be worn on a belt or harness. There are issues of sample stability with whole-air samples. For example, many aromatic compounds are not stable in Tedlar bags over periods greater than 24 h, and their stability depends on the type of fitting used, with polypropylene providing greater stability than stainless steel. 1,3-Butadiene, on the other hand, is very stable in Tedlar bags, while dimethylformamide disappears very rapidly. Sulfur compounds are more stable in fused-silica lined canisters than in polished stainless steel. Tedlar bags should probably not be re-used as their integrity may be compromised, although they frequently are in practice. The expense of canisters ensures multiple re-use although carry-over to future samples is an issue when working from high concentrations to low, and contamination with oil mist renders a canister useless. There are also issues of sample recovery, due to photochemical reaction in transparent bags, or through moisture condensation on the interior of canisters.

The widespread development of sampling equipment to meet the combined needs of being lightweight, unobtrusive and carried by the worker, and of being able to provide time-weighted average results, has led to a simple method for a wide range of gases and vapours using a battery-operated pump to pull air through a tube filled with a sorbent (Figures 1 and 2). Changing the type or quantity of sorbent extends the range of vapours that can be collected. Another advantage is adjustable flow rate that can be raised to obtain sufficient sample to exceed detection limits at low concentrations or lowered to reduce the sample so that breakthrough does not occur at high concentrations.

Sorbents generally can be classified as being of two types: those that react with the chemical of interest and those that use adsorption to collect airborne vapour molecules. The former type is preferred for gases that are not readily condensed at room temper-

Figure 1 Typical personal air sampling train comprising sorbent tube and air-mover (pump). This is the commonest method of sampling worker exposure to hazardous gases and vapours.

atures, for chemicals that are unstable or reactive, or where the reaction product can be detected with a better sensitivity. Some examples are reaction of aldehydes to stable hydrazone derivatives with analysis by GC or high performance liquid chromatography (HPLC), and the reaction of ethylene oxide with hydrobromic acid to form bromoethanol, which gives a good response with an electron-capture detector.

The second type of sorbent, using microporous materials with high surface area, is more common. Activated carbons can have surface areas as high as $1000 \text{ m}^2 \text{ g}^{-1}$ or more, with a network of large pores

Figure 2 Personal air sampling train attached to a worker.

leading to successively smaller pores with diameters in the nanometre range. Molecules that enter this region are affected by forces extending from the pore walls and from other molecules held in close proximity to them. Adsorption is strong and essentially complete at the low concentrations encountered in the air. Transport from the air stream to the sorbent is by molecular diffusion, and both diffusion and adsorption are relatively rapid. Thus only a small quantity of sorbent is required (as little as 100 mg) for effective removal of molecules from the air. The adsorbed chemicals are liberated from the charcoal after sampling by application of a polar solvent, commonly carbon disulfide.

Other sorbents are used routinely for particular applications. Many of these are the same polymeric resin materials used in chromatographic column packings. The range of sorbents is large, and complicated by the number of trade names used (e.g. Porapak® N or Q, Chromosorb® 102, 104 or 106, Amberlite® XAD-2, XAD-4 or XAD-7, or Tenax®

Figure 3 Diffusive sampler attached to a worker. This method is more acceptable to workers but the uptake rate varies from chemical to chemical and cannot be altered by field hygienists.

TA or GR). One specific use for these sorbents is in thermal desorption, where the application of heat rather than a solvent is used to remove the collected chemicals. Graphitized carbon blacks are also used in this application.

An alternative to the use of pumps is to allow the molecules of the chemical being sampled simply to diffuse to the sorbent surface (Figure 3). Several styles of diffusive sampler are available, some of which develop colour reactions for on-site analysis, and others which contain the same types of sorbent used in the pumped tubes, and which are analysed in a similar manner.

Semi-volatile chemicals are normally sampled using a filter prior to the sorbent tube. A range of filters is available, including glass or quartz fibre, cellulose ester and polymeric membranes. The filter is extracted with a solvent, which may be the same as that used for the sorbent. This same arrangement is used where mists of volatile components are encountered.

Biological Sampling

Many occupational hygiene methods involve the analysis of breath, urine or blood samples. GC analysis may involve the chemical of interest or a metabolite such as the phenol content of urine used as a monitor of benzene exposure. While breath sampling is the least invasive, it may not be the best estimate of exposure over a period of time, and is often the most variable. Urinary analysis is also quite variable, and correction for concentration is often made using the analysis of the creatinine component. Blood is the most difficult fluid to take on a

Table 1 Organic chemicals with biological exposure indices

<i>Chemical</i>	<i>Measured marker</i>
<i>Organic chemicals monitored in urine</i>	
Acetone	Acetone
Aniline	<i>p</i> -Aminophenol
Benzene	<i>s</i> -Phenylmercapturic acid
Carbon disulfide	2-Thiothiazolidine-4-carboxylic acid
Chlorobenzene	4-Chlorocatechol or <i>p</i> -Chlorophenol
<i>N,N</i> -Dimethylacetamide	<i>N</i> -Methylacetamide
<i>N,N</i> -Dimethylformamide	<i>N</i> -Methylformamide
2-Ethoxyethanol and 2-ethoxyethyl acetate	2-Ethoxyacetic acid
Ethyl benzene	Mandelic acid
Furfural	Furoic acid
<i>n</i> -Hexane	2,5-Hexanedione
Methanol	Methanol
2-Methoxyethanol and 2-methoxyethyl acetate	2-Methoxyacetic acid
1,1,1-trichloroethane	Trichloroacetic acid or trichloroethanol
4,4'-Methylene bis(2-chloroaniline) (MBOCA)	MBOCA
Methyl ethyl ketone	Methyl ethyl ketone
Methyl isobutyl ketone	Methyl isobutyl ketone
Nitrobenzene	<i>p</i> -Nitrophenol
Parathion	<i>p</i> -Nitrophenol
Pentachlorophenol	Pentachlorophenol
Perchloroethylene	Trichloroacetic acid
Phenol	Phenol
Styrene	Mandelic acid or phenylglyoxylic acid
Tetrahydrofuran	Tetrahydrofuran ^a
Toluene	Hippuric acid or <i>o</i> -cresol ^a
Trichloroethylene	Trichloroacetic acid or trichloroethanol
Xylenes	Methylhippuric acid
<i>Organic chemicals monitored in blood (venous unless otherwise specified)</i>	
1,1,1-trichloroethane	Trichloroethanol
Pentachlorophenol	Pentachlorophenol (in plasma)
Perchloroethylene	Perchloroethylene
Styrene	Styrene
Toluene	Toluene
Trichloroethylene	Trichloroethylene or trichloroethanol
<i>Organic chemical measured in breath (end exhaled air)</i>	
Ethyl benzene	Ethyl benzene

regular basis, but it is used, for example, in the regulation of exposure to lead. The American Conference of Governmental Hygienists (ACGIH®) TLV booklet also includes a listing of Biological Exposure Indices (BEI®s). A list of current BEIs and the marker compounds is given in **Table 1**.

Breath samples may be collected in special containers, or passed through sorbent tubes to concentrate the chemicals of interest. The sample can then be introduced into a gas chromatograph using a gas-

sampling loop, or through solvent or thermal desorption of the sorbent. The humidity of the exhaled breath is an interfering factor, as is also the presence of chemicals manufactured by normal biological processes within the body. Blood and urine samples are more difficult to analyse chromatographically because of the matrix. Urine samples can be injected into a GC if the injection liner is replaced frequently, but blood contains surfactants and is a much more difficult medium. Liquid-liquid or liquid-solid

extraction, static and dynamic head space analysis, or solid-phase microextraction have all been used as sample preparation techniques. Many metabolites are highly polar, water-soluble compounds and HPLC is often the preferred analytical technique, especially where the presence of aromatic rings allows ultraviolet detectors to be used. However, many of the compounds listed can be analysed by GC as they are, or after derivatization. The final choice of method may depend on a number of factors.

Special care must be taken in the timing of the sample in relation to the work-periods, and also in the taking of the sample. For example breath samples should be of end-exhaled air, and blood samples should be of venous rather than capillary blood. In addition, some standards are based on total urinary excretion and others on urinary concentration. The sample container and the presence of sample preservatives are also important.

Sources of Methods

The US National Institute for Occupational Safety and Health (NIOSH) has been responsible for the *NIOSH Manual of Analytical Methods* (NMAM), now in its fourth edition. The NMAM is the largest repository of methods in the world, and many of its methods have been adopted by government agencies in other countries, such as the Health and Safety Laboratory of the UK. **Table 2** gives a list of commonly used NIOSH methods together with the chromatographic columns used (most methods use carbon disulfide, sometimes with a polar modifier, as the desorbing solution and flame ionization detection).

Validation of Methods

The validation of methods should encompass all stages of the method, including both the sampling and analysis steps. The NMAM contains details of the NIOSH method validation objectives, and a detailed validation manual for pumped sampling methods has been published (see Further Reading section). In addition, the NIOSH has supported the ASTM Standard D6246 for evaluating the performance of diffusive samplers. The US Occupational Safety and Health Administration (OSHA) Methods Manual contains similar documentation. The UK Health and Safety Executive also has standard method validation protocols (e.g. MDHS 27 for diffusive samplers). **Table 3** lists the American Society for Testing and Materials (ASTM) standards covering the analysis of air samples.

Sorbent Selection for Air Sampling Methods

The choice of chromatographic analysis procedure is intimately associated with the selection of the sorbent and the desorption procedure. Both the column type and the detector possibilities depend on the type of sample finally presented for analysis. While published methods give guidance, experienced analysts can develop or modify procedures to meet most eventualities. For example, the analysis of benzene may vary depending on whether benzene has been collected as part of a simple or complex mixture, and whether it is necessary to quantify only the benzene or all components, whether the sample was collected on charcoal or a polymer sorbent, whether the desorption is with a simple solvent or a mixture or by heat, and whether detection is by flame ionization (FID), photoionization (PID) or mass spectrometry (MS).

Charcoal is the most widely used sorbent for organic vapours. Various sources of charcoal are used, but in all cases the porosity has been enhanced by activation. Charcoals normally require solvent desorption. Anasorb® 747 is a popular charcoal from petroleum precursors that has wide application in the OSHA methods. Ambersorb®s are charcoals derived from controlled carbonization of organic polymers.

Porous polymers include cross-linked styrene and divinyl benzenes, which can have relatively large pores (Chromosorb 102, Amberlite XAD-2) or smaller micropores (Chromosorb 106, Porapak or Hayesep Q, Amberlite XAD-4). Also used are polar sorbents derived from acrylonitrile (Chromosorb 104, Amberlite XAD-7) or pyrrolidones (Porapak N, R). Tenax has a very small surface area and is normally only used for sampling low concentrations. It has the advantage of having a very low adsorption capacity for water. Because of its higher surface area and adsorption capacity, hydrophobicity, and compatibility with both solvent desorption and thermal desorption, Chromosorb 106 has been generally regarded as the most suitable polymer for occupational hygiene sampling. However, if thermal desorption is used the upper temperature limit of Chromosorb 106 is only 250°C, compared with 350°C for Tenax or Carbotrap® (a graphitized carbon), rendering it unsuitable for the collection of semi-volatile components. Styrene polymers such as chromosorb 106 also tend to have significant background when used for thermal desorption of the low concentrations found in ambient or residential indoor air, so that Tenax or Carbotrap are better.

The graphitized carbons mentioned above are available in different surface areas (e.g. Carbotrap C is approximately 10 m² g⁻¹ and Carbotrap B is

^a6 m column.

approximately 100 m² g⁻¹) and are used with thermal desorption in environmental applications. They have been used less often in occupational hygiene investigations, although the NIOSH has recently included a semi-quantitative screening method involving tubes containing multiple layers of sorbents including graphitized carbons in combination with carbon molecular sieves. Carbon molecular sieves,

such as the Carboxen® series, can be used to sample the most volatile compounds, but have the disadvantage of also trapping large amounts of water vapour from atmospheres of high humidity.

Silica gel is a highly polar and quite strong adsorbent, useful for very polar compounds such as methanol or amines. Strong adsorption of water is a problem with using this sorbent for other chemicals. Because of this adsorption of water, silica gel is used in specific applications, such as the collection of methanol with subsequent desorption by water and analysis on a packed Tenax column with FID.

Solvent versus Thermal Desorption

There are significant drawbacks to the use of solvents for the recovery of chemicals from sorbent samples, not the least of which is the added hygiene and safety burden of handling a solvent such as carbon disulfide. Solvents do not always give 100% recovery, and recoveries significantly less than 75% may be associated with increased variability in the precision of recovery. It may be difficult to optimize a solvent for best recovery of a mixture of polar and nonpolar chemicals, and the solvent may interfere with chemicals in the mixture. There are special problems relating to the adsorption of water from atmospheres of high humidity, and its subsequent release from the sorbent on addition of the desorbing solvent. For

example, charcoal can absorb large quantities of water (hundreds of milligrams per gram) from atmospheres of humidity greater than 50%. This water is displaced by carbon disulfide but does not mix with it. Polar compounds such as acetone can partition into the separate water phase causing an apparent drop in recovery. Several options have been developed to deal with polar compounds, including adding a polar modifier (e.g. 2-propanol or dimethylformamide) to carbon disulfide, or switching to an altogether different solvent (e.g. 95% dichloromethane/5% methanol). However, it is difficult to substitute entirely for carbon disulfide because of its small response with the FID and its good recovery of nonpolar compounds. New carbon sorbents such as Anasorb 747 exhibit much better adsorption and desorption properties under these conditions. When using polymer sorbents, care must be taken in the choice of recovery solvent. While styrene polymers are compatible with most solvent systems, Tenax will swell in some solvents, and pyroolidone polymers may dissolve.

An alternative to solvent desorption is thermal desorption. In this technique the sorbent tube is heated while a stream of carrier gas removes the collected vapours. Because this transfer can take several minutes the recovered vapours are usually focused in a secondary trap. There are several varieties of secondary trap in common use, including large sorbent traps at ambient temperature, open capillary tubes cooled cryogenically, and narrow-bore sorbent traps cooled to sub-ambient temperatures by Peltier cooling. The latter method provides for rapid transfer of the analytes to the column, with effective transfer of compounds in the range C_2 - C_{30} , and without risk of ice blockage or condensation of permanent gases such as oxygen. Some specialized analyses of thermally labile compounds such as nerve agents or vesicants may require derivatization prior to desorption.

Thermal desorption has existed since the mid-1970s, but has not significantly replaced solvent desorption in most countries for several reasons. Efficient thermal desorption requires a sorbent with less attraction for the vapours of interest than charcoal. The use of sorbents with lower surface areas and smaller capacity can lead to premature breakthrough of the sample during the sampling period. Sorbent tubes for solvent desorption are designed with a 'back-up' sorbent section that can be analysed to detect such breakthrough but sorbent tubes for thermal desorption are not. There are also quality assurance issues that must be addressed, for example, in calibrating the analysis (standards must be added as solutions to blank tubes and then the solvent re-

moved), using internal standards (more easily added to a solvent) or making multiple analyses (which would normally require taking multiple samples). Water management can also be a problem with thermal desorption of real-world samples. The transfer of desorbed water onto a capillary chromatographic column can alter the pressure gradient across the column and the polarity of the system, changing both retention time and peak area. Where sorbent tubes contain hydrophilic sorbents their performance can be improved by drying the sample with 300 mL of helium prior to desorption. Thermal desorption is often used for the analysis of canister samples, with the contents of the canister being drawn through the secondary trap or focusing tube, which is then desorbed and analysed. Water management may also be necessary in the analysis of canister samples. The UK Health and Safety Laboratory is the main source of published thermal desorption methods.

One important major advantage of thermal desorption is the possibility of increasing the quantity of sample that can be placed on the chromatographic column, by means of the secondary focusing trap. Recent developments in optimizing the technology now allow complete on-column injection of the entire sample, raising detection limits as much as two orders of magnitude over solvent injections. This is very useful for ambient and indoor air investigations at ppb levels, and also is making the system attractive for workplace analyses where there are chemicals with exposure limits at 1 ppm or below (e.g. benzene). When using thermal desorption for such trace analyses particular attention must be paid to the background levels of the sorbent (typically no more than 1 ng per component and 10 ng total) and handling, transport and storage procedures for the tubes. Thermal desorption also has potential applications in the analysis of biological samples, either through sorbent trapping from breath, or from direct heating of blood or urine samples. Both solvent and thermal desorption systems can be automated.

Types of Columns

When methods were being selected and validated in the early 1970s capillary chromatography was not far advanced commercially. Nor was it particularly necessary, since neither sensitivity nor selectivity was an issue. Typical occupational exposure limits at that time ranged from 10 to 1000 parts per million by volume of air for an 8-h time-weighted average. Assuming a full-shift sample using a sample tube operated at 20 mL min^{-1} (approximately 10 L of air), the tube could contain up to 10 mg of sampled chemical. Even if this were diluted in several millilitres of

solvent, a single injection into the gas chromatograph typically contained micrograms of the chemical. In addition, chemicals were less often used in complex blends, so that interfering peaks were less common. Typically, the only separation required was between the solvent, a single chemical in the sample and an internal standard. This was achieved easily with 1/8th inch (3.2 mm) packed columns, even in isothermal mode, and this procedure could be extended to cover many simple solvent mixtures used in industrial applications. A selection of the columns used in the NMAM is given in Table 2.

Packed columns continue to be used today for permanent gases, such as the sulfur gases (sulfur dioxide, sulfur trioxide, hydrogen sulfide, carbonyl sulfide, carbon disulfide and mercaptans), or for very volatile compounds such as 1,3-butadiene. The packings are typically zeolite or carbon molecular sieves, or, in the case of the two examples just given, alumina-PLOT columns have been used. However, as occupational exposure limits continue to fall (on average by an order of magnitude between 1980 and 1990), and the number of regulated chemicals increases and complex mixtures become more common, there is a distinct move towards the use of capillary columns, which is supported by laboratories wishing to speed up analytical procedures. This has been recognized by the NIOSH, who intend to begin a programme of updating the methods in the NMAM to include capillary columns. The typical modern occupational hygiene laboratory will have a collection of capillary columns from 15 to 100 m length, both microbore (0.32 mm) and megabore (0.53 mm), with different films and thicknesses. A standard all-purpose column might be a DB-1 or DB-5 or equivalent from other manufacturers. A typical example of a complex analysis is the determination of trace benzene (American Conference of Governmental Industrial Hygienists threshold limit value (TLV) for 1999 is 0.5 ppm) in the presence of gasoline (see Figure 4).

Types of Detectors

The flame ionization detector has been the traditional detector of choice in industrial hygiene analyses. It has a very wide linear range. With packed columns, limits of quantitation range typically from 2 to 20 ng of chemical per injection. The sharper peaks obtained with capillary columns can allow quantitation at lower concentrations, but this must be balanced against the smaller sample loading. Sample loading can be increased with megabore capillary columns, or by preconcentration at the injection stage. Overall limits of quantitation of 0.1–1 ng per injection are possible. Halogenated hydrocarbons do not provide

as many ions in the flame and therefore have smaller detector responses. In addition, reactions with remnant ions from the carbon disulfide solvent can alter the response of halogenated hydrocarbons at low concentrations. Photoionization detectors (PIDs) are often used with portable gas chromatographs since only a single source of gas is required; however, care must be exercised in keeping the lamp clean in field use. The PID is also useful for the detection of aromatic hydrocarbons in the presence of aliphatic hydrocarbons (e.g. benzene in gasoline). The electron-capture detector (ECD) is often preferred for halogenated solvents, but the ECD is not compatible with large quantities of carbon disulfide solvent and other solvent recovery systems (e.g. hexane, ethyl acetate, toluene) do not provide as efficient recovery from charcoal sorbents.

Mass spectrometry (MS) has become popular for the analysis of trace organic components in the atmosphere through methods promulgated by the EPA. The development of quadrupole detectors has allowed the rapid scan of spectra in the timescale of a capillary peak. When the spectra are matched to a reference library, compound identification is possible, especially when this information is cross-referenced to specific compound retention times from Kováts indices. However, because MS detectors have been costly to purchase and maintain, while FIDs have had adequate sensitivity and the compounds of interest are known in advance, MS methods have not been developed for occupational hygiene analyses. This is changing and a recent example from the NMAM (method 2539) is a screening method for aldehydes (Figures 5 and 6). In investigations of the quality of ambient or indoor air, the dilution of the sample by solvent desorption effectively puts most contaminants below the limits of quantitation of both the FID and MS. The mass spectrometer therefore is most suitable in combination with thermal desorption for sampling multiple unknown contaminants at low concentrations. For this application a semi-quantitative NIOSH screening method (method 2549) has been developed. MS in single-ion mode can increase detection limits by a factor of 10 or more. Two examples are given showing the usefulness of the MS detector in compound identification and quantitation. Both involve the analysis of benzene in complex samples. In Figure 4 the single peak at the retention time of benzene is resolved in the MS scan as a mixture of benzene and another compound (possibly cyclohexane). In Figure 7 the single peak is resolved into benzene and butanol. In both cases benzene could be quantified at low concentrations without interference by measuring the m/z 78 ion in single ion mode.

Figure 4 Determination of benzene in gasoline using GC-MS. The GC column was a 5% phenylmethylsiloxane HP-5MS. (A) Total ion chromatogram (note an FID trace would be similar). Retention time of benzene is 2.06 min. (B) Mass spectrum of peak at 2.06 min resolves interference from a C_6H_{12} compound. (C) Single ion scan at m/z 78 can be used to quantify benzene.

Other alternatives to the FID are normally used in trace-level compound-specific analyses, and detection limits may be enhanced by derivatization. For example, formaldehyde may be determined as a derivative with hydroxymethylpiperidine using a nitrogen-phosphorous detector. Sulfur compounds are often detected using a flame photometric detector (FPD).

Quality Assurance

The number of samples taken per investigation will depend on the number of exposed workers and the perceived extent of any problem and may vary from

one to several hundred. The best choice of laboratory for analysing occupational hygiene samples is one that specializes in such samples and accepts them on a routine basis. Laboratories may voluntarily participate in Proficiency Analytical Testing (PAT) schemes or, once they have established proficiency in these schemes, request accreditation by various recognized bodies. In the USA the proficiency samples for organic solvents include aliphatic, aromatic and chlorinated hydrocarbons, alcohols, ketones and esters. Many other countries have similar proficiency testing and accreditation programmes. For example, the UK Health and Safety Laboratory operates the Workplace Analysis Scheme for Proficiency (WASP).

Figure 5 Determination of multiple aldehydes as their derivatives with 2-hydroxymethylpiperidine. Total ion chromatogram of aldehyde mix from spiked sorbent tube separated on a 15 m DB-1301 column.

In addition to documentation of methods and practices, the following specific elements are considered appropriate for good analytical practice:

- *Initial calibration verification.* This is based on a range of standards diluted from a stock solution. Multiple points encompassing the expected sample range are used to create a calibration curve. If the samples fall outside this range, further standards are prepared. The response of the detector to the standards, and their correlation coefficient, should be within control limits. Field-portable detectors may use packaged calibration gases.
- *Continuing calibration verification.* At least one of the standards used for the initial calibration is repeated each 10–20 injections (or more frequently if considered desirable).
- *Internal standards.* An internal standard is useful to compensate for minor variations in the sample size injected into the GC, but because it may mask a chemical of interest internal standards are not always employed where the sample is not well characterized.
- *Reagent blanks.* The solvent used to make up standards and desorb samples is checked for contamination. This procedure is essential if low concentrations of analyte are to be determined.
- *Matrix blanks.* The sampling medium is checked for contamination.
- *Matrix spikes.* A known quantity of the analyte is added to a blank sample medium, which is carried through the full analytical procedure to ensure proper recovery.
- *Replicates.* Used to ensure the precision of analysis. Particularly useful at low sample concentrations.
- *External standards.* Known concentrations of the chemical of interest obtained from a source other than the laboratory. Standard mixtures of com-

monly analysed chemicals are obtainable from speciality sources.

Other quality assurance methods used less often include: using a surrogate (a compound that behaves similarly to that of interest, but which can be separated, such as a deuterated analogue, which is used in the same way as a matrix spike with actual samples), matrix additions (direct addition of known quantities of the chemical of interest, which are subtracted from the final result) and splitting the sample (division of the sample for separate analyses).

Portable Gas Chromatographs

The detectors used in GC, especially the FID and the PID, are often used as stand-alone instruments for 'total' hydrocarbon analysis. They are calibrated to a standard concentration of an alkane in air. These detectors may also be used with a portable gas chromatograph to transfer laboratory analytical techniques to the field. Time-integrated samples can be collected using a sampling bag and are introduced using a gas-tight syringe. Built-in sampling pumps can give semi-'real time' measurements. Some instruments operate at ambient temperatures, but are limited to gases and very volatile compounds; most have some capability for temperature programming. Both packed and capillary column instruments are available, but since their introduction in the early 1980s wide-bore capillary columns have become standard. A detection limit of 0.1 ppb is claimed by one manufacturer (probably for an ECD), but most are higher, up to 0.1 ppm using PIDs or FIDs. Some are available with an option for different detector or injector types. Most can be linked to a personal computer. Many are mains powered but some use rechargeable batteries with a life of around 8 h or better. All are relatively heavy (< 20 kg), and none are truly considered 'personal' samplers. There are significant issues of user training and field calibration, and compressed gases (for carrier gas or instrument calibration) and radioactive sources (e.g. ECDs) cannot be transported on commercial aircraft. A very recently developed instrument uses ambient air as the carrier gas. While detection limits and separations are not as good as with helium, no compressed gases are required for instrument operation if the detector is a PID, or an FID with hydrogen generated by electrolysis of water.

To date, portable gas chromatographs have not been used for compliance monitoring by the OSHA, nor have they replaced traditional personal sampling methods, although the NIOSH has developed several analytical methods that use a portable gas chromatographs for analysis of exhaled breath, or

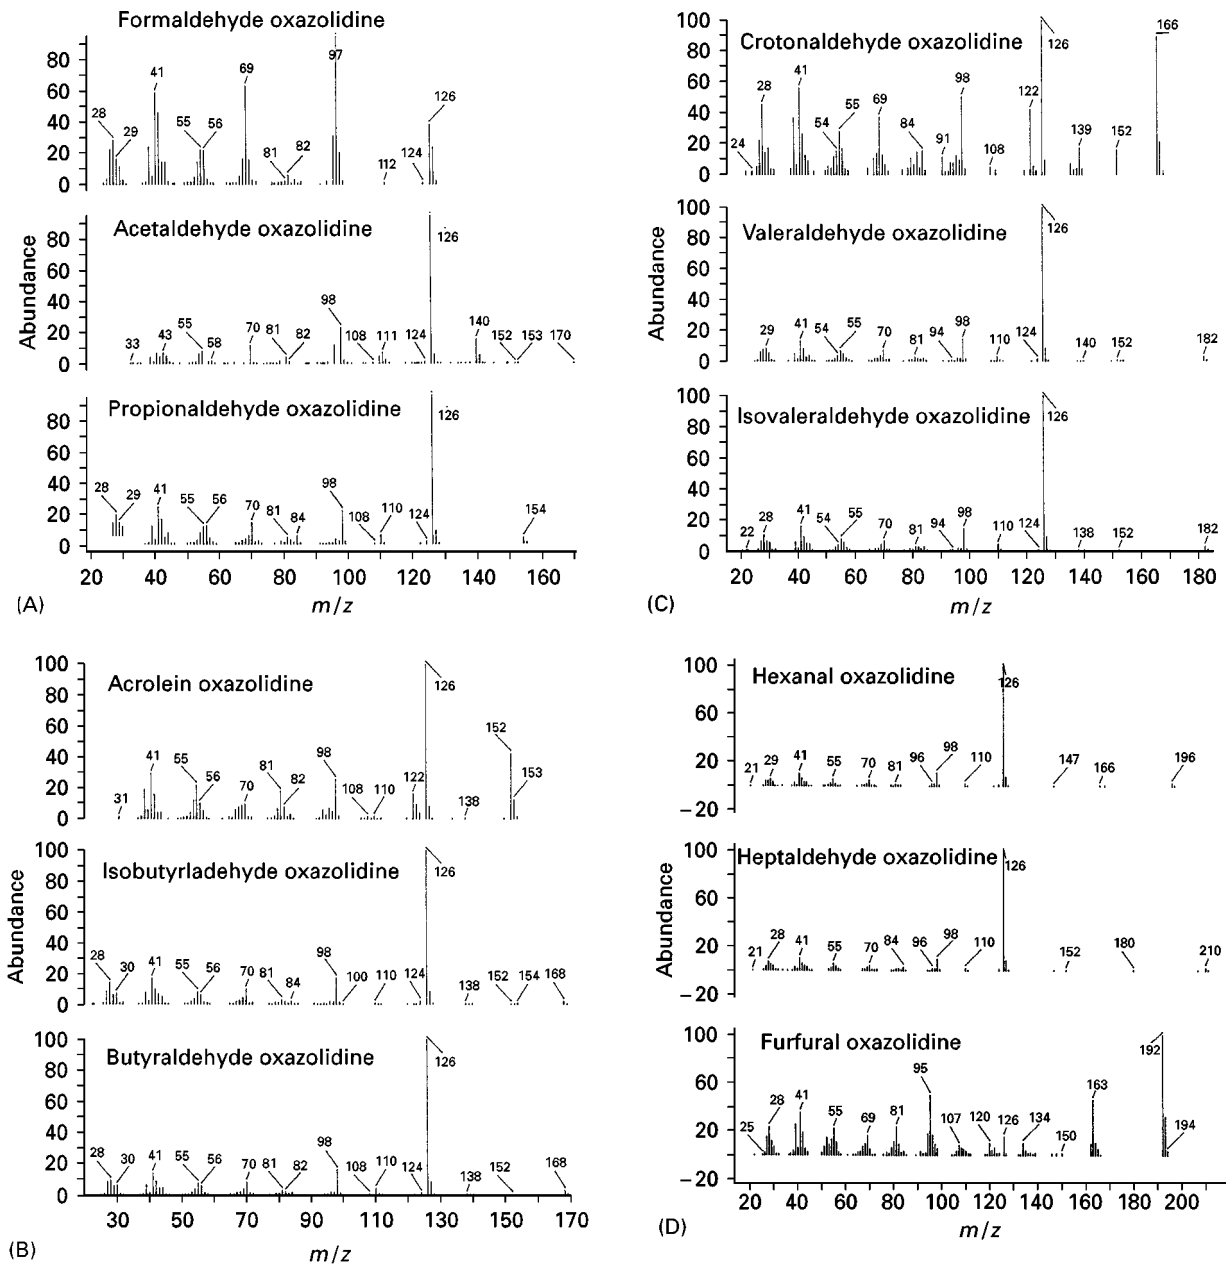

Figure 6 Determination of multiple aldehydes as their derivatives with 2-hydroxymethylpiperidine. Individual reference spectra using a 70 eV HP 5970 mass selective detector at 20–400 a.m.u. scan (30 m DB-1 column).

polluted air, or in ventilation studies (3700 for benzene, 3702 for ethylene oxide and 3701 for trichloroethylene using a PID, 6603 for carbon dioxide (TCD) and 6602 for sulfur hexafluoride (ECD)). In all cases these methods require samples to be collected in bags before analysis. Portable gas chromatographs have the advantage of near real-time response, which can be combined with observation of the work activity, for example by video monitoring, to gauge the effect of different work practices and control measures. Other applications include exhaled

breath analysis, measuring the penetration of organic chemicals through protective clothing, providing assurance of safe entry into confined spaces, and monitoring at hazardous waste sites and spills.

The Future

Traditional occupational hygiene sampling and analysis is already facing problems with sensitivity. As an example one can cite the NIOSH method for acrylonitrile. The NIOSH recommended exposure

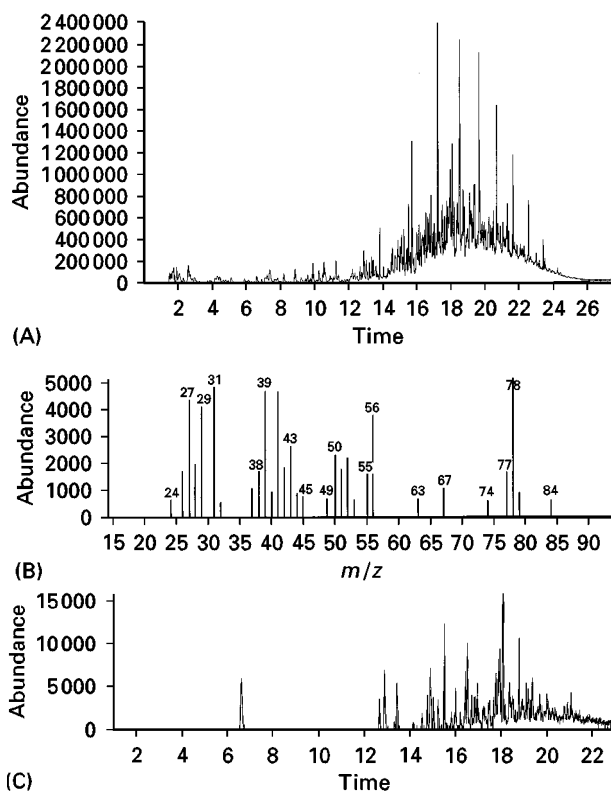

Figure 7 Air sample taken during asphalt paving operations analysed by TD-GC-MS (30 m DB-1 column). (A) Total ion chromatogram. Retention time of benzene is 6.6 min. (B) Mass spectrum of peak at 6.6 min showing the presence of butanal in addition to benzene. (C) Single ion chromatogram of m/z 78 benzene ion, eliminating other hydrocarbon interferences.

limit is 1 ppm, but the lower limit of the method is only slightly less at 0.7 ppm. Several other chemicals (e.g. benzene, 1,3-butadiene, vinyl chloride, ethylene oxide, etc.) have exposure limits close to the lower limit of their method range. In almost no case has an exposure limit been raised – the limit for benzene fell from 100 ppm (1946) to 25 ppm (1961) to 10 ppm (1978), and the current Threshold Limit Value® (TLV) is 0.5 ppm. Clearly the challenge is to find more sensitive methods of detection. One route is to use capillary chromatography, another is to use thermal desorption, and another is to use MS detection. The combination of all three can yield a sensitivity of around 0.1 ng per sample (equivalent to $0.03 \mu\text{g m}^{-3}$, or 0.1 ppb, for a 3-L sample). One problem with such a combination is the cost, which can be as much as ten times that of the analysis of a conventional charcoal tube by solvent desorption and GC-FID. The advent of fast GC systems may lower the cost by allowing a greater daily sample throughput.

Another issue for the field is the long turn-around time for the result (sometimes weeks). Detectors that can give on-site results are clearly preferable. With

micro-miniaturization (the ‘GC-on-a-chip’) this may become achievable in the near future.

Introduction

The analysis and characterization of lipids and waxes is of great importance in the food industry, pharmaceutical and cosmetic industry, in surfactant and detergent technology and in natural product research. Lipid analysts have always been on the forefront of developments in separation sciences and new techniques in chromatography have often been developed for the separation of lipids. The first application of gas chromatography, for instance, was the separation of fatty acids by James and Martin. Since then, all chromatographic techniques, including capillary gas chromatography (CGC), high performance liquid chromatography (HPLC), thin layer chromatography (TLC), capillary zone electrophoresis (CZE), micellar electrokinetic chromatography (MEKC), capillary electrochromatography (CEC) and supercritical fluid chromatography (SFC) have been applied to the analysis of lipids and also waxes which have similar physico-chemical characteristics.

It is not possible to give a complete overview of the possibilities and limitations of each of these techniques in comparison to supercritical fluid chromatography for these analytes. For a detailed description of the use of supercritical fluids in the analysis of oils, fats and waxes, we refer to a number of recently published books listed in the Further Reading. The possibilities of both capillary column supercritical fluid chromatography (cSFC) and packed column supercritical fluid chromatography (pSFC) in the analysis of lipids and related compounds will be illustrated. The experiences gained in the authors' laboratories over the years are summarized.

The Analytical Challenge

According to Christie, lipids can be defined as 'fatty acids and their derivatives, and substances related biosynthetically or functionally to these compounds'. This is a rather broad definition and covers a large

number of organic substances. In general, two lipid classes can be distinguished: simple lipids, yielding maximum two primary hydrolysis products after saponification; and complex lipids, yielding three or more hydrolysis products. Triglycerides, natural waxes and sterol esters are examples of simple lipids as they yield fatty acids and glycerol, fatty acids and an aliphatic alcohol or fatty acids and a sterol, respectively, on saponification. Phosphatidylethanolamine (a phospholipid) on the other hand, is a complex lipid as it yields glycerol, phosphoric acid, fatty acids and ethanolamine on saponification.

Lipid mixtures as they occur in natural fats, oils and waxes, are quite complex in their composition. A vegetable oil, for instance, mainly consists of triglycerides, but also contains free fatty acids, monoglycerides, diglycerides, sterols and sterol esters. Within these classes, different combinations of fatty acids are possible. All constituents contribute to the specific characteristics of the lipidic nature and are therefore important to analyse. No single analytical technique can, however, offer sufficient resolution power to separate all possible constituents. The different analytical techniques are therefore more complementary to each other than competitive. In the authors' laboratories, all these chromatographic techniques are therefore used to unravel the complexity of lipids.

The most important types of lipid analyses will be discussed below

Lipid Analysis

Separation of Fatty Acids

The type of fatty acids in fats, oil and waxes determine the physical (melting and boiling point, viscosity) and chemical (nutritional, fragrance) properties of the product. Therefore the determination of the fatty acid composition is often the first step in lipid characterization. Fatty acids need to be separated according to chain length, unsaturation and in some cases also according to the location of the unsaturation and the *cis/trans* configurations. For fatty acid profiling, CGC is the most widely used technique. The lipids are saponified and methylated into the fatty acid methyl esters (FAMES) before analysis. In comparison to CGC, no other technique can provide the same resolution per unit of time. Christie has given an overview of GC separations of fatty acids,

including the determination of *trans* isomers. For the analysis of *cis/trans* isomers, HPLC or SFC on silver-doped columns or argentation HPLC using a mobile phase containing silver ions offers, however, more powerful alternatives.

Analysis of Triglycerides

The analysis of oils and fats without saponification is becoming more and more important as it provides typical fingerprints for each oil and fat. The triglycerides need to be separated according to the number of carbon atoms in the fatty acid chains (carbon number, CN), separation). In a carbon number separation, the tristearin (SSS), triolein (OOO) and trilinolein (LLL) elute as one peak. CGC and cSFC can perform carbon number separations. In addition, it is also interesting to differentiate triglycerides according to unsaturation. For this type of analysis, CGC, HPLC, SFC and CEC have been used.

Profile of Mono-, Di- and Triglycerides

Additional information is also obtained by the analysis of mono- and diglycerides. This is especially important for the characterization of emulsifiers and food additives. Several emulsifiers are esters of fatty acids or fatty alcohols and glycerol, sorbitol, sorbic acid, tartaric acid or lactic acid. Also some polymer additives (slip and antistatic agents) are based on mono- and diglycerides. Often, only saturated fatty acids are used here, and a carbon number separation is sufficient. For this analysis, also CGC, HPLC and SFC can be applied.

Sterol and Sterol Ester Analysis

Sterol and sterol esters are minor constituents in oils and fats, but they are important for the quality of the products. Olive oil quality, for instance, can be monitored by the analysis of the sterol profiles. Sterols and sterol esters can be analysed by CGC, HPLC and SFC. Since the relative concentrations of sterolic compounds are low ($\text{ppm} = \text{mg kg}^{-1}$), prefractionation and enrichment are needed. Prefractionation can be done by classical techniques, such as saponification and liquid-liquid extraction, column chromatography or solid-phase extraction. Recently HPLC and SFC fractionation have been developed and the application of these techniques allows automation and on-line coupling to GC or GC-MS.

Phospholipids

Phospholipids form a special class of lipids. They are composed of a glycerol molecule substituted by one or two fatty acids and one additional polar group. The latter group can be choline (phosphatidylcholine

or lecithin), ethanolamine, serine or inositol. Phospholipids are very polar and ionic. None the less, the fatty acid chains give to phospholipids hydrophobic properties, making them very useful as emulsifiers. The analysis of intact phospholipids by CGC or SFC is not possible due to the limited temperature stability of the solutes. Phospholipids can only be analysed by HPLC or MEKC.

Other Oleochemicals

According to the definition of Christie, other organic compounds also containing fatty acid chains can be considered as lipids. This includes waxes (mostly esters between long-chain fatty acids and long-chain fatty alcohols), ethoxylated alcohols and glycolipids. Depending on the molecular weight, CGC, HPLC or SFC can be used.

In this article examples of separation by SFC are presented for the classes of organic solutes mentioned. An overview of the nomenclature used in lipid analysis is given in the Appendix.

Supercritical Fluid Chromatography

Supercritical fluid chromatography (SFC) is a separation technique similar to gas and liquid chromatography, but using a supercritical fluid as mobile phase. If a liquid or a gas is used above its critical temperature and pressure, it changes to a supercritical fluid. The characteristics of supercritical fluids are intermediate between those of gases and liquids. A supercritical fluid can be considered as a dense gas. The lower viscosity and high diffusivity in comparison to a liquid make supercritical fluids interesting for chromatography (faster stationary phase-mobile phase mass transfer), while the higher density, in comparison to a gas, allows the solubilization and transport of the solutes through the column at lower temperatures. Moreover, the solubilization power can be modified by changing the density through temperature and/or pressure. Selective extraction (supercritical fluid extraction) and gradient supercritical fluid chromatography are possible. The low critical temperature (31.3°C) and low critical pressure (72.9 atm), together with the low toxicity and high availability, make carbon dioxide (CO_2) the only practical usable supercritical fluid.

SFC was first performed using packed columns (pSFC). Only in the late 1980s did a first generation of dedicated SFC equipment become available. At that time, however, most SFC research work was focusing on capillary SFC (cSFC) using ultranarrow bore columns ($25\text{--}100 \mu\text{m i.d.}$), pure carbon dioxide as mobile phase, (in most cases) a syringe type pump,

a fixed restrictor and typically a GC detector (mostly FID). In this article, some examples of lipid analysis by cSFC separations will be given. In the mid 1990s, a second generation of SFC instruments became available. These instruments are more dedicated to pSFC and consist of a reciprocating supercritical fluid pump, a modifier pump (modifiers are not used with capillary columns), a variable restrictor and typically an HPLC detector. pSFC has been used more successfully than cSFC for lipid analysis. Detailed information on SFC theory and instrumentation is given in Anton and Berger. See also Further Reading.

Capillary Supercritical Fluid Chromatography for the Analysis of Lipids

The analysis of neutral lipids, such as triglycerides, is one of the first successful applications of cSFC. Using an apolar capillary column (SE-54, 5% phenylmethylsilicone), good carbon number separations are obtained. This is illustrated in Figure 1 with the analysis of palm kernel oil.

The triglycerides from CN 28 (combination of, for instance, two decanoic acid and one octanoic acid chain) to CN 54 (combination of three C₁₈ fatty acids) are separated in a 30 min analysis time. For most applications, cSFC and high-temperature capillary gas chromatography (HT-CGC) provide similar quantitative data. In HT-CGC, injection and column temperature programming are however, critical, and it has been observed that highly unsaturated triglycerides (trilinolein, trilinolenin) tend to polymerize in the column at 330–360°C. cSFC offers an advantage in this respect since the analysis temperature is much lower (100–150°C). In cSFC with FID detection, the response factors of saturated and unsaturated triglycerides are very similar and calibration is easy. Especially for the analysis of oils with a high degree of unsaturation (e.g. fish oils containing mostly 22:6 n-3 docosahexaenoic acid and 20:5 n-3 eicosapentaenoic acid), cSFC offers an advantage over HT-CGC although complete separation of the lipids is not possible without a multidimensional approach.

The analysis of triglycerides according to carbon number and unsaturation, is much more difficult. The highest resolution can be obtained using HT-CGC on a diphenyldimethylsilicone phase (more than 35% phenyl substitution, e.g. OV-17, HP-50 +). As demonstrated by Geeraert, the combination of the high efficiency of the capillary column with the high selectivity of the stationary phase at 330–360°C, gives a detailed triglyceride profile. cSFC using polar cyanopropyl silicone columns (25% cyano substitution,

Figure 1 Carbon number separation of palm kernel oil by cSFC. Column: 10 m × 100 μm i.d × 0.2 μm SE-54. Temperature: 170°C. Pressure programmed from 19 to 29 MPa in 30 min.

e.g. OV-225, SB cyano-25) has also been used for this separation. A separation according to unsaturation of a mixture of triglyceride reference compounds is given in Figure 2.

For natural lipid mixtures, this separation is, however, insufficient to resolve all possible fatty acid combinations and several co-elutions occur. The lower resolution obtained with cSFC in comparison to HT-CGC is a result of the strong dependence of the column efficiency on the supercritical fluid mobile phase velocity. Although a 10 m L × 50 μm i.d.

Figure 2 cSFC analysis of triglyceride standards on a polar column. Column: 10 m \times 100 μ m i.d. \times 0.1 μ m OV-225. Temperature: 150°C. Pressure programmed from 15 to 30 MPa at 0.5 MPa min⁻¹.

Figure 3 cSFC analysis of palm oil mono- (M), di- (D) and triglycerides (T). Column: 20 m \times 100 μ m i.d. \times 0.2 μ m SE-54. Temperature: 150°C. Pressure programmed from 15 to 25 MPa at 1 MPa min⁻¹, then to 30 MPa at 0.1 MPa min⁻¹.

column, theoretically should correspond to an effective plate number (N) 200 000, this efficiency cannot be applied in practice. The optimum linear velocity is only 0.2 cm s⁻¹ and this would result in a 83 min void time and a 15 hr analysis time for a solute with capacity factor $k = 10$. In practice, the narrow bore columns are used in cSFC at much higher velocities, resulting in effective plate numbers smaller than 10 000. This is even lower than in pSFC (see below). H.J. van Oosten has published a detailed study on the qualitative and quantitative aspects of cSFC for the analysis of triglycerides.

Another interesting application of cSFC is the separation of mono-, di-, and triglycerides. For GC analysis, the mono- and diglycerides need derivatization into the trimethylsilyl derivatives. With SFC, they can be analysed without derivatization. A typical chromatogram is shown in **Figure 3**.

Glycerol monopalmitate (M16), glycerol monostearate (M18), glycerol dipalmitate (D32), palmitoylstearyl glycerol (D34), glycerol distearate (D36) and the triglycerides are well separated according to their carbon number. For complex mono-, di- and triglyceride mixtures, such as some types of emulsifiers, the higher resolving power of HT-CGC is, however, needed.

cSFC has also been used for the analysis of waxes, sterols and sterol esters and ethoxylated alcohols. An example of a beeswax analysis is given in **Figure 4**.

The analysis of phospholipids by cSFC has also been described. For this analysis, the phospholipids are derivatized using diazomethane methylation (phosphoric acid group), acylation (amine or alcohol functionality) and/or demethylation (quaternary ammonium group). Using an apolar column, the phospholipids could be separated according to the carbon number. Group-type separations of phospholipids could not be realized by cSFC.

Figure 4 cSFC analysis of beeswax. Column: 10 m \times 50 μ m i.d. OV-1. Temperature: 100°C. Pressure programmed from 10 MPa (7.5 min) to 30 MPa at 0.4 MPa min⁻¹.

Although interesting separations could be obtained, cSFC is not widely used in routine laboratories for lipid separations. The main restriction is the robustness of the instrumentation. Column installation, restrictor maintenance and injection problems make state-of-the-art cSFC insufficiently robust for routine work.

Packed Column Supercritical Fluid Chromatography for the Analysis of Lipids

A few years after the introduction of cSFC, a second generation of SFC instrumentation was introduced on the market. This equipment was primarily dedicated to pSFC and the performance was based on specially designed reciprocating supercritical fluid pumps and new restrictor technology. The use of modifiers extended the applicability of SFC and the variable restrictors are much more robust than fixed restrictors (used in combination with capillary columns). The same performance as standard HPLC equipment in terms of repeatability, stability and robustness was realized.

Interesting pSFC separations of lipids can be made on conventional HPLC columns. Octadecyl silica (ODS), the most universal HPLC phase (reversed phase HPLC) can also be used in pSFC. The term 'reversed phase supercritical fluid chromatography (RP-SFC)', however, we consider inadequate, due to either the adsorption of carbon dioxide as a high-density layer or adsorption of the polar modifier on the stationary phase surface. Consequently, separations are actually achieved according to a normal phase mechanism. Therefore we prefer the term 'pSFC-ODS' for separations in supercritical conditions realized on ODS stationary phases rather than RP-SFC.

Triglycerides are separated on ODS columns according to the carbon number, but the presence of double bonds reduces retention. Separation of triglycerides by means of non-aqueous reversed phase high pressure liquid chromatography (NARP-HPLC) can be realized according to the equivalent chain number (ECN), whereby $ECN = CN - [2 \times NDB]$ in which CN is the carbon number and NDB the number of double bonds.

Separation of triglycerides using pSFC-ODS is achieved according to the separation number (SN), whereby the separation number equals carbon number (CN) minus the number of double bonds (NDB), thus $SN = CN - NDB$.

An example of such a separation is given in Figure 5 for the analysis of peanut oil. In this separation, the peak at SN 48 corresponds to LLL and

Figure 5 pSFC-ODS fractionation of triglycerides from peanut oil. Column: Adsorbosphere C18 (25 cm \times 4.6 mm i.d. \times 5 μ m) serially coupled to Shandon ODS Ultrabase (25 cm \times 4.6 mm i.d. \times 5 μ m). Temperature: 25°C. Flow rate: 2 mL min⁻¹. Modifier: methanol 2.5%, isocratic. Pressure: 150 bar. Detection: UV 210 nm. Injection volume: 5 μ L. Sample concentration: 100 mg mL⁻¹.

PLL, SN 49 corresponds to OLL and PLO and SN 50 to OLO + SLL + POO.

In comparison to HPLC, pSFC has the advantage of a much lower pressure drop across the column due to the lower viscosity of the mobile phase. While the efficiency of the column in pSFC is equal to the efficiency in HPLC, serial coupling of several columns is feasible in pSFC. This results in much higher total effective plate number ($N = \text{sum of plate number of each column}$). One of the best packed column SFC separations of triglycerides has used seven 12-cm columns in series (84-cm column length in total, 5- μ m ODS packing material, $N = 200\,000$). A typical separation is shown in Figure 6. In comparison to the separation shown in Figure 5, this chromatogram exhibits increased resolution. Both the efficiency and selectivity are increased in comparison to the SN separation shown in Figure 5. Group separation is made this time according to the ECN number, exactly as in NARP-HPLC. Resolution within a group is illustrated by the separation of PLL, POL_n, OLL and OOL_n, all characterized by ECN 44.

The change in the elution order can be explained either by the use of a more polar modifier (methanol-acetonitrile mixture) and by the use of subcritical elution conditions (16°C).

Another very interesting separation is obtained by pSFC using a silver-doped stationary phase. On this stationary phase, separations according to unsaturation and to some extent according to the geometrical configuration are obtained. The separation mechanism can be explained by two processes: (1) the over-

Figure 6 pSFC-ODS separation of triglycerides from rapeseed oil. Column: Hypersil ODS (12 cm \times 4.6 mm i.d. \times 5 μ m) seven columns serially. Temperature: 16°C. Flow rate: 3 mL min⁻¹. Modifier: acetonitrile-methanol mixture 9 : 1, 6%, isocratic. Pressure: 100 bar. Detection: UV 210 nm. (Reproduced from Leselier E and Tchapl A (1996) Mise au point de l'analyse des triglycerides en chromatographie subcritique sur colonnes remplies. *Proceedings du 3^{eme} Colloque sur les Fluides Supercritiques, Grasse, France*, pp. 115-126.)

lapping of the π orbitals belonging to the unsaturated site of the solute with the 5s orbital of the silver ion and (2) the interaction between an antibonding π^* orbital of the unsaturated site of the solute with a 4d-filled orbital of the silver ion.

Figure 7 pSFC-SI separation of triglycerides in sunflower oil. Column: Silver-loaded Nucleosil 100-5 SA (25 cm \times 4.6 mm i.d. \times 5 μ m). Temperature: 65°C. Flow rate: 1 mL min⁻¹. Modifier: acetonitrile-isopropanol mixture 6 : 4, programmed from 1.2% (2 min) to 7.2% (28 min) at 0.3% min⁻¹, then to 12.2% at 0.54% min⁻¹, 2.5%. Pressure: programmed from 150 bar (2 min) to 300 bar at 1.5 bar min⁻¹. Detection: UV 210 nm. Injection volume: 5 μ L. Sample concentration: 100 mg mL⁻¹.

Recently, stable silver ion HPLC columns could be made by using silica-based cation exchange columns as support for silver ions. The ions are linked to the silica support via ionic bonds to phenylsulfonic acid groups chemically bonded to the silica.

Such columns have been successfully used in our laboratory both in HPLC and in pSFC. In pSFC, excellent triglyceride separations are obtained. This is illustrated in Figure 7, showing the analysis of sunflower oil. Within each group with the same number of double bonds, an additional separation according to chain length is observed. When solutes are characterized by the same number of double bonds, a higher retention corresponds to a higher carbon number, e.g. PLL elutes before SLL. Finally, an additional separation is obtained between lipids with the same number of double bonds and carbon number, but containing a different number of unsaturated fatty acids. Thus, SLL, containing only two unsaturated fatty acids elutes before OOL, which contains three unsaturated fatty acids.

Figure 8 pSFC-SI separation of a standard mixture of geometrical isomers of fatty acids as methyl esters (FAMES). Column: Silver-loaded Nucleosil 100-5 SA (25 cm \times 4.6 mm i.d. \times 5 μ m). Temperature: 80°C. Flow rate: 2 mL min⁻¹. Modifier: acetonitrile-isopropanol mixture 6 : 4, programmed from 0.5% (15 min) with a gradient of 0.1% min⁻¹, 2.5%. Pressure: 250 bar. Detection: UV 210 nm. Injection volume: 5 μ L.

Figure 9 pSFC-SI separation of fatty acids as phenacyl esters (FAPes) from sardine oil. Column: Silver-loaded Nucleosil 100-5 SA (25 cm \times 4.6 mm i.d. \times 5 μ m). Temperature: 80°C. Flow rate: 2 mL min⁻¹. Modifier: acetonitrile–isopropanol mixture 6 : 4, programmed from 1% (2 min) to 41% at 0.2% min⁻¹. Pressure: 250 bar. Detection: UV 254 nm. Injection volume: 5 μ L.

As can be deduced from Figures 5 and 7, the pSFC-ODS separation and the silver ion pSFC separations are complementary to each other. Very detailed triglyceride analysis can therefore be obtained by using a multidimensional approach. First a SN separation is obtained on an ODS column. The fractions of different SN number are collected and re-analysed by silver ion SFC. pSFC is especially suitable for fraction collection, since the largest part of the mobile phase is a gas after decompression and concentrated fractions are obtained.

On silver-doped stationary phases, a separation of geometrical isomers of fatty acids can also be achieved. In **Figure 8**, a standard mixture of C16:1 *cis-trans*, C18:1 *cis-trans* and C18:2 *cis-trans* fatty acid methyl esters (FAMEs) was separated. In comparison to cSFC, detection in pSFC is normally done by UV detection, because of the use of modifiers which are not compatible with FID detection. In comparison with HPLC, pSFC allows the use of low wavelengths. In the case of fatty acids, derivatization of the carboxyl group with phenacyl bromide (2-bromoacetophenone) allows detection at higher wavelengths which results in higher sensitivity. **Figure 9** shows the separation of fatty acids from sardine oil as phenacyl ester derivatives (fatty acid phenacyl esters, FAPes) on a silver-doped stationary phase.

Another very interesting detector for pSFC is the evaporative light-scattering detector. This detector is especially useful in lipid analysis since the response

factors are less dependent on the number of double bonds and very similar for saturated and unsaturated lipids.

Packed-column SFC has also been applied to other oleochemicals including sterols, sterol esters and waxes. Fractionation of free sterols from the complex matrix of vegetable oils can be achieved in a short analysis time by pSFC on an aminopropyl silica-gel (APSG) column as shown in **Figure 10**. This separation, in combination with collection of the sterol

Figure 10 Isolation of the sterolic fraction in sunflower oil by pSFC. Column: Aminopropyl silica-gel APSG (20 cm \times 4.6 mm i.d. \times 5 μ m). Temperature: 70°C. Flow rate: 2 mL min⁻¹. Modifier: methanol 10% isocratic. Pressure: 150 bar. Detection: UV 210 nm. Injection volume: 5 μ L. Sample concentration: 10%.

fraction and subsequent CGC-MS analysis, was used for the characterization of vegetable oils.

Future Outlook

The next step in the use of pSFC in the analysis of oils, fats and waxes is interfacing the technique to spectroscopic detectors such as mass spectrometry or nuclear magnetic resonance spectrometry.

Supercritical fluid chromatography interfaced to mass spectrometry (SFC-MS) has already become a valuable technique in the hands of specialists. State-of-the-art pSFC-MSD interfacing has recently been reviewed by Combs *et al.*

The separation of triglycerides in vegetable oils by interfacing pSFC on a silver-doped stationary phase to atmospheric pressure chemical ionization-mass selective detection (APCI-MSD) has been described. The coupling was made using a commercially available LC interface, without any modification. No loss of resolution was noted, while sensitivity was 100 times higher compared to UV detection. The molecular $[M-H]^+$ ions could be elucidated in the mass spectra. However, the lower the degree of unsaturation, the more fragmentation occurred. Elucidation of the position of the fatty acids on the glycerol backbone (POP versus PPO for example) was feasible.

The combination of pSFC with NMR also offers a bright perspective. The mobile phase, mainly consisting of carbon dioxide, does not interfere with the 1H spectra. pSFC-NMR has been reviewed by Albert.

Last, but not least, the preparative-scale features of SFC are worth mentioning. Process-scale pSFC has been applied for the production of high purity ω -3 fatty acids and their ethyl esters from fish oils. A preparative pSFC approach for the production of pure eicosapentaenoic acid has been described, highlighting again its tremendous economic impact.

Appendix: Nomenclature in Lipid Analysis

For carbon number separations, triglycerides are coded as Tnn, indicating a triglyceride with a total of nn carbon atoms in the fatty acid chains (sum of three fatty acids). T54 can thus be tristearin, triolein or another combination of three C_{18} fatty acids or C_{16} , C_{18} , C_{20} . In the same way, monoglycerides are indicated as Mnn with nn the number of carbon atoms in the fatty acid and diglycerides are indicated by Dnn, with nn the sum of the carbon atoms in the two fatty acid chains.

For detailed separations, the triglycerides are coded XYZ, indicating the fatty acid substitutes in the molecule. Abbreviations for common fatty acids are listed

Table 1 Abbreviations used for common fatty acids

Abbreviation	Fatty acid name	Carbon number : number of double bonds
P	Palmitic acid	16 : 0
S	Stearic acid	18 : 0
O	Oleic acid	18 : 1
L	Linoleic acid	18 : 2
Ln	Linolenic acid	18 : 3

Table 2 Shorthand designation used for common fatty acids

Systematic name	Trivial name	Shorthand designation
<i>cis</i> -9-Tetradecenoic acid	Myristoleic acid	C14 : 1 (n-5)
<i>cis</i> -9-Hexadecenoic acid	Palmitoleic acid	C16 : 1 (n-7)
<i>cis</i> -6-Octadecenoic acid	Petroselinic acid	C18 : 1(n-12)
<i>cis</i> -9-Octadecenoic acid	Oleic acid	C18 : 1 (n-9)
<i>cis</i> -11-Octadecenoic acid	<i>cis</i> -Vaccenic acid	C18 : 1 (n-7)
<i>cis</i> -9-Eicosenoic acid	Gadoleic acid	C20 : 1 (n-11)
<i>cis</i> -11-Eicosenoic acid	Gondoic acid	C20 : 1 (n-9)
<i>cis</i> -13-Docosenoic acid	Erucic acid	C22 : 1 (n-9)
<i>cis</i> -15-Tetracosenoic acid	Nervonic acid	C24 : 1 (n)

in Table 1. SLO, for instance, corresponds to a triglyceride with a stearin-linolein-olein fatty acid combination.

For detailed separations of fatty acids, each analyte is identified as Cmm : p (n - q), where mm corresponds to the number of carbon atoms in the fatty acid molecule, p is the number of double bonds and q is the number of carbon atoms from the double bond in the terminal region of the molecule. C 18:1 (n-9), for instance, is 9-octadecenoic acid (one double bond in 9 position from terminal side of molecule). The relation between the systematic name, the trivial name and the short designation mentioned above for common fatty acids is given in Table 2.

Introduction

Over the past few years, there have been several advances in the use of new sample-preparation strategies prior to chromatographic analyses. These include supercritical fluid extraction (SFE), solid-phase microextraction (SPME) and accelerated solvent extraction (ASE). Each of these techniques is relatively new and will be used in more analytical strategies. SPME, for example, stands out in the realm of sample preparation in that the technique is solventless. ASE is also particularly exciting since the technique represents a modern version of long-established Soxhlet extractions. Therefore, by elevating temperatures and pressures to keep the liquid solvent from vaporizing, ASE approaches can be thought of as a 'universal' sample-preparation tools. The advantage of SFE is the fact that a supercritical fluid (i.e. carbon dioxide)

is utilized with its blend of liquid and gaseous properties to achieve selective extraction of target analytes without major interference (depending on the sample). Of these three techniques, only SPME and SFE can be considered selective tools and they are also the only ones that can be interfaced directly to a chromatograph. The discussion in this article will focus on the use of SFE as a viable and selective strategy for sample preparation.

SFE continues to evolve as it is applied to a more and more diverse range of sample matrices. In the early years, much emphasis was placed on using SFE for environmental methods but, this has now blossomed into the wide application of SFE for food and agricultural analyses, polymer characterization, and pharmaceutical assays.

One of the distinct advantages of SFE (besides the physical properties of liquid-like density, gas-like viscosity, no surface tension and intermediate diffusivity) is the ability to directly couple the extraction effluent from a sample matrix to an analytical chromatograph for quantitative or qualitative determination.

In analytical chemistry, sample preparation is often the most error-prone step, requiring arduous and sometimes lengthy procedures before the actual sample can be analysed. SFE directly addresses the problem and provides analysts with the option of directly coupling the sample preparation procedure to the various forms of column chromatography to effectively achieve the analytical objectives. An added advantage is that the nature of the online interfacing of SFE does not exclusively limit the use of the chromatographic instrument to only SFE sample introduction. The flexibility exists whereby the analyst can use SFE in an offline collection mode as well as online. Offline SFE gives the analyst the most capability for manipulation in method development and analytical characterization, since the extracted effluent can be collected and then taken to any analytical instrument (i.e. GC, LC, SFC, MS, NMR, IR, UV).

This chapter will describe the use of online SFE/GC and SFE/SFC in terms of theory of operation, interface mechanics, instrumentation and application examples. In addition, some examples of selectivity enhancements in SFE will be described.

On-line Interfacing Mechanics

A generalized scheme of online SFE is shown in **Figure 1**. A SFE system delivery pump compresses the primary extraction fluid (usually carbon dioxide) and solubilizes the analytes from a matrix which is contained in a heated extraction vessel. These solubilized

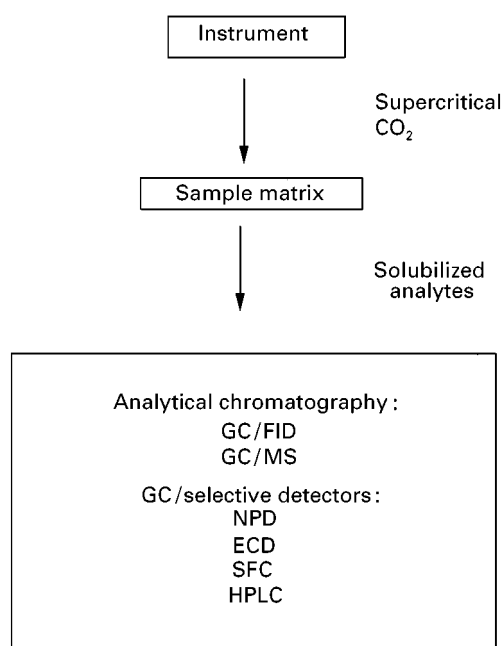

Figure 1 Generalized scheme for online SFE.

analytes are then transferred online to an analytical chromatograph (i.e. GC, SFC or HPLC). The transfer line is used to control the volume of supercritical fluid that is flowing through the sample matrix. Depending on the analytical need, there is considerable flexibility obtainable when interfacing SFE online to a capillary GC. For many determinations, flame ionization and mass spectrometric detectors have been employed. However, it is also possible to utilize the more selective and sensitive detectors such as nitrogen-phosphorus and electron-capture detectors, depending on the application. In all of these cases, the detectors have a very low response to CO₂, depending for the most part on the impurities present in the commercial supply of CO₂. Most of the published online SFE/GC applications have utilized capillary columns ranging from 0.20-mm internal diameter to 0.53-mm internal diameter and have encompassed the full range of GC stationary phase coatings. To date, there have been no reports of SFE fluids stripping off capillary column stationary phase coatings after online interfacing.

As a means of sample introduction to GC, online SFE presents itself as an alternative to other means of sample introduction such as headspace, purge and trap, thermal desorption, pyrolysis, and even conventional syringe injection. **Figure 2** shows a comparison of online SFE/GC with conventional syringe injection using eucalyptus leaves and a fuel-contaminated sediment sample. The two modes of online SFE/GC, namely, split and on-column, were utilized. As can be seen, the GC peak shapes and amplitudes were comparable for online SFE and conventional syringe injection. A noticeable difference in the chromatograms is the absence of a solvent peak from the flame ionization detector. In comparison to headspace, purge and trap and thermal desorption, SFE has the potential to encompass a wide range of volatile to non-volatile analytes, depending on the sample and the extraction conditions that solubilize the entire sample (e.g. certain polymer matrices).

Figure 3 shows a generalized schematic diagram of a typical online SFE/GC. A typical procedure for performing online SFE/GC involves first loading (usually weighing out) a small sample into an extraction vessel, depending on analyte sensitivities and analytical objectives. After weighing out a sample, the end caps of the vessel are tightened and the extraction cell is placed in the extraction oven. After pressure and thermal equilibration for the charged extraction vessel in the static mode (closed outlet of vessel to CO₂ flow), an electronic high-pressure switching valve changes position and shifts the extraction to the dynamic mode (opened outlet of the vessel for flow) transferring the extraction effluent through a heated

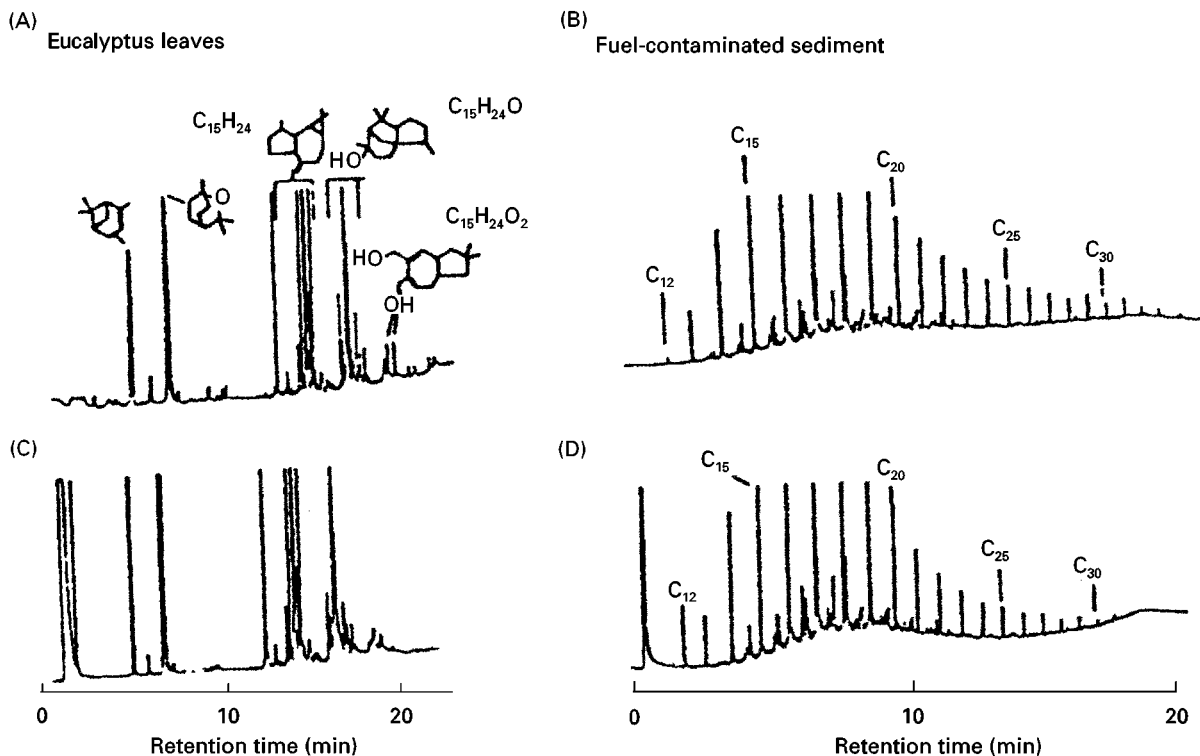

Figure 2 Comparison of chromatographic peak shapes obtained using (A) on-column SFE/GC and (B) split SFE/GC with (C) conventional on-column and (D) split GC injections of methylene chloride extracts. Reproduced with permission from Hawthorne SB *et al.* (1989) *Journal of Chromatographic Science* 27: 347–354 and Hawthorne SB *et al.* (1990) *Journal of Chromatographic Science* 28: 2–8.

transfer line (made of fused silica or stainless steel) directly into a capillary GC injection port as shown in **Figure 3**.

The flow through the transfer line is regulated by restricting (crimping) the stainless-steel line or by using small inner-diameter fused silica. The decompressed CO_2 , gaseous flow typically ranges from 35 to 300 mL min^{-1} depending on the extraction vessel void volume (i.e., sample size). To achieve highly efficient extractions, three to five void volumes of

supercritical fluid need to be flushed through the charged extraction vessel. The decompressed gas flow into the GC needs to be set at each extraction pressure setpoint to achieve efficient extractions.

Two modes of online SFE/GC exist, namely split SFE/GC and on-column SFE/GC. **Figure 4** is a pictorial representation of what is occurring during SFE introduction into GC. During split SFE/GC, the solubilized analytes exit the extraction vessel through a stainless steel ($1/32$ in \times 0.007 in internal diameter) transfer line which is inserted directly through the septum and septum cap of an unmodified split/splitless capillary injection port. The supercritical fluid state is maintained until it reaches the tip of the transfer line (i.e. restrictor) and decompresses directly inside the heated injection port. So therefore, in theory, the analytes are purposely not allowed to fall out of solution until they are completely transferred to the GC injection port. The heat of the injection port aids in minimizing the expansive cooling of the supercritical fluid upon decompression. After decompression, the analytes vaporize inside the heated injection port, mix with the GC carrier gas, are homogenized inside the existing glass split-injection port liner, and decompressed gaseous CO_2 (and

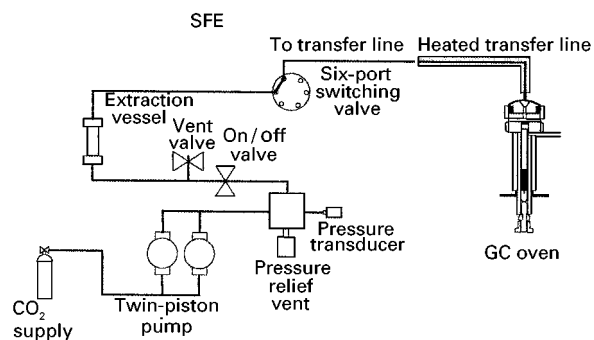

Figure 3 Generalized online SFE/GC interface: schematic diagram.

Figure 4 Pictorial representation of online SFE/GC interfacing. Left, split SFE/GC; right, on-column SFE/GC.

analytes) flows out of the split vent during the dynamic extraction transfer mode. This is reproducible and potentially quantitative since the split ratio does not change from run to run. The development of temperature-programmable injection ports has allowed even further advances in focusing techniques after SFE deposition.

During on-column SFE/GC, the solubilized analytes exit the extraction vessel through a fused silica transfer line (10–50 μm internal diameter) which is inserted directly into an on-column capillary injection port. All of the solubilized analytes and decompressed gaseous CO_2 enter the GC capillary column, maximizing the sensitivity of an analysis (analogous to on-column syringe GC injection). For this reason, however, the fused silica transfer line needs to be physically removed after the dynamic extraction transfer mode since the decompressed CO_2 would essentially become the GC carrier gas and possibly extinguish a flame ionization detector. In split SFE/GC, the transfer line normally remains inserted in the injection port during the entire analytical run. The majority of published applications have been accomplished using online split SFE/GC. In general, split SFE/GC is better suited for generalized method development and characterization of a variety of different samples.

For both online split and on-column SFE/GC, the stationary phase of the GC capillary column is

responsible for focusing the extracted analytes. Depending on the volatility range of the analytes, additional cooling (i.e. a cooled injection port) may be necessary to achieve sharp chromatographic peak shapes. This can be accomplished with a temperature-programmable injection port or by cooling the entire GC oven. An example of this is shown in Figure 5, demonstrating the effect of the cryogenic trapping temperature on the SFE/GC characterization of BTEX and n-alkanes from Tenax-TA. During the extraction, the GC capillary column was maintained at -50 , -25 , 5 or 25°C . After each extraction the GC oven was heated to 40°C at $50^\circ\text{C min}^{-1}$ and then at 8°C min^{-1} to 300°C . The lower the setting of the GC oven temperature, sharper chromatographic peak shapes were obtained for the earlier eluting (more volatile) species. Maintaining the GC oven temperature at -50°C yielded the best chromatographic performance. In practice, at temperatures below -50°C , plugging of the transfer line occurs because of the freezing of the decompressed CO_2 inside the capillary column. The duration of the dynamic extraction transfer mode is usually the same as the duration of the initial (cryogenically cooled) temperature of the GC oven. After the dynamic transfer, normal GC temperature programming is performed and analytical GC results are obtained. This same routine can be applied if a temperature-programmable injection port is available.

Figure 5 Effect of cryogenic trapping temperature on the online SFE/GC/FID analysis of rosemary. Reproduced with permission from Burford MD and Hawthorne SB (1994) *Journal of Chromatography A* 685: 79–94.

Figures 6–8 represent several example applications displaying the advantages of utilizing online SFE/GC. In each of these cases, flame ionization detection (FID) was utilized for the target analyte characterizations. In Figure 6, a rapid field survey was conducted using online SFE/GC to determine the carbon number range for total petroleum hydrocarbons (TPH) in soil. A fouled isocracker catalyst from a refinery was analysed and the aromatic component contamination was determined using online SFE/GC-MS, shown in Figure 7. In Figure 8, orange oil was spiked into an extraction vessel filled with hydromatrix (i.e., pelleted diatomaceous earth) and rapidly extracted. In this, online SFE with CO₂ as the extraction fluid was invaluable since early eluting components in the orange oil were not overwhelmed by the response from classical liquid solvents.

Selectivity in On-line SFE/GC

Compared to conventional liquid extractions like Soxhlet or ASE, a distinct advantage of SFE is the ability to tune the operational extraction parameters to achieve the selective extraction of certain analytes from a complex sample. An obvious approach in controlling SFE selectivity is by varying extraction temperatures and pressures. These parameters directly control extraction densities which in turn affect the threshold solubilities or mobilities of specific analytes. Certain classes of compounds, in theory, have distinct threshold solubilities. For example, a qualitative SFE/GC characterization of polynuclear aromatic hydrocarbons (PAHs) at different extraction pressures has been performed. In going from low to high SFE pressures, a noticeable difference, despite some overlap, was experienced in the distribution of the chromatograms by retention time and peak amplitude, indicating the potential for online SFE class fractionation. At 80 atm, two-ring, alkylated two-ring, three-ring, and lower alkylated three-ring PAHs are extracted. At 125 atm, the extracted fraction consists of alkylated three-ring, four-ring and some alkylated four-ring PAHs. At the highest pressure, 200 atm, alkylated four-ring and larger PAHs are extracted. The ability to tune selectivities by varying SFE densities is not only dependent on the target analytes of interest but also on the sample matrix. This is due to the contributions of other SFE mechanisms besides solubility, namely diffusion and adsorption effects.

Another means of enhancing SFE selectivities and efficiencies is by the use of modifiers such as methanol. These modifiers enhance extraction efficiencies by affecting solubilities, diffusion rates or surface adsorption, depending on the sample matrix and the target analytes. In SFE, modifiers can be added to the primary supercritical fluid by using dual-supply pumps or by uniquely adding a specific volume of modifier directly to the extraction vessel with the sample. In online SFE/GC, depending on the modifier identity, the modifier may elute in the GC as a discrete peak together with the extracted analytes. Depending on the modifier concentration, a retention gap or thick-film capillary column may be needed to separate the large (solvent-like) modifier peak and focus the target analyte peaks. Some modifiers such as formic acid, do not have an appreciable response with conventional flame ionization detectors. Figure 9 shows the results for the online SFE/GC-FID characterization of sucrose esters in ground tobacco with and without BSTFA (*N,O*-bis(trimethylsilyl)trifluoroacetamide) as a derivatizing agent. In this case, BSTFA was added for derivatization during the

Figure 6 Online SFE/GC determination of total petroleum hydrocarbons in soil (diesel fuel range).

extraction but also functioned as a modifier as well. It is clearly evident when comparing the two chromatograms that the BSTFA derivatized the sucrose esters during the SFE step, and therefore improved the detectability of these compounds. **Table 1** lists another example of the use of modifiers in online SFE/GC to enhance the extraction efficiency of selected aromatics analytes from a petroleum residue. The percentage recoveries for the selected aromatics were low when using only supercritical CO_2 for SFE and were distinctly enhanced when different modifiers were added to the residue in the extraction vessel. A period of static equilibration was required under the outlined extraction conditions, for the full modifier effect. Moreover, by varying only the modifier identities (keeping the modifier concentrations con-

stant at 7%) obvious differences in percentage recoveries were obtained. Propylene carbonate and benzene achieved comparable efficiencies as opposed to the lower efficiencies obtained with methanol for this particular sample matrix and analyte.

Further selectivities can be obtained in online SFE/GC by the use of alternative supercritical fluids such as sulfur hexafluoride (SF_6) and nitrous oxide (N_2O). The use of these supercritical fluids in online SFE has been limited compared to CO_2 , but has demonstrated certain distinct advantages due to their physical properties.

Different adsorbents can also be used to selectively immobilize interfering analytes from a complex sample before analytical determinations. Adsorbents, such as Celite, sodium sulfate, magnesium sulfate,

Figure 7 SFE/GC of a fouled isocracker catalyst. Reproduced from Hawthorne SB.

Figure 8 Online SFE/GC characterization of Orange Oil.

Florisil, alumina, polyurethane foam, and hydromatrix (diatomaceous earth) have been used in online SFE applications to remove interfering analytes and water. An obvious disadvantage could be situations where target analytes are irreversibly bound to the adsorbents or where interferences are introduced by the adsorbent. Adsorbents have been utilized by mixing them with proportionate amounts of sample before introduction into an extraction vessel or by utilizing two extraction vessels in series, the first containing the sample, and the second containing adsorbent before the GC.

On-line SFE/SFC

Supercritical fluid chromatography (SFC) has been used widely as an analytical tool for the separation of relatively nonpolar, thermally unstable and high molecular weight solutes beyond the range of GC. The physical properties of supercritical fluids have unique characteristics to solve many problems, where both GC and high performance liquid chromatography (HPLC) fail. The online modes of SFE/SFC have several distinct advantages that are beyond the scope of either technique when used separately. These

1,2,4-Trimethylbenzene	99%	87%	98%	38%

^aSFE: 300 mg of petroleum residue, 425 atm, 65°C, 10 min static, 7 min dynamic.

^bGC: 30 × 0.25 mm I.D. DB-1, inlet programmed from 0°C to 300°C at 600°C min⁻¹, 30°C (7 min) to 325°C at 7°C min⁻¹.

advantages are (a) trace analysis capability, (b) preparation with minimal sample contamination, (c) higher reproducibility, (d) increased productivity, and (e) online automation of the sample preparation step with the chromatographic analysis step. In the online mode, a high pressure extraction cell and the extracted components are trapped or focused in a device prior to SFC analysis. SFE/HPLC has been practised by several groups but has been demonstrated in only limited applications. This is largely due to the fact that coupling to GC and SFC is much more straightforward compared to coupling to HPLC. One main limitation is the fact that the LC mobile phase needs to be gas-free since bubbles can cause problems for most LC detectors.

SFE/SFC Interface Mechanics

The arrangements in these hyphenated techniques usually involved several valves, one or two pumps and ovens. A simple approach has been applied to perform online SFE/SFC in both static (after pressurization of the extraction cell, extraction is allowed without passing any flow of supercritical fluid through the cell) and dynamic (after pressurization of the extraction cell, supercritical fluid continuously flows through the outlet of the cell) modes. Another method which has been used frequently for online SFE/SFC is the use of a second supply pump to pressurize the extraction vessel and the sample while the first supply pump is used solely to obtain chromatographic separation. Applying the second pump for extraction usually creates less technical problems and more freedom since both modes of extraction can be achieved and the chromatographic system is independent of the extraction system.

Other approaches that have been used to perform online SFE/SFC have been systems with multiple switching valves that permit collection of the extrac-

ted sample in a cooled adsorbent trap. After extraction and collection, the valves are switched and the cryogenic trap temperature is increased. By switching the valves and heating the trap, the supercritical fluid carries the extracted materials onto the analytical column. **Figure 10** shows an online SFE/SFC system which uses a cryofocusing region to collect the extracted material. In this system, the selector valve is first placed to the column position. During this period the temperature of the cooled region is adjusted to a desired level. Next, the valve is switched to the extraction vessel where the supercritical fluid of the desired density removes the extracted material from the region. During the decompression of CO₂, at the tip of the restrictor, the selector valve is switched to the column position and the supercritical fluid moves the analytes from the trap flow to the column. Meanwhile, the trap is also heated to the necessary temperature to help move the analytes onto the column.

Another system which uses a cryofocused trap to perform online high pressure SFE/SFC is shown in **Figure 11**. The system is comprised of three different valves (ten-port/two-position, five-port/four-position and four-port/two-position selector valves) and a zero dead-volume tee. During the extraction period, the mobile phase from the pump enters the tee. Tubing from one outlet of the tee leads the mobile phase to the injector valve for use only in conventional SFC applications. Tubing from the other outlet of the tee goes through the ten-port valve to the extraction vessel and then into the five-port selector valve. From the ten-port valve, the extracted analytes are held at a specified extraction temperature with industrial grade, dry carbon dioxide. All of the extracted material is then collected in the cryofocusing trap. The decompressed CO₂ gas from the trap is then vented through the ten-port valve into the oven atmosphere. After completion of the extraction, the pump is equilibrated for SFC. Upon reaching equilibrium, the ten-port and five-port selector valves are switched simul-

Figure 10 SFE/SFC system and a cryogenic cooling trap with multiple valves.

Figure 11 SFE/SFC system and cryogenic trap with multiple valves in extraction (top) and injection (bottom) modes.

taneously (Figure 11). In this configuration, mobile phase passes through the tee, the injection valve, and the ten-port valve into the cryofocused trap, which is then ballistically heated to the specified injection temperature. After backflushing, the mobile phase carries the extracted components from the trap back to the ten-port valve into the chromatographic column. Additional CO_2 flow from the other outlet of the tee to the cryofocused trap restrictor prevents backflushing of the extracted material into the restrictor.

Most of the SFE/SFC devices described above are designed to obtain qualitative results. A later design

gave quantitative results for different hydrocarbon standards using an online SFE/SFC system. The results showed that the amount of material extracted was directly proportional to the volume of sample placed in the extraction vessel. Later they demonstrated the quantitative analysis for different additives in low-density polyethylene using an FID.

A very elegant use of online SFE/SFC is shown in Figure 12 which is a chromatogram of five different additives extracted from low-density polyethylene. For this experiment, a polymer was placed in the extraction vessel, extracted (450 atm, 100°C),

Figure 12 Online SFE/SFC of different additives from low-density polyethylene. 1, BHT; 2, BHEB; 3, Isonox 129; 4, Irganox 1076; 5, Irganox 1010. (Reproduced from Levy JM and Ashraf-Khorassani M (1992) *Journal of Chromatography Library Series 53*: with permission from Elsevier Science.)

Figure 13 Online SFE/SFC of additives from polyethylene concentrate. 1, Irgafos 168; 2, Cyasorb 3346; 3, Cyanox 1790. (Reproduced from Levy JM and Ashraf-Khorassani (1992) *Journal of Chromatography Library Series 53*: with permission from Elsevier Science.)

collected and cryofocused at -25°C . After extraction and collection, the trap was backflushed and the extracted component was flushed into the analytical SFC poly(ethylene glycol) (PEG) column. Each additive was identified and quantitated at the 200–300 ppm level. **Figure 13** shows the extraction and separation of three different additives from another polyethylene sample. Again, after extraction (450 atm , 100°C) and collection (-25°C), the extracted components were backflushed into the SFC octadecyl column, with each additive being determined at the 100–200 ppm level. Besides, polymer applications, online SFE/SFC also has been used for the characterization of caffeine in teas, as shown in **Figure 14**.

Conclusions

Both directly coupled SFE/GC and SFE/SFC fall into the realm of problem-solving tools that can be

Figure 14 Online SFE/SFC of tea.

effectively utilized by analytical chemists for qualitative or quantitative characterizations or determinations. For GC, SFE presents itself as a selective sample introduction means for liquid or solid matrices with volatile and nonvolatile analytes. The nature of SFE instrumentation provides an added feature with the potential capability of sample preparation in the field with analytical determinations using an online GC/MS. Online SFE/SFC complements SFE/GC when target analytes are thermally labile or beyond the volatility range of GC. An added feature with SFE/SFC is the wide range of method development capability since SFC can be interfaced to a full array of GC and LC detectors (e.g., flame ionization, ultraviolet absorbance, mass spectrometer, infrared, nitrogen-phosphorus and sulfur chemiluminescence). As SFE technology further evolves, additional capabilities will be added and refined in the area of selectivity enhancement (i.e., modifiers, absorbents, *in situ* derivatization) and operational parameter optimization (what conditions to use for specific analytes and sample matrices).

ORGANELLES

Centrifugation

J. A. Garner, University of Southern California,
Keck School of Medicine, Los Angeles, CA, USA

Copyright © 2000 Academic Press

Introduction

Centrifugation techniques are commonly used to fractionate and separate intracellular organelles of many cell types. Here, common reasons for separation of those organelles, as well as brief description of different types of subcellular organelles, are presented. This is followed by a description of the physical principles upon which centrifugal separations are based, and common methods applied for this purpose. Last, a brief description of the types of equipment available for these separations, as well as the advantages and disadvantages of different tools, will be presented. The reader is directed to additional reviews in the Further Reading section for more detailed information. Another source of valuable information is the literature provided by manufacturers of centrifuges, rotors, and separation media.

Subcellular Organelles

Higher eucaryotic cells contain numerous intracellular (or subcellular) organelles (Figure 1). These are structurally distinct entities located within the boundaries of the cell's plasma membrane and are generally associated with one or more specific cellular functions. Indeed, one of the distinguishing features of eucaryotic cells as compared with prokaryotes, is that they have attained the ability to compartmentalize their cellular functions into these organelle 'packages'. This has allowed eucaryotic cells to evolve into larger cells, cells that can have highly specialized functional domains by limiting organelles to particular cellular regions, and eventually allowed the evolution of specific cell types, tissue types and complex organisms.

Subcellular organelles can generally be divided into two broad classes: the membrane-bounded organelles and cytoplasmic organelles. Membrane-bounded organelles are structures enclosed within one or more lipid-based membranes. These organelles include vesicular structures of different sizes, such as the cell's

nucleus, mitochondria, lysosomes, peroxisomes, vacuoles, secretory vesicles, endosomes, and less well-defined vesicular structures. The Golgi apparatus and endoplasmic reticulum are large, complex structures that, during the process of disruption of the cell to release organelles, are usually broken and reform into smaller vesicles (termed 'microsomes') in a wide range of sizes. Certain plasma membrane fractions from certain cells may also be obtained during subcellular fractionation owing to the presence of highly specialized plasma membrane domains that may differ structurally and functionally (see Mircheff in the Further Reading).

Separate from the membrane-bounded organelles are the cytoplasmic organelles, distinct structural entities that are not enclosed within intracellular membranes. Examples of cytoplasmic organelles include the intracellular filament systems, such as microtubules, microfilaments, and intermediate filaments. Other cytoplasmic organelles are free ribosomes (not membrane-associated) and specialized cellular inclusions. Stretching the definition of cytoplasmic organelles slightly would allow the inclusion of multi-enzyme complexes found in the cytoplasm and separable by centrifugal and other techniques in this class.

Last, centrifugal techniques may be used to enrich parts of cells that have highly specialized functional domains. Examples of these subcellular fractions include synaptosomes (pinched-off neuron terminals and associated postsynaptic structures from the central nervous system) or the brush border of intestinal epithelial cells. These are complex parts of cells that are functionally distinct, and their isolation by centrifugal techniques allows for increased ease of their study.

For an in-depth description of the structure and function of all of the intracellular organelles described above, the reader is referred to the cell biology text by Alberts *et al.*

Purpose of Separating Subcellular Organelles

The separation of subcellular organelles by centrifugal techniques allows the enrichment (but not usually the purification) of these organelles. This enrichment may then serve as a starting point for use of other techniques that can more effectively isolate organelles. Obtaining an enriched sample may also be the first step towards biochemical purification of

Figure 1 Diagram of a cell with subcellular organelles. A stylized diagram of an epithelial cell is shown with various common intracellular organelles drawn inside. Membrane-bounded organelles include the nucleus (N), the rough endoplasmic reticulum (rER), the Golgi Apparatus (GA), mitochondria (M), immature and maturing secretory vesicles (SV), endocytic vesicles (EV), and lysosomes (L). Cytoplasmic organelles include free ribosomes (FR), actin filaments (AF), microtubules (MT), and intermediate filaments (IF). Specialized regions of the plasma membrane include the brush border (BB) of the cell and the basolateral membrane of the cell (BLM).

individual proteins, glycoproteins, or other macromolecules that may be of considerable functional significance. Preparative centrifugation of lysed cells is a common technique that is used to perform the primary crude enrichment of these molecules.

A separate feature of interest to many cell and molecular biologists has to do with intracellular processing of macromolecules, whether they be destined for export from the cell or are specifically targeted to a particular domain of interest. Centrifugation techniques that allow separation of the various intracellular organelles such as the Golgi apparatus, the endoplasmic reticulum and various secretory vesicle pathways can be used to identify the compartment a particular molecule of interest is entering at various times after initiation of transcription. Combination of these centrifugal techniques with timed processing of a tagged protein or other cellular product can allow detailed elucidation of the intracellular route and compartments inhabited by that protein and its ultimate target location.

Homogenization of Cells to Free Subcellular Organelles

Organelles do not randomly float in the cytoplasm of cells; they are instead highly organized in a cytoplasmic matrix of very high protein concentration. The cytoplasmic matrix is a proteinaceous web or net of varying viscosity that organizes the organelles and maintains them within specialized functional do-

mains of the cell. Before beginning to enrich for certain subcellular organelles, it is necessary first to break open the plasma membrane, and disrupt the matrix that holds the organelles. This is done by the process of homogenization of cells or tissues, and dilution of the cellular contents with at least 10 volumes of aqueous buffer prior to any centrifugation.

Tissue or cells of interest plus neutral aqueous buffer and protease inhibitors are placed in a ground glass/glass, glass/Teflon®, or Dounce cell homogenizer. A ground glass/glass homogenizer disrupts cells but also will likely damage nuclei. This causes the release of large amounts of highly viscous nucleic acids (which can severely compromise the subsequent isolation of subcellular organelles). A glass/Teflon® or Dounce homogenizer (using the loose pestle followed by the tight pestle) should break open cells but leave nuclei intact. The latter is the more desirable for subsequent subcellular fractionation of organelles.

If a large quantity of material must be processed, or a tissue of origin has large amounts of connective tissue within it (such as muscle) then other types of tissue or cell disruptors may be used. Examples are the Omnimixer® (Sorvall Instruments, Inc.) or Polytron® (Brinkmann Instruments, Inc.) in which a motor-driven propeller drives the sample through small apertures in the shaft to cause cell disruption.

Fractionation of Subcellular Organelles

The type of centrifugation technique used to separate organelles after homogenization will be determined by the physical properties of the desired organelles, and generally will depend on the sedimentation rate of the organelle of interest in a medium of defined density and viscosity. The sedimentation rate of any particular organelle obeys the principal of Stokes' law as it refers to the settling of a sphere in a gravitational field, as follows:

$$1/6\pi d^3(\rho_p - \rho_l)g = 3\pi d\mu v$$

where v = sedimentation rate or velocity of the sphere, d = diameter of the sphere, ρ_p = particle density, ρ_l = liquid density, μ = viscosity of liquid medium, and g = gravitational force.

'Sedimentation rate', or the rate at which an organelle moves through a medium of defined density and viscosity in a centrifugal field, is a function of the intrinsic buoyant density (density being mass per unit volume), the shape of the organelle in the medium, and the centrifugal force exerted on the or-

ganelle. The shape of the organelle plays a role in that a highly asymmetric organelle may sediment more slowly than a tight spherical organelle of the same mass. Sedimentation rate is determined by the following:

$$v = dr/dt = (s)(\omega^2 r)$$

where v = sedimentation rate, s = sedimentation coefficient in seconds or Svedberg units, r = the distance between the particle and the centre of rotation (cm), ω = the rotor speed in radians s^{-1} , and dr/dt = the rate of movement of the particle (cm s^{-1}).

The sedimentation rate of an organelle is proportional to the relative centrifugal force (RCF) on that organelle. It is determined by the following:

$$RCF = 1.12r(\text{rpm}/1000)^2$$

where rpm is the revolutions per minute, and r , or radius, is the distance from the centre of rotation to periphery of rotation. The maximum centrifugal force would be experienced at the bottom of the centrifuge tube (r_{max}), and the minimum centrifugal force would be experienced at the top of the centrifuge tube (r_{min}), and the average at r_{ave} .

The sedimentation rate is proportional to the size of that particle; hence, the sedimentation rate of a cell's nucleus is usually higher than that of a smaller mitochondrion or endocytic vesicle of similar density. Each population of organelles has an average buoyant density. However, this average value may be of limited value in that the range in variation in both structure and buoyant density for individuals within the population of organelles can be quite substantial. **Table 1** lists buoyant densities for common membrane-bounded subcellular organelles, and it demonstrates the similarity in buoyant density among membrane classes. As a result of this similarity – and

this is an important point – it is virtually impossible to completely purify an individual organelle from all other organelles on the basis of its buoyant density alone, although a given type of organelle may be significantly enriched by these processes (which may be sufficient for certain studies).

An exception to this rule can be found for certain organelles such as microtubules (major polymeric cytoskeletal structures in cells), which can be purified to near homogeneity by centrifugal techniques. However, in these cases, one must usually make use of techniques that take advantage of that organelle's unique biological properties. For example, microtubule polymers and tubulin (the constituent protein subunit) have substantially different buoyant densities. Sample conditions can be easily altered so that they either favour assembly of the tubulin into the polymer, which pellets during centrifugation, or disassembly of the polymer into tubulin subunits, which remain in solution. Thus microtubules can be purified away from other organelles by 'cycling' the tubulin between its assembled and disassembled states and using centrifugation to separate the fractions appropriately.

In addition to the intrinsic buoyant density of organelles, it should also be appreciated that the buoyant density of a particular organelle may be altered in response to the osmolarity of the medium. For example, the high osmolarity of sucrose solutions in a sucrose gradient can cause a depletion of water from mitochondria, resulting in their shrinkage and a concomitant increase in buoyant density. This is sufficiently significant to account for differences in mitochondrial fractionation patterns in sucrose solutions as compared with media of high density but low osmolarity such as Ficoll®. On occasion, this feature of certain intracellular organelles can be exploited to help in their enrichment.

Types of Centrifugation Used for Organelle Enrichment

The enrichment of subcellular organelles may be provided by any one or a combination of different centrifugal techniques, including differential, rate zonal, or isopycnic centrifugation. These types of centrifugation would be termed 'preparative', as their ultimate goal is the enrichment of organelles. Analytic ultracentrifugation, where the goal is to determine the physical nature of a particle, is discussed elsewhere in the chapter.

Differential centrifugation (Figures 2 and 3) uses gross differences in buoyant density to sequentially pellet or sediment organelles of decreasing buoyant density. Starting with low centrifugal force spins for

Table 1 Densities of common membrane-bounded organelles in sucrose solutions^a

Organelle	Density ($g\ cm^{-3}$)
Golgi apparatus	1.06–1.10
Plasma membrane fractions	1.16
Smooth endoplasmic reticulum	1.16
Mitochondria	1.19
Lysosomes	1.21
Peroxisomes	1.23
Soluble proteins	1.30
Ribosomes	1.60–1.75

Figure 2 The principles of differential and density-gradient centrifugation. Differential centrifugation operates on the principle that denser particles sediment more rapidly and at lower g forces than lighter particles. Density-gradient centrifugation allows a mixture of particles or organelles of different densities to be separated: they band in a density gradient at the zone of the medium that has the same density as the particles.

short times, to remove the densest organelles from a sample homogenate, increased centrifugal force and length of time pellets lighter organelles. The first material pelleted from a homogenate at approximately $1000\text{--}1500 \times$ the force of gravity, g , for 10–15 min are nuclei, along with cellular and extracellular debris remaining in the homogenate. The supernate from this spin would be subsequently spun at approximately $10\,000 \times g$ for 20–30 min, to pellet mitochondria, lysosomes, and organelles of similar buoyant density. Microsomes, or small vesicles, pellet from the supernate of the mitochondrial spin after centrifugation at approximately $100\,000 \times g$ for several hours. Centrifugation speeds and times may be considerably lower for specific microsomal fractions, as determined empirically.

As mentioned above, use of these differential centrifugation steps is not sufficient to purify individual organelle types, primarily because of the range in size of the population. In addition, the mechanics of differential centrifugation allow for substantial trapping of lighter organelles within the pellets of heavier organelles. This latter can, to a certain extent, be compensated for by vigorous resuspension of the pellet and repetition of the centrifugation step. Effective resuspension of pellets into homogenous samples is imperative if those pellets are to be either subjected to further gradient fractionation or alternative treatment. If lumps are present, the sample will not fractionate according to individual organelle buoyant density. Use of a 3–10 mL syringe attached to a 4-inch,

14-gauge blunt-ended Popper Laboratory Pipetting cannula (Fisher Scientific, Inc.) allows thorough resuspensions. The same tool may be used in layering sample on gradients or retrieving fractions from the centre of density gradients as described below.

Each of the resuspended pellets and supernates obtained in the scheme described above (Figure 3) can be subjected to further centrifugation, usually by isopycnic or rate-zonal separation on density gradients, to more completely separate desired populations of organelles.

Isopycnic Centrifugation

In isopycnic centrifugation, using a continuous gradient, a fairly homogeneous population of organelles will ‘band’ in the gradient at their actual buoyant density over several hours. This method of separation is independent of time, and relies solely on the actual buoyant density of the particle. Banded organelles or particles can be recovered from the gradient by subjecting it to fractionation (either by punching a hole in the bottom of the tube and draining it, or by taking specific volumes of fractions from the top of the gradient). If bands are visible, they may be removed individually with a syringe with a long needle.

Rate-zonal Centrifugation

In rate-zonal centrifugation, the sample to be analysed is layered on a preformed density gradient and subjected to centrifugal force for a defined length of

Figure 3 Differential centrifugation. A flow chart showing a common scheme for the differential centrifugation of a cellular homogenate. The first pellet is resuspended and recentrifuged, and the two supernates are combined as S₁. Both the microsomal and mitochondrial pellets may be further fractionated on sucrose density gradients or by other mechanisms. CF = centrifuge.

time. The particles sediment through the gradient at a rate that is a function of their sedimentation coefficient. Once sufficient separation of the desired organelles is achieved, the run is terminated, and once again, banded organelles can be obtained by fractionation of the gradient.

Depending upon the medium used, density gradients may either be self-generated, or may be formed within the centrifuge tube prior to sample administration (see later). Media that can generate their own gradient in a centrifugal field are usually mixed with samples at a density equivalent to the mid-density of the desired gradient, prior to gradient formation. Alternatively, preformed density gradients can be generated from a two-chambered gradient mixer, and sample layered on top of, or within, the gradient prior to centrifugation (Figure 4). Preformed gradients may also be made by layering decreasing densities of medium in 'steps' rather than a continuous gradient in a tube, then allowing diffusion over time to produce the gradient.

Equipment

Preparative or high-speed centrifuge A high-speed centrifuge (e.g. Beckman J21) will spin samples at

speeds up to 20 000 rpm, with g forces of up to 48 000 (JA-20 rotor). With other rotors, both speed and centrifugal force vary. Rotors for use in this centrifuge can vary substantially in radius and volume of sample carried. High-speed centrifuges are generally refrigerated but do not achieve a vacuum. In differential centrifugation, the process of cellular fractionation up to the mitochondrial spin is usually performed in a high-speed centrifuge.

Preparative ultracentrifuge A preparative ultracentrifuge (e.g. Beckman L8-80M[®]) is a centrifuge capable of spinning a sample at up to 80 000 rpm, and, depending again upon the rotor radius, at maximal centrifugal forces in the hundreds of thousands × g. Ultracentrifuges spin rotors under vacuum, limiting frictional forces upon the rotor, and are refrigerated. There are numerous rotor types, varying in style and volume, that can be used in an ultracentrifuge. Centrifugal force placed upon an organelle is an important aspect of its fractionation, and, as described earlier, centrifugal force varies with the radius of the circle in which the sample is spun. Since rotors have varying radii, a simple nomogram can be used (Figure 5) to determine the rpm necessary to achieve the same centrifugal force in two different rotors.

Rotors

The rotor used in a protocol is chosen on the basis of the type of centrifugation being performed (e.g. rate zonal or density gradient), the g forces necessary, and the capacity of the rotor tubes. The manufacturer's literature is an excellent source for further information about the specifics of individual rotor types. Three different types of rotors are commonly used in the fractionation of subcellular organelles: swinging-bucket rotors, fixed-angle rotors, and vertical or near-vertical tube rotors (Figure 6). Continuous-flow rotors may also be used for certain large-scale applications.

In fixed-angle or vertical tube rotors, the sample orientation is fixed in space, and the liquid contents reorient during acceleration and deceleration. The angle at which fixed-angle rotors hold the tubes can vary among rotors up to completely vertical in vertical tube rotors. Fixed-angle rotors are excellent for pelleting material, since the pellets move both downward and outward to accumulate in a small restricted zone at the outer base of the tube. Fixed-angle and vertical tube rotors are often used for isopycnic runs. They are capable of superior separation of sample densities because of the large cross-sectional area of material banded, and the change in orientation of the sample during acceleration and deceleration does not

Figure 4 Generation of density gradients. A defined volume of high concentration medium is put in one chamber that is connected through a stopcock with a second chamber. A defined volume of low concentration medium is put in the second chamber. The second chamber contains a mixing bar. Fluid is drawn out of the second chamber into the bottom of the centrifuge tube by gravity or peristaltic pump, and concurrently drawn from the first chamber into the second. The medium concentration thus increases continuously, with the heavier medium displacing the lighter medium upwards as it enters the bottom of the gradient tube. Sample is usually carefully layered in lighter medium on the top of the gradient, with particles travelling to their buoyant density after being subjected to centrifugal force. Samples may be alternatively layered within the central part of the gradient, then organelles travel up or down the gradient to reach their own buoyant density.

appear to affect the relative separation of materials. Fixed-angle and vertical tube rotors can achieve equilibrium more rapidly than swinging-bucket rotors because of the decreased path length, resulting in a much shorter run.

Swinging-bucket rotors are most commonly used for density-gradient centrifugation. In accelerating swinging-bucket rotors, the buckets containing the samples swing outward until horizontal, where they remain for the entire run. They return to their original position on deceleration. Thus the tube is always oriented in the direction of centrifugal force. This effectively reduces artifactual problems introduced by wall effects. Swinging buckets also usually have a relatively long path length, which allows increased spatial separation of the contents. However, this increased resolution of the contents comes at a slight cost in terms of separation time. The volume of the sample which can be applied to the gradient in a swinging-bucket rotor is a function of the cross-sectional area of the tube. If too large a sample volume is applied, there is insufficient radial distance to allow effective separation of the subcellular particles. Similarly, there is a limit on the sample concentration that is effectively applied to a tube; if the concentration is too high, 'streaming' of the sample may result.

Zonal rotors can handle sample sizes of 50 to 100 times that of swinging-bucket rotors and are highly useful for large-scale purification of a variety of different types of particles. These rotors have an internal large cylindrical chamber that is divided into sectors by vanes attached to the central core. There is additionally a rotating seal assembly which allows fluid to be pumped in or out of the cavity while the rotor is spinning. Particles are purified on the basis of their rate-zonal separation. Buffer of known density is pumped in either the central core or at the periphery and fractions are collected exiting through the edge port or at the rotor centre.

Examples of Media Used for Fractionation

Most membrane-bound organelles have a density that is not widely variant from the buffer itself. In addition, the biological nature of most organelles requires that they be maintained in medium that will not alter their biological properties in a way that masks function. This has necessitated the development of media that are consistent with maintaining biological function yet can differentiate buoyant densities that are only marginally different from each

Figure 5 Nomogram. A nomogram is an invaluable diagram which allows one to compute the rpm necessary in order to achieve the same RCF in two rotors with different r values. Use a straight edge to connect the values known in two of the columns, and the appropriate value for the third column can be read where the straight edge intersects it. (Data compiled from *Beckman Rotors and Tubes for Preparative Ultracentrifuges, a User's Manual*, Spinco Business Unit Technical Publications, Palo Alto, CA, USA, 1993.)

other. These media are usually dissolved in neutral, aqueous buffers (phosphate, Tris, etc.) of physiological osmolarity.

A good separation medium (a) can establish a gradient over the appropriate density range, (b) does not affect biological activities of interest, (c) is isosmotic in the presence of sensitive organelles, and (d) does not interfere with assays that may be necessary for the characterization of particular bands. The medium should be easily removable from the sample either by dialysis or by dilution and pelleting of the

band, and the medium material should not bind irreversibly to biological samples. It is further helpful if the medium does not absorb light in the UV or visible range because fractionation of gradients may require monitoring. A last consideration is cost and availability.

Sucrose, sorbitol and, to some extent, cesium chloride are the three media most commonly used for subcellular fractionation. Sucrose and sorbitol are often used because they are fairly neutral, they can be easily removed from the sample of interest by dialysis

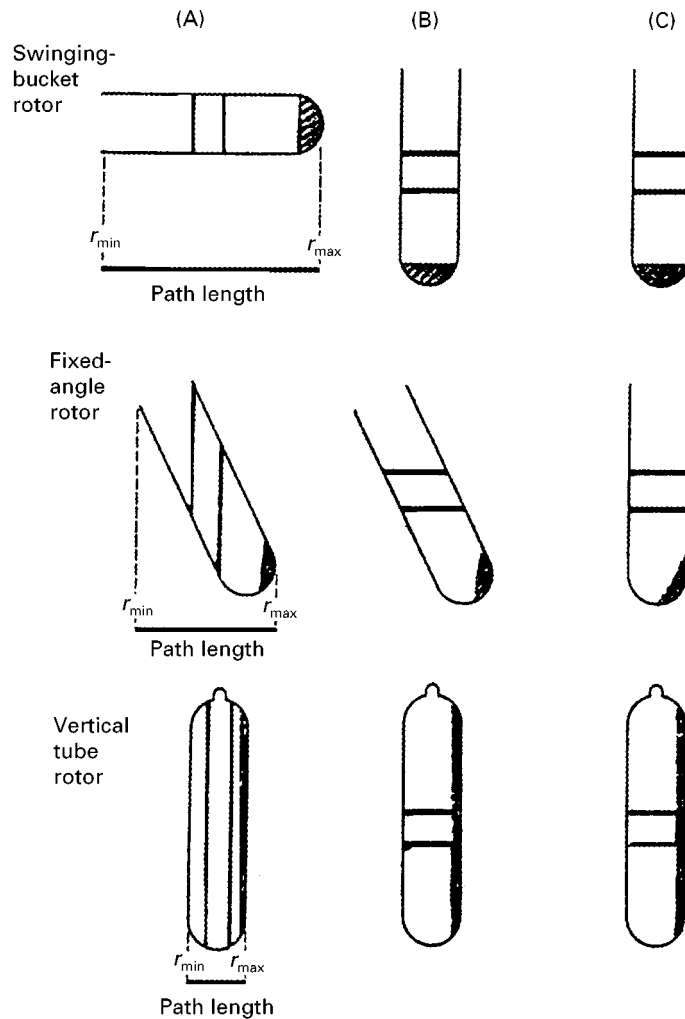

Figure 6 A comparison of gradient samples run in swinging-bucket, fixed-angle, and vertical rotors. This diagram shows the location of sample bands in centrifuge tubes during the centrifugation (A), at rest in the rotor (B), and at rest outside the rotor (C) for each type of rotor commonly used to separate subcellular organelles. Swinging-bucket rotors have the longest path length, can achieve the widest separation of sample bands, and the samples are always oriented in the direction of centrifugal force. Thus, there is little, if any, disruption of the bands. Run lengths, however, are longer because of the increased pathlength. Fixed-angle rotors allow for efficient pelleting within a short time over a shorter path length. Vertical tubes require shortest time for separation as they have a very short path length, and achieve good separation because of the large cross-sectional area of the sample within the tube. However, sample can mix with materials pelleted against the outside wall. (Reprinted as modified with permission from *Beckman Rotors and Tubes for Preparative Ultracentrifuges: a User's Manual*, Spinco Business Unit Technical Publications, Palo Alto, CA, USA, 1993.)

or by dilution and re-centrifugation, and are relatively inexpensive. Cesium chloride is more often used for isolation of macromolecules than organelles, but has the added advantage that it self-generates gradients in a centrifugal field. The refractive index of both sucrose and cesium chloride can be measured with a refractometer, which allows one to determine the actual density of each fraction recovered from a gradient (Tables 2 and 3). Alternatively, use of markers of known buoyant density in control gradients (Pharmacia Density Marker Beads) or oscillating densitometers can be used to determine density.

If osmolarity is a factor, in that the organelle to be separated can be made to swell or shrink in hypo- or hyperosmotic media respectively, a medium that is high in density but composed of extremely large molecules should be chosen, thus increasing density but decreasing osmolarity. Examples of such media are Ficoll® (Pharmacia), a synthetic polymer of copolymerized sucrose and epichlorohydrin of average molecular weight 400 000 daltons, Percoll® (Pharmacia), a colloidal suspension of polyvinylpyrrolidone-coated silica, and Nycodenz® (Nycomed), a non-ionic, tri-iodinated derivative of benzoic acid. All of these media are higher in molecular weight

than sucrose, and each has its own intrinsic advantages. Ficoll® is neutral, can achieve concentrations up to 50% covering a density range up to 1.2 g mL⁻¹, and does not penetrate biological membranes. Ficoll® is, however, difficult to remove from the sample by dialysis because of its large molecular weight. Percoll® is non-toxic and can be used over wider density ranges (up to 1.3 g mL⁻¹). Percoll® has the added advantage of being a medium that self-generates gradients in a centrifugal field, and the gradients formed are isosmotic throughout. However, Percoll® has the disadvantage that it is difficult to remove from the sample by dilution and recentrifugation, or by dialysis. In addition, Percoll®, Ficoll® and

metrizamide (similar to Nycodenz®) are precipitated at low pH, eliminating the possibility of purification of protein from samples by acid precipitation. Nycodenz®, with a density range up to 1.4, can be used to effectively fractionate subcellular particles (particularly small ones). Its advantages include its solubility at low pH, its self-forming gradients, and its lack of interference with enzyme assays. Its relatively low molecular weight (821) allows removal by dialysis. All of these media are significantly more expensive than sucrose or sorbitol.

Tables 2–5 provide data concerning density, refractive index, and concentration of different commonly used media.

Summary

In this review, the principles behind, and the utility of, fractionation of subcellular organelles by centrifugal techniques have been explored. Common methods used, and a review of the advantages and disadvantages of certain experimental tools (centrifuges, rotors, and aqueous media used for fractionation) were also reviewed and tables and graphs useful for designing protocols were also provided.

PAINTS AND COATINGS: PYROLYSIS: GAS CHROMATOGRAPHY

T. P. Wampler, CDS Analytical, Inc.,
Oxford, PA, USA

Copyright © 2000 Academic Press

Because they are complex polymeric materials, usually compounded with coloured or opaque fillers, paints and coatings, especially when dry, pose a difficult analytical problem. Gas chromatography in particular, and mass spectrometry, may seem unlikely tools for the analysis of such materials, but when combined with pyrolysis as a sample introduction technique, they may be used routinely. Via pyrolysis, the polymers used in paints and coatings are fragmented to produce molecules small enough to be compatible with gas

chromatography–mass spectrometry (GC-MS), but still characteristic of the original material. Natural polymers, including plant resins and drying oils, as well as synthetic polymers like polyesters, acrylics and polyurethanes, have been studied extensively, and may be easily differentiated using this technique.

Pyrolysis

The general purpose of paints and coatings is to apply a protective or decorative film of material on to a substrate. The range of materials which may be used to form such a film is extremely wide, as is the range of techniques used to apply it. Soluble materials may be dissolved in a suitable solvent and applied as a thin

coat which produces a film as the solvent evaporates, as in the case of many varnishes and lacquers. On the other hand, materials may be applied which react in place, linking into a complex polymer network. Materials may even be applied as a powder which is subsequently melted into a film. The paint or coating may include many different constituents, both organic and inorganic, to give it the required physical and visual properties, including opacity, flexibility, colour, resistance to water, shine, durability and so on.

Once applied and set, paints and coatings have one characteristic in common: the molecules which comprise the finished product are almost always much too large to be analysed by GC. In fact, chemical analysis of dried paint is a difficult challenge by any technique, since the sample material is such a complex mixture of different polymers, additives, pigments and fillers. Analytical pyrolysis, however, permits the use of GC and MS in the investigation of these materials by breaking the large molecules into fragments small enough to be compatible with these instruments. Samples are typically heated rapidly to temperatures in the range of 600–800°C. At these temperatures, the organic macromolecules undergo bond dissociations based on the relative strengths of the bonds employed in the compound. Consequently, the molecule will fragment in a reproducible way, consistent with the chemistry of the compound, and form products which are directly indicative of the composition. This is true for simple homopolymers such as polystyrene, but also true for complex systems involving multiple monomers and various constituents. Frequently, the small molecules formed include the monomer or monomers of polymers, in addition to indicative products specific for various polymer types.

Instrumentation

The following sections discuss specific types of paints and coatings, with example pyrograms for many of these types. Unless indicated in the figure legends, all of the chromatograms were produced using the instrument parameters described here.

Pyrolysis

Samples were pyrolysed using a platinum coil filament autosampler (model 2500 autosampler, CDS Analytical Inc, Oxford, PA, USA). Approximately 100 µg of sample material was placed into a quartz tube and held in place using quartz wool. The samples were placed online with the GC carrier flow, and then heated to the indicated temperatures for the specified times, typically 750°C for 15 s.

Gas Chromatography–Mass Spectrometry

A model 6890 (Hewlett-Packard, Wilmington, DE) gas chromatograph was equipped with a HP-5 column (30 m long, 0.25 mm diameter, 0.25 µm film) operated with a 75:1 split ratio and helium as the carrier gas, in the constant pressure mode at 5.9 psi. The oven initial temperature was 40°C for 2 min, then programmed at 6°C min⁻¹ to 300°C, held for 5 min. A mass selective detector (model 5972A, Hewlett-Packard, Wilmington, DE) provided the mass spectra. Scans were taken at a rate of 2.4 s⁻¹ over the mass range of 35–550.

Paints and Varnishes

Varnishes

Clear, decorative or protective finishes are formulated and applied in a variety of ways. A varnish may be as simple as a plant resin (such as mastic, sandarac or dammar) or shellac (secreted by insects) dissolved in a solvent. A film of the solid organic material is left on the surface of the object varnished after the solvent evaporates. More likely, the formula includes drying oils – unsaturated fatty acids which polymerize when exposed to air – plus natural or synthetic resins, thinners and other additives. When pyrolysed, the dried varnish film creates indicative molecules from the various constituents, revealing much about its composition. The natural resin dammar, for example, is comprised extensively of triterpenes, made from three terpene units or six isoprene units. When pyrolysed, dammars generate chromatograms (pyrograms) showing groups of terpenes, as do the other plant resins used in making varnishes. **Figure 1** is a pyrogram of Kremmer dammar, which was heated to 650°C for 15 s. The peaks at about 25 min are sesquiterpenes, having three isoprene units, and the materials eluting at about 45 min are diterpenes (two terpene or four isoprene units). Other terpenoid resins used in making varnishes behave in a similar way, producing characteristic chromatograms permitting them to be differentiated. By contrast, when shellac is pyrolysed, it reveals a mixture of complex fatty acids, esters and olides, as shown in **Figure 2**.

Polyurethanes are formed from the reaction of a diisocyanate with a di- or polyfunctional alcohol. When pyrolysed, the most characteristic material formed is the regeneration of the diisocyanate. This is the case whether the polyurethane is a foam rubber-type polymer, or used as part of a paint or varnish. Hexane diisocyanate and toluene diisocyanate (TDI) are two commonly used polyurethane constituents, but others, both aromatic and aliphatic, are encountered as well. **Figure 3** is a pyrogram obtained by

Figure 1 Kremmer dammar pyrolysed at 650°C for 15 s.

heating a sample of a polyurethane film to 700°C for 20 s, in which the large peak at 21 min is identified as TDI.

Oil finishes, based on large amounts of drying oils, are popular for furniture. Tung oil in particular is high in C₁₈ polyunsaturated fatty acids, which polymerize when exposed to oxygen. Pyrolysis products from pure tung oil include some of the unsaturated acids, plus hydrocarbons, both aromatic and aliphatic, formed from the long chain of the acid. Commercial tung oil finish products are likely to contain other polymerizing agents as well. **Figure 4** shows the pyrogram of a recently dried film produced from a commercial tung oil product. The peaks at 32 and 36 are unsaturated fatty acids seen in pure tung oil, but there is also a peak at 21 min marked T,

which is TDI, showing that this product incorporated polyurethane as well. Exterior waterproofing finishes may also incorporate drying oils, and other things as well. The pyrogram shown in **Figure 5**, from a wood waterproofing product, reveals both long chain fatty acids (for example, the largest peak at 37 min) as well as a series of hydrocarbons eluting from 38 to 45 min.

House Paints

Alkyd Glyceryl phthalate polyesters have been used for many years to make paints for a wide range of uses, including interior and exterior housepaint. The reaction of the difunctional acid and the polyfunctional alcohol creates the polyester film. When pyrolysed, the ester linkage of the polyester is cleaved,

Figure 2 Pyrolysis of shellac at 700°C for 15 s.

Figure 3 Pyrolysis of a polyurethane film at 750°C for 20 s. TDI at about 21 min is toluene diisocyanate.

resulting in the formation of phthalic anhydride, the characteristic pyrolysate for these paints. An example of this is shown in **Figure 6**, produced from a light green interior semi-gloss trim paint. The large peak at 20 min is phthalic anhydride, the most abundant pyrolysis product. Smaller constituents elute before this peak, mostly oxygenated degradation products from the alcohol portion of the polyester. In addition, peaks are generated from the drying oils in the formulation, in this case eluting at about 33 min (C_{16}) and a small peak at 36 min (C_{18}).

Latex Latex housepaints are substantially different. These water-based emulsions are almost always formulated using a variety of different polymers

and copolymers, offering an essentially unlimited range of formulations. Typical polymers used include polyvinylacetate (PVA), polymethylmethacrylate (PMMA), polystyrene and polybutylacrylate (PBA) as well as higher acrylics. When pyrolysed, many of these polymers regenerate sufficient monomer to be identified in the pyrolysate. This is true for PMMA, polystyrene, PBA and other acrylates and especially for methacrylates. Acrylates, like PBA, and polystyrene also produce higher oligomers, especially the dimer and trimer. In cases of copolymers, there may be mixed dimers and trimers as well, if the different monomers are part of the same polymer chain. PVA, however, does not produce monomer. Because of the relative bond weakness, acetic acid is split from the

Figure 4 Pyrolysis of dried tung oil finish. Peak labelled T is toluene diisocyanate; UFA is a C_{18} unsaturated fatty acid.

Figure 5 Pyrolysis of a waterproofing film at 750°C for 20 s. Peak marked UFA is a C₁₈ unsaturated fatty acid. The peaks marked with a W are from a hydrocarbon wax.

polymer backbone before the chain is broken. As the acetic acid leaves the polymer, the backbone becomes highly unsaturated. Consequently, when the chain finally does break, it generates aromatics. Therefore, instead of vinyl acetate monomer, the pyrolysis products include acetic acid, benzene, toluene and other substituted aromatics.

The pyrogram of a flat green latex wall paint shown in **Figure 7** illustrates much of this. The paint is largely PVA, as shown by the large acetic acid peak eluting at about 3 min. Peak number 2 is one of the aromatics formed from the PVA chain (toluene). In

addition, the paint included styrene and butyl acrylate, which elute at about 8 min. The white latex analysed in **Figure 8** is significantly different. For this paint, the largest peak is styrene, with the amounts of styrene and butyl acrylate both substantially increased relative to the PVA, and therefore dimers and trimers of these monomers may be seen eluting later in the chromatogram. In addition, there is a peak for methyl methacrylate as well.

Spray paint The flat black, indoor/outdoor spray paint shown in **Figure 9** was deposited from a spray

Figure 6 Pyrogram of a glyceryl phthalate alkyd housepaint. The peak labelled PA is phthalic anhydride.

Figure 7 Pyrolysis of a latex paint at 750°C. 1, Acetic acid (from PVA); 2, toluene; 3, styrene; 4, butyl acrylate.

which contained acetone and xylenes. In fact, the peak at about 7 min is a xylene, probably retained in the paint matrix and released as the sample was heated. The pyrogram shows methyl methacrylate (4 min) phthalic anhydride (20 min) and a series of peaks between 32 and 37 min derived from drying oils, especially a C_{18} fatty acid.

Beverage container paint The paint pyrolysed to produce the chromatogram in **Figure 10** was scraped from an aluminium can which contained a carbonated soft drink. The paint was formulated using mostly methyl methacrylate, with some butyl acrylate and a little styrene.

In all of the paint examples here, only the major polymer constituents have been stressed. Paints, of course, contain many other ingredients, such as stabilizers, catalysts, solvents and additives, and peaks from some of these may appear in the chromatogram. In addition, there are pigment and materials to make the paint opaque. Many of these are inorganic, and although they may be present in large quantities (for example, TiO_2), their presence rarely affects the progress of the pyrolysis in creating identifiable fragments from the polymers.

Automotive paints Through the 1950s, automobile paints were likely to be glyceryl phthalate polyesters.

Figure 8 Pyrogram of latex paint at 700°C. 1, Acetic acid; 2, methyl methacrylate; 3, toluene; 4, styrene; 5, butyl acrylate.

Figure 9 Pyrolysis of a flat black spray paint. 1, Methyl methacrylate; 2, xylene; 3, phthalic anhydride; 4, drying oils.

As described above, these phthalate polyesters pyrolyse to produce a characteristic peak for phthalic anhydride, plus other small molecules from the polymer. To control shrinkage and provide flexibility, plasticizers were added to these paints, generally in the form of a phthalate ester. When the paint sample is pyrolysed, it is typical to find that the plasticizer has been volatilized intact, and consequently it shows up in the pyrogram as well, even though strictly speaking it is a thermally desorbed molecule, not a pyrolysis product. This can be seen in the pyrogram shown in **Figure 11**. The paint is a black du Pont product used on a 1955 Chevrolet, and the sample pyrogram it produced has a large peak for phthalic anhydride at

about 19 min, and peak for the plasticizer (dibutyl phthalate) at 31 min. In the 1960s these paints were replaced with other formulations, initially using mostly PMMA with a phthalate plasticizer. In the 1970s other monomers were added to the mix, including styrene, butyl acrylate and butyl methacrylate. Since polymers using these monomers produce significant amounts of monomer when pyrolysed, pyrograms of such an automotive finish look like the example in **Figure 12**, where peak 1 is methyl methacrylate, 2 is styrene, 3 is butyl acrylate, 4 is butyl methacrylate and 5 is butyl benzyl phthalate.

It must be pointed out that automotive finishes may be very complex systems, incorporating multiple

Figure 10 Paint from an aluminum soda can. 1, Methyl methacrylate; 2, styrene; 3, butyl acrylate. GC programme 40°C for 2 min, then 10°C min⁻¹ to 300°C.

Figure 11 Paint from a 1955 black Chevrolet. 1, Phthalic anhydride; 2, dibutyl phthalate, a plasticizer.

layers, each of which is probably a different paint formulation. Further, these layers may be cross-linked with specific reagents, filled, coloured, etc. The examples shown here will deal primarily with the polymer composition of the paints, but information is frequently present concerning additives, especially plasticizers and light stabilizers, as well.

In an effort to reduce the amount of solvent vented to the air when a car is painted, manufacturers have developed paints with a higher solids load (and consequently less solvent per application). These paints are usually solutions of smaller polymer molecules, which

are linked together during drying to form larger, cross-linked polymers. The standard monomers (methyl methacrylate, styrene, butyl acrylate, butyl methacrylate) are still used, but others are added to provide sites for cross-linking. These are frequently hydroxy compounds, and the OH functionality is used to form urethane, epoxy or other bonds during cross-linking. Hydroxyethyl methacrylate and hydroxypropyl methacrylates are used in the paint polymer chain to provide these sites. When paints incorporating the hydroxy methacrylates are pyrolysed, these monomers are produced just as the others are, and the pyrogram looks like

Figure 12 Pyrogram of automobile paint including multiple monomers. 1, Methyl methacrylate; 2, styrene; 3, butyl acrylate; 4, butyl methacrylate; 5, butyl benzyl phthalate (plasticizer).

Figure 13 Pyrolysis of black acrylic enamel car finish. 1, Styrene; 2, butyl acrylate; 3, butyl methacrylate; 4, hydroxy propyl methacrylate.

Figure 13, in which styrene (peak 1), butyl acrylate (2) and butyl methacrylate (3) are major pyrolysis products. Peak 4 is 2-hydroxy propyl methacrylate, a common monomer added to provide cross-linking sites.

It is not unusual to see evidence of other polymers and polymer constituents in automotive finishes, either as the cross-linkers or from one of the many paint layers. Urethanes and epoxies are frequently used, and the characteristic compounds from these materials are frequently identifiable. The paint shown in **Figure 14** employed a urethane in addition to the monomers already discussed. When pyrolysed, it re-

veals methyl methacrylate, styrene, butyl acrylate and butyl methacrylate (peaks 1–4 in the pyrogram) and also shows TDI (peak 5 at about 17 min). Epoxies are frequently made using bisphenol A, which is regenerated on pyrolysis and provides a good indicator. The very complex pyrogram of a 1993 red car paint shown in **Figure 15** includes a peak at 31 min for bisphenol A, evidence of an epoxy formulation, in addition to standard monomers and a large peak of phthalic anhydride at about 17 min.

As a further step in improving the performance of automotive finishes, manufacturers are incorporating

Figure 14 Pyrogram of automotive finish including urethane bonds. 1, Methyl methacrylate; 2, styrene; 3, butyl acrylate; 4, butyl methacrylate; 5, toluene diisocyanate (TDI).

Figure 15 Read automobile paint with epoxy constituents. 1, Styrene; 2, butyl acrylate; 3, phthalic anhydride; 4, bis-phenol A (from epoxy).

the plasticizing agents into the polymer itself, instead of using an additive like a phthalate ester. Consequently, pyrograms of paints produced in the 1990s are likely to show no phthalate plasticizers, but to have peaks for long chain methacrylates instead. These methacrylates with long aliphatic substituents become part of the paint polymer, with the aliphatic tail providing flexibility in a way which will not be lost from the polymer by evaporation. **Figure 16** shows a pyrogram of a paint which used a substantial amount of styrene (1), made flexible by the addition of octyl methacrylate (2) which elutes at about 17 min, and is the largest peak in the chromatogram.

Paper Coatings

Papers are coated with a variety of polymeric materials to provide qualities such as gloss for magazines and waterproofing for food packaging, in addition to decorative and functional uses of inks and toners from printers and photocopiers. Although it is sometimes difficult to separate the coating from the paper fibres, this may not be required for many analyses. This is because the polymer coating and the paper will be pyrolysed essentially independently of each other, and the resulting pyrogram will contain information about each of the constituents. The pyrolysis products of cellulose are well documented, and consist of many oxygenated materials such as furans,

Figure 16 Automobile paint with long alkyl chain methacrylate. 1, Styrene; 2, octyl methacrylate.

Figure 17 Coating for freezer carton. 1, Styrene; 2, α -methyl styrene.

plus levoglucosan, whereas the products from most coatings include monomers like styrene, acrylics and hydrocarbons, so differentiating them is generally straightforward. **Figure 17**, for example, shows the products of pyrolysing a coating used on cardboard boxes made for storing frozen foods. The two large peaks, eluting at about 6 and 8 min, are styrene and α -methylstyrene, respectively. When a piece of a box coated with this polymer is pyrolysed, the result is the pyrogram shown in **Figure 18**. Most of the peaks are cellulose pyrolysates, including furancarboxaldehyde (1), hydroxymethylfurancarboxaldehyde (4) and levoglucosan (5). The monomers styrene and α -methylstyrene, however, are superimposed on the cellulose products, and are seen as peaks

2 and 3. The furans, especially furancarboxaldehydes and levoglucosan, are reliable markers for cellulose and should be seen in any paper, coated or not.

In **Figure 19** they can be seen again, this time from a piece of glossy magazine paper. Since the paper is thinner than the cardboard box, the relative amount of the coating is larger here, and the polymer constituents forming the glossy finish show up readily. In this case, the coating is a copolymer of styrene, butadiene and methyl methacrylate, and each of the monomers represents one of the major peaks in the pyrogram.

Polyolefins are frequently used as coatings or laminates on to papers for a variety of purposes. The

Figure 18 Pyrolysis of cardboard with coating shown in **Figure 17**. 1, Furancarboxaldehyde; 2, styrene; 3, α -methylstyrene; 4, hydroxymethylfurancarboxaldehyde; 5, levoglucosan.

Figure 19 Pyrogram of a piece of glossy coated paper stock. 1, Butadiene; 2, methyl methacrylate; 3, styrene; 4, levoglucosan.

glossy coating on a photograph is likely to be polyethylene, as is the protective film on paper used as freezer-wrap. When polyethylene is pyrolysed, it is broken into many long chain hydrocarbons, including alkanes, alkenes and dienes. These polymer fragments elute in a series of triplet peaks, making a characteristic pattern for polyethylene. When a piece of paper coated with polyethylene is pyrolysed, the cellulose peaks are again seen, co-eluting with the polyethylene hydrocarbon fragments. **Figure 20** shows an example of this, being the pyrogram of a piece of coated freezer paper. Most of the larger peaks before 18 min are from cellulose, and the poorly shaped peak at 22 min is levoglucosan. All of the

triplet peaks, including the one at 18 min and almost everything after 24 min, are normal hydrocarbons indicative of polyethylene pyrolysis.

Glass surfaces are also frequently covered with a coating, such as a silk screen ink for decorative pieces, a film for colouring or shading, or a layer to provide a working surface. **Figure 21** shows an interesting application of glass coating, in which laboratory glass slides were coated with a Teflon material to create wells for aqueous reagents. When Teflon is pyrolysed, it reverts almost entirely to monomer, tetrafluoroethylene. The coating which had been applied to the glass consisted largely of Teflon, plus a styrene/ethyl acrylate copolymer. When pyrolysed,

Figure 20 Pyrolysis of freezer paper (polyethylene-coated cellulose paper) at 750°C for 15 s.

Figure 21 Coating applied to glass, pyrolysed at 750°C for 20 s. 1, Tetrafluoroethylene; 2, ethyl acrylate; 3, styrene.

a simple chromatogram results, revealing peaks for all three monomers, tetrafluoroethylene, ethylacrylate and styrene.

Future Developments

The development of more complex, specialty or high performance coatings will reinforce the need for detailed analysis in both quality control and product development laboratories. Pyrolysis-capillary GC-MS should become increasingly relied upon to unravel these complex polymer matrices. The development of fast GC techniques will do much to expand the use of this technique, since the time required to produce a well resolved pyrogram is perhaps the greatest drawback. The introduction of several automated systems for pyrolysis-GC-MS has already made the technique routine, enhancing reproducibility and efficiency of instrument use.

PARTICULATE CHARACTERIZATION: INVERSE GAS CHROMATOGRAPHY

D. Butler and D. R. Williams, Surface Measurement Systems, London, UK

Copyright © 2000 Academic Press

Introduction

Inverse gas chromatography (IGC) represents a unique refinement of a classic chromatographic method in which an unknown solid material such as a powder, fibre or film may be characterized. By reversing the traditional role of unknown mobile phases and known reference stationary phases, the gas–solid chromatographic retention processes may be used to characterize an unknown particulate sample by eluting a series of known gas or vapour molecules through a column packed with the sample materials. IGC is the only chromatographic technique in which a solid-state material may be characterized in its native state. Despite the fact that over 500 papers have been published over the last 8 years using IGC, the technique is still not well known nor well appreciated by many scientists. However, this article will highlight the opportunities that IGC offers for surface and materials characterization generally as well as briefly reviewing the principles and main IGC methodologies. Finally, recent trends in material characterization applications will be briefly reviewed.

History

The intrinsic relationship between gas–solid chromatography and the adsorption isotherm was established by a number of workers starting in the 1940s and going through the 1950s. Gluckauf, Martin, James, Gregg, Purnell, Wilson, Wicke and Stock all contributed to our early understanding of gas–solid chromatographic retention/adsorption processes which forms the basis of analytical gas chromatography (GC) as we know it today.

The first systematic use of GC as a technique for characterizing solid-state materials was pioneered by Russian scientists in the early 1960s led by Professor Kiselev at Moscow University who also coined the terminology IGC. Their work was motivated by an interest in understanding the fundamental nature of gas–solid retention behaviour for high energy solid surfaces including carbons, zeolites, silica, alumina and catalyst materials as well as other porous solids.

Their work resulted in a very detailed fundamental understanding of the gas-phase adsorption processes on these particulate materials which were additionally being evaluated as stationary phases for traditional analytical chromatography. Their work allowed a detailed understanding of the adsorption processes including heats of adsorption, diffusion processes, adsorption processes, specific surface interactions and surface areas. Work was undertaken at both low and high solute concentrations.

Through the 1960s and 1970s research activity on IGC moved on to other classes of materials for study, most notably polymers. New refinements in both experimental technique as well as data analysis were pioneered. Many studies of polymer glass transition temperatures, small molecule diffusion, polymer–polymer interactions and crystallinity were first reported in this period. Workers such as Guillet, Conder, Smidsrod, Laub, Schrieber and Gray were all productive during this period.

During the 1980s and 1990s we have seen a much wider range of materials being studied using IGC. Initially this commenced with surface studies on fibres and filler particles for advanced materials, and more recently we have seen growing interest in IGC for food and pharmaceutical characterization. Techniques have remained very much unchanged during this period with virtually all work published being based on low solute concentrations. Refined analyses have been developed to determine the surface energy and acid–base properties of particulate materials as well as methods for determining polymer–polymer interaction constants and solubility parameters. Workers including Gray, Lawrence, Duda, Papirer, Schultz, Balard, Munk, DiPaola-Baranyi have all published significant work during this period. The recent availability of commercial IGC equipment which can perform a wide new range of experimental IGC methods is certain to catalyse growth in this technique in the new millennium.

Instrumentation

Virtually all of the published work on IGC has been undertaken on either home-built or modified commercial GC equipment. Though both analytical and physicochemical measurement approaches such as IGC are intrinsically very similar, the demands for

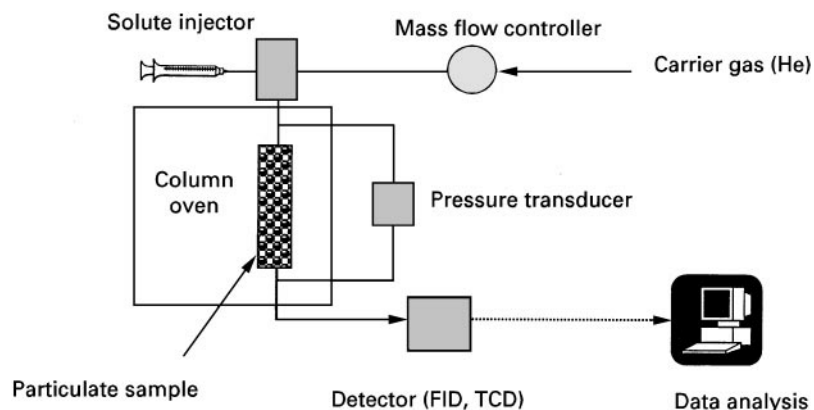

Figure 1 Typical schematic of an IGC system for infinite dilution studies. FID, Flame ionization detector; TCD, thermal conductivity detector.

accurate and precise retention data for physicochemical measurement have required additional experimental refinement not normal nor standard for analytical GC equipment.

Ideally, well-designed IGC equipment for low solute concentrations should incorporate:

1. thermal conductivity mass flow controllers
2. pressure sensors for measuring pressure drop along the column
3. computerized data acquisition of detector signals
4. full statistical analysis of solute peak/boundary shapes

Figure 1 shows a typical schematic diagram of an IGC system for infinite dilution studies used by the author.

To undertake work at high solute concentrations – finite concentration (FC) work – much more complex experimental instrumentation must be employed. The main feature of FC studies is the need to be able to generate both simple, and sometimes complex, concentration profiles of multiple solutes at concentrations, perhaps as high as P/P_0 of 0.95. This necessitates the generation of solute vapours with very stable concentration profiles. Condor and Purcell, amongst other workers, have developed appropriate GC systems to undertake such studies. Current commercial systems incorporate similar instrumental approaches as well as other experimental refinements.

Theory

IGC methods fall into two primary categories. The most common case is infinite dilution (ID) studies in which the solute concentration is low, normally less than $0.01 P/P_0$. In this case the solute molecules behave independently and retention behaviour is thus in the Henry's law region. At higher concentrations,

when solute–solute interactions become significant, then Henry's law is no longer valid and we refer to FC techniques. These later methods require special experimental techniques as well as complex data analysis.

Infinite Dilution

IGC studies under ID conditions represent over 95% of all IGC papers published in the last 10 years. Subsequently this section will especially highlight the ID approach.

Figure 2 shows four overlaid chromatograms obtained for alkane vapour species interacting with a GC column packed with crystalline fibres at 40°C under conditions of infinite dilution. The quantity t_M is the time for an inert non-interacting species to sweep through the packed column. This time is known as the experimental dead time and is typically measured using methane or nitrogen. This retention time t_M , multiplied by the carrier gas flow rate, F , approximates the dead volume, V_M , within the system. This dead volume consists of the internal volume of the instrumentation plumbing as well as dead space within the sample column.

As the hydrocarbon chain length increases, so does the ability of the solute species to interact with the fibre surface. This results in increasing retention times for the solute molecules. This trend is clearly shown in the peaks shown for hexane through octane. The increased residence time in the GC column results in broader and less intense solute peaks due to increased longitudinal diffusive broadening. The peaks nevertheless maintain their Gaussian shape.

The retention time, t_R , per unit of sample mass for an adsorbing solute vapour allows the net retention volume, V_N , to be determined using eqn [1]:

$$V_N = j t_R F(T/273.15) - j t_M F(T/273.15) \quad [1]$$

Figure 2 Overlaid chromatograms for alkane vapours on crystalline fibre surface.

where F is the carrier gas flow rate, T is the column temperature, t_M is the dead time and j is a correction term allowing for the pressure changes along the column.

The retention process for the solute with the stationary phase is determined by the solute partitioning between the stationary and mobile phases at the relevant temperature, pressure and concentration. For the case in which the retention process is due to solid–vapour adsorption, solute partitioning between the mobile and stationary phases is given by the appropriate adsorption isotherm. At low solute concentrations ($< 0.01P/P_0$) the adsorption isotherm is typically linear and this region is commonly described as the Henry’s law region. In this region solute molecules adsorbing on to a surface are independent and nearest neighbour interactions are not significant. Gaussian-shaped chromatograms, as shown in Figure 2, result in the case of adsorption in the Henry’s law region.

In this linear region of the adsorption isotherm, the net retention volume V_N may be related directly to the surface area of the sample A and the partitioning coefficient K_S in the case of surface retention of the solute:

$$V_N = AK_S \quad [2]$$

In the case in which both surface and bulk retention mechanisms operate, we must modify eqn [2]:

$$V_N = AK_S + VK_B \quad [3]$$

where the second term relates to bulk sorption into a volume V with a solubility K_B . K_S is also the slope of

the adsorption isotherm at infinite dilution and is simply defined as the ratio of the solute concentration q in the stationary phase to the solute concentration c in the mobile phase:

$$K_S = q/c \quad [4]$$

If a dynamic experimental technique is being used to study equilibrium processes, certain precautions need to be performed to confirm the equilibrium nature of the retention data. The simplest and most useful tests to perform are experiments with at least two different flow rates to confirm that the V_N is independent of the carrier gas flow rate.

It is thus apparent that the net retention volume V_N is directly proportional to the slope of the adsorption isotherm and thus the equilibrium constant for the adsorption process. Consequently, standard thermodynamic analysis may be applied to the data. For example, from the temperature-dependent partitioning coefficient K_S the heat of adsorption ΔH_A° using eqn [5] may be determined. Choice of appropriate standard states for the adsorbed species allows both free energies of adsorption ΔG_A° and entropies of adsorption ΔS_A° to be determined as well:

$$q_d = -\Delta H_A^\circ = R d(\ln K_S)/d(1/T) \quad [5]$$

$$\Delta G_A^\circ = -RT \ln(K_S p_{s,g}/\pi_s) \quad [6]$$

$$\Delta S_A^\circ = -(q_d + \Delta G_A^\circ)/T \quad [7]$$

A study of V_N as a function of temperature thus allows a detailed study of surface adsorption thermodynamics to be undertaken.

Measuring the retention behaviour of a series of alkane probes allows the dispersive (long range) component of the surface energy of the surface, γ_s^d to be estimated. By estimating the change in retention volume as one increases the size of the alkane probe, the differential free energy of adsorption for an imaginary $-\text{CH}_2-$ species can be determined. Using the assumption that an infinite surface of $-\text{CH}_2-$ groups is equivalent to a poly(ethylene) surface and with the use of the Fowkes' geometric mean work of adhesion analysis, γ_s^d may be estimated using eqn [8]:

$$\gamma_s^d = (4/\gamma_{s-v})((\Delta G_A^{\text{CH}_2})/(Na_{\text{CH}_2}))^2 \quad [8]$$

where N is Avogadro's constant, a_{CH_2} is the area of a $-\text{CH}_2-$ group and γ_{s-v} is the surface energy of polyethylene. This simple ratio measurement has become very popular, not least because there is no need to know the exact surface area for the sample.

The above physicochemical properties represent some of the basic IGC measurement types. There exists an extensive range of much more complex analyses which are beyond the scope of this article, including retention by bulk rather than surface retention mechanisms. Other methods include:

1. acid-base interaction constant-donor/acceptor numbers
2. free energies for specific chemical interactions
3. polymer-polymer (Flory-Huggins) interaction constants
4. solubility constants
5. diffusion constants
6. glass transition temperature of polymeric materials

Finite Concentration

Though very little work has been published using FC techniques in the past 10 years, there exists a substantial body of research using these approaches from the preceding 20 years. This work has proven the power and utility of these IGC methods. Like ID, FC is not simply a method but rather a family of experimental approaches linked simply by the use of high solute concentrations. Unlike ID, however, the shapes of the FC chromatograms are rarely Gaussian, but rather take on very complex and nonsymmetrical shapes. Conder and Young's book is still the definitive review of FC methods and should be studied for more detail (see Further Reading).

The fundamental equation from which FC work is based is given below:

$$V_N = A(1 - j\gamma_0)d_q/d_c \quad [9]$$

where γ_0 is the mole fraction of solute in the gas phase at the column inlet and d_q/d_c is the slope of the adsorption isotherm at concentration c .

In this section a brief review of the major FC methods will be provided as well as a general list of the major classes of information which can be determined using FC methods.

The simplest FC method is known as the frontal analysis (FA) approach. In this case a step change in solute concentration is introduced into the IGC column. This concentration boundary will migrate along the column and the time at which the boundary is seen by the detector (minus dead time) will depend upon how much such solute is adsorbed by the stationary phase. A knowledge of the solute concentration and the carrier gas flow rate allows the amount of solute adsorbed to be determined. By undertaking this measurement at differing solute concentrations, an adsorption isotherm may be determined.

Another useful technique is the frontal analysis by a characteristic point (FACP). In this case the shape of the boundary produced by a step change in concentration is analysed. The shape of the tailing of this FC chromatogram can be analysed to provide an adsorption isotherm from one chromatogram via recourse to various analyses based around eqn [9].

For both FACP and FA, very specially modified GC equipment must be used. These modifications are nontrivial and have in turn limited the recent use of these methods. One of the most common FC methods reported in the literature is elution of a characteristic point (ECP). The popularity of this method is simply because it can be undertaken with a standard GC injection system. The technique involves injecting a solute, typically a liquid in one large injection, down the IGC column. The resulting large solute peak will migrate along the column, resulting in the production of a highly nonsymmetrical peak. Analysis of the boundary shape based on eqn [9], not unlike the FACP methods, can allow the adsorption isotherm to be determined from a single or a family of chromatograms.

The final major class of FC techniques is elution on a plateau (EP). In this technique a steady-state concentration profile is established along the IGC column. With an essentially constant concentration profile along the column, a small positive or negative variation in concentration is introduced and the time for the perturbation to propagate along the column is determined (Figure 3). This net retention volume will correspond to the K_s for the plateau concentration c under investigation. By undertaking experiments at different concentrations, an adsorption isotherm may be accurately constructed. This method has the major

Figure 3 The relationship between frontal and elution chromatograms (after Conder).

advantage over other FC methods that the experiment is undertaken under conditions of essentially constant solute concentration.

Finite concentration methods can be used to determine the following:

1. adsorption isotherms
2. competitive adsorption phenomena
3. porosity and diffusion
4. total uptake/break-through profiles

Applications

Fibres and Filler Particles

The last 20 years have seen a substantial amount of research published on the surface characterization of fibre and filler particles. Invariably these materials are for incorporation in advanced composite materials for which the interfacial properties are known to depend on the surface properties of the reinforcing entities. Measurements of the thermodynamics of adsorption for both weak and strong adsorbing probes are well established for carbon, glass, aramid, cellulose and polyethylene fibres. In many cases their acid-base properties have also been reported. Many high energy inorganic particulate materials have also been investigated, including silica, activated carbon, alumina, bentonite and calcium carbonate. In many cases surface properties have been investigated as a function of heat treatments, surface chemical modifications as well as comminution operations such as milling. Most studies reported have used ID techniques, though FC techniques are also reported periodically.

Pharmaceuticals

The last 5 years have seen a very rapid rise in the interest of the pharmaceutical industry in the use of IGC for the characterization of pharmaceutical ma-

terials. The importance of solid dosage forms and the rapid development of novel and complex approaches to solid-state drug delivery have fuelled this interest. Work has already been reported for highly crystalline materials including α -lactose monohydrate, salbutamol sulfate, caffeine, theophylline and microcrystalline cellulose. These studies have focused on changes in surface energies associated with these materials using ID techniques. Such IGC work has already been demonstrated to be a valuable technique for quantifying batch-to-batch variations in pharmaceutical powders not readily, if at all, identifiable using any other experimental approach. The development of IGC instrumentation with multiple solute capabilities has led to work being recently reported for the surface energy of pharmaceutical powders as a function of relative humidity. Such data are also important for understanding practical storage and stability behaviour of pharmaceutical materials. A rapid expansion of work in this area can be expected over the next few years.

Food

IGC work on food materials has been very sporadic during the last 10 years. In many ways this reflects the complex and multicomponent nature of these materials. However, some trends are becoming apparent in this industry. Use of IGC in combination with mass spectroscopic techniques shows great promise for determining the evolution of volatile flavour species from food systems. The ability of IGC to be used for small molecule/polymer solubility has led to the increasing use of IGC for studying base food materials such as starch.

Polymers

Recent highlights include the use of IGC for measuring the permeability of packaging materials to gases and other small solute molecules. Techniques have also been developed for determining the diffusion constants for small molecules, especially for capillary columns coated with polymeric materials. These studies highlight some of the most complex IGC phenomena when both surface and bulk retention mechanisms are operative. Use of IGC to measure the glass transition temperature (T_g) for polymeric materials still attracts significant research interest. IGC is especially sensitive to such a transition due to a change in the retention mechanism from surface dominated below T_g to bulk retention above T_g . T_g has also been measured for thin polymeric coatings which cannot be easily analysed using traditional thermal techniques. Work has also been reported on mesophase transitions for liquid crystalline polymers.

Porous Materials

Porous materials are one of the most complex materials to analyse by any technique, including IGC. This complexity is due to the combination of heterogeneous surface sites and an intricate system of internal and external surfaces. Progress has been made in developing methods for estimating surface basicity and acidity as well as deriving adsorption energy distribution functions. The ability to differentiate solute adsorption due to micropore filling versus surface adsorption has been demonstrated using IGC. This ability allows the true external surface area to be estimated, which is difficult to accomplish with traditional static techniques. Developments in the characterization of these materials have been facilitated by the use of traditional IGC methods combined with thermal ramped desorption approaches which allow information on a wide range of adsorption energies to be determined.

Other Materials

Work has been reported on the use of IGC to characterize coal, sand, conducting polymers, soils and crude oils.

Conclusions

IGC has been shown to be a powerful technique for studying physicochemical interactions between solutes and solid-state materials, especially those at the surface. Indeed, the more extensive use of the technique has clearly been hampered by the lack of commercially available IGC equipment during the past 30 years. Though the number of techniques for surface characterization has increased substantially in the last 20 years (SIMS, XPS, etc.), most of these methods do not provide thermodynamic but rather analytical information. The realization that thermodynamic information about solid-state-solute interactions is important and the very recent advent of commercial IGC instrumentation is likely to result in

a significant increase in research using IGC during the next 10 years.

Introduction

High performance liquid chromatography (HPLC) has proved extremely versatile in aiding the isolation of peptides from a wide variety of sources, including complex proteolytic and/or chemical cleavage mixtures of proteins as well as crude mixtures arising from the ever-increasing employment of solid-phase peptide synthesis. The complexity of such peptide mixtures may vary considerably depending on the source. Thus, for instance, peptides obtained from biological tissues are often found in very small quantities and may require extensive purification, while impurities arising from peptide synthesis are usually closely related to the peptide of interest (deletion, terminated or chemically modified peptides), missing perhaps only one amino acid residue, and may be difficult to separate. The development of high performance separation techniques has enabled the much more efficient utilization of peptide size (size exclusion chromatography or SEC) and net charge (ion exchange chromatography or IEC) compared to the much inferior and slower separations achievable by classical SEC and IEC. In addition, reversed-phase chromatography (RPC), a technique that does not have a classical predecessor, has proved to be an excellent means of analysing peptides based on their relative hydrophobic/hydrophilic characteristics.

With the requirement for efficient separation protocols constantly fueling demands for improvements in HPLC instrumentation and packings, it is perhaps not surprising that researchers have generally overlooked the potentially useful mixed-mode properties of high performance packings which, with careful manipulation of mobile-phase conditions, can offer a novel addition to the HPLC arsenal. In our experience, all HPLC packings have exhibited some deviation from ideal solute retention behaviour; thus, SEC packings often exhibit some hydrophobic and ionic characteristics, IEC packings exhibit hydropho-

bic character to a greater or lesser extent and RPC packings frequently also exhibit some ion exchange properties. Mobile phases may then be designed to minimize or eliminate such mixed-mode characteristics which, if left unchecked, can lead to poor resolution and broad, tailing peaks. The mixed hydrophobic and charged characteristics of peptides make these molecules particularly susceptible to such nonideal retention behaviour. However, the reverse is that certain so-called nonideal packing characteristics – in the sense that they represent an unintended, nonspecific property of a column packing – may significantly enhance the resolving power of that packing.

As noted above, the hydrophobic/hydrophilic characteristics of peptides, a result of the nonpolar/polar nature of the side chains making up the peptide, are well recognized, particularly in terms of peptide elution from a reversed-phase column in order of increasing peptide hydrophobicity. What has not been so well recognized until relatively recently, however, is that since ion exchange stationary phases are designed to be as hydrophilic (or as neutral) as possible to avoid hydrophobic interactions, such hydrophilic characteristics may be used to advantage if harnessed properly. The present article describes, and illustrates with practical examples, how the ionic nature of a strong cation exchange matrix may be overlaid with hydrophilic characteristics, thus effecting peptide separations by a combined hydrophilic/cation exchange mechanism. This novel mixed-mode approach, termed hydrophilic interaction-cation exchange chromatography (HILIC-CXC) offers drastically different selectivity to RPC, underlining its value as a complementary approach.

General Principles and Conditions of HILIC-CXC

The term hydrophilic interaction chromatography (HILIC) was originally coined to describe separations based on solute hydrophilicity. Thus, separation by HILIC, in a manner similar to normal-phase chromatography (to which it is related), depends on hydrophilic interactions between the solutes and a hydrophilic stationary phase, i.e. solutes are eluted in order of increasing overall hydrophilicity (decreasing hydrophobicity). Characteristic of HILIC-CXC separations is the presence of a high initial organic

modifier (e.g. acetonitrile) concentration in the mobile phase which, concomitant with overcoming any undesirable hydrophobic column behaviour, serves to promote hydrophilic interactions between the solute and the stationary phase, specifically a strong cation exchange stationary phase with significant hydrophilic characteristics. Such characteristics generally only become apparent once any matrix hydrophobicity has been suppressed. Hydrophilic interactions between peptides and the cation exchange packing are then overlaid on the ionic interactions between basic (potentially positively charged) peptides and the negatively charged packing.

Different ion exchange matrices exhibit differing degrees of hydrophobic characteristics. In order to gain the full benefit of the HILIC mode, it is important to overcome unwanted hydrophobic properties of the matrix with as low a level of organic modifier as possible – the ion exchange matrix should be as hydrophilic as possible. In this way, there is a greater organic modifier range open to the researcher to effect mixed-mode HILIC-CXC peptide separations. In our hands, the PolySulfoethyl A strong cation exchange column (based on a polypeptide coating, poly[2-sulfoethylaspartamide], covalently bonded to silica) has proven to be very hydrophilic, hence its use in the separations shown in the current article.

Typical conditions for mixed-mode HILIC-CXC are a linear increasing sodium perchlorate (NaClO_4) gradient ($2\text{--}20\text{ mmol L}^{-1}\text{ NaClO}_4\text{ min}^{-1}$) at pH 3–7, with the mobile phase containing 15–80% acetonitrile (ACN). Thus, the cation exchange column separates peptides based on net positive charge and this separation mode is then complemented by the presence of ACN overcoming undesirable hydrophobic interactions and promoting desirable hydrophilic interactions. NaClO_4 is suitable for this mixed-mode approach due to its excellent solubility in aqueous solution even in the presence of high concentrations of organic modifier. Where the charged characteristics of the components of a specific peptide mixture are unknown, relatively low pH conditions are a good starting point in order to maximize the basic character of the peptide solutes and, hence, enhance ionic interactions with the negatively charged strong cation exchange matrix. Thus, at pH 3, any acidic (potentially negatively charged) residues (aspartic acid, glutamic acid) will be mainly in the protonated, neutral form. In addition, a full positive charge on the basic residue histidine ($\text{p}K_a = 6.5$) is also assured at low pH. Although perhaps a less obvious concern, there is also a need to be cautious with the pH of the mobile phase when considering basic residues such as lysine ($\text{p}K_a \sim 10$) and arginine ($\text{p}K_a \sim 12$). This caution arises from reduction in $\text{p}K_a$ of such basic resi-

dues frequently observed in a nonpolar environment, represented in the present case by the nonpolar (relative to water) organic modifier ACN. Thus, due to the presence of high concentrations of ACN (up to 90%) characteristic in HILIC-CXC mobile phases, the use of relatively low pH conditions to ensure full protonation (i.e. a full positive charge) of basic side chains is a wise precaution. As an additional benefit, silica-based ion exchange columns tend to be more stable over a period of time at pH 3 compared to pH values around neutrality.

The general principles of HILIC-CXC are well demonstrated in **Figure 1** which compares the separation of four random coil peptides, denoted S2, S3, S4 and S5 (**Table 1**), by RPC (top), CXC (middle) and HILIC-CXC (bottom). This four-peptide mixture contains peptides with the same net positive charge (+2) and subtly increasing hydrophobicity ($\text{S2} < \text{S3} < \text{S4} < \text{S5}$). Note that the only difference between the CXC and HILIC-CXC runs is the presence of 10% (v/v) ACN in the former compared to 80% (v/v) in the latter.

From **Figure 1**, peptides are as expected, eluted from the RPC column (top) in order of increasing hydrophobicity. Under characteristic cation exchange conditions (middle), the presence of 10% (v/v) ACN helps to eliminate unwanted hydrophobic interactions between solutes and the stationary phase, and the four peptides are very poorly resolved, as expected given the identical net charge on the peptides. Note, however, that the low concentration of ACN (10%) has already induced hydrophilic interactions with the matrix in that the elution order is already opposite to that of RPC (the most hydrophobic peptide is eluted first and the most hydrophilic last). In comparison, under HILIC-CXC conditions (bottom), the elution order remains the same but the peptides are now well resolved. Clearly, to effect a separation of these peptides on the cation exchange column, an increased concentration (80% (v/v)) of ACN is required in the mobile phase in order to promote hydrophilic interactions with the stationary phase to complement the ionic interactions.

Optimization of HILIC-CXC Run Conditions

While flow rates of $0.5\text{--}2.0\text{ mL min}^{-1}$ are generally favoured for analytical ion exchange separations and, by extension, mixed-mode HILIC-CXC runs, the effect of varying flow rates is somewhat limited. In contrast, variations in gradient rate (increasing counterion concentration per unit time) have the potential for large effects on the efficiency of separation. In addition, one option available to HILIC-

Figure 1 General principles of HILIC-CXC versus RPC: (A) RPC; (B) CXC; (C) HILIC/CXC. Columns: Zorbax SB300-C₈ reversed-phase column (150 × 4.6 mm i.d., 5 μm particle size, 30 nm pore size) from Hewlett-Packard PolySulfoethyl a strong cation exchange column (200 × 4.6 mm i.d., 5 μm, 30 nm) from PolyLC Conditions: RPC, linear AB gradient (0.5% acetonitrile min⁻¹) at a flow rate of 1 ml min⁻¹, where eluent A is 20 mmol L⁻¹ aq. triethylammonium phosphate (TEAP), pH 3, and eluent B is eluent A containing 60% (v/v) acetonitrile, both eluents containing 100 mmol L⁻¹ NaClO₄; CXC, linear AB gradient 5 mmol L⁻¹ NaClO₄/min⁻¹, following 5 min isocratic elution with eluent A at a flow rate of 1 ml min⁻¹, where eluent A is 20 mmol L⁻¹ aq. TEAP, pH 3, containing 10% (v/v) acetonitrile and eluent B is eluent A containing 400 mmol L⁻¹ NaClO₄. HILIC/CXC, same conditions as for CXC, except for 80% (v/v) acetonitrile in eluents A and B; all runs carried out at 30°C and peaks detected by absorbance at 210 nm. (Reproduced with permission from Mant *et al.*, 1998a.)

CXC, but not to separations based solely on an ion exchange mechanism, is to vary the ACN concentration in the mobile phase in order to modulate the magnitude of hydrophilic interactions overlaying the ion exchange process.

Variation of Salt Gradient Rate

Figure 2 shows the effect of varying gradient rate of NaClO₄ (under conditions of a consistent and high ACN concentration) on the HILIC-CXC elution profile of a mixture of six cyclic, amphipathic β-sheet peptides. These peptides offer a particularly stringent test of the capabilities of the HILIC-CXC approach in that only the two residues making up the hydrophilic face (the face binding preferentially to the ion exchange matrix) of the β-sheet are varied (Table 1): the overall net charge of all the peptides is identical (+2); note that the hydrophobic face of all six peptide analogues, made up of leucine and valine residues (Table 1), is constant. From Figure 2, reducing the gradient rate from 5 mmol L⁻¹ NaClO₄ min⁻¹ to 2.5 mmol L⁻¹ min⁻¹ and, finally, to 1 mmol L⁻¹ min⁻¹ clearly affects the efficiency of the separation with, interestingly, optimal separation in this mixed mode being achieved at the intermediate rate of 2.5 mmol L⁻¹ min⁻¹. Thus, while reducing the gradient from 5 mmol L⁻¹ min⁻¹ (top) to 2.5 mmol L⁻¹ min⁻¹ (middle) achieved an expected improvement in resolution (peptides Dap and Arg are co-eluted at the higher gradient rate), further reduction to 1 mmol L⁻¹ min⁻¹ (bottom) results in a deterioration of the separation, with peptides Orn and Dab now co-eluted. Such results, while illustrating the efficacy of varying salt gradient rate, also serve to indicate the complexity of peptide retention behaviour when responding to variations in run parameters.

Variation of Acetonitrile Concentration

Figure 3 demonstrates the effect of ACN concentration on the elution of a mixture of 12 peptides with negligible secondary structure; the numbers denote the number of potentially positively charged groups on the peptides (Table 1). With 20% ACN in the mobile phase (Figure 3A), the overall elution order of all 12 peptides is essentially based on increasing net positive charge (+1 < +2 < +3 < +4) – ionic interactions dominate the separation process. At 50% ACN (Figure 3B), ionic interactions are still dominant since peptides are still generally eluted in order of increasing net positive charge. However, a hydrophilic interaction mechanism also becomes more substantial, as evidenced by the improvement in the separation of peptides of like charge. Also, note the elution of peptide 14 before the lesser charged (but more hydrophilic) b3 and a3, a clear example of how more highly charged peptides may still be eluted prior to less highly charged peptides if the latter are significantly more hydrophilic than the former. A further increase in ACN concentration to 90% (Figure 3C)

shows the most dramatic change in column selectivity with the hydrophilic interactions now dominating the separation process, producing a much different elution profile compared to those seen at lower ACN concentrations. For instance, peptide i1 (+1 net charge) is eluted after the less hydrophilic h2 (+2 net charge); similarly, e2 (+2 net charge) is eluted after the much less hydrophilic k3 and, most dramatically, peptide l4 (+4 net charge) is eluted before the more hydrophilic c3, b3 and a3 (+3 net charge).

The flexibility of HILIC-CXC is also demonstrated in Figure 3D, where a double gradient (increasing salt gradient with concomitant decreasing ACN gradient) is employed to effect the separation, thus maintaining dominant hydrophilic (over ionic) interactions while reducing analysis time (relative to the chromatogram

shown in Figure 3C) but retaining good column selectivity. From Figure 3D, this is achieved by a lower level of ACN in buffer B (50% as opposed to 90% in buffer A), which leads to a decrease in peptide retention relative to that effected by maintaining 90% acetonitrile in both mobile-phase buffers (Figure 3C). The peptide elution order obtained with this combined salt and ACN gradient is almost identical (save for a reversal of e2 and k3) to that shown in Figure 3C, but is obtained in about two-thirds of the time and with sharper peaks.

Although the results shown in Figures 2 and 3 are derived from mixtures of only a limited range of peptides, they do at least provide a useful summary of the major optimization options available. Indeed, the double-gradient approach shown in Figure 3D is

Figure 2 Effect of salt gradient steepness on HILIC-CXC of peptides. CXC column: see Figure 1. Conditions: same as HILIC-CXC conditions in Figure 1, save for 90% (v/v) acetonitrile in eluent A and 80% (v/v) acetonitrile in eluent B; linear AB gradients at (A) $5 \text{ mmol L}^{-1} \text{ min}^{-1}$; (B) $2.5 \text{ mmol L}^{-1} \text{ min}^{-1}$; (C) $1 \text{ mmol L}^{-1} \text{ min}^{-1}$. (Reproduced with permission from Mant *et al.*, 1998b.)

a good starting point when first applying mixed-mode HILIC-CXC to a peptide mixture of interest. Initial run conditions similar to those described for Figure 3D, save for a lower pH (e.g. pH 3) to ensure the maximum degree of positively charged character of the peptides, are recommended. The observed elution profile can be subsequently optimized by varying gradient rate and/or mobile-phase ACN concentration as required; in addition, if acidic (potentially negatively charged) residues are present in the peptides, the pH can also be manipulated to modulate the positively charged character of the peptides and,

hence, vary the strength of ionic interactions between peptides and the cation exchange matrix.

Practical Applications of HILIC-CXC for Peptide Separations

In order to appreciate fully the unique selectivity advantages of HILIC-CXC for peptide separations,

Figure 3 Effect of acetonitrile concentration on HILIC-CXC of peptides. CXC column: see Figure 1. Conditions: (panels A–C), linear AB increasing salt gradient ($2\% \text{ B min}^{-1}$, equivalent to $5 \text{ mmol L}^{-1} \text{ NaClO}_4 \text{ min}^{-1}$, starting with 100% A at a flow rate of 1 ml min^{-1} , where A is 5 mmol L^{-1} aqueous TEAP, pH 7, and B is A plus $0.25 \text{ mol L}^{-1} \text{ NaClO}_4$, pH 7, both A and B containing 20% (panel A), 50% (panel B) or 90% (panel C) (v/v) acetonitrile; panel D, linear AB gradient) $2\% \text{ B min}^{-1}$, equivalent to a linear increasing salt gradient of $5 \text{ mmol L}^{-1} \text{ NaClO}_4 \text{ min}^{-1}$ and a linear decreasing acetonitrile gradient of $0.8\% \text{ acetonitrile min}^{-1}$, starting with 100% A at a flow rate of 1 ml min^{-1} , where A is 5 mmol L^{-1} aqueous TEAP, pH 7, containing 90% (v/v) acetonitrile and B is 5 mmol L^{-1} aqueous TEAP, pH 7, containing $0.25 \text{ mol L}^{-1} \text{ NaClO}_4$ and 50% (v/v) acetonitrile; all runs carried out at 26°C and peaks detected at 210 nm . (Reproduced with permission from Zhu *et al.*, 1992.)

it is important to demonstrate the resolution of mixtures of peptides with different characteristics, e.g. random coil peptides, peptides with a defined secondary structure, constrained peptides, etc. Such a range of peptides is well represented by those presented in Table 1. In addition, the value of the HILIC-CXC is also better appreciated if its ability to resolve peptide mixtures is compared to that of the RPC mode.

HILIC-CXC is a Complementary Mode to RPC for Peptide Separations

Figure 4 compares the RPC and HILIC-CXC elution profiles of the same mixture of peptides with negligible secondary structure used in Figure 3. In fact, the HILIC-CXC double-gradient system at pH 7 (increasing salt gradient, decreasing ACN gradient) resulting in the elution profile shown in Figure 3D is here being compared to RPC at pH 7 (Figure 4A: including the presence of $250 \text{ mmol L}^{-1} \text{ NaClO}_4$ to suppress any

undesirable ionic interactions between negatively charged free silanols on the silica surface and any positively charged residues) in order to create as direct a comparison as possible between the two modes. From Figure 4A, the elution profile shown represents a relative measure of the hydrophobicity of the 12 peptides, from the least hydrophobic to the most hydrophobic as expressed by their increasing RPC elution times. Under HILIC-CXC conditions (Figure 4B), instead of a simple reversal of peptide elution, cation exchange interactions overlaid on interactions involving the hydrophilic/hydrophobic nature of the peptides now lead to useful selectivity differences between the two modes, major examples of which are denoted by arrows in Figure 4. The resolution of the peptide mixture is satisfactory using either RPC or HILIC-CXC, although that achieved by HILIC-CXC is superior and the complementary aspects of the two modes are quite clear.

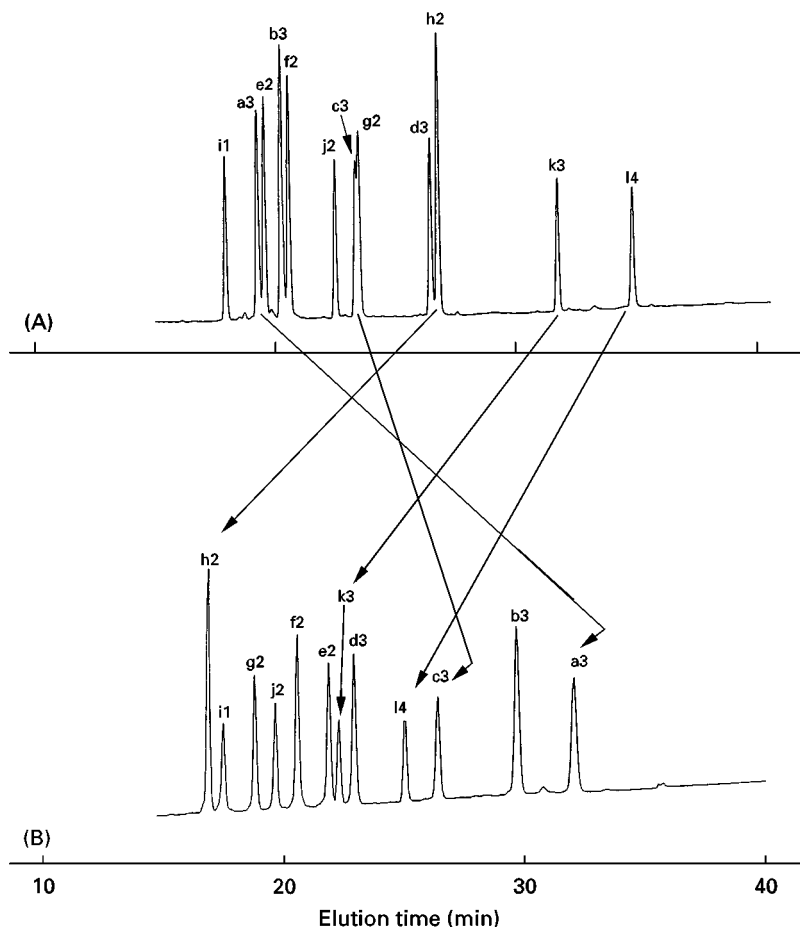

Figure 4 (A) RPC versus (B) HILIC-CXC of peptides with negligible secondary structure. Columns: see Figure 1. Conditions: RPC, linear AB gradient ($1\% \text{ acetonitrile min}^{-1}$) at a flow rate of 1 mL min^{-1} , where eluent A is $10 \text{ mmol L}^{-1} \text{ aq. } (\text{NH}_4)_2\text{HPO}_4$, pH 7, and eluent B is eluent A containing $50\% \text{ (v/v) acetonitrile}$, both eluents containing $200 \text{ mmol L}^{-1} \text{ NaClO}_4$; HILIC-CXC, same conditions as Figure 3 panel D; runs carried out at 26°C and peaks detected at 210 nm . Numbers above the peptide peaks denote the number of potentially positive charges they contain. (Reproduced with permission from Mant and Hodges, 1996.)

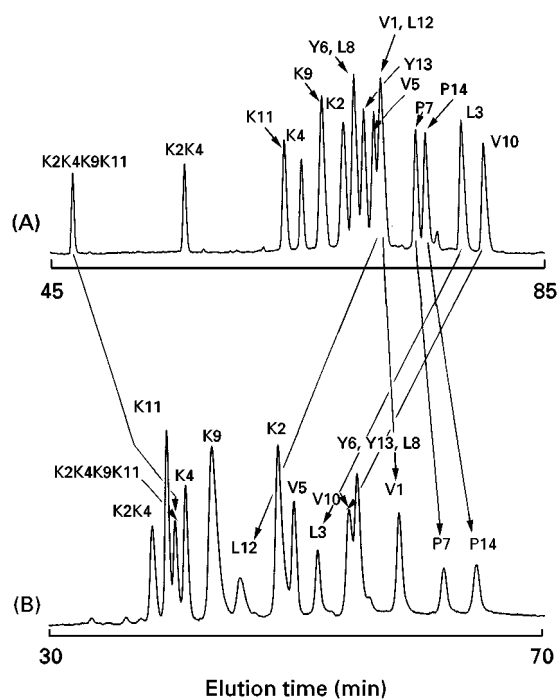

Figure 5 (A) RPC versus (B) HILIC-CXC of cyclic peptides. Columns: see Figure 4. Conditions: RPC, linear AB gradient (0.5% acetonitrile min^{-1}) at a flow rate of 1 mL min^{-1} and a temperature of 70°C , where eluent A is 0.05% aq. trifluoroacetic acid (TFA) and eluent B is 0.05% TFA in acetonitrile; HILIC-CXC, linear AB gradient $2.5 \text{ mmol L}^{-1} \text{ NaClO}_4 \text{ min}^{-1}$, following 5 min isocratic elution with 100% eluent A at a flow rate of 1 mL min^{-1} and a temperature of 30°C , where eluent A is 20 mmol L^{-1} TEAP, pH 3, and eluent B is eluent A containing $400 \text{ mmol L}^{-1} \text{ NaClO}_4$, with eluents A and B also containing, respectively, 90% and 80% (v/v) acetonitrile. Peaks were detected at 210 nm. (Reproduced with permission from Mant *et al.*, 1998.)

Even more dramatic selectivity changes are illustrated in Figure 5, which compares the RPC and HILIC-CXC chromatograms for a mixture of cyclic 14-residue analogues of gramicidin S, an amphipathic β -sheet peptide. Each residue in the native GS14 sequence (Table 1) has been systematically replaced with its enantiomer, i.e. 14 diastereomers; two additional analogues are included with either double (peptide K2K4) or quadruple (peptide K2K4K9K11) L-Lys to D-Lys substitutions. The result of each enantiomeric substitution within the framework of GS14 disrupts the β -sheet structure to varying degrees, depending on the position of the substitution. Due to their isomeric nature, the 16 diastereomeric analogues have the same intrinsic hydrophobicity; thus, the differences in their RPC elution times (Figure 5A) are due to their effective hydrophobicities, i.e. the ability of a particular analogue to form a preferred hydrophobic binding domain and present this hydrophobic face to the reversed-phase matrix. From Figure 5B, the analogues with the longer reten-

tion times can present a relatively greater hydrophobic face to the reversed-phase matrix compared to analogues with low retention times which cannot present such a hydrophobic face due to more severe disruption of β -sheet structure and, hence, amphipathicity. In an analogous manner to RPC, since all 16 peptides have the same inherent hydrophilicity, their relative positions in the HILIC-CXC elution order (Figure 5B) must also be dependent on the relative disruption of β -sheet structure and amphipathicity and, hence, their effective hydrophilicities, i.e. the ability of a particular analogue to form a preferred hydrophilic binding domain and present this hydrophilic face to the ion exchange matrix.

The two elution profiles shown in Figure 5 are markedly different, reflecting profound differences in the selectivity of the two modes. Despite the complexity of the peptide elution shifts between RPC and HILIC-CXC, the more dramatic selectivity shifts (denoted by arrows) are readily apparent. Thus, peptides V1 and L12 are completely co-eluted by RPC but widely separated by HILIC-CXC; peptides L3 and V10 are the last eluted peptides during RPC, but are eluted towards the middle of the HILIC-CXC chromatogram; peptide K2K4K9K11 is eluted early during RPC, but moves significantly later in retention time relative to the other peptides during HILIC-CXC. Although both modes achieve reasonable separation of the 16-peptide mixture, this is an excellent example of where a two-column approach (e.g. HILIC-CXC followed by RPC of collected HILIC-CXC fractions), taking advantage of complementary chromatographic selectivities, is required to achieve optimal separation.

Figure 6 compares the relative effectiveness of RPC and HILIC-CXC in separating 10-residue amphipathic cyclic β -sheet analogues of gramicidin S, where substitutions have only been made on the hydrophilic face of the peptides (Table 1). Since the hydrophobic preferred binding domain of all six analogues is constant, i.e. all substitutions have been made in the hydrophilic face which tends to be oriented away from the reversed-phase stationary phase, the poor resolution of the peptides by RPC (Figure 6A) is not surprising; in contrast, these peptides are much better separated by HILIC-CXC (Figure 6B), since the preferential binding of the hydrophilic face of the peptides to the cation exchange matrix now enhances the separation. The arrows again denote relative positions of the peptide analogues between the HILIC-CXC and RPC runs in order to highlight selectivity differences between the two modes.

A similar effect of amphipathic secondary structure on the relative utility of HILIC-CXC and RPC is shown in Figure 7, which compares the relative

Figure 6 (A) RPC versus (B) HILIC-CXC of cyclic, amphipathic β -sheet peptides. Columns: see Figure 1. Conditions: RPC, same as Figure 1 save for 50% (v/v) acetonitrile in eluent B; HILIC-CXC, same as Figure 2 for 2.5 mmol L⁻¹ NaClO₄ min⁻¹ run. Peaks were detected at 210 nm. (Reproduced with permission from Mant *et al.*, 1998.)

effectiveness of the two modes in separating amphipathic α -helical peptide analogues LL7, LV7, LT7 and LS7 (Table 1), where substitutions have only been made in the hydrophilic face of the helices. From Figure 7A, in RPC the identical hydrophobic-preferred binding domains of the peptides bind to the hydrophobic matrix, resulting in co-elution of all four peptides under RPC conditions. Therefore substitutions in the hydrophilic face, which is oriented away from the reversed-phase matrix, have little effect on the RPC retention behaviour. In contrast to RPC, all four peptides are well resolved by HILIC-CXC (Figure 7B), even though they all have the same net positive charge, with the substitution sites in the hydrophilic faces able to interact intimately with the ion exchange matrix and, hence, influence the retention behaviour of the four analogues. Note that elution is in order of decreasing hydrophobicity, with the Leu analogue being eluted first, followed by the Val, Thr and Ser analogues, exactly as expected based on the most hydrophilic peptide being eluted last in HILIC.

HILIC-CXC for Purification and Analysis of Solid-phase Synthetic Products

In addition to RPC being the method of choice for most preparative separations of peptides, it is also

commonly employed analytically to check the purity of a purified product. However, a single peak obtained during RPC is not necessarily a guarantee of peptide purity. Thus, a complementary method, such as HILIC-CXC, is required for a more accurate assessment of peak purity as well as offering an alternative approach to obtaining the required purity.

Figure 8A outlines the purification and analysis of a 35-residue cysteine-containing synthetic peptide (peptide 01118 from Table 1). The RPC elution profile of the reduced crude peptide (top) suggests a successful synthesis, i.e. a major single peak with relatively few impurities. Analysis of the subsequently RPC-purified major component by RPC (middle) shows a single, symmetrical peak. The lack of any shoulder on the peak, obtained on a very efficient column, suggests excellent peptide purity. However, mass spectrometry of this peptide showed not only the expected product mass, but a second strong signal exhibiting a peptide mass 103 units less than expected, indicating deletion of the Cys residue at position 2 of the peptide (Table 1). Although it might have been expected that deletion of a relatively hydrophobic residue such as Cys would be detected by RPC, apparently the loss of this residue has been masked by the diminishing contribution a residue

Figure 7 (A) RPC versus (B) HILIC-CXC of amphipathic α -helical peptides where substitutions have been made in the hydrophilic face. Columns: see Figure 1. Conditions: RPC, same as Figure 5; HILIC-CXC, same as HILIC-CXC run in Figure 1. Peaks were detected at 210 nm. (Reproduced with permission from Mant *et al.*, 1998.)

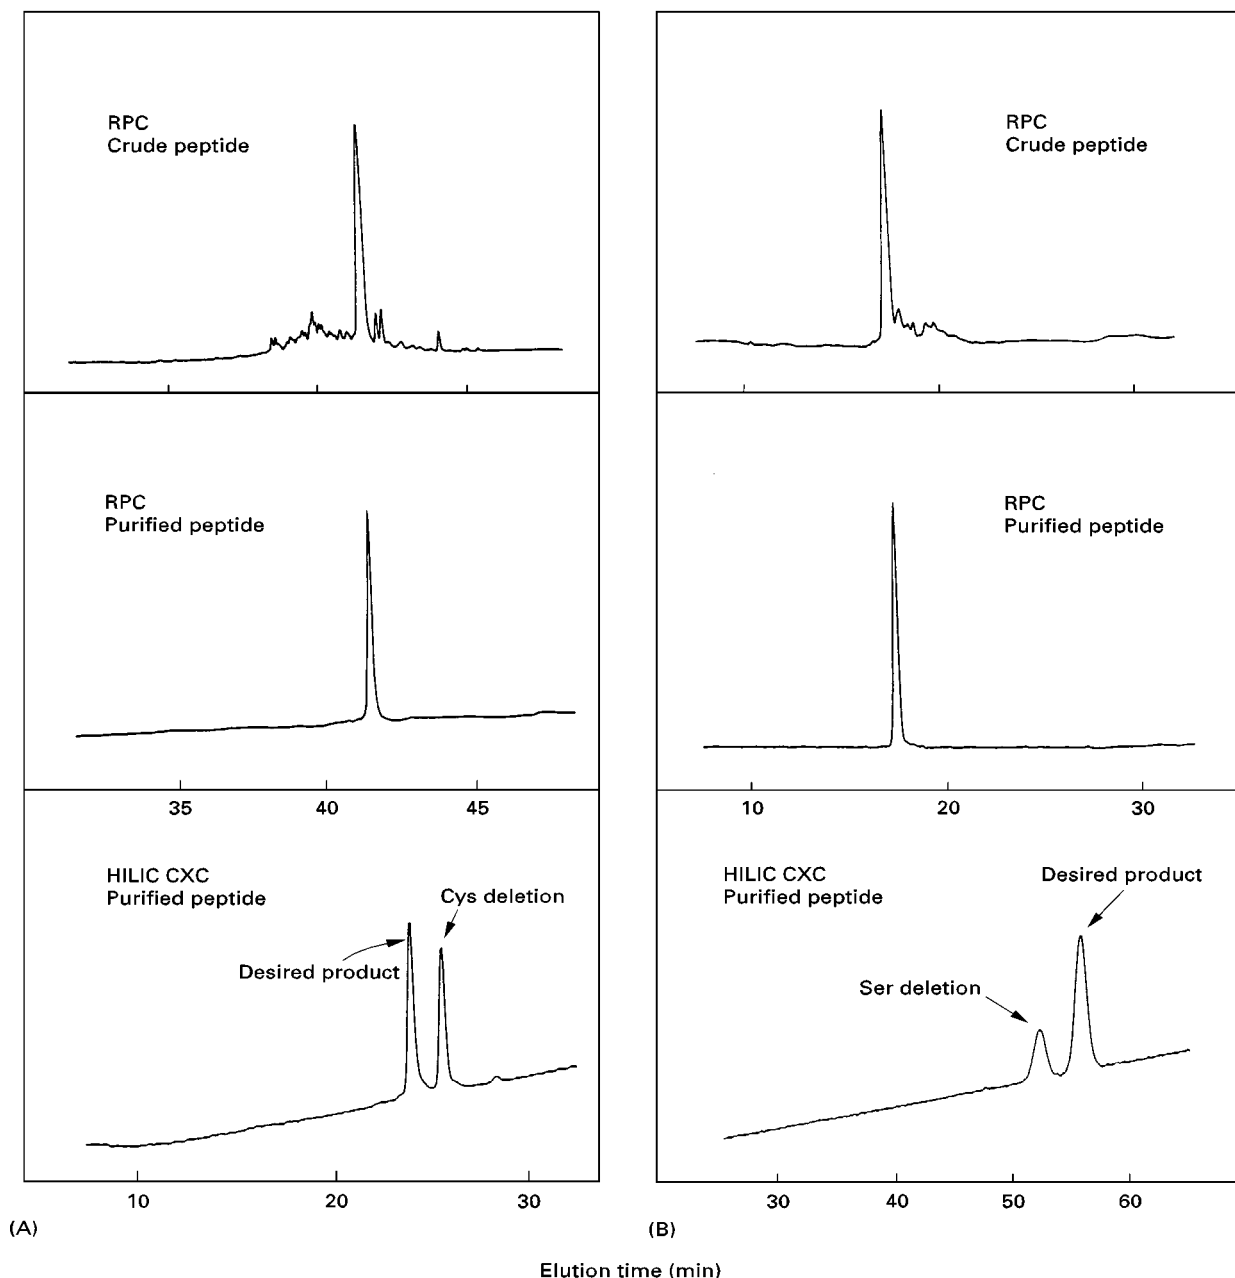

Figure 8 Analysis and purification of synthetic peptides by RPC and HILIC-CXC. (A) 35-residue Cys-containing α -helical peptide; (B) 17-residue intrachain disulfide-bridged peptide. Column: see Figure 1. Conditions: RPC, same as Figure 5 save for a gradient rate of 1% acetonitrile min^{-1} ; HILIC/CXC, linear AB gradient ($2.5 \text{ mmol L}^{-1} \text{ NaClO}_4 \text{ min}^{-1}$ from $30 \text{ mmol L}^{-1} \text{ NaClO}_4$, following 10 min isocratic elution with $30 \text{ mmol L}^{-1} \text{ NaClO}_4$) at a flow rate of 1 ml min^{-1} and a temperature of 26°C , where eluent A is 5 mmol L^{-1} aq. TEAP, pH 7, containing 65% (v/v) acetonitrile and eluent B is eluent A containing $400 \text{ mmol L}^{-1} \text{ NaClO}_4$. Peaks were detected at 210 nm. (Reproduced with permission from Mant *et al.*, 1997.)

makes to the overall hydrophobicity/hydrophilicity with increasing peptide chain length together with any other conformation effects specific to the peptide. **Figure 8A** bottom now illustrates the excellent separation of the two peptides when HILIC-CXC is applied to the purified peptide shown in the middle RPC profile. The loss of the Cys residue makes the peptide more hydrophilic (i.e. less hydrophobic), hence the

later elution of the Cys-deletion impurity. Note that neither IEC nor SEC is suitable as a complementary purification mode for this particular mixture owing to the identical net charge and essentially identical size of the two peptides. From **Figure 8A** a suitable purification protocol is HILIC-CXC of the crude peptide mixture followed by RPC of the desired product for desalting and final purification.

Figure 8B outlines the purification and analysis of a 17-residue synthetic peptide containing an intrachain disulphide bridge (peptide 03138 from Table 1). Following purification of the crude oxidized peptide mixture (top) by RPC, analysis of the purified product showed a single symmetrical peak (middle), indicating, in a similar manner to Figure 8A middle, excellent peptide purity. However, mass spectrometry of this single peak again showed, in addition to the expected mass, a second signal; in this case, this second signal exhibited a peptide mass 87 units less than the desired product, indicating deletion of one of the Ser residues. In RPC terms, Ser is classed as only a slightly hydrophilic group and hence contributes little to the retention behaviour of a peptide during RPC; thus, it is not surprising that the deletion product is difficult to detect, let alone resolve, by RPC. This is particularly true considering (as was subsequently determined) the position of the residue within the intrachain disulphide bridge as well as the 17-residue length of the peptide (see comments above concerning peptide chain length effects). IEC and SEC are again not suitable for isolation of the desired peptide product. However, Figure 8B bottom again illustrates the efficacy of the HILIC-CXC approach to resolving two peptides inseparable by RPC. Indeed, this mixed-mode approach appears to enhance the hydrophilic contribution of a Ser residue, as the Ser-deletion impurity is now baseline-resolved from the desired product. The Ser-deletion peptide is eluted prior to the desired product, since loss of this residue has made the peptide less hydrophilic (i.e. more hydrophobic) than the native peptide. In a similar fashion to the purification problem outlined in Figure 8A for the Cys-containing product, peptide 03138 is also best purified by an initial HILIC-CXC step followed by RPC of the desired peptide product.

Another excellent example of the utility of mixed-mode HILIC-CXC is illustrated in Figure 9 which follows the protocol required to purify a synthetic 21-residue α -helical peptide (denoted J1 in Table 1) from the peptide crude mixture. From the RPC elution profile (top) of the crude peptide, a major peak is obtained with a number of more hydrophilic and hydrophobic impurities, some of which are eluted very close to the main component. Subsequent attempts to improve the isolation of this main peak by varying the pH and/or the ion-pairing reagent used in the RPC mobile phase were unsuccessful, thus ruling out the possibility of an efficient one-step purification by RPC. Application of mixed-mode HILIC-CXC to the crude mixture resulted in the middle elution profile which shows a major peak as well as several other smaller, yet substantial, peptide components. Collection of the major peak followed by RPC produced the

Figure 9 Two-step HILIC-CXC and RPC purification protocol for synthetic peptide. (A) RPC of crude peptide; (B) HILIC/CXC of crude peptide; (C) RPC of HILIC/CXC main peak. Columns: see Figure 1. Conditions: RPC, linear AB gradient (1% acetonitrile min^{-1}) at a flow rate of 1 mL min^{-1} , where eluent A is 0.05% aq. trifluoroacetic acid (TFA) and eluent B is 0.05% TFA in acetonitrile; HILIC-CXC, linear AB gradient $2.5 \text{ mmol L}^{-1} \text{ NaClO}_4 \text{ min}^{-1}$, following 10 min isocratic elution with eluent A at a flow rate of 1 mL min^{-1} , where eluent A is 10 mmol L^{-1} aq. TEAP, pH 6.5, containing 65% (v/v) acetonitrile and eluent B is eluent A containing $350 \text{ mmol L}^{-1} \text{ NaClO}_4$; all runs were carried out at 30°C and peaks were detected at 210 nm. The fraction denoted by the bar in the HILIC-CXC elution profile (panel B) was collected and subsequently purified by RPC (panel C).

bottom elution profile, with the major purified peak shown subsequently by mass spectrometry to be the desired product. Clearly, this two-step protocol was very successful in solving a difficult purification problem. Note that the middle separation, which efficient-

ly removed from the desired product the impurities eluted close to this peptide during RPC (top), could not be achieved by IEC alone, i.e. the high ACN level characteristic of HILIC-CXC was vital to the separation.

A closer look at the HILIC-CXC separation (middle profile), specifically taking note of the three major impurities (denoted A, B and C), again highlights the unique selectivity properties of this mixed-mode approach. Peak A contains Lys-deletion peptide and is thus easily resolved from the desired product due not only to the loss of a positively charged residue but also to the concomitant significant loss of hydrophilicity represented by this decrease in charge character. In contrast, peaks B and C are not deletion products, i.e. they exhibit the same net charge as the product, but are in fact peptides representing modifications of the desired peptide where random acetylation of Ser residues has occurred. Subsequent investigation identified peak B as a peptide analogue with acetylation of a single Ser at position 3 of the sequence (Table 1); peak C represents a peptide analogue with acetylation of a single Ser at position 10 or position 17 of the sequence or possibly a mixture of these two modified analogues. Thus, not only is HILIC-CXC able to resolve these Ser-modified analogues from the desired product, but it is also able to distinguish between the subtle differences in hydrophilicity/hydrophobicity arising from the sequence position of modification.

An explanation for the marked superiority of HILIC-CXC to resolve the Ser-modified impurities from peptide J1 may be gleaned from Figure 10 which presents the sequence of peptide J1 as a helical net with the residues between the lines representing a wide, relatively hydrophilic face compared to the narrow hydrophobic face made up of Ile and Leu residues. The Ser residues (boxed to highlight positions of potential acetylation) lie in this wide hydrophilic face and would thus be expected to interact closely with the ion exchange matrix; conversely, they would be generally oriented away from a reversed-phase matrix, leading to a lesser effect of Ser-modification during RPC. Note that the environment (i.e. residues) surrounding Ser 10 and Ser 17 is identical while that of Ser 3 is quite different, probably accounting for the HILIC-CXC resolution of the Ser 3-modified peptide from that of analogues arising from acetylation at either of the other two positions.

Future Prospects

Clearly, HILIC-CXC offers a valuable, complementary alternative to RPC for peptide separations; indeed, such an approach often rivals RPC for

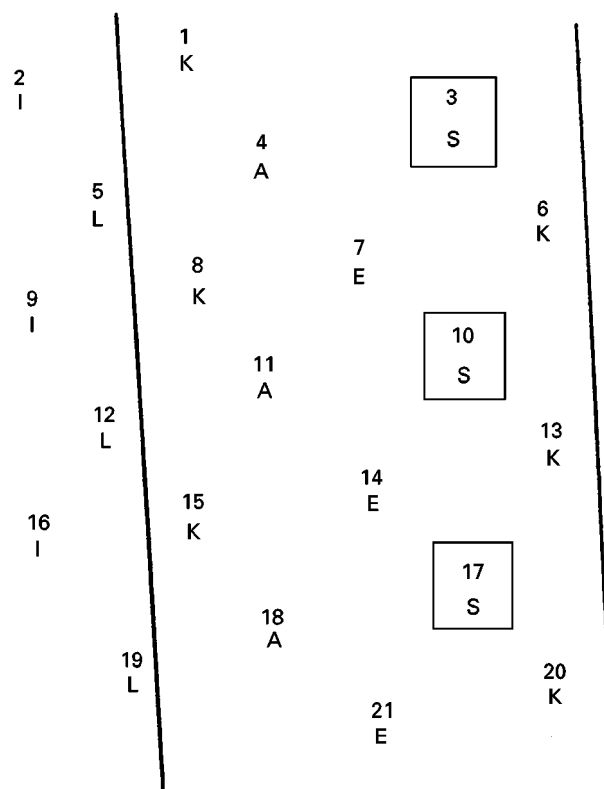

Figure 10 Sequence of synthetic amphipathic peptide J1 presented as an α -helical net. The radius of the α -helix is taken as 0.25 nm with 3.6 residues per turn, a residue translation of 0.15 nm and thus a pitch of 0.54 nm. The area between the lines represents the more hydrophilic face of the peptide, with the Leu and Ile residues representing the narrow hydrophobic face. The boxed Ser residues represent potential sites of side chain acetylation.

resolution of specific peptide mixtures. While the present article offers only a brief overview of the potential of HILIC-CXC for separation of peptides, it has already been successfully employed for protein separations where RPC alone was unable to effect the required resolution. In addition, since the need to identify peptide mixture components as well as to separate and quantify them is great, e.g. HPLC in conjunction with electrospray mass spectrometry (HPLC-MS), the utility of HILIC-CXC separations will be enhanced even further with the development of volatile mobile phases.

Thin-Layer (Planar) Chromatography

Introduction

Thin-layer chromatography (TLC) has found extensive application in protein chemistry including recovery of peptides in microgram and nanogram quantities for further primary structural analysis, identification of peptides in partial hydrolysates, in correlating the chromatographic properties of the intact peptides with those of individual amino acids, peptide mapping to characterize or to identify a protein available in very small quantities, resolution of diastereomeric and enantiomeric peptides without any derivatization, fractionation of proteins on the ultramicro scale, testing the optical homogeneity of synthetic peptides, and determination of relative molecular masses.

Application of TLC to the following aspects of peptide studies have also been reported: experimental studies of solute retention and support matrix effects in reversed-phase TLC (RP-TLC) of peptides; a rapid thin-layer immunochromatography method using monoclonal antibodies of two distinct specificities for quantitation of protein antigens; non-stoichiometric models for theoretical treatment of the chromatographic process on ion exchange phases; determination of amino acid configuration of synthetic peptide analogues on Chiralplate[®] with MeCN/MeOH/H₂O (4 : 1 : 1), prepared from the

racemic aromatic amino acids; dependence of the silanophyl effect on the chemical structure of peptides and on the type of mobile phase; study of the salting out behaviour of some peptides with aromatic groups by adsorption TLC on cellulose; separation of peptides on Empore TLC sheets and blotting onto polyvinylidene difluoride (PVDF) membranes with subsequent gas-phase sequencing; analysis of peptide and protein hydrolysates by 2D cellulose TLC and densitometry and its application to luteinizing hormone.

A knowledge of the behaviour of peptides and proteins with both the mobile and stationary phases, particularly with respect to information about kinetics of diffusion, adsorption and desorption, denaturation or conformation changes, is required. Optimization of chromatographic separations of peptides and proteins means a complete resolution of all components in a minimum time, on a preparative scale and with the retention of bioactivity. Various principles of liquid chromatography have successfully been applied to TLC resolution of peptides and proteins, e.g. reversed-phase, size exclusion, ion exchange, etc. The different thin-layer materials used for the purpose include silica gel, cellulose, mixtures of silica gel and cellulose, hydroxyapatite and cross-linked dextran gel filtration media like Sephadex[®] (various grades from Pharmacia, Uppsala, Sweden). The ordinary porous silica-based stationary phases containing chemically bonded alkyl chains of varying lengths have several disadvantages such as low stability at alkaline pH values (pH > 8), secondary equilibria caused by low diffusion kinetics within the pores,

and ion-exchange effects due to ionized underivatized silanol groups. Therefore, alternative stationary phases are being developed, e.g. coated silica phases, polymer-based phases, and nonporous materials. The separation and purification of peptides and proteins by ion exchange offers advantages because of mild separation conditions providing higher bioactivity recovery.

Sample Preparation

Depending on the nature and source, the proteins may be digested before applying them to thin-layer plates; some of the methods reported in the literature are described below.

1. Proteins are dissolved in ammonium bicarbonate (0.5%, pH 8.0) and digested with trypsin (1% w/w) for 4 h at 37°C. Chymotrypsin (1% w/w) may be added for trypsin–chymotrypsin digest and the digestion continued for a further 4 h. The peptides are recovered by freeze-drying.
2. Proteins may either be alkylated with iodoacetic acid or oxidized with performic acid to render them susceptible to enzymatic digestion. The treated proteins are then dissolved in ammonium bicarbonate buffer (0.05 mol L⁻¹, pH 8.4) to a concentration of 2 mg mL⁻¹ and TPCK-treated trypsin (L-(1-tosylamide-2-phenylethyl chloromethyl ketone)) is added to give a final enzyme-to-substrate ratio of 1 : 75. The digest is incubated for 5 h at 30°C, freeze-dried, and redissolved in 10% isopropanol for application to the plates.

For TLC of smaller peptides, the samples have either been synthesized or obtained commercially. The stock solutions (0.025 mol L⁻¹) are prepared in aqueous 2-propanol (10%) and are kept refrigerated when not in use. For proteins, solutions can be prepared in dilute saline solutions or in an appropriate buffer.

Preparation of Thin-Layer Plates

Commercially available precoated silica or cellulose plates have generally been used. Sometimes these plates have uneven coatings that can be checked by holding the plates against a light box and looking for dark streaks or patches that indicate uneven thickness. Such plates should be rejected or used for initial trial runs only. The following method has been widely used for making plates with cellulose powder. Preparation of thin-layer plates from Sephadex is also described.

Thin-Layer Plates from Cellulose

Cellulose powder is slurried with methanol/water (4 : 1, 200 mL). The slurry is poured into a Büchner funnel and is washed successively with 2-propanol/water/acetic acid (3 : 1 : 1, 300 mL); methanol/water (1 : 3, 200 mL); methanol/1 mol L⁻¹ HCl (3 : 2, 200 mL); water (200 mL), and finally with methanol (200 mL). The powder is dried overnight *in vacuo* before use. The purified cellulose powder (15 g) is spread as a slurry over five plates (20 × 20 cm) at an initial thickness of 400 µm. The coated plates are allowed to dry overnight in a horizontal position before use.

Thin-Layer Plates from Gel Filtration Media

Sephadex G-100 (6 g) or Sephadex G-200 is suspended in 100 mL of the solvent (e.g. 0.5 mol L⁻¹ NaCl solution). Care should be taken to ensure that no aggregates are present in the final gel suspension. The dextran gels usually take 48 h to proceed to complete swelling. Thoroughly cleaned and dry glass plates (10 cm × 20 cm) are coated with a 0.9 mm-thick layer of a suitable thin-layer spreader. The plates are kept in a closed vessel containing a dish of the solvent and stored in the horizontal position for at least 18 h before use. The layers may be stored for fairly long periods in a wet chamber; if they dry out or show cracking, a very mild spray with buffer solution is applied to regenerate the layers.

Development of Chromatograms

The silica gel or cellulose-based chromatograms are developed in the usual manner, while the development of gel plates is carried out as shown in Figure 1.

Various solvent systems, support materials, and detection procedures for the TLC of a variety of proteins and peptides have been summarized in

Figure 1 Apparatus for thin-layer chromatography of proteins. Solvent (0.5 M NaCl) is led to plate P by means of Whatman No. 3 filter paper wick W. The wick should overlap about 1 cm onto the gel layer. T is the solvent trough.

Table 1. The R_F values for some of these systems have been recorded in Tables 2–6.

For two-dimensional peptide mapping, conventional chromatography follows electrophoresis. The plate is dampened with electrophoresis buffer, taking care not to smudge the applied sample, and run at 1000 V for 40–90 min, for 20 cm × 20 cm plates. The electrophoresis plate is removed from the apparatus and dried overnight in a fume hood (there should be no smell of acetic acid on the plates). The plate is then developed using a suitable chromatographic solvent (Table 1). The composition of the solvent is critical for the mobility of peptides. More organic solvent in the mixture tends to increase the relative mobility of the hydrophobic peptides, since the stationary phase is hydrophilic. Some of the solvent systems used for two-dimensional work are mentioned in Table 7.

Detection of Peptides on Thin-Layer Chromatograms

Various peptides and proteins are located on the thin layer chromatograms by using ninhydrin, fluorescamine, o-phthalaldehyde, iodine vapours or UV. Quantitation is performed by densitometric scanning or by spectrophotometry after eluting the peptides; immunochromatography using monoclonal antibodies has also been used for quantification.

Detection on Cellulose or Silica Gel Plates

The plates can be viewed using a long-wavelength (366 nm) UV source or stained with a suitable reagent as described in Table 1. Certain other detection methods are described below.

1. *Morin reaction.* The dried chromatograms are sprayed with a 0.05% solution of morin (3,5,7,2',4-pentahydroxyflavone) in methanol, and heated for 2 min at 100°C. The *N*-protected amino acids and peptide derivatives give yellowish-green fluorescence on a green fluorescent background, or dark absorption spots under UV. The detection limit is about 2 µg per spot.
2. *Iodine starch reaction.* The chromatogram is placed in an iodine vapour atmosphere for 5 min. The excess iodine is removed by leaving the plate in the open air, and then the layer is sprayed with 1% aqueous starch solution. The peptides (and amino acids) give blue spots.

Detection on Gel Layers

The gel layer is covered with dry filter paper (Whatman 3 mm), avoiding bubble formation and is carefully smoothed down over it. The layer and the paper

are dried together at 120°C or the paper is carefully peeled off the layer and dried at 110°C.

The proteins on the paper are detected by the usual paper chromatographic methods. The dried paper is immersed for 15 min in Amido black 10 B (0.6 g) dissolved in a mixture of methanol or ethanol (750 mL), water (450 mL), and glacial acetic acid (100 mL) and washed three times with 1% acetic acid for 30 min each time. Alternatively, the paper is stained in 1% solution of Bromophenol blue saturated with mercuric chloride for 5 min and then washed five times with 0.5% acetic acid for 30 min each time.

Recovery of Peptides

After detection, the peptide spots on the cellulose or silica gel thin layers are carefully scraped and are transferred to 150 mm long Pasteur pipettes that have been tightly plugged with one-quarter of a glass fibre membrane filter (20 mm diameter, Sartorius SM 13400) and prewashed with 2 mL of 6 mol L⁻¹ HCl; 200 µL of 6 mol L⁻¹ HCl containing 0.02% β-mercaptoethanol is added to each of the Pasteur pipettes and the peptide is extracted at room temperature for 15 min. The HCl is then forced through the filter with nitrogen (1 atm).

TLC of Diastereomeric and Enantiomeric Dipeptides

Successful separation of dipeptide diastereomers, either as the free peptides or as the *N*-protected methyl esters, has been reported. Starting from pure *L*-methionine and *DL*-alanine, *Np*-*S*-*L*-Met-*DL*-Ala-*O*-*Np* and *Np*-*S*-*L*-Met-*L*-Met-*DL*-Ala-*O*-*Np* were synthesized and the separation of diastereomeric *p*-nitrophenyl (*Np*) esters of *N*-protected di- and tripeptides was achieved on silica gel F₂₅₄ precoated (Merck) plates. TLC separation of diastereomeric dipeptides has been well documented.

Typical examples of the separation of enantiomeric dipeptides on Chiralplates® are given in Table 5. It was observed that the antipodes with *C*-terminal *L*-configuration always gave a smaller R_F value than the corresponding enantiomeric dipeptide with *C*-terminal *D*-configuration. The method also resolves diastereomeric dipeptides. A comparison of resolution of four isomeric Try-Try, Ala-Ala, Phe-Phe, Tyr-Tyr, Lys-Ala, and Asp-Ala mixtures on Chiralplates® and on microcrystalline cellulose plates showed that the separation of *L,L* and *D,D* pairs of all tested dipeptides was better on microcrystalline cellulose plates while *L,D*, and *D,L*, pairs were better separated on Chiralplates® (Figure 2A, B).

Table 1 Solvent systems, support materials, and detection procedures for TLC of proteins and peptides

No.	Protein/peptide	Developing system	Detection
1	Carbazo peptides	(a) <i>n</i> -Butanol/acetone/acetic acid/5% NH ₄ OH/water (9 : 3 : 2 : 4) (b) <i>n</i> -Butanol/acetone/5% NH ₄ OH (11 : 6 : 3) (c) <i>n</i> -Butanol/acetone/pyridine/water (15 : 3 : 10 : 12) (d) <i>n</i> -Butanol/acetone/5% NH ₄ OH/H ₂ O two-phase mixture (6 : 1 : 1 : 2)	0.2% Ninhydrin spray (<i>n</i> -Butanol/2 N acetic acid, 95 : 5) followed by a spray of a saturated solution of K ₂ Cr ₂ O ₇ in conc. H ₂ SO ₄
2	Leu-Try-Leu	CHCl ₃ /(34%)NH ₄ OH/ethanol (2 : 1 : 2)	Dried for 2 h at 60°C, sprayed with 1% (v/v) triethylamine in acetone followed by 0.1% fluorescamine in acetone
3	Np-S-L-Met-DL-Ala-O-Np, Np-S-L-Met-L-DL-Ala-O-Np, Np-S-Met-Ala-Met-OMe	Solvents and <i>h</i> R _F given in Table 3	Iodine
4	<i>N</i> - <i>t</i> -butoxy peptides	Ethanol/pyridine/water/acetone (5 : 5 : 3 : 1)	Exposure to chlorine followed by spraying with <i>o</i> -toluidine reagent or dicarboxidine reagent
5	Lysino alanine	(a) Butanol/anhydrous acetic acid/water (4 : 1 : 1) (b) Phenol/water (3 : 1)	Ninhydrin
6	Peptides from proteases	(a) Chloroform/methanol (3 : 1) (b) Chloroform/methanol/acetone (45 : 4 : 1)	(a) Aqueous 2% sodium nitroprusside (b) 4% Ninhydrin in acetone/pyridine/acetone acid (97 : 3 : 2) (c) 1-Naphthol/NaBrO (Sakaguchi reagent)
7	Insulin	(a) 0.1 N HCl/96% ethanol (1 : 1) (b) 0.5 N HCl/ethanol/acetone (5 : 3 : 0.5)	0.5% Ninhydrin in acetone
8	Pepsin, trypsin and α -chymotrypsin	(a) 0.1 N HCl/ethanol (1 : 1) (b) 0.5 N HCl/ethanol/acetone (5 : 3 : 0.5)	0.5% Ninhydrin in acetone, heated at 100°C
9	Angiotensin	(a) <i>n</i> -Butanol/acetone/water (4 : 1 : 1) (b) <i>n</i> -Butanol/pyridine/water (15 : 10 : 3)	Ninhydrin
10	Bradykinin	<i>iso</i> -Propanol/methyl acetate/conc. ammonia (9 : 7 : 4)	UV
11	Dansyl peptides from ATP-creative phosphotransferase	Methyl acetate/ <i>iso</i> -propanol/conc. ammonia (9 : 7 : 4)	UV after exposure to dioxane vapours
12	Glycopeptides from <i>Escherichia coli</i> and <i>Bacillus megaterium</i>	<i>n</i> -Butanol/pyridine/acetone/water (130 : 20 : 6 : 24)	Chlorine/toluidine
13	Lipopeptides from <i>Nocardia asteroides</i>	Chloroform/methanol (1 : 1)	P ₂ O ₅ , 130°C
14	Cyclotriptides from <i>Aspergillus ochraceus</i>	Five different solvent systems	Chlorine/toluidine, KMnO ₄
15	Basic polypeptides	(a) <i>n</i> -Butanol/25% ammonia/water (34 : 3 : 3) (b) Chloroform/methanol (9 : 1)	Ninhydrin/chlorine/toluidine
16	Lipase, diastase, papain, emulsin, invertase	96% Ethanol/0.1 N HCl (1 : 1)	0.5% Ninhydrin in acetone, heated at 100°C for 10 min
17	Lipopeptides from <i>E. coli</i>	Chloroform/methanol/water (68 : 25 : 4)	Radioactivity

Table 1 Continued

No.	Protein/peptide	Developing system	Detection
18	Angiotensin antagonists	(a) Chloroform/acetone (5 : 1) (b) <i>n</i> -Butanol/acetic acid/water (4 : 1 : 1)	Ninhydrin
19	Vasopressin and xylocin, tripeptide amides	Butanol/acetic acid/water (4 : 1 : 1)	UV
20	<i>N</i> -methyl oligopeptides	(a) Chloroform/methanol (9 : 1) (b) Chloroform/acetone (8 : 2 or 9 : 1)	Chlorine/toluidine, UV, iodine UV, iodine
21	Dansyl peptides of lipoproteins	Three different solvent systems	Ninhydrin
22	Glycoprotein-derived oligosaccharides	Propanol/acetic acid/water (3 : 3 : 2)	Orcinol
23	Various peptides	Chloroform/methanol/aq.17% ammonia (2 : 2 : 1)	Sprayed with 0.1% solution of 4-chloro-7-nitrobenzofuran in ethanol, followed by 50% methanol (adjusted to pH 11 with (NaOH)
24	Enantiomeric and diastereomeric dipeptides (on Chiralplate)	Solvents and hR_F given in Table 5	0.1%
25	<i>Boc</i> - β Ala-Try-Met-Asp-Phe	Chloroform/methanol/acetic acid (18 : 2 : 1); sec-butanol/3% ammonia (25 : 11 and 3 : 1); ethanol/acetic acid/water (20 : 6 : 11); <i>n</i> -butanol/acetic acid/water (4 : 1 : 5, upper phase)	Ninhydrin, Ehrlich reagent, fluorescamine reagent
26	Oligopeptides (8 standard samples)	(a) <i>iso</i> -Amyl alcohol/ethanol/anhyd. acetic acid/pyridine/water (175 : 50 : 13 : 175 : 150) (b) <i>iso</i> -Propyl alcohol/ethanol/aq.ammonia (4 : 4 : 3)	Ninhydrin
27	Lysino alanine	(a) <i>iso</i> -Propyl alcohol/1 M HCl (3 : 1) (b) <i>tert</i> -Butyl alcohol/acetone/methanol/water/conc. ammonia (4 : 4 : 1 : 14 : 5); electrophoresis in glacial acetic acid/98% formic acid/water (17 : 5 : 28, pH 2)	Ninhydrin
28	Ribonuclease B, globin, R17-bacteriophage coat protein, carboxymethylated protein, subunits from BI component of TYMV; tryptic digest of glyceraldehyde 3-phosphate dehydrogenase of yeast	(a) <i>n</i> -butanol/pyridine/acetic acid/water (15 : 12 : 3 : 12) (b) <i>iso</i> -Butanol/pyridine/water (7 : 7 : 6) (c) <i>iso</i> -Amyl alcohol/pyridine/water (7 : 7 : 6) (d) Butanol/acetic acid/water (5 : 1 : 4), upper phase	Cd-Ninhydrin spray followed by heating at 60°C
29	Dipeptides with Leu/Ile as N-terminal residues	Solvent and hR_F given in Table 4	Cd-Ninhydrin spray followed by densitometry
30	Several di- and tripeptides (see Table 2)	Solvents and hR_F given in Table 2	Cd-Ninhydrin spray followed by heating at 60°C for 15 min
31	S-Carboxymethyl insulin chain-A, Ala-Leu-Gly, Leu-Leu-Val-Tyr, Glu-Gly-Phe	(a) Pyridine/acetic acid/water/acetone (2 : 4 : 79 : 15) at pH 4.4, electrophoresis (b) <i>n</i> -Butanol/pyridine/acetic acid/water (915 : 10 : 3 : 12)	(a) 0.3% Ninhydrin in collidine/acetic acid/ethanol (3 + 100 + 87) (b) 1% Fluorescamine (w/v) in acetone (c) 0.05% α -Phthalaldehyde in methanol (w/v) containing 0.2% β -mercaptoethanol and 0.09% Brij-35; sheets pre- and postsprayed with 10% triethylamine in methylene chloride

Table 1 Continued

No.	Protein/peptide	Developing system	Detection
32	Tryptic peptides from polyoma virus	(a) Acetic acid/0.5% pyridine, pH 3.5 (25 V cm ⁻¹) for electrophoresis (b) <i>n</i> -Butanol/acetic acid/water/pyridine (5 : 1 : 4 : 1)	Ninhydrin spray
33	Ribonuclease S protein	(a) 1.25 mol L ⁻¹ Pyridine acetate buffer, pH 6.45, 400 V for electrophoresis (b) Butanol/acetic acid/pyridine/water (30 : 6 : 20 : 24), TLC	Cd-Ninhydrin
34	Actinomycinhydrolysate	(a) Formic acid/acetic acid, pH 6.0 10 mA, electrophoresis (b) Butanol/water/acetic acid (5 : 4 : 1) TLC	Cu-Ninhydrin, fluorescamine
35	Acid hydrolysates of collagen	(a) <i>iso</i> -Propanol/butanone/1 mol L ⁻¹ HCl (12 : 3 : 5) (b) 2-Methyl-2 butanol/butanone/acetone/methanol/conc. ammonia (5 : 4 : 7 : 1 : 4)	Cd-Ninhydrin, <i>o</i> -phthaldialdehyde
36	Cystine peptides	Butanol/acetic acid/water (71 : 7 : 22)	Ninhydrin
37	Streptococcal peptides	Aq. 10% trichloroacetic acid	Ninhydrin
38	Enantiomeric dipeptides, Try-Try, Ala-Ala, Phe-Phe, Tyr-Tyr, Lys-Ala, Asp-Ala (synthesized)	Pyridine/water (2 : 1 or 4 : 1) at -10°C	Ninhydrin
39	Bovine serum-albumin, bovine γ -globulin, α -chymotrypsin, cytochrome <i>c</i> , haemoglobin, lysozyme, myoglobin, ovalbumin, ovomucoid, pepsin, ribonuclease, thyroglobulin, trypsin (Sephadex G-100, G-200)	Solvent and R_{fb} given in Table 6	Staining in 0.2% Ponceau S in 10% aq. acetic acid for 30 min followed by washing with water
40	Ornithine carbamoylphosphate transferase (Sephadex G-200, G-200 superfine)	0.5 mol L ⁻¹ NaCl	Amido black 10B in methanol/water/glacial acetic acid (5 : 4 : 1)
41	α -Chymotrypsin, aldose, catalase, bovine serum albumin, ovalbumin, lysozyme, phosphorylase b, β -galactosidase, alkaline phosphatase, lactate dehydrogenase, glyceraldehyde phosphate dehydrogenase (Sephadex G-75 and G-100)	6 mol L ⁻¹ guanidine hydrochloride (descending chromatography)	On paper, by spraying with diazotized sulfanilic acid
42	Small peptides on aluminium-backed thick silica gel	-	Fluorescence
43	Cystine and its peptides on polyamide or silica gel	-	Spraying with dilute 2-nitro-5-sulfothiobenzoate
44	Peptides from soya bean meals on KHSO ₄ -coated silica gel plates	Butanol/dioxane/water (4 : 5 : 1)	Treated with saturated thiobarbituric acid solution 85% H ₃ PO ₄ (1 : 1), then with ethanolic naphthoresorcinol/20% H ₂ SO ₄ (10 : 1), heated at 105°C
45	Phenyl alanine peptides on ammonium tungstophosphate-coated silica gel	0.1 mol L ⁻¹ Nitric acid/1 mol L ⁻¹ ammonium nitrate	

Table 1 Continued

No.	Protein/peptide	Developing system	Detection
46	Small peptides	Suspended over aq. 2,4,6-trimethyl pyrylium tetrafluoroborate and alkaline with 0.5 mL of triethyl amine then adjusted to pH 3 by acetic acid (chamber temp 80°C)	SIMS
47	Peptides on silica gel 60H	Water or aq. methanol	Ninhydrin
48	Oleoyl-L-alanyl-L-alanine	Water/MeCN (7 : 3), pH 5.0	Ninhydrin
49	Peptides on cellulose, impregnated cellulose or alumina layers (reversed-phase)	Propan-1-ol as organic component	-
50	Enantiomeric peptides on Chir® plate	-	-
51	Peptide from <i>Schumanniohyton magnificum</i> with anti-cobra venom activity on silica, or silica impregnated with 5% liq. paraffin in petrol ether	Acetone/methanol/10% ammonia (3 : 1 : 1); butanol/methanol/10% ammonia (3 : 1 : 1); chloroform/methanol (1 : 1)	Spraying with Dragendorf reagent, 5% ferric chloride, or 2% ninhydrin in acetone
52	HBsAG (hepatitis B virus) segments in soln on silica	Ethyl acetate + stock soln of pyridine/acetic acid/water (20 : 6 : 11) in various proportions	Spraying with toluidine/KI after chlorination
53	Protein antigens	A sandwich assay format using monoclonal antibodies of two distinct specificities, on covalently immobilized to a defined detection zone on a porous membrane while other serves as a label. Sample is mixed with the coating, and the mixture is then passed along a porous membrane in detection zone.	Monoclonal antibodies immobilized to a defined detection zone on a porous membrane; blue colour
54	Thyrotropin hormone, on silica	Chloroform/methanol (9 : 1), or ethyl acetate + stock soln of pyridine/acetone/water (20 : 5 : 11) in ratio 6 : 4.	-

Layer material for S. nos 1-25, 42-45, 51-52, 54, silica gel, for S. nos 26-38, cellulose; for S. nos 39-41, Saphadex; for S. no. 49 cellulose or alumina; and for S. no. 50, Chir® plate.

Table 2 $^a hR_F$ values of peptides from L-amino acids after one-dimensional TLC on cellulose

Peptides	Solvent systems				
	A	B	C	D	E

Val-Gly-Gly	65	28	52	65	61

$^a hR_F$ is the R_F value multiplied by 100.

Solvent systems: A, 2-propanol/butanone/1 M HCl (60 : 15 : 25); B, 2-methyl butan-2-ol/butanone/propanone/methanol/water/ammonia (10 : 4 : 2 : 1 : 3 : 1); C, 2-propanol/water (3 : 1); D, 2-propanol/water/acetic acid (15 : 4 : 1); E, 2-propanol/water/ammonia (15 : 4 : 1). All proportions are v/v.

Separation of Peptides on Reversed-Phase Plates Impregnated with Ion Pair Reagents

Successful separations of a large number of di- and tripeptides, and some tetra- and pentapeptides, on home-made silanized silica gel plates and reversed-phase (RP-2, RP-8, RP-18) plates impregnated with dodecylbenzenesulfonic acid, anionic and cationic detergents such as triethanolaminedodecylbenzene sulfonate (DBS), sodium dioctylsulfosuccinate (Na-DSS), and *N*-dodecylpyridinium chloride (*N*-DPC), and on ammonium tungstophosphate layers have been reported in the literature. The separation conditions and hR_F values of some polypeptides of moderate size and of similar structure on home-made layers of silanized silica gel and RP-2 plates are recorded in Table 8. The separation of such pep-

Table 3 hR_F values for dipeptides and tripeptides

Solvents: A, acetic acid/diethyl ether (1.5 : 20, v/v); B, acetic acid/diethyl ether (0.2 : 20, v/v); C, diethyl ether/iso-propanol (20 : 0.25, v/v). Np = p-nitro phenyl-.

tides is, however, a difficult problem of analytical importance.

The different solvent systems and chromatographic conditions used for these separations are summarized in Table 9. The description of the peptides and their structures is omitted. These systems may thus provide helpful guidance for choosing or developing a solvent system according to the actual requirement of the experiment.

Table 4 Chromatographic behaviour of dipeptides from L-amino acids on thin layers of cellulose

Peptides	hR_F			Colour yield ($\text{mm}^2 \mu\text{mol}^{-1}$) $\times 10^{-4}$	
	A	B	C	405 nm	490 nm
Ile-Ala	90	68	56	3.5	7.8

Solvent system: A, methanol/water/acetonitrile (1 : 1 : 4, v/v); B, methanol/water/acetonitrile (5 : 5 : 3, v/v). Length of run 13 cm. Detection: 0.1% ninhydrin reagent.

Table 6 $^aR_{Hb}$ values of proteins on Sephadex plates

Protein	Molecular weight $\times 10^{-2}$	$^aR_{Hb}$	
		A	B
Cytochrome-C	13.0	0.68	0.74
Ribonuclease	13.6	0.68	0.74
Lysozyme	14.5	0.65	0.70
Myoglobin	16.9	0.79	0.80
α -Chymotrypsin	22.5	0.87	0.87
Trypsin	23.8	0.83	0.86
Ovomucoid	27.0	0.94	1.03
Pepsin	35.0	0.99	1.04
Ovalbumin	45.0	1.03	1.04
Haemoglobin	68.0	1.00	1.00
Bovine serum albumin	65.0	1.28	1.54
Bovine γ -globulin	180.0	1.28	1.54
Thyroglobulin	650.0	1.33	1.83
Macroglobulin	1000		1.86

$^aR_{Hb} = d_p/d_{Hb}$, where d_p and d_{Hb} are the distances traversed by the test protein and by hemoglobin, respectively.

A, plates of Sephadex G-100, developed in 0.5 mol L⁻¹ NaCl solution; B, plates of Sephadex G-200, developed in 0.5 mol L⁻¹ NaCl solution.

Table 7 Conditions for fingerprinting tryptic peptides on silica gel G thin-layer plates (20 cm \times 20 cm \times 0.1–0.25 mm)

First dimension: electrophoresis
 pH 3.5, pyridine/acetic acid/water (2 : 20 : 978, v/v) 1000 V, 45 min
 pH 6.5, pyridine/acetic acid/water (100 : 3 : 897, v/v) 1000 V, 40 min
 pH 4.7, *n*-butanol/pyridine/acetic acid/water (2 : 1 : 1 : 18, v/v)

Second dimension: chromatography at 25°C
 Chloroform/methanol/ammonium hydroxide (2 : 2 : 1, v/v)
n-Propanol/ammonium hydroxide (7 : 3, v/v)
n-Butanol/pyridine/acetic acid/water (97 : 75 : 15 : 60, v/v), pH 5.3

Determination of Relative Molecular Mass of Proteins

Since there is a close correlation between the logarithm of the relative molecular mass of a protein and its chromatographic behaviour (the distance covered in a constant time on a given layer), TLC of proteins and polypeptide chains on cross-linked dextran gel provides a method that allows rapid estimation of relative molecular masses of polypeptides. Relative molecular masses of several polypeptides estimated via TLC on Sephadex G-75 and G-100 plates developed with 6 mol L⁻¹ guanidine hydrochloride are shown in Table 10. Sephadex G-75 is used for the chromatography of polypeptide chains with relative

Table 8 hR_f values of polypeptides on home made layers of silanized silica gel and on RP-2 plates

Compound	Silanized silica gel		RP-2	
	A	B	B	C
Angiotensin III inhibitor	47	76	75	81
Angiotensin III	16	55	53	71
Angiotensin II	37	75	73	79
Angiotensin I	22	63	59	75
Melittin	00	00	00	52
Glucagon	00	33	26	72
Insulin B chain	00	36	31	72
Actinomycin C ₁	00	03	02	25
Actinomycin V	00	04	03	22
Actinomycin I	00	08	05	32

A, 1 mol L⁻¹ acetic acid in 30% methanol; B, 1 mol L⁻¹ acetic acid + 3% potassium chloride in 50% methanol; C, 3% potassium chloride in water/methanol/tetrahydrofuran (4 : 3 : 3). Migration distance was 11 cm for home-made layers and 6 cm for RP-2 plates. Actinomycins were yellow; other compounds were located by 1% ninhydrin in pyridine/acetic acid (5 : 1). Actinomycins I and V differ from C₁ by having one of the two prolines replaced by 4-hydroxy- and 4-ketoproline, respectively.

Figure 2 Chromatograms of Trp-Trp isomers. (A) Microcrystalline cellulose plate; eluent, pyridine/water (2 : 1). (B) Chiral plate; eluent, methanol/water/acetonitrile (50 : 50 : 200).

Table 9 TLC conditions for the separation of peptides on impregnated and RP silica gel plates

- RP-2, RP-8, RP-18, plates impregnated with 4% HDBS
 - 1 mol L⁻¹ acetic acid in methanol/water (1 : 1)
 - 1 mol L⁻¹ acetic + 0.2 mol L⁻¹ HCl in methanol/water (1 : 1); at high methanol percentage, i.e. methanol/water (4 : 1), the R_F values increased and more polar peptides gave elongated spots. The RP plates cannot be used with aqueous organic eluents containing more than 30% water.
- Untreated thin layers of silanized silica gel or impregnated with different detergents
 - Water/methanol/acetic acid (64.3 + 30 + 5.7), for untreated plates
 - 0.1 mol L⁻¹ or 0.05 mol L⁻¹ HCl + 1 mol L⁻¹ acetic acid in 30% methanol (pH 1.25 or 1.55); 0.1 mol L⁻¹ NaCl + 1 mol L⁻¹ acetic acid in 30% methanol (pH 2.75 or 3.30); 0.1 mol L⁻¹ sodium acetate + 0.1 mol L⁻¹ acetic acid in 30% methanol (pH 5.10); 1 mol L⁻¹ sodium acetate in 30% methanol (pH 8.15), for plates impregnated with 4% HDBS.
 - Water/acetic acid (7 : 3 or 1 : 1), for plates impregnated with 4% HDBS.
 - 0.1 mol L⁻¹ acetic acid + 0.1 mol L⁻¹ sodium acetate in 30% methanol, 1 mol L⁻¹ acetic acid in 30% methanol; 1 mol L⁻¹ sodium acetate in 30% methanol, for plates impregnated with 4% N-DPC. Alkaline elements, which cannot be used in RP column chromatography, can be used here. Separation on layers impregnated with N-DPC is better with an eluent of pH 5.10 than with an eluent of pH 2.75.
- Layers of ammonium tungstophosphate + CaSO₄ · (1/2)H₂O in the ratio 4 : 2
 - Aqueous solutions of ammonium nitrate (1 mol L⁻¹, 2 mol L⁻¹)
 These plates provided compact spots and good resolutions. Mainly di-, tri-, tetra- and homopeptides were resolved by the above methods. The peptides were detected by spraying the wet layers with a solution of 1% ninhydrin in pyridine/glacial acetic acid (5 : 1) and then heating the layers at 100° for 5 min.

HDBS, Dodecylbenzenesulfonic acid; N-DPC, N-dodecylpyridinium chloride.

Table 10 Relative molecular masses of proteins on Sephadex plates

Protein	M_r	No. of PC	M_r of PC	M_r results (SD)
Lysozyme	14 500	1	14 500	17 500(520)
Lactate dehydrogenase	12 600	4	31 500	31 000(500)
Glyceraldehyde phosphate dehydrogenase	140 000	4	35 500	35 500(1200)
Alkaline phosphatase	41 000	1	41 000	41 500(800)
Phosphorylase b	188 000	2	94 000	98 000(500)

SD, standard deviation; PC, polypeptide chain.

Results are mean of 15 runs.

molecular masses less than 100 000, while Sephadex G-100 is used for higher molecular mass proteins. The solutions of proteins are prepared in guanidine hydrochloride (10 mg mL^{-1}), and cytochrome *c* (10 mg mL^{-1}) is used as an internal standard. Descending chromatography is carried out at room temperature under an inclination angle of 25° to the horizontal. After 3 h of development the quotient R_s protein/ R_s cytochrome *c* is calculated for each protein–cytochrome *c* combination. A standard calibration line is obtained by plotting the log relative molecular masses of standards against protein–cytochrome quotient; the relative molecular masses of the unknown proteins are calculated from this plot.

Introduction

The future of membranes in liquid–liquid separation lies in their potential to replace conventional unit operations such as distillation and cryogenic separation. Pervaporation, which has elements in common with reverse osmosis and membrane gas separation, is a liquid–liquid membrane separation process that can be employed for aqueous–organic or organic–organic separations. The most developed area of pervaporation is the separation of aqueous–organic mixtures but a vast potential lies in the area of organic–organic separations, specifically in the separation of azeotropic organic mixtures, where conventional separation processes tend to be complex and uneconomical.

The first pervaporation studies were carried out in late 1950 by Binning and coworkers at American Oil. However the process was not commercialized owing

to lack of technology to prepare a membrane that would withstand the commercial application. By the 1980s, membrane technology was advanced to the extent that a commercially viable pervaporation technology could be developed. However, the only commercialized applications today are the alcohol dehydration and separation of volatile organics from aqueous solutions. A few pilot-plant studies have been carried out on the industrially more significant organic–organic separations.

The applications of pervaporation can be categorized as follows: (1) dehydration of organic solvents; (2) removal of volatile organic compounds from aqueous streams; and (3) separation of organic–organic mixtures. There is a tremendous amount of literature on the first two applications. Pervaporation has been successful in these applications because the properties of organic components are very different from water and exhibit distinct membrane permeation properties. The feed solutions are also relatively non-aggressive and do not chemically degrade the membrane. However, in the case of separation of organic–organic mixtures, it is much more difficult to select membranes that would exhibit selectivities for one component over the other. This article

Figure 1 Schematic of pervaporation-distillation scheme for azeotrope separation.

is focused on this type of organic-organic separation. In a typical pervaporation process, even though the membrane selectivity is high, the mass flux achieved is fairly low ($2 \text{ kg m}^{-2} \text{ h}^{-1}$). Thus pervaporation is most advantageously used, when combined with another operation such as distillation. A schematic of such a hybrid process scheme is shown in **Figure 1**. An azeotropic mixture A + B is subjected to one-stage pervaporation to give a permeate rich in A and retentate rich in B. Both the streams are individually subjected to fractional distillation to yield pure A and pure B, and a recycle stream of azeotropic mixture of A + B.

In pervaporation, the liquid mixture is brought in contact with one side of the membrane and permeated product is removed from the other side by applying vacuum (**Figure 2A**). Alternatively, the vapour product can also be removed by use of a carrier gas (**Figure 2B**). The permeate is then cooled and the organic phase condensed and collected to obtain the product.

The ability of a pervaporation membrane to perform separation is usually characterized by a separation factor defined as:

$$\alpha_{ab} = \frac{C_{a_p}/C_{b_p}}{C_{a_f}/C_{b_f}} \quad [1]$$

where, C_a , C_b are concentrations of A and B, and the subscripts p and f designate permeate and feed, respectively. The separation factor depends upon the operating conditions of the pervaporation processes and the solubility and affinity of the compounds in the feed solution towards the membrane. The selectivity can be of two types: solubility selectivity and

diffusivity selectivity. In most of the organic separations, dense membranes are employed and the diffusivity selectivity is generally low. Hence, of importance here is the solubility selectivity. For high solubility, membranes should have high affinity for one component and little affinity for the other component. However, excessive affinity for one component causes significant swelling of the membrane leading to loss in selectivity and mechanical strength. In the case of organic-organic separations, the membrane selection is particularly difficult. Several different methods such as polymer alloys, crosslinking, concentrated emulsion polymerization, microphase separation, copolymerization, and plasma graft filling polymerization have been proposed to prepare the membranes with the desired properties.

Selection of Membrane for Pervaporation

The choice of membrane to perform a particular separation is determined by the membrane's stability, productivity, and selectivity. Membrane productivity is the measure of the quantity of a component that permeates through a specific area of membrane in a given unit time and depends on the intrinsic permeability and the thickness of the membrane. The ability of a membrane to separate the desired component is characterized by its selectivity. Selectivity depends on the preferential sorption and relative permeability of the components. There is usually a trade-off between membrane permeability and selectivity. In 1993, Huang and Feng introduced a composite number called a pervaporation separation index (PSI) to take into account both these aspects.

Figure 2 Schematic of pervaporation process. (A) By vacuum. (B) By carrier gas.

The stability of the membrane strongly depends on chemical, mechanical, and thermal properties of the membrane and the type of the environment.

Although the use of pervaporation for the separation of organic–organic mixtures represents a large opportunity for energy and cost savings, it is the least developed application of pervaporation. This is because of problems associated with the choice of proper membrane for the concerned application. Organic–organic separations involve relatively harsh conditions and the stability of the membranes under these conditions is often low. The polymeric membranes that are commonly used for aqueous systems are not stable in organic environment. This is an area of active research.

Once the stable membrane material is identified, attention should be focused on obtaining maximum separation with large production rate. As mentioned earlier, separation is achieved by virtue of the difference between the permeability or the solubility (affinity) values of the component in the membrane. The permeability in the membrane depends on the molecular size, and small molecules tend to permeate faster through the membrane. However, their permeation can be restricted by selecting a membrane material that offers less solubility to these components. Hence, the polarity of the membrane can conveniently be manipulated in such a way that it offers preferential treatment for the components to be separated on the permeate side. For instance, to improve the permselectivity towards certain non-polar organics, the membrane can be filled with organophilic adsorbents.

Materials used for pervaporation membranes are normally polymeric in nature. Polymeric membranes can be classified in three different categories: glassy

polymer membranes, elastomeric polymer membranes and ionic polymer membranes. Glassy polymers are water-selective whereas elastomeric polymers are organo-selective. However, for organic–organic separations, the selection of material becomes highly system-specific and is based on relative polarity and molecular size of the components to be separated. Hence, all the polymer membrane types have shown selectivity to certain components in organic–organic mixtures. Hydrophilic–hydrophobic composite membranes containing polystyrene as the dispersed phase and polyacrylamide as the continuous phase have shown tremendous selectivity towards aromatic difluoride compared to aliphatic ones. Membranes made from cellulose esters, polyethylene, and poly(vinylidene difluoride) modified to contain various Werner complexes, have been successfully used on a laboratory scale for separation of isomer mixtures such as *p*-xylene–*o*-xylene. Ionic membranes of perfluorosulfonic acid have been found to be effective for the selective pervaporation of relatively polar organic compounds such as alcohols. A list of organic–organic separations attempted by pervaporation is shown in Table 1.

In the interest of improving the membrane productivity, either membrane structures are modified or a different configuration such as a hollow-fibre membrane is used. The membrane structure can be altered by introducing an asymmetry during the membrane preparation procedure and most industrially important membranes are asymmetric. These membranes have a thin dense selective surface layer supported on a much thicker microporous layer. When the support material and layer material are different, then the membranes are called composite membranes. One of the advantages of the com-

Table 1 Examples of organic–organic separation by pervaporation

Type of system	Example	Membrane(s) used ^a
Aromatic–alcohol	Benzene–methanol, ethanol, propanol Toluene– <i>n</i> -butanol	Polyethylene, cellulose acetate Polypropylene, polyethylene
Aromatic–naphthalene	Benzene–cyclohexane	PVA, acrylonitrile copolymers, plasma grafted, composite

posite membranes is that different polymers may be used as the barrier layer and the porous support, which allows a combination of properties that may not be available in a single material. The hollow-fibre membrane configuration is constructed similarly to a shell-and-tube heat exchanger. This configuration provides advantages over a flat plate-and-frame configuration such as large membrane area per unit volume, self-supporting ability, etc.

Applications

We will discuss here a few commercially important organic-organic systems that have potential of adapting pervaporation-assisted separation schemes.

Pervaporation-Distillation

Pervaporation-distillation process for MTBE production Methyl-*t*-butyl-ether (MTBE) is manufactured through the reaction of isobutylene from the C₄ fraction with methanol. The reaction is limited by equilibrium. The current technologies use a combination of reaction and either normal distillation or reactive distillation. The former process can exploit the potential of pervaporation before, during or after the distillation step to recover methanol from the reaction mixture. Figure 3 shows the two possible configurations, which use pervaporation as an intermediate step in MTBE manufacture.

The first configuration uses pervaporation to separate methanol from the reactor effluent (Figure 3A).

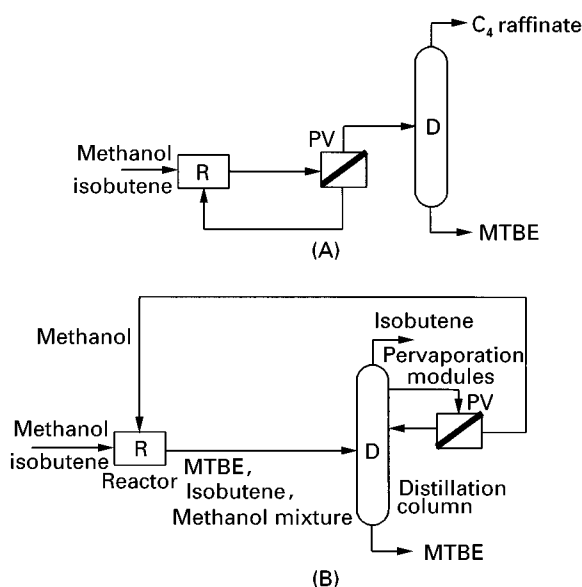

Figure 3 Different configurations of hybrid pervaporation-based MTBE processes.

The methanol-rich permeate is fed back to the reactor. This increases the overall conversion and also reduces the load on the methanol recovery unit. Moreover, this modification is easily possible in an existing MTBE plant without any major investment. The second configuration involves the withdrawal of a side-stream from the rectifying section of the distillation column to subject it to pervaporation (Figure 3B). Methanol from this stream can be separated and the retentate is again fed back to the distillation column. By doing this, the load on methanol recovery can be substantially reduced. Both configurations have been proved to be beneficial in view of reducing the investment cost by about 5–20%. The second configuration appears to be attractive compared to one that incorporates pervaporation before distillation. It involves low flow rates, low amount of methanol to be separated and a large driving force owing to high methanol concentration. Hence a membrane with a small surface area serves the purpose. A variation of the second scheme is also possible where the top product of the distillation column is liquefied and fed to the pervaporation unit to separate the methanol. The methanol-rich permeate is recycled back to the reactor. A highly permselective asymmetric aromatic polyimide membrane is used with a separation factor greater than 200. As a separate methanol recovery unit is not required, the process is more promising than the two options mentioned above.

A general advantage that is realized by adopting the hybrid process using pervaporation is the considerable savings in energy (especially steam) consumption. An organophilic (methanol-philic) plasma-polymerized PERVAP 1137 membrane (Sulzer Chemtech/GFT) has been suggested for this operation.

Pervaporation-distillation process for ETBE production

Typically ethyl *t*-butyl ether (ETBE) is produced by acid-catalysed etherification of isobutylene with ethanol. The products are separated by distillation, the top product being the C₄ fraction and the bottom consisting of ethanol and ETBE. Pervaporation can be incorporated into this process to purify the bottom of the distillation column wherein ethanol is separated from ETBE (Figure 4). An organophilic (ethanol-philic) copolymer PERVAP 2051 membrane is used for this purpose and this brings down the ethanol content in the ETBE product stream to less than 1% w/w. A significant reduction in operating cost is realized with the help of the hybrid process. Pervaporation can also be used to recover ethanol from the top product of distillation. The liquid retentate may be fed back to the distillation through

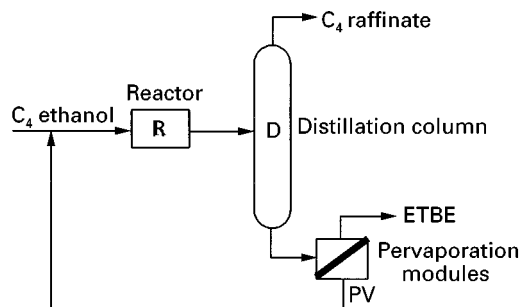

Figure 4 Hybrid pervaporation process for ETBE.

the column feed. The hybrid process is more economical than the conventional process.

Separation of Benzene–Cyclohexane

Cyclohexane is industrially produced by hydrogenation of benzene. They have close boiling points (within 1°C) and also form an azeotrope and hence cannot be separated by simple distillation. With the right choice of membrane, the separation can be achieved via the pervaporation route. However, the similar molecular size of benzene and cyclohexane makes the selection of a pervaporation membrane challenging. Poly(vinyl alcohol), acrylonitrile/methyl methacrylate, acrylonitrile/vinyl acetate, polymer metal complex membranes, plasma-grafted polymer membranes, and composite membranes of acrylic acid/styrene have all been employed with each having their own advantages/disadvantages. The process has been successfully demonstrated on a laboratory scale but there is no commercial process so far. Rautenbach and Albrecht made a comparative study of different separation schemes for this system. A comparison of a cascade of pervaporation processes with extractive distillation using furfural shows that the pervaporation process is more capital intensive. However, the conventional two-column extractive distillation process does not give the desired purity of the benzene and cyclohexane stream. A hybrid pervaporation–extractive distillation process shown in **Figure 5** proves to be the economically attractive alternative and gives the highest purity product. Furfural is used as an extractive carrier to carry benzene down in the first column. The bottom of the first column contains benzene and furfural, which are separated to obtain 99.5% pure benzene in the second column. The top product of the first column is subjected to a one-stage pervaporation where benzene is selectively removed to obtain 99.2% cyclohexane. The hybrid process can save up to 20% of the overall costs of the extractive distillation process.

Dimethyl Carbonate–Methanol Separation

Dimethyl carbonate (DMC) finds use in gasoline products as a fuel oxygenate and can be blended with alcohols or MTBE. It can serve as an MTBE substitute or as a phase enhancer in gasoline containing alcohol. DMC is prepared industrially by the reaction of methanol with carbon monoxide and oxygen. The process produces a mixture of methanol and DMC, which cannot be separated by simple distillation owing to the formation of an azeotrope. In the conventional process, a two-pressure distillation scheme is employed to split the azeotrope. The degree of separation achieved is nevertheless insufficient to meet the product specifications so a supplementary physical separation process such as crystallization is needed to obtain the desired product purity. Another route is to employ extractive distillation, where water is preferably used as an extractant. This means the separation of water–methanol needs to be carried out to recover the methanol. Owing to the high specific and latent heat of water, this process becomes very energy intensive.

Pervaporation combined with distillation can be advantageously employed to separate the methanol–DMC azeotrope as shown in **Figure 6**. The azeotropic methanol–DMC mixture is subjected to pervaporation. The retentate is 45% DMC, which is further separated by a distillation column into 99% DMC at the bottom and a near-azeotropic methanol–DMC mixture at the top. The top stream is recycled to the pervaporation. The further advantage of this scheme is that the top composition at the distillation column is not required to be azeotropic. This further brings down the number of stages required in the rectifying section of the column. This, combined with the elimination of high-pressure column, brings down the investment cost by 60% from the conventional process to the pervaporation–distillation hybrid process. Organophilic composite

Figure 5 Hybrid process for separation of benzene–cyclohexane.

Figure 6 Pervaporation–distillation hybrid process for DMC.

membranes are used to carry out the pervaporation separation.

Separation of Aromatics–Saturates

The separation of aromatics from saturates is of considerable importance in the petrochemical industry. The boiling range of the aromatics and saturates is the same and hence simple distillation fails to separate the products. Pervaporation can be efficiently employed for this separation. A copolymer of polyimide–aliphatic polyester is advantageously used as a membrane. The polyimide provides the stability at high temperature whereas the polyester provides for the selectivity to aromatics. Other membranes that can be used for this application are polyurea urethane, polyurethane imides, and polyester imides. The process shown in **Figure 7** gives high selectivity towards the aromatics. A part of the aromatic permeate (25–40%) is recycled back to the pervaporation stage where it is mixed with the fresh feed. This scheme gives unexpectedly high selectivity than when the feed is exclusively either fresh feed or recycle permeate. Heavy cat naphtha can be separated by the

Figure 7 Pervaporation scheme for the separation of aromatics–saturates.

above process into aromatic-rich permeate for high-octane gasoline use and aromatic lean retentate suitable for diesel fuel. The process can also be applied to intermediate cut naphtha, diesel oil, gas oil, and light aromatic streams boiling in the C_5 range.

Conclusion

Pervaporation of organic–organic mixtures has the great potential of replacing conventional processes. The key areas of applications are separation of azeotropes and close boiling mixtures. However, the challenge for pervaporation to prevail in organic–organic separation is enormous, as there is a lot of inertia of the industry to change from the conventional distillation processes. Finding a suitable membrane is the most important hurdle in devising a pervaporation system. Hence, the major thrusts in this field should be towards developing new membranes with high flux, selectivity, and stability. At the same time, to warrant commercialization, high surface area modules must be developed. With emerging trends in membrane research and newer techniques such as asymmetric and composite membranes, the day is not too far off when pervaporation will be the preferred process. As outlined earlier, pervaporation combined with conventional separation is the way forward in most of the applications. Hence, overall integrated process development needs to be given equal importance. Ultimately, in order to achieve a complete success, membrane development efforts should be backed by more theoretical research for a better understanding of the complicated phenomenon of pervaporation.

PESTICIDES

Extraction from Water

M.-C. Hennion and V. Pichon, Laboratoire
Environnement et Chimie Analytique, Paris, France

Copyright © 2000 Academic Press

Introduction

Pesticides and their metabolites have received particular attention in the last few years in environmental trace organic analysis because they are regularly detected in surface and ground waters especially throughout Europe and North America as a consequence of their widespread use for agricultural and nonagricultural purposes. Several priority lists have been published to protect the quality of drinking and surface waters.

Pesticides, as organic compounds, are usually determined by chromatographic and related techniques. However, they are present in the environment at trace levels and despite advances in separation and quantification, no sample can be directly analysed and an extraction and concentration step is required, whatever the matrix. The detection levels required for monitoring pesticides in drinking water at a regulatory level depend on the particular country. In the USA, a priority list has been established on the basis of the toxicity of the analytes which contains about 25 pesticides and metabolites with a health advisory level in the range $1\text{--}700\ \mu\text{g L}^{-1}$. Europe has more drastic regulations since the concentration of each pesticide should be lower than $0.1\ \mu\text{g L}^{-1}$, and quantification at this level requires detection limits of $0.01\ \mu\text{g L}^{-1}$ for the analytical procedure. For the monitoring of ground and surface water, several parameters have been taken into account such as quantities used, water solubility, hydrolysis half-life and soil adsorption coefficient. In surface water, in the USA, the recent National Pesticide Survey (NPS) list includes almost 150 pesticides with many degradation products; in Europe, a priority list was published in 1992 which contained 55 compounds.

Therefore, in order to reduce the price and time of environmental monitoring, it is relevant to perform multiresidue analysis which includes modern polar pesticides and their degradation products. Sample preparation remains the weakest link and the time-

determining step in the whole procedure for trace analysis of pesticides. Before implementing any strategy it is important to consider the strong interdependence of the various steps of the whole procedure, i.e. sample handling, separation and detection. There is no unique strategy for the sample handling step, because it depends on the nature of the pesticides to be determined (e.g. volatility and polarity), on the nature of the matrix and on the degree of preconcentration necessary. Interference removal is a critical step which is strongly related to the concentration of the analyte of interest and of the matrix. It is evident that the strategy for determining pesticide below the micrograms per litre level in drinking water may be different from that used in a very polluted river.

The methods for extraction and concentration of pesticides are mainly liquid-liquid extraction and solid-phase extraction. One key problem in pesticide analysis comes from the diversity of their chemical functional groups with varying polarity and physico-chemical properties.

Liquid-Liquid Extraction

Liquid-liquid extraction (LLE) is the simplest extraction method and is described in US EPA (Environmental Protection Agency) official methods. The large choice of solvents which provide a wide range of solubility and selective properties, is often given as an advantage of the method. But, in fact, each solvent is not really specific for a class of compounds. Hexane and cyclohexane are typical solvents for extracting nonpolar compounds, such as organochlorine and some organophosphorus pesticides, whereas dichloromethane and chloroform are the common solvents used for the extraction of medium-polarity pesticides. EPA method 507 allows the determination of 46-nitrogen- and phosphorus-containing pesticides in water, with an extraction of a 1 L sample of water with 200 mL of dichloromethane, followed by an evaporation step, a reconcentration in 5 mL of methyl t-butyl ether (MTBE) and an analysis step using GC with a nitrogen-phosphorus detector (NPD). Detection limits are estimated in the range $0.1\text{--}4.5\ \mu\text{g L}^{-1}$, depending on the analyte. EPA method 508 uses a similar extraction step for chlorinated pesticides in ground water using GC electron capture detector (ECD) with detection limits in the range $0.02\text{--}1.3\ \mu\text{g L}^{-1}$. The detection limits of these two methods are in agreement with Health Advisory

Levels in the USA. Many European laboratories use LLE methods which are derived from the EPA methods; the enrichment factor can be easily increased by greatly reducing the final volume which allows detection limits closer to the EU regulatory level of $0.1 \mu\text{g L}^{-1}$ for each pesticide.

However, due to the trend shown by the EPA for reducing the consumption of organic solvents, new methods involve micro-LLE extraction. As an example, EPA method 504 for the determination of organochlorine pesticides in water requires only 2 mL of dichloromethane or hexane for a 35 mL aqueous sample volume with detection limits in the range $0.08\text{--}7 \mu\text{g L}^{-1}$. Micro-LLE of this sort cannot be adapted to meet the EU detection limits.

LLE allows a fractionation into acidic pesticides and basic/neutral fraction with successive extractions at different pH values. However, extraction of relatively polar and water-soluble organic compounds is difficult. The recovery obtained from 1 L of water using dichloromethane is 90% for atrazine but only 16% and 46% for deisopropyl- and deethylatrazine. When using a mixture of dichloromethane and ethyl acetate with 2 M ammonium formate these metabolites of atrazine are extracted with recoveries of 62% and 87% respectively.

The main advantages of LLE are its simplicity and requirements for simple equipment, but the glassware must be carefully washed and stored under rigorous conditions. LLE is not free from practical problems (such as formation of emulsion) which are difficult to break. The disposal, use and evaporation of large volumes of solvent, often toxic and flammable, are the main drawbacks. These organic solvents should be of pesticide grade which makes them rather expensive. Automation requires the use of robots and LLE is typically an offline procedure, with risks of loss and contamination during transfer and evaporation steps. Therefore, the trends in reducing the use of organic solvents in analytical laboratories and the low performances in extracting polar compounds explain the increasing replacement of LLE by solid-phase extraction.

Solid-Phase Extraction

Recent Developments of SPE Formats

Offline SPE materials are mainly disposable cartridges and disc membranes. The recent developments tend to increase the sample throughput and to use solid-phase sorbents able to broaden the polarity range of analytes.

Limitations of packed SPE conventional cartridges and discs include restricted flow rates and plugging of the top frit when handling water containing sus-

pended solids, such as surface water. Therefore, the percolation of natural samples can take a long time for a typical 500 mL volume unless the sample has been carefully filtered beforehand. Various approaches have been developed to solve this problem. One consists in depth filters which can be placed above the cartridge or membrane extraction disc, or which are now integrated in some SPE cartridges providing fast flow rates. Empore discs have recently become available with sorbent trapped in a PTFE matrix. These discs are also included in cartridges, known as disc cartridges. New discs, which consist of a thin bed of microparticles supported in a laminar structure, allow the percolation of 1 L of surface water without any previous filtration in less than 5 min.

With regard to sorbent technology, many are now specified as specially made for broadening the polarity range of analytes. These include not-end-capped C_{18} silicas and monofunctional C_{18} silicas, the aim being to increase the number of unmodified silanol groups on the bonded silica surface in order to provide secondary polar interactions with basic polar solutes. Cross-linked styrene-divinylbenzene (SDVB) copolymers with high specific areas in the range $500\text{--}1200 \text{ m}^2 \text{ g}^{-1}$ are now available from all manufacturers in cartridges and/or discs. Typical amounts of sorbent are 100–200 mg and the cartridge designs have been optimized for rapidly processing large volumes of water. Carbonaceous sorbents have also been shown to extract very polar analytes.

Automation

A typical SPE sequence includes four steps: (i) conditioning of the sorbent; (ii) application of the sample; (iii) rinsing and clean up of the sample; and (iv) desorption of the analytes to be separated. These steps can be performed sequentially for up to 24 cartridges at the same time using extraction units working under positive or negative pressure. The whole sequence can also be easily automated using devices which can accept any commercial cartridges or extraction discs. Examples are the ASPEC from Gilson, Microlab from Hamilton, AutoTrace and RapidTrace from Zymark. The possibility exists with some of these devices for automatic injection of an aliquot of the final extract into the chromatographic system. Complete automation also exists which couples SPE directly with online LC analysis (ASPEC XL from Gilson; Prospekt from Spark Holland; OSP-2 from Merck). These last two pieces of equipment improve productivity since the next sample is automatically prepared while the previous sample is being analysed.

Selection of the Sorbent for Multiresidue Extraction

LC has been shown to be suitable for multiresidue separation of many compounds over a wide range of polarity without previous derivatization and examples can be found in the literature, the most impressive one being the multiresidue separation of 72 pesticides in one run published by Di Corcia and Marchetti. Identification of compounds is widely performed with UV diode array detectors which can provide the whole spectrum of the analytes. Fluorescence is also used because of its sensitivity for the detection of *n*-methyl carbamates, following a post-column derivatization reaction. LC with mass spectrometry is also increasingly used in environmental laboratories.

The extraction of analytes from water requires the selection of an extraction sorbent which will provide a 90–100% recovery with the sample volume required for the necessary quantification. According to the detection limits obtained with conventional LC-UV diode array detectors or MS interfaces, typical sample volumes using offline extraction procedures are in the range 300–500 mL in order to provide detection limits in drinking water as low as 0.01–0.03 $\mu\text{g L}^{-1}$ and 0.1 $\mu\text{g L}^{-1}$ in surface waters for transport and fate studies.

The same sorbents as those used in reversed-phase LC are utilized and there is an analogy between the SPE processes and classical elution chromatography. Processes involved in SPE are a frontal chromatographic process during the extraction step and displacement chromatography during the desorption step. It is then possible to predict and optimize the main SPE parameters from data generated by LC. Among the various tools for selecting the sorbent and predicting the recovery according to the percolated sample volume, the most important is the retention factor of the analyte in water, k_w . Therefore, developing a SPE method only requires knowledge of the retention behaviour of the analytes with the extraction sorbent in LC with water as mobile phase, as measured by k_w . Both breakthrough curves and recovery curves have been modelled according to the sample volume. With an amount of sorbent of 500 mg, a recovery in the range 90–100% will require a sorbent providing $\log k_w > 3$ for the analytes. Whatever the SPE format, disc or cartridge, the process is the same and the criteria for the selection of the sorbents are similar. It is just necessary to know the amount of sorbent.

A good stability has been observed for analytes on SPE sorbents which allows the percolation of samples on site and further analysis in the laboratory.

Multiresidue Extractions Using *n*-Octadecyl Silicas

Prediction from the water–octanol partition coefficient of the compound Octadecyl- and octyl-bonded silicas have been the universal extraction sorbents for many years. Since the retention mechanism is primarily governed by hydrophobic interactions between the analyte and the carbonaceous moieties of the alkyl chains grafted to the silica surface, a relation has been observed between the retention factors of the analytes and their water–octanol partition coefficient (K_{ow}). Therefore, k_w values can be approximated without any additional measurements from K_{ow} values which were reported in a recent edition of the *Pesticide Manual*.

Limitation for the extraction of polar pesticides in a multiresidue mixture For LC purposes, trifunctional silanes are preferred over monochlorosilanes for the bonding synthesis because a layer or multiple carbon–siloxane covalent bonds on the silica surface is formed. The objective in SPE is to increase to a maximum hydrophobic interactions and the surface coverage so that rather highly porous silica is usually selected, with an average surface area above 500 $\text{m}^2 \text{g}^{-1}$ and with average carbon content of 17–18% for *n*-alkyl silicas. These C_{18} silicas will provide the highest retention for the more polar analytes. Like LC phases, the SPE alkyl silicas were first end-capped but, in order to enhance secondary interactions, the number of residual silanol groups has been increased by eliminating end-capping procedures, or by using monofunctional silane and no end-capping. Hydrogen bonding interactions and, especially, ionic interactions with polar basic compounds after pH adjustment can be increased and that is the reason for the broader range of polarity which can be achieved by these silicas specially designed for polar analytes. However, even if an increase of recoveries for some polar basic analytes has been observed, the increase in $\log k_w$ values is small at 0.2–0.5 in log units.

The limitation in using C_{18} silicas is in the extraction of polar pesticides and/or metabolites, which are characterized by $\log K_{ow}$ below 2. To give an example, recoveries of deisopropylatrazine and phenol ($\log K_{ow}$ values of 1.2 and 1.5 respectively) are lower than 20% with a sample volume of 500 mL and using an extraction disc containing 450 mg of C_{18} silica. Increasing the amount of sorbent to 1 g in the cartridge, gives a recovery of deisopropylatrazine of 52% and 44% from a sample volume of 1 L using respectively C_{18} Polar Plus from J.T Baker and LiChrolut RP-18 from Merck.

Application to drinking water samples Figure 1 illustrates the potential of C_{18} silica for determining many pesticides over a wide range of polarity in

drinking water at $0.1 \mu\text{g L}^{-1}$. The triazines and phenylureas have been selected because they include some polar analytes such as the degradation products

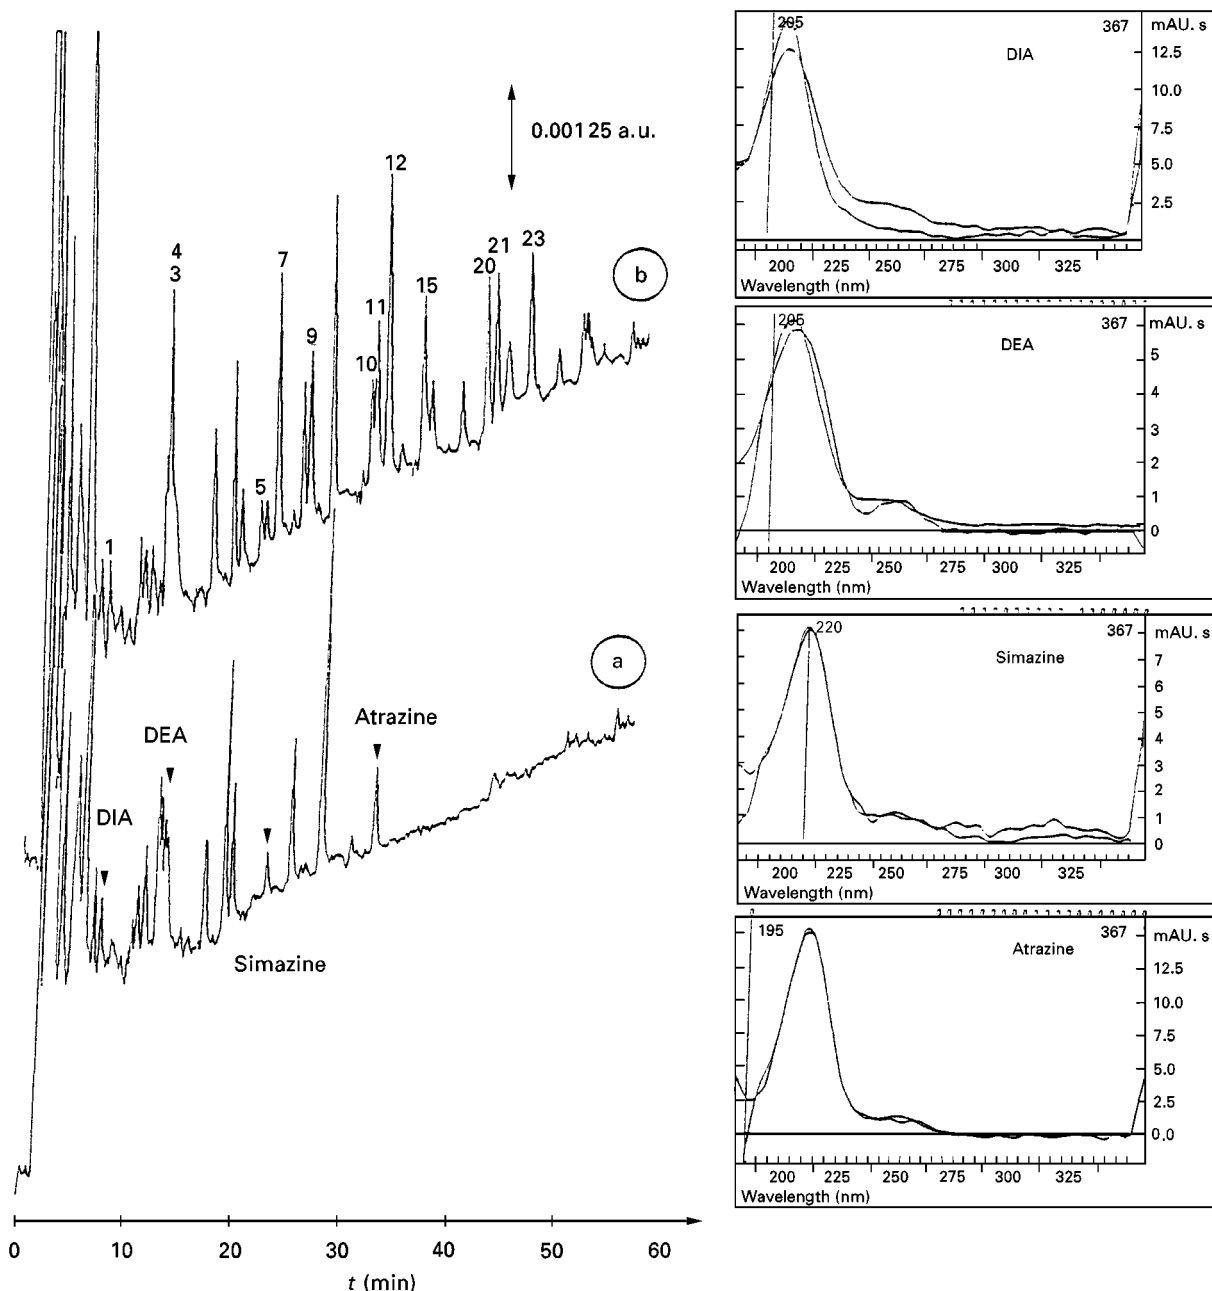

Figure 1 Chromatogram corresponding to the preconcentration of 500 mL of drinking water and spectra of the peaks identified using the UV DAD software: (a) non-spiked and (b) spiked with $0.1 \mu\text{g L}^{-1}$ of each analyte.

Preconcentration using a 500 mg C_{18} silica cartridge, desorption with 4 mL of methanol, evaporation to dryness, and addition of 500 μL of an acetonitrile/water mixture (20/80, v/v). Injection of 50 μL . Analytical column: Supelcosil LC-18-DB 25 cm \times 4.6 mm i.d.; acetonitrile gradient with 0.005 M phosphate buffer at pH 7; UV detection at 220 nm. Peaks: 1, DIA; 2, fenuron; 3, OHA; 4, DEA; 5, hexazinone; 6, metoxuron; 7, simazine; 8, monuron; 9, cyanazine; 10, metabenzthiazuron; 11, simetryne; 12, atrazine; 13, chlortoluron; 14, fluometuron; 15, prometon; 16, monolinuron; 17, isoproturon; 18, diuron; 19, difenoxuron; 20, sebutylazine; 21, propazine; 22, buturon; 23, terbutylazine; 24, linuron; 25, chlorbromuron; 26, chloroxuron; 27, difluzbenzuron; 28, neburon. (Reproduced from *International Journal of Environmental and Analytical Chemistry* 65, Pichon V, Cau Dit Coumes C, Chen L and Hennion M-C, Solid-phase extraction, clean-up and LC for routine multiresidue analysis of neutral and acidic pesticides in natural waters in one run, pp. 11–25, Copyright (1996), with permission from Gordon and Breach, Science Publishers.)

of atrazine, i.e. deisopropylatrazine (DIA), hydroxyatrazine (OHA) and deethylatrazine (DEA), and fenuron or metoxuron (with $\log k_w$ around 2.5 or lower), many moderately polar compounds and rather apolar pesticides such as neburon ($\log K_{ow}$ 4.3). The separation was not optimized because the occurrence of each compound in the same sample is unlikely. Co-eluted analytes do not belong to the same group and can easily be differentiated by the UV diode array detector. The chromatogram in Figure 1b represents the chromatogram obtained for an extract from 500 mL of drinking water spiked with $0.1 \mu\text{g L}^{-1}$ of each pesticide. Recoveries were above 85–90% for each analyte, except the early eluted peaks 1 to 4 for which recoveries were 26, 51, 68 and 68%. Recoveries of peaks 7 and 12 were higher, due to the presence of these compounds in the sample, as shown in Figure 1a where a nonspiked sample was analysed under the same experimental conditions. The occurrence of simazine (peak 7) and atrazine (peak 12) was confirmed by comparison of retention times and of UV spectra from the library of the DAD at concentrations of $0.016 \pm 0.003 \mu\text{g L}^{-1}$ and $0.12 \pm 0.02 \mu\text{g L}^{-1}$ respectively. The match between the retention times and the two UV spectra was excellent so that no further confirmation was required. The peaks which showed up at 7.9 and at 13.3 min may be deisopropylatrazine and deethylatrazine, but the match was not good and another method is required for confirmation.

Multiresidue extraction including acidic pesticides: pH and matrix effects Acidic herbicides are very slightly retained by C_{18} silica in their ionic form so that they can be extracted using a C_{18} silica cartridge provided the sample has been previously acidified before percolation. Table 1 shows the low extraction recoveries measured for some acidic herbicides when percolating 500 mL of spiked drinking water at pH 7 and the much better results when acidified at pH 2 or 3 with perchloric acid. When natural water

Dinoterb	5.0	72	49	30

samples are acidified at pH 2, there is an interfering peak due to humic and fulvic acids as shown when comparing the chromatograms of Figure 2a and b. The strong acidity of humic and fulvic acids (pK_a around 3) explains why interferences are only detected at acidic pH. This co-extraction of humic and fulvic acids requires an optimization of the mobile phase gradient in order to elute the first compounds after the interfering peak, so that most of the pesticides can still be determined at the $0.1 \mu\text{g L}^{-1}$ level in drinking water samples. In Figure 2b, only the very polar ones will show up in the interfering peak if the mobile phase gradient is adjusted in order that most of the peaks are eluted after 20 min. Surface water contains higher amounts of humic and fulvic acids and determination of pesticides at the $0.1 \mu\text{g L}^{-1}$ level becomes impossible, as shown in Figure 2c. An additional clean-up step using a Florisil cartridge was applied to the extract obtained after desorption from the C_{18} cartridge and detection limits could be improved as shown in Figure 3b. However setting up the analytical conditions for this step is not straightforward but laborious, time-consuming and generates additional losses in recovery.

Multiresidue Extractions Using Apolar Styrene-Divinylbenzene (SDVB) Copolymers

Potential for extraction of very polar analytes as compared with C_{18} silicas In recent years, ultra-clean highly cross-linked styrene-divinylbenzene (SDVB) polymers with relatively high specific surface areas have been introduced by most manufacturers of disposable cartridges and have shown high capability for the extraction of polar analytes. This is demonstrated by 100% recoveries for phenol and deisopropylatrazine from a sample volume of 1 L and using 200 mg of SDVB sorbents. Table 2 compares the retention factors in water, which have been measured or estimated for a C_{18} silica and SDVB with different specific surface areas. The higher retention of SDVB sorbents over C_{18} silicas is due to strong π - π interactions between analytes and the SDVB matrix in addition to common hydrophobic interactions. The effect of the surface area is very important and an increase in retention by a factor of 20 to 100 may be observed when the specific area of the SDVB sorbent increases from 400 to 1000 $\text{m}^2 \text{g}^{-1}$.

Therefore, highly cross-linked SDVBs are the sorbents of choice for multiresidue extraction of a mixture containing highly polar analytes.

Application to the determination of acidic, neutral and basic pesticides in the same run with removal of humic and fulvic acid interferences The retention of acidic pesticides was studied at neutral pH in order to

Figure 2 Effect of sample pH and of the sample matrix on the pre-concentration of 500 mL of (a) drinking water spiked with $0.1 \mu\text{g L}^{-1}$ of each analyte at pH 7; (b) drinking water spiked with $0.1 \mu\text{g L}^{-1}$ of each analyte at pH 2; and (c) River Seine water spiked with $0.1 \mu\text{g L}^{-1}$ of each analyte at pH 2.

Preconcentration using a 500 mg C_{18} silica cartridge, desorption with 3 mL of methanol, evaporation to dryness, and addition of 500 μL of a dichloromethane/water mixture (20/80, v/v). Analytical column: Bakerbond narrow pore C_{18} silica, 25 cm \times 4.6 mm i.d.; acetonitrile gradient with 0.005 M phosphate buffer at pH 3. UV detection at 220 nm. Peaks: 1, chloridazon; 2, aldicarb; 3, metoxuron; 4, simazine; 5, cyanazine; 6, bentazone; 7, atrazine; 8, carbaryl; 9, isoproturon; 10, difenoxuron; 11, ioxynil; 12, MCPP; 13, 2,4-DB; 14, 2,4,5-TP; 15, metolachlor; 16, dinoterb. still not retained at pH 7 is due to their high polarity because of the numerous ionized groups and/or to their different configuration at pH 7 and their possible occurrence in the colloidal fraction. However, the consequence of a high retention of acidic pesticides in their ionic form together with the absence of retention of humic and fulvic interferences gives the remarkable possibility of determining acidic and neutral pesticides in surface water samples without any clean-up at the low 0.1 µg L⁻¹ concentration level as shown in Figure 5.

Use of Porous Graphitic Carbon for the Extraction of very Polar Metabolites

The most commonly used carbonaceous sorbents are graphitized carbon blacks (GCB). Their higher efficiency over C_{18} silica for trapping polar pesticides has been extensively shown by the group of Di Corcia *et al.* GCB is not pressure resistant enough to be used in LC so that no data indicating the LC behaviour of solutes are available. In recent years, a porous graphitic carbon (PGC) has been available in SPE cartridges. It has been derived from that made for LC (under the trade mark Hypercarb). PGC has been shown to be particularly efficient for the extraction of some very polar analytes which cannot be extracted by the SDB polymers, such as for instance di- and tri-hydroxyphenols, aminophenols, and other aromatic derivatives containing several polar functional substituents. They have been shown to extract the highly polar degradation products of atrazine including cyanuric acid. As an example Figure 6 shows the determination of the degradation products of atrazine, DEA and DIA as well as the didealkylated metabolite deethyl-deisopropylatrazine (DDA) in ground water. Recoveries were in the range 90–95% for each analyte using a SPE cartridge packed with

200 mg of Hypercarb and a sample volume of 500 mL. DDA is a very polar metabolite, with a $\log K_{ow}$ value of 0, and its occurrence in ground water has never been shown, due to the difficulty of extraction and analysis. It was shown that in soil DEA is stable whereas DIA is rapidly transformed into DDA. Our results have confirmed this hypothesis because DEA is detected in high amounts, DIA at

Figure 5 Preconcentration of 500 mL of River Seine water spiked with 0.1 µg L⁻¹ of herbicides at pH 7. Experimental conditions as in Figure 4b. trace level and DDA has half the concentration of DEA. This last figure illustrates the persistence and importance of the degradation products in ground water, since the sum of the concentration of metabolites is twice the concentration of the parent compound atrazine.

Further Trends

Research for sample preparation is a very active area at the moment, partly explained by the need for reducing as much as possible the use, disposal and release in the environment of toxic solvents, together with a reduction of the total analysis cost. In Europe, chemists are faced with the drastic drinking water regulatory level of $0.1 \mu\text{g L}^{-1}$ for each pesticide. Therefore, trends are for setting up multiresidue analysis.

Trends are also for simplifying the labour of sample preparation, increasing its reliability and

eliminating the clean-up step of aqueous samples by decreasing as much as possible the amount of interfering components extracted from complex matrices. Regarding these last two aspects, the new polymeric extraction sorbents have a remarkable potential. Sorbents based on immunaffinity extraction are also promising for their high selectivity, and extraction, concentration and clean-up are performed in the same step.

Introduction

A pesticide is usually defined as any organism or substance that is manufactured for direct or indirect control or prevention of any pest. Pesticides often alter the growth, development or characteristics of insects and plants. Most pesticides are synthetic chemicals that can be classified into six classes, according to their chemical type: organochlorine compounds, organophosphorus compounds, carbamates, phenoxyalkanoic acid derivatives, substituted ureas and triazines. Currently, several hundred pesticides are widely applied to a broad variety of crops to reduce losses from weeds, insects and diseases. Herbicides are employed in agriculture for pre- and post-emergent weed control of corn, wheat, barley and sorghum; they are also used on railways and roadside

verges. In general, organochlorine compounds are resistant to hydrolysis, and those that undergo photochemical reaction tend to form compounds with a persistence comparable to, or greater than, their parent compounds. Some organochlorine pesticides have been banned due to their toxicity, persistence and bioaccumulation in environmental matrices. Owing to the environmental impact of pesticides, several priority lists, also called 'black' or 'red' lists, have been published to protect the quality of surface and tap water. Thirty-nine pesticides are listed in priority order in the 76/464 EEC (European Economic Community) Council Directive on pollution caused by certain dangerous substances discharged into the aquatic environment of the community. The US Environmental Protection Agency (EPA) has established drinking water regulations and health advisory levels for individual pesticides.

Since the publication of Rachel Carson's book *Silent Spring* in 1962, many countries have legislated for public health protection. Such regulations have ultimately focused on protecting the general public

from pesticide residues. An illegal residue is defined as one that is above US EPA tolerance, one for which the 76/464/EEC Directive on the Quality of Water Intended for Human Consumption sets a maximum admissible concentration (MAC), or one that rises above the detection limit listed in the Department of Food and Agriculture's Multiresidue Pesticide Screen. The surveillance of various bodies of water is one of several important activities that provide information on present pollutant levels and future trends in waters. Monitoring pesticide residues in water is one of the important parameters in surveillance activity and environmental study. Regardless of the timing of the application, most pesticides applied to the soil are only lightly incorporated into the soil. Minimizing the risks of above-ground environmental contamination and reducing the hazard to nontarget organisms are very important for human health. Monitoring of pesticide residues in food of animal origin might also indicate a major source of exposure for humans. Therefore, pesticide residue determination has become a critical part of environmental analysis.

Many kinds of pesticides have been released into the environment, making it impossible to separate all pesticides in a single analysis. Thus, the analytical procedure for monitoring pesticide residues must be fast, easy, applicable to a number of different sample classes with only slight modification, and sufficiently sensitive and selective.

Many analytical procedures for analysing pesticide residues have been proposed in the development of multiclass, multiresidue; single-class, multiresidue; and single-residue methods, for a wide variety of sample types. Most pesticide residue analyses have been performed using multiresidue methods involving solvent extraction of the analytes from the sample matrix. Multidimensional analytical systems combining gas chromatography (GC) and high performance liquid chromatography (HPLC) with multiple detectors give many multiresidue methods. Qualitative and quantitative determination by GC with element-selective detectors and confirmation of results using an ancillary method such as mass spectrometry (MS) is the predominant method in pesticide residue analysis. The accuracy and precision of pesticide analyses depend on both sample preparation and instrumental performance. The chromatographic technique requires efficient isolation and concentration procedures. This study presents information on the analysis of pesticides using GC and introduces methods for sample preparation including various types of extraction techniques and derivatization procedures. The effectiveness of the techniques described are demonstrated by determining pesticide residues in real samples.

Sampling, Extraction, Clean-up and Derivatization

Pesticide residue analysis determines not only the parent compounds, but also their metabolites and degradation products. As many investigations have confirmed, determining pesticide residues in the range below ng mL^{-1} is difficult and extremely complex because of the need to isolate, accurately identify, and measure such minute quantities in large amounts of extraneous material. Gas chromatography is the most widely adopted technique in pesticide residue analysis. Pesticides that are amenable to direct analysis by means of GC should preferably be determined by means of this method because it separates well, is fast, and has available many selective and sensitive detectors. The sample generally cannot be analysed directly by using GC for pesticide residues; extraction is required to isolate the target contaminants from the sample matrix.

Clean-up is also necessary to isolate the target pesticides from interfering co-extractives before injection into a GC column. In pesticide extraction, classical solvent extraction method is the conventional method. Conventional extraction and matrix solid-phase dispersion methods have been used for organochlorine pesticides (OCPs) in fish muscle. Carbon dioxide is used as an extractant in high pressure Soxhlet extraction for determining organochlorine pesticides in olive oil, vegetable and fish tissue samples. Solid-phase extraction is extensively employed for the trace enrichment of pesticide residues from complex matrices. Common adsorbents are charcoal and porous polymers. Charcoal is widely used to extract low relative molecular mass polar pesticides and their metabolites, which are highly retained in water.

The homogeneous structure of polymers results in greater reproducibility in enrichment experiments. The most widely used types of polymers are 2,6-diphenyl-*p*-phenylene oxide (Tenax GC), acrylate polymers (Separon SE, XAD-8), ethylvinylbenzene-divinylbenzene (Porapak Q) and styrene-divinylbenzene copolymers (Polysorbs, Amberlite, XAD-2, PRP-1). The bonded silicas, including C₁₈, C₈, cyano and amino, have been widely applied for the preconcentration of various types of pesticides from water samples. Octadecyl-bonded SPE has been proposed by the US EPA in Method 525.

A wide range of polarities of pesticide residues can be separated from sample coextractants by optimizing the SPE elution solvent. Homogeneous sample pulp, prepared from vegetables and fruits, is adsorbed on the surface of activated Florisil, which is then extracted in a glass column with ethyl acetate or

methylene chloride mixed with acetone. Kadenczki found a recovery rate of over 80% for pesticide residues, including carbamate, organochlorine, organophosphate, synthetic pyrethroid, triazine and miscellaneous pesticides. The recovery is also independent of the sample material. Snyder investigated the use of a supercritical fluid extraction method to extract 12 organochlorine and organophosphate pesticides from four soils: sand, clay, top soil and river sediment. The soils were extracted at a pressure of 350 atm and a temperature of 50°C with supercritical CO₂ modified with 3% methanol. The recovery of pesticides was greater than 85% for each of the matrices.

Solid-phase microextraction (SPME) has been introduced by Pawliszyn and his group. The mechanism of SPME is mainly based on adsorbing analytes from aqueous solutions onto a fused silica fibre coated with a polymeric adsorbent. An equilibrium occurs of analyte concentration between the sample and the solid-phase fibre coating. Extracted compounds are then thermally desorbed in the injector of the gas chromatographic system. Sampling in the SPME method can be done rapidly, directly, and without any solvent. Pawliszyn selected a 100 µm poly(dimethylsiloxane) (PDMS) fibre to extract ametryn, parathion, prometryn, simetryn and terbutryn pesticides. Different modes of absorption were evaluated included static, magnetic stirring, fibre vibration and flow-through extraction cell methods. Montury has investigated using the SPME technique with 100 µm PDMS, to determine the residues of insecticides and fungicides commonly used for vineyard protection at the level of 20 µg L⁻¹.

Carbamates and some pesticides that have high polarity and low vapour pressure are generally not amenable to direct GC analysis. Derivatization is a convenient means of obtaining better chromatographic separations with increasing volatility and detector sensitivity, particularly with the electron capture detector (ECD). A chemical derivatization technique is also a highly effective procedure for confirming a pesticide residue's identity. By using this approach, the resulting derivatives examined by GC provide specific identification. Dehydrochlorination with KOH or NaOH is used to confirm the residues of DDT and its analogues. Reductive dechlorination with CrCl₂ is applied to identify heptachlor, endrin, metabolites of endrin, and some organophosphorus pesticides. For determining carbamate pesticides, silylation and acylation are the most widely applied derivatization procedures. Some halogenated silylating reagents are chloromethyldimethylchlorosilane, bromomethyldimethylchlorosilane, and 1,3-bis(chloromethyltetramethyldisilazane). The acyla-

tion reagents are trichloroacetic anhydride, pentafluoropropionic anhydride, trichloroacetyl chloride, heptafluorobutyric anhydride and trifluoroacetic anhydride.

Environmental Applications

The maximum levels of pesticide residue allowed in the European Union (EU) are 0.1 µg L⁻¹ in drinking water and 1–3 µg L⁻¹ in surface water. Pico presented a procedure for analysing water samples using online, solid-phase extraction gas chromatography. A cartridge packed with styrene–divinylbenzene polymer was used in sampling and ethyl acetate was used as the elution solvent. Organophosphorus pesticides and several triazines in tap water were tested using a GC flame photometric (FPD), flame ionization (FID), or nitrogen-phosphorous (NPD) detector. When a 10 mL sample of the tap water was analysed, the detection limit for all pesticides was lower than 0.1 µg L⁻¹. NPD and FPD are very much more sensitive and selective than FID. Hence, the SPE-GC-NPD system has been used widely for the analysis of pesticides, particularly organophosphorus pesticides in surface water samples. Tan compared solvent extraction using hexane and Freon TF (trichlorotrifluoroethane) and solid-phase extraction using octadecyl (C₁₈)-bonded porous silica, to determine the presence of organochlorine pesticide residues in water. It was concluded that the recoveries and precision using the SPE method for detecting organochlorine pesticides were poorer than those using the extraction method.

We have developed a methylation post-derivatization method on the fibre following SPME with GC-MS to analyse acidic herbicides from an aqueous sample. The acidic herbicides included 2-(4-chloro-2-methylphenoxy)propionic acid (MCP), 2-methoxy-3,6-dichlorobenzolic acid (dicamba), 4-chloro-2-methylphenoxyacetic acid (MCPA), 2-(2,4-dichlorophenoxy)propionic acid (2,4-DP), 2,4-dichlorophenoxyacetic acid (2,4-D), 2-(2,4,5-trichlorophenoxy)propionic acid (2,4,5-TP), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), 2-(*sec*-butyl)-4,6-dinitrophenol (dinoseb), and 2-(2,4-dichlorophenoxy)butyric acid (2,4-DB). A polyacrylate (PA)-coated SPME fibre yielded a higher extraction efficiency than that obtained with PDMS. The selected ion monitoring (SIM) mode in MS was used to quantitatively analyse the sample. **Figure 1** displays the mass chromatogram of the 100 µg L⁻¹ acidic herbicides solution determined in this way.

Detection limits at the level of 10–30 ng L⁻¹ are achieved for all herbicides by using this technique. Linearity is obtained over a wide range, with pre-

Figure 1 Mass chromatogram of $100 \mu\text{g L}^{-1}$ acidic herbicides solution by post-derivatization following SPME with PA fibre in GC-MS analysis. Peaks: 1, MCPP; 2, dicamba; 3, MCPA; 4, 2,4-DP; 5, 2,4-D; 6, 2,4,5-TP; 7, 2,4,5-T; 8, dinoseb; 9, 2,4-DB.

cision below 12% relative standard deviation (RSD). In addition, various degradation compounds of acidic herbicides in basic solution including 2,4-dichlorophenol, 2,4,5-trichlorophenol and 4-chloro-3-methylphenol have been detected.

Durand has studied the confirmation of chlorotriazine pesticides, their degradation products, and organophosphorus pesticides in soil samples, using GC-MS with electron impact and positive and negative chemical ionization. Sample pretreatment of soil samples was carried out via Soxhlet extraction for 12 h with methanol. Glass columns filled with 2 g of Florisil effected clean-up. The elution solvent was hexane. Residue levels of chlorotriazine pesticides and organophosphorus pesticides were determined in soil samples at levels from 5 ng g^{-1} to $9 \mu\text{g g}^{-1}$. Snyder compared supercritical fluid extraction with classical sonication and Soxhlet extraction for organophosphorus and organochlorine pesticides from soils. Supercritical fluid extraction was found to have the best overall precision over either the Soxhlet or the sonication extractions, and was also less labour-intensive. We have compared different methods of mass spectrometry including GC-MS (EI, CI), GC-MS-MS, and GC-ECD to determine ethion from soil. The largest recoveries (over 96%) were achieved with a 1:1 mixture of methanol and acetone as extraction solvent for 3 h in Soxhlet extraction. The limit of detection of ethion for all techniques is below the nanogram level. The mass chromatogram of GC-MS-MS selected reaction monitoring (SRM, m/z 384 \rightarrow m/z 231) in electron impact ionization mode, of a soil sample containing 0.5 ng g^{-1} ethion, is illustrated in Figure 2. The best ethion detection limit (170 pg g^{-1} of soil) was obtained using this technique.

Agricultural Applications

Leoni described a multiresidue method for the quantitative analysis of 28 organophosphorus pesticides in vegetable and animal foods using GC. The pesticides were extracted with different solvents from either fatty or nonfatty foods. Clean-up was carried out on active carbon-celite and on disposable minicolumns of bonded-phase silica, according to fat and pigment content. A wide-bore column (SPB-5) with flame photometric detection, operated in phosphorus mode, was chosen for GC analysis. The recovery tests obtained were 81–85% for apples, whole milk, pasta and eggs, and 89% for olive oil. Schenck described a procedure for screening organochlorine and organophosphorus pesticide residues in eggs using an SPE clean-up and GC detection. The pesticides were extracted from the eggs using acetonitrile. A tandem C_{18} and a Florisil SPE column were used for extract clean-up with recoveries ranging from 80% to 90%. The limit of quantitation was $0.005 \mu\text{g mL}^{-1}$ for organochlorine pesticides and $0.01 \mu\text{g mL}^{-1}$ for organophosphorus pesticides. Torres proposed a multiresidue extraction method based on matrix solid-phase dispersion (MSPD) for the extraction and GC screening of 18 insecticides including aldrin, ethion, and dicofol, from oranges. The limits of detection were from 2 to $171 \mu\text{g kg}^{-1}$, which is about 10 times lower than the maximum residue level established by the European Community. Sulfuric acid pretreatment for the simultaneous GC screening of organochlorine and organophosphorus pesticides in herbal essential oils was studied by Yoon. A mixed phase of 17% (v/v) of sulfuric acid to organic solvent (hexane/ethyl ether 9:1, v/v) and a reaction time of 30 s was used to carry out steam distillation to extract pesticides from herbs; this was followed by GC-FID. The recovery of the studied pesticides was in the range of 75% to 111% for organochlorine pesticides

Figure 2 Mass chromatogram of a soil sample containing 0.5 ng g^{-1} ethion produced by using GC-MS-MS selected reaction monitoring (m/z 384 \rightarrow 231) in EI mode.

Figure 3 Mass chromatogram of a real orange sample for monitoring ethion in GC-MS analysis. A C_{18} SPE cartridge was used to extract ethion from oranges. A mixed solvent of hexane and dichloromethane, in a ratio of 1 : 1, was used as the elution solvent. A capillary fused silica DB5-MS column was used in the GC-MS analysis.

and 72% to 116% for organophosphorus pesticides. A SPME method was developed and validated by Simpli'cio to determine the level of organophosphorus pesticides, including diazinon, fenthion and triazophos, in fruits and fruit juice using an FPD in phosphorus mode. Limits of detection of the method for fruit and fruit juice matrices were below $2 \mu\text{g kg}^{-1}$ for all pesticides. Monitoring of ethion residues and its degradation compounds in oranges, using C_{18} SPE cartridges for extraction followed by GC-MS and GC-MS-MS, was studied in our laboratory. **Figure 3** presents the mass chromatogram of a real orange sample obtained using selected ion monitoring (m/z 384 of ethion).

Next, a comparison was made of GC-MS and GC-MS-MS with various ionization modes. The EI mode in GC-MS with selected ion monitoring was the best method, obtaining a $0.96 \mu\text{g g}^{-1}$ limit of detection. Various extraction methods, including Soxhlet extraction, SPE and SPME, were used to study the extraction of 19 organochlorine pesticides found in Chinese herbal medicines. GC-ECD and GC-MS were evaluated to determine the presence of the pesticides. **Figure 4** presents the analysis of 200 ng g^{-1} of spiked pesticides by using SPME-GC-ECD. The limits of detection for all organochlorine pesticides are below ng g^{-1} .

Biological Applications

Petty investigated a method for the analysis of nine organochlorine pesticides in wildlife urine. The urine samples collected from a single domestic dog were spiked with a standard mixture containing lindane, aldrin, chlordane, DDE, endrin and DDT. The extraction of organochlorine pesticides from urine was performed on a C_{18} SPE column. The method's limits of detection ranged from 1.4 to $2.7 \mu\text{g L}^{-1}$ when using an ECD.

Lott proposed a multiresidue isolation technique using matrix solid-phase dispersion (MSPD) and GC-ECD for screening 14 organochlorine pesticides in crayfish hepatopancreas. In the MSPD extraction, 0.5 g of the homogenized fish tissue was blended with 2 g of C_{18} silica, and the resulting mixture was then transferred to a 10 mL syringe-barrel column that contained 2 g of activated Florisil. Pesticides were eluted by gravity flow with 8 mL of acetonitrile. Two microlitres of the elute was directly analysed by GC. The results showed that the MSPD technique combined with GC-ECD enabled the successful extraction and determination of the 14 organochlorine pesticides at $125\text{--}2000 \text{ ng g}^{-1}$ levels.

Diserens has proposed the extraction and clean-up for multiresidue determination of pesticides in lanolin. Lanolin, a waxy material extracted from wool, is one of the raw materials used in cosmetic products. The diatomaceous earth in an Extrelut column was used to adsorb a light petroleum solution containing lanolin. The acetonitrile extract was passed through an SPE cartridge containing a C_{18} column. Organophosphorus pesticides were determined by GC using FPD in the phosphorus mode. Organochlorine pesticides were determined by GC-ECD after extraction and clean-up in a Florisil column. The limits of detection for the various pesticides are about $5 \mu\text{g kg}^{-1}$ for organochlorine compounds and $50 \mu\text{g kg}^{-1}$ for organophosphorus pesticides.

We have evaluated GC-MS with selected ion monitoring for determining organochlorine pesticides in fish. Petroleum ether was used to extract pesticide residue from 2 g of fish tissue. The gas chromatogram

Figure 4 Gas chromatogram of spiked 200 ng g^{-1} 19 organochlorine pesticides in a herbal medicine formula analysed by SPME GC-ECD. Peaks: 1, α -BHC; 2, γ -BHC; 3, β -BHC; 4, heptachlor; 5, δ -BHC; 6, aldrin; 7, heptachlor epoxide; 8, endosulfan I; 9, p,p' -DDE; 10, dieldrin; 11, endrin; 12, o,p' -DDT; 13, p,p' -DDD; 14, endosulfan II; 15, p,p' -DDT; 16, endrin aldehyde; 17, endosulfan sulfate; 18, Methoxychlor; 19, endrin ketone.

from a shad fish captured from the Taiwan Strait gave limits of detection for the organochlorine pesticides in fish below ng g^{-1} . The concentration of *p,p'*-DDE was detected at 90 ng g^{-1} .

Future Prospects

In recent years, new and improved methods and technologies to analyse pesticide residues have rapidly evolved. Analytical methods for most residue pesticides have detection and quantification limits at the low parts per billion to parts per trillion for water analysis, and low parts per million to parts per billion for other samples such as crops, soils and biological matrices. Many preconcentration methods have been developed in clean-up procedures, including exhaustive solvent extraction, automated Soxhlet extraction, microwave-assisted extraction, MSPD extraction, SPE using microcolumns, cartridges, and Empore discs, and SPME. Qualitative and quantitative determination by GC with element-selective detectors, and confirmation of results using MS, continues to be the predominant technique for multiresidue pesticide analysis. MS has been widely used for confirmation of trace pesticide identification and quantitation. Tandem mass spectrometry (MS-MS) is replacing the conventional approaches to confirmation and GC added to the MS-MS will increase the specificity obtained. Now that ion trap mass spectrometry has been introduced, pesticide residue confirmation can be obtained through experiments involving MS-MS or MS^n on compounds of high relative molecular mass, to yield a pyramid of related product ions. With mass spectrometry developments the MS-MS technique will become inexpensive, and eventually the GC-MS-MS technique will be the conventional means of analysing pesticide in most classes of sample matrices.

Supercritical Fluid Chromatography

M. E. P. McNally, E.I. DuPont de Nemours and Co., Inc., Wilmington, DE, USA

Introduction

Supercritical fluid chromatography (SFC) is a useful tool in the analysis of pesticides and herbicides. Typically, this is done with liquid or gas chromatography and there are basic advantages and disadvantages to each of these methods of analysis. For LC, the liquid

phase offers the unique advantage of a wide range of solubilities but detection interfaces tend to be the limiting factor. GC has the ability to be more easily interfaced to specific detection capabilities but has significant limitations in the area of solubility; compounds must be able to be readily volatilized. For agriculturally active compounds, the lack of a universal detector for HPLC limits the scope of its applicability to compounds which do not contain UV chromophores. GC is limited to thermally stable volatile compounds since they must move through the

chromatographic column in the gaseous state. Not all pesticides and herbicides contain a chromophore, others are thermally labile, or are not volatile, and therefore require derivatization for GC analysis. The analysis of pesticides and herbicides by supercritical fluid chromatography is a reasonable alternative to LC and GC. SFC offers the ability to be coupled to a wide variety of detectors that are both LC and GC compatible. In addition, the solubilizing powers of a supercritical fluid at low operating temperatures can easily mimic those achieved with liquids, thus making SFC more applicable to a wider range of pesticide and herbicide classes than either LC or GC.

Since the mid-80s, the advantages of SFC in pesticide and herbicide analysis have been well documented. SFC has also been used to solve separation problems. In the main stream of pesticide and herbicide analysis however, SFC remains a niche technique that is employed when classical LC and GC analysis are not successful in solving a problem. Even in those examples where SFE may be used to remove the herbicidal or pesticidal analyte of interest, the follow-up technique is still predominantly gas or liquid chromatography.

This report outlines typical examples of the use of supercritical fluids for the chromatographic analysis of pesticides and herbicides by pesticide class. Table 1 lists these pesticides, their common and trade names, mode of action and pesticide class.

Carbamates and Methyl Carbamates

Carbamate pesticides were rapidly analysed with flame ionization detection by Wright and Smith. The compounds investigated were propoxur, chlorpropham, carbaryl, and phenmedipham and baseline resolution was achieved in less than 1.5 min. To achieve this rapid separation, the authors used a short capillary column ($0.9\text{ m} \times 25\text{ }\mu\text{m}$ i.d.) coated with 5% phenyl polymethylsiloxane that had been cross-linked with azo-tert-butane. This type of rapid separation represents one of the other distinct advantages of SFC. The high diffusivities of supercritical fluids allow for rapid equilibration, as the compounds of interest travel through the chromatographic column achieving higher separation factors in less time. Overall analysis times are therefore reduced. In this separation, pure carbon dioxide was used as the mobile phase with pressure programming rates of 100 atm min^{-1} . The baseline resolution of propoxur, dicamba, carbaryl, 2,4-D, silvex, and phenmedipham was achieved later in approximately 120s by these same authors, again demonstrating the rapid analysis of carbamate pesticides by SFC. For this mixture of

six pesticides, the separation was achieved on a $1.5\text{ m} \times 25\text{ }\mu\text{m}$, 5% phenyl polymethylsiloxane column with pressure programming at 50 atm min^{-1} . This mixture was further expanded with the addition of picloram and chloramben and baseline resolution was obtained on a 1.5 m capillary column in approximately 120s, demonstrating consistently the rapid analysis times that can be achieved using SFC for carbamates.

In more typical separation timeframes, Richter reported the separation of four carbamate pesticides on a more standard size column $15\text{ m} \times 50\text{ }\mu\text{m}$ i.d. fused silica column with an SE-33 stationary phase ($0.25\text{ }\mu\text{m}$ film thickness). Aldicarb, methomyl, diflufenbuzon, and phenmedipham were baseline resolved in a little more than 20 min.

UV detection at 254 nm was used to analyse carbamate pesticides by Games and co-workers using analytical-scale packed columns with modified carbon dioxide. The pesticides analysed were chlorpropham, pirimcarb, methiocarb, carbaryl, phenmedipham and asulam. Resolution was achieved in approximately 5 min on a $10\text{ cm} \times 4.6\text{ mm}$ i.d. LiChrosorb column. 12% methanol-modified carbon dioxide was the mobile phase and the flow rate was programmed to help achieve the rapid separation by increasing the rate from 2 mL min^{-1} to 4 mL min^{-1} after the first 2 min.

Although nitrous oxide, especially when mixed with alcohol modifiers, has since been shown to be a safety hazard under supercritical conditions, initially investigators explored the use of nitrous oxide as an alternative to carbon dioxide to obtain alternative separation mechanisms. Capillary SFC for the separation of free amines and their carbamate and amide derivatives was investigated by Mathiasson *et al.* with nitrous oxide as the mobile phase. A thermionic nitrogen-phosphorus detector was used and its performance optimized by systematic variation of the makeup gas flow rate (nitrogen), the hydrogen and air flow rates, and the bead current. The effects of increasing nitrous oxide pressure on detector response were explored and a dependence of peak area on the system pressure was observed. This same effect on detector response was seen with the addition of methanol modifier to the nitrous oxide. Concentrations of methanol above 0.8% resulted in a significant loss in signal from the detector.

Aldicarb, methomyl, mesurol, oxamyl, carbofuran, and carbaryl were analysed by capillary SFC by Richter and coworkers in parsley extracts. The column was a $10\text{ m} \times 50\text{ }\mu\text{m}$ i.d. SB-methyl-100 and a nitrogen-phosphorus detector was used. Practical limits of detection were achieved, the pesticides were determined in the parsley extract at levels of approximately 2 ppb.

Table 1 Compound classes of herbicides, insecticides and pesticides

<i>Compound common name</i>	<i>Trade name</i>	<i>Mode of action</i>	<i>Compound class</i>
α -BHC or Benzene Hexachloride		Ingested insecticide	Organochlorine insecticide
Alachlor	Lasso™	Cell division inhibitor	2-Chloroacetanilide herbicide
Aldicarb	Temik	Cholinesterase inhibitor	Carbamoyloxime insecticide
Aldrin	Octalene		Organochlorine insecticide
Atrazine	Gesaprim	Photosynthetic electron transport inhibitor	1,3,5-Triazine
β -BHC or Benzene hexachloride		Ingested insecticide	Organochlorine insecticide
Bendiocarb	Ficam, Garvox, Seedox	Cholinesterase inhibitor	Methyl carbamate insecticide
Captafal	Difolatan	Protective non-systemic fungicide	Phthalimide fungicide
Captan	Orthocide™	Protective spray, root or dip fungicide	Phthalimide fungicide
Carbaryl	Sevin	Cholinesterase inhibitor	Methyl carbamate insecticide
Carbofuran	Furadan, Curaterr, Yaltox	Cholinesterase inhibitor	Carbamate insecticide
Carbophenothion	Trithion	Acaricide	Organophosphorus insecticide
Chlorbromuron	Maloran	Photosynthetic electron transport inhibitor	Urea herbicide
Chlordane	Octachlor	Non-systemic contact and ingested insecticide	Chlorinated hydrocarbon insecticide
Chlorpyrifos	Dursban, Lorsban	Cholinesterase inhibitor	Organophosphorus insecticide
DDD	Rhothane		Organochlorine insecticide
DDE	Gesarol, Guersarol™	Non-systemic ingested contact insecticide	Organochlorine insecticide
DDT	Gesarol, Guesarol, Neocid	Non-systemic ingested and contact insecticide	Organochlorine insecticide
Dieldrin	Octalox		Organochlorine insecticide
Diflubenzuron	Dimilin	Chitin synthesis inhibitor	Benzoylurea insecticides
Dioxathion	Delnav		Organophosphorus insecticide
Disulfoton	Di-Syston, Dithiosystox, Frumin AL, Solvirex	Cholinesterase inhibitor	Organophosphorus insecticide
Diuron	Karmex	Photosynthesis inhibitor	Urea
Ethyl parathion	Thiophos, Bladan, Folidol, Fosferno, Niran™	Cholinesterase inhibitor	Organophosphorus insecticide

Table 1 Continued

Compound common name	Trade name	Mode of action	Compound class
Fenclorphos	Nankor Trolene Korlan	Systemic insecticide	Organophosphorus insecticide
Fenitrothion	Accothon, Cytel, Cyfen, Folithion, Sumithion	Cholinesterase inhibitor	Organophosphorus insecticide
γ -BHC or benzene hexachloride	Lindane, Gammexane	Ingested insecticide	Organophosphorus insecticide
Hexachlorobenzene, HCB	Voronit C	Selective fungicide used to control <i>Tilletia caries</i> on wheat	Organochlorine fungicide
Malathion, Carbofos Metalaxyl	Cythion Apron, Ridomil, Fubol	Cholinesterase inhibitor Systemic fungicide	Organophosphorus insecticide Acetalanine
Methidathion	Supracide Ultracide	Cholinesterase inhibitor	Organophosphorus insecticide
Methomyl	Lannate, Nudrin TM	Cholinesterase inhibitor	Carbamoyloxime insecticide
Methoxychlor	Marlate	Contact and stomach insecticide	Bridged-di-phenyl insecticide
Methyl parathion	Trithion	Cholinesterase inhibitor	Organophosphorus insecticide
Metobromuron	Patoran	Photosynthetic electron transport inhibitor	Urea herbicide
Oxamyl	Vydate	Cholinesterase inhibitor	Carbamoyloxime insecticide
Parathion	Thiophos, Bladan, Folidol, Fosferno, Niran	Cholinesterase inhibitor	Organophosphorus insecticide
Pentachlorophenol	Dowacide G, Santobrite	Termite control	Phenolic herbicide, insecticide and fungicide
Phenmedipham	Betanal	Photosynthetic electron transport inhibitor	Bicarbamate herbicide
Phorate	Thimet, Agrimet TM	Cholinesterase inhibitor	Organophosphorus insecticide
Tetrachlorvinphos	Gardona, Rabond,	Cholinesterase inhibitor	Organophosphorus insecticide
Tetradifon	Tedion V-18	Non-systemic acaricide	Bridged diphenyl acaricide
Thiodicarb	Larvin, Semevin	Cholinesterase inhibitor	Carbamoyloxime insecticide
Tri-allate	Avadex BW, Far-Go	Cell elongation inhibitor	Thiocarbamate herbicide

The separation of the thermally labile acid and carbamate pesticides propoxur, BPMC (fenobucarb), propachlor, carbofuran, alachlor, carbaryl, linuron, and diuron was achieved by Wright *et al.* using

SFC/MS with ammonia chemical ionization. Capillary SFC was used for sample introduction into the MS instrument. Resolution of all compounds except BPMC and propachlor was obtained on

a 10 m × 50 μm 5% phenyl methylpolysiloxane stationary phase. Ammonia provided softer ionization with an (M + 18) + molecular ion and little fragmentation, while methane chemical ionization resulted in an (M + 1) + molecular ion and increased fragmentation when the two reagent gases were compared. These same authors conducted additional work comparing the same reagent gases for the chemical ionization of a larger group of carbamate and acid pesticides. Again, capillary SFC was used as a means of sample introduction. The separated and identified carbamate pesticides were: aldicarb, aldicarb sulfoxide, aldicarb sulfone, carbaryl, BPMC, propoxur, chlorpropham, carbofuran, asulam, desmedipham, and penmedipham. The acid pesticides explored were 2,4-D, 2,3-D methyl ester, dicamba, piclotam, Silvex and Silvex methyl ester. The capillary columns were short (2 m × 50 μm i.d.) the pressure ramps rapid (50 atm min⁻¹). Spectra obtained using ammonia resembled thermospray HPLC/MS spectra. The general rule for carbamates was that the ammonium adduct ion was the base peak. The absence of significant thermal degradation was indicated since the molecular species was present.

Carbofuran, its 3-keto, and 3-hydroxy metabolites extracted from the gullet of a bird were analysed by multidimensional SFC/SFC. A 1.0 μL aliquot of bird extract was injected allowing for detection limits for both metabolites and carbofuran at levels in the range 1 to 10 ng. A flow-switching interface demonstrated the use of two 50-μm-i.d. capillary columns in tandem. In this example, a biphenyl column was first in the series, a glyme column second. The use of solvent venting allowed for the injection of large volumes.

A multichannel UV detector for capillary SFC was used to analyse the pesticides bendiocarb and carbaryl and the herbicides alachlor, diuron and metalaxyl. A photodiode array spectrophotometer acquired the UV spectra. The detector flow cell volume was 710 nL made from a fused silica capillary (0.32 mm i.d.) with the polyimide coating removed. The capillary column a 12 m × 100 μm i.d. 5% phenylmethyl polysiloxane achieved baseline resolution in 31 min. Full spectra over the range 190 to 310 nm were collected at the peak apexes for each compound. Excellent sensitivity was achieved, for example the limit of detection of bendiocarb (S/N = 5) was 3.8 ng.

Triazines

Both packed and capillary column SFC have been successfully used for the analysis of triazine herbicides. To achieve good signal/noise ratios at concentrations as low as 5 ppm, Ashraf and coworkers

reported using solvent-vented injections of as much as 1.0 μL samples onto a 2 m × 110 μm i.d. retention gap. The gap was connected through a venting valve to a 10 m × 50 μm i.d. fused silica capillary SFC column. The valve was switched to the inject position for a controlled amount of time when as little as 0.2 μL of sample was delivered, or for the full length of the chromatographic run for the delivery of 1.0 μL of sample. During the injection process, the sample loop was purged with nitrogen gas. After injection, the repositioned venting valve passed the flow of nitrogen through to the vent, concentrating the injected compounds on the pre-column. Another switch of the venting valve brought the analytical column in-line for the chromatographic analysis. This injection technique was successful for up to 20 ppm solutions of the two triazine herbicides, atrazine and cyanazine. Two pyrethroids and one benzophenylurea compound were also successfully injected using this technique.

Packed column SFC was used by Taylor *et al.* to investigate the behaviour of triazine and triazole herbicides. Carbon dioxide flow rate, outlet pressure, and oven temperature were explored using an analytical scale, 25 cm × 4.6 mm i.d., Deltabond CN column. Baseline resolution of the eight compounds of interest was obtained in approximately six minutes again illustrating the rapid equilibration and elution possible with supercritical fluids. In an atypical flow delivery method, the flow of carbon dioxide was held constant, while the flow of methanol was increased during the chromatographic run. Over the course of the six minute chromatographic run, the methanol concentration was increased from 2.4% to approximately 30%. The outlet pressure during the separation was 270 atm (4000 psi) and the oven temperature was held constant at 60°C. There is little question that supercritical conditions were not maintained during the analysis. Specifically, once the methanol concentration reached levels at or above 12 to 15%, sub-critical or enhanced fluidity chromatography were the most likely mobile phases affecting the separation. Despite the change in mobile phase state throughout the chromatographic process, the separation was successfully achieved.

Concentration ranges from 2.5 ppb to 25 ppm were examined by Ashraf *et al.* using a 'three electrode' thermionic detector. Both the phosphorus and nitrogen selective modes were explored with capillary SFC as the means of sample introduction. The compounds of interest included two triazine herbicides, two pyrethroids, a benzophenylurea, and a chlorophenyl vinyl diethylphosphone. The capillary SFC column was a 10 m × 50 μm i.d. biphenyl methyl polysiloxane. Significant baseline rise was observed during pressure programming. To reduce this effect,

optimization experiments for hydrogen, air, and nitrogen flow rates (as makeup gas), and the position of the alkali source in relation to the flame tip were conducted. In the phosphorus mode, detection in the picogram range was demonstrated for the vinyl phosphone. Detection was only slightly improved over what could be obtained with flame ionization detection when nitrogen-containing compounds, such as the triazines, were examined in the phosphorus mode. In the nitrogen mode, the background current was much lower. This did not result in a less severe baseline increase with pressure programming. This detector was found to demonstrate enhanced sensitivity in the nitrogen mode, with detection limits in the range 0.6 to 60 pg.

SFC/MS and GC/MS were both easily connected with capillary SFC via a capillary-direct interface. The interface used required no modification of the mass spectrometer. Hawthorne and Miller reported the analysis of a triazine herbicide metabolite using capillary SFC/MS and obtaining spectra collected in the CI mode with methane as the reagent gas.

A minimum detection limit of approximately 35 pg ($S/N = 3$) was obtained for a triazole fungicide metabolite on a $5\text{ m} \times 50\ \mu\text{m}$ SB-methyl-100 column. An electron capture detector was utilized for this capillary SFC analysis. Pressure programming from 100 to 350 atm (1500 to 5100 psi) at $40\ \text{atm min}^{-1}$ was performed without a substantial increase in detector background signal. Makeup gas of 10% methane in argon was used with a detector operating temperature of 350°C . The optimum conditions for system operation were found with makeup gas flow rate of $15\ \text{mL min}^{-1}$, and the restrictor positioned approximately 3 cm from the column nut at the entrance to the detector.

The effects of 'enhanced fluidity' mobile phases on s-triazines: ammeline, hydroxyatrazine, desethyl-desisopropyl atrazine, atrazine, terbutyne and terbutylazine have been shown. Figure 1 shows the names, structures and pK_a values of these herbicides. Enhanced fluidity chromatography uses carbon dioxide at lower percentages and mobile phase modifiers such as methanol at higher percentages than SFC. This yields gains in diffusivity and viscosity over liquid chromatography but not to the level obtained with SFC. Figure 2 shows the chromatographic separation of four of these triazines at elevated pressures and temperatures with three different mobile phase compositions. Table 2 shows the chromatographic efficiencies and retention times of analytes with different mobile phase conditions. These values are taken from the chromatograms illustrated in Figure 2. Ultimately, for these triazine herbicides the viscosity reduction of the 'enhanced fluidity' mobile phase yielded higher optimum flow rates, higher efficiency, shorter analysis time, and decreased pressure drop. These are the same advantages seen when a supercritical fluid mobile phase is used, but to a lesser extent. The example has been included in this review of SFC to be inclusive and to illustrate to the reader that many examples in the literature which claim to be 'supercritical', fall in and out of the supercritical region of a phase diagram. Even so, advantages over liquid chromatographic separations can be seen.

Ureas and Sulfonylureas

Much work has been carried out using supercritical techniques on ureas and sulfonylureas. This class of herbicides was newly introduced in the early 1980s.

Figure 1 Chemical structures and pK_a values of triazine herbicides.

Figure 2 Chromatograms at 238 atm, 0.35 mL min⁻¹ for different mobile phase conditions: (A) 64:36 mol% methanol-H₂O; (B) 51:29:20 methanol-H₂O-CO₂; (C) 51:29:20 methanol-H₂O-CHF₃. Peaks: 1. hydroxyatrazine; 2. desethyl-deisopropyl atrazine, 3. atrazine, 4. terbutylazine.

They have low use rates in the agricultural arena and so require low analytical detection limits and they are thermally labile. The desired low detection limits make liquid chromatography more difficult and the thermal lability make GC inappropriate. Wheeler and McNally compared packed and capillary supercritical fluid chromatography with HPLC using representative ureas and sulfonylureas. Five herbicides were analysed by the three techniques. For both the capillary and the packed column SFC experiments and LC, UV detection was used. Limits of detection, reproducibility, and linearity of response were compared. The compounds investigated were the moderately polar herbicides, Oust®, Glean®, Harmony®, Karmex® and

Nustar®, Oust®, Glean® and Harmony® are sulfonyl urea herbicides. Karmex® or diuron is a phenyl methyl urea, and Nustar® is a silicon fungicide. Results indicated that faster analysis, lower detection limits, and greater injection-to-injection reproducibility were obtainable with packed column SFC. No appreciable difference in the linearity of response between the three techniques was observed. Using capillary SFC with FID detection, short capillary columns were used to examine these same compounds. Relative standard deviations for peak area were 3 to 5% range. The linear range was found to be fairly compound dependent, and detection limits were reported in the range 20 to 80 µg mL⁻¹.

Baseline resolution of dimethylcarbanilide, dimethylphenylurea (linuron), diphenylmethylurea (diuron), monuron, and carbanilide was achieved in eight minutes. Shah and Taylor used an analytical scale packed cyanopropyl column. Using a methanol modified carbon dioxide mobile phase, the separation was achieved holding the methanol concentration constant at 2%, and the flow rate at 3 mL min⁻¹. Ureas, sulfonylureas and their manufacturing precursors have been separated using packed and capillary SFC columns, a carbon dioxide mobile phase and an on-line FTIR detector. The column used in the urea separation was a packed 10 cm × 1 mm i.d. cyano column. Capillary columns and split-less injections of 0.1 µL were employed for precursors at concentrations of approximately 3 mg mL⁻¹. The ureas studied were: dimethylphenyl urea, diphenylmethyl urea, monuron, and carbanilide. On the packed column, baseline resolution of all compounds except for the partially resolved dimethylcarbanilide and dimethylphenyl urea, was obtained. Peak assignments were made based on retention time and spectral interpretation comparison with pure standards. After attempts to develop the separation on the packed CN column failed, capillary SFC columns were used to separate the benzamide-anilide mixture. The baseline resolution of six precursors was achieved in approximately 25 min.

The packed SFC retention behaviour of a variety of urea and sulfonyl urea precursors was studied with modified carbon dioxide mobile phase by McNally and co-workers. Methyl, phenyl, nitro, amide, carboxamide and chloro functional group positioning were examined to gain an understanding of retention characteristics. Extensive modifier interactions were investigated in this study, using methanol, ethanol, isopropanol, hexanol and tetrahydrofuran at 2% w/v in carbon dioxide. A silica stationary phase was chosen to simulate polar matrices, i.e. soil and plant materials. Comparisons with supercritical fluid extraction retention were drawn. This was the first

Table 2 Efficiencies and retention times of analytes with different mobile phase conditions at the same flow rate: 0.35 mL min⁻¹^a

Peak	Mobile phase (mol%), flow rate					
	64/36 methanol/H ₂ O, 0.37 mL min ⁻¹		51/29/20 methanol/H ₂ O/CO ₂ , 0.35 mL min ⁻¹		51/29/20 methanol/H ₂ O/CHF ₃ , 0.37 mL min ⁻¹	
	Efficiency	<i>t</i> (min)	Efficiency	<i>t</i> (min)	Efficiency	<i>t</i> (min)
1	3714	4.05	4271	3.54	4908	3.81

3	9672	6.4	10870	5.72	11588	5.59
4	10306	7.2	11332	6.14	11738	5.92

^aPeak numbers are the same as in Figure 2. The values provided are averages of at least three replicated chromatograms with RSD ≤ 5%.

comparison of the two made in the literature. Since that time, several extensive reports have proven this correlation to be true. In this functional group study, specific interactions were observed which were attributed to the polarity of the compound, steric interactions between individual functional groups of the molecules, the functional group molecular make-up, and the polarity of the modifier used.

A benchtop thermospray mass spectrometer has been coupled with packed column SFC for the detection of the packed column SFC separation of ureas. The column used to separate dimethylcarbanilide, dimethylphenyl urea, diphenylmethyl urea, monuron, diuron, and carbanilide was a 1-mm i.d. cyanopropyl column. Significant baseline rise with pressure programming was noted and attributed to hydrocarbon contamination in the carbon dioxide mobile phase. This was eliminated in the selective ion monitoring (SIM) mode of the mass spectrometer.

Diuron was the target analyte in a study which examined the effect of repeller potential on spectra obtained by SFC/MS using a thermospray interface. The influence of the repeller potential on the degree of fragmentation was studied. An analytical scale (4.6 mm i.d.) packed column was used for sample introduction with 2% methanol carbon dioxide mobile phase. Spectra of diuron at low repeller potentials resembled CI spectra while at high repeller potentials the result was close to the EI spectra of diuron. High vaporizer temperature led to the thermal decomposition of diuron.

As has been stated, the advantages of SFC are that separation is achieved rapidly, with a high number of theoretical plates, leading to resolving powers that are far superior to those found in liquid chromatography. The use of SFC for the separation of a wide range of sulfonylurea compounds has been demonstrated in the analysis of environmental water samples. Preceded by a simple concentration step on an SPE cartridge, as low as 0.5 ng mL⁻¹ detection levels

in the original sample were achieved reproducibly. No additional sample clean-up was required. This was not the case with capillary electrophoresis and liquid chromatography. **Figures 3(A), 3(B) and 3(C)**, show the SFC/UV chromatograms obtained for spiked Milli-Q water, and spiked river and spike creek water respectively. As is illustrated, chromatographic interference was not seen in any of the chromatograms. The SFC conditions coupled six standard 5 μm packed analytical columns in series, one Zorbax[®] ODS, 4.6 mm × 25 cm, and five Zorbax Silica also 4.6 mm × 25 cm. The mobile phase was a carbon dioxide methanol gradient, initial methanol percentage 1% at 90 bar held constant for four minutes, then ramped to 7% at 150 bar at 10 min, then held at 150 bar but ramped to 16% methanol in an additional ten minutes. The temperature was 60°C, flow rate 2.00 mL min⁻¹. Retention times were in the 30 to 40 minute range. This was quick considering the total length of the six columns. An example chromatogram of twelve separated sulfonylurea compounds is illustrated in **Figure 4**. Again, no interference is seen in the creek water, in the retention time of interest.

Organophosphorus Pesticides

Malathion, phoxim, ethion, dimethoate, and azinphos-methyl in onion and tomato extracts have been separated by packed capillary SFC with a phosphorus-selective thermionic detector. Attempts at separating these compounds with pure carbon dioxide were unsuccessful; methanol and 2-propanol were used as modifiers. 1.5% methanol resulted in baseline resolution in nine minutes. 3.5% 2-propanol also achieved baseline resolution but inferior peak shape. The packed column was a 5 μm C-18 15 cm × 0.32 mm i.d. packed. The detector performance was optimized with regard to mobile phase composition, hydrogen and air flow rates, and the

Figure 3 (A) Millo-O water at 0.5 ppb. (B) White Clay Creek water at 0.5 ppb. (C) Brandywine River water at 0.5 ppb.

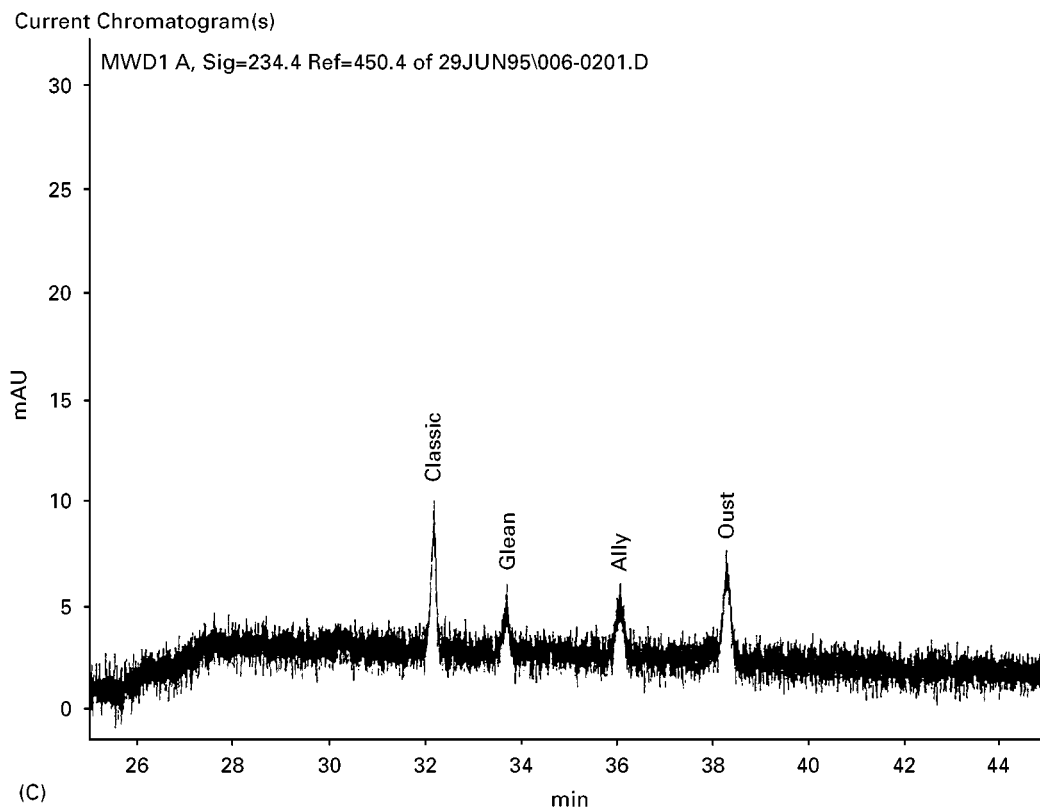

Figure 3 Continued

distance between the detector jet and bead. Standard calibration plots were compared for standards dissolved in acetone and into tomato and onion extracts. Slopes of the calibration curves were unchanged, suggesting an absence of matrix effects. Limits of detection for these organophosphorus insecticides ranged from 15 to 62 pg with methanol modifier.

The organophosphate pesticides chlorpyrifos, chlorpyrifos methyl, iodofenphos, leptophod, methidanthion, tetrachlorvinphos, phosmet, and famphur were separated using microbore packed column SFC with mass spectrometric detection. The separation was achieved with an amino column and 2% 2-propanol modified carbon dioxide. Baseline resolution was achieved in approximately 7 min except for chlorpyrifos and chlorpyrifos methyl. A high flow rate (HFR) interface between the SFC system and the mass spectrometer allowed for the use of packed columns. CI spectra were collected using ammonia or 2-propanol as the reagent gas. 94 pg on-column detection of chlorpyrifos in the selected ion monitoring mode yielded a S/N ratio of 21. An extract of cherries spiked with this mixture of insecticides was analysed utilizing this method.

Sulfur chemiluminescence detection with capillary SFC has been demonstrated for the analysis of

malathion, carbophenothion, dioxathion, fenitrothion, and methyl and ethyl parathion. Restrictor tip positioning in relation to the chemiluminescence chamber was found to have a large effect on the quality of the chromatographic separation.

The capillary SFC was carried out on a 3.5 m \times 100 μ m DB-5 fused silica column with pure carbon dioxide mobile phase. The analysis of malathion from a commercial formulation was demonstrated. Detection limits were compound specific for malathion; 4.5 mg or 77 pg s^{-1} was reported while 39 ng (65 pg s^{-1}) was demonstrated for methyl parathion.

Phorate, Di-Syston, malathion, and ethion were investigated using capillary SFC and a microwave-induced plasma for detection. The 10 m \times 50 μ m, SB-cyanopropyl-50 capillary SFC column was used to introduce the pesticide samples into the plasma, using nitrous oxide as the mobile phase. Detection was conducted at the sulfur line. Baseline disturbances with both positive and negative slopes were observed at differing helium flow rates. An optimum helium flow rate for sulfur line monitoring was determined. With the use of nitrous oxide as a mobile phase, interference from CN-band emission was found with most of the lines investigated. Sensitivities were com-

Figure 4 White Clay Creek water at 1.0 ppb.

pound and mobile phase dependent. The sensitivity reported for sulfur with carbon dioxide as the mobile phase was 73 pg s^{-1} .

The separation of two organophosphorus insecticides (i.e. methidathion and chlorpyrifos) and a carbamate insecticide (i.e. carbofuran) was demonstrated by capillary SFC coupled with flame ionization and radio-frequency plasma detectors. When a FID was used, all three compounds were detected. When the RFP detector was used, either the chlorpyrifos or both the chlorpyrifos and the methidathion were detected, depending on whether the wavelength of chlorine emission or sulfur emission was being monitored. Short capillary columns, 2 to 3 m \times 50 μm , and slow flow rates were used to prevent the introduction of too much mobile phase, and subsequent quenching of the plasma. The emission spectra of carbon dioxide and nitrous oxide did not show significant background or interference in the regions of interest for sulfur and chlorine.

Organochlorine Pesticides

A comparison between micro-column liquid chromatography and capillary SFC was conducted for the analysis of a series of organochlorine and

other select pesticides from water samples. Small injection volumes in the SFC analysis limited the sensitivity, but the savings in analysis time was significant, 50 min compared to 10 h.

Acceptable recoveries of 2,4,5-T, 2,4-D, p,p'-DDD, methoxychlor, atrazine, dioctylphthalate, pyrene, pentachlorophenol, cabazole, and hexachlorobenzene were demonstrated for the microbore LC isolation method using UV detection. The capillary SFC separation with a 10 m \times 50 μm , SE-30 column and FID detection showed interfering peaks when SepPak cartridges were used. To eliminate this, water samples were preconcentrated through lyophilization. Both lake and river water samples were studied.

Detection limits of 0.64 pg were reported for Chlordane, a chlorinated hydrocarbon, Tri-allate, a thiocarbamate herbicide using capillary SFC and ECD detection. Arochlor 1254, and Arochlor 2565 were also separated and detected from the mixture. A 6 m \times 50 μm capillary column and frit restrictors to provide back pressure to the system were used. Optimum make-up gas flow rate (10% methane/argon) was determined to be between 20 and 30 mL min^{-1} . Detector temperature affected the sensitivity in a compound-dependent manner. Separations of seven

thermally labile pesticides including metobromuron, fenitrothion, fenchlorphos, chlorbromuron, tetra-chlorvinphos, tetradifon and diruon were accomplished in approximately 20 minutes.

Fourier transform mass spectrometry has been used for the detection of lindane, aldrin, DDE, dieldrin, DDD, DDT and methoxychlor in a mixture separated by SFC. Previously, this had been difficult due to the extreme difference in pressure requirements between the mass spectrometer and the supercritical fluid chromatograph. Relatively long capillary columns, $20\text{ m} \times 100\text{ }\mu\text{m}$, were used for this work. Typical chromatographic detection limits were in the low-nanogram range, although the sensitivity for aldrin and dieldrin was not as great due to the extent of fragmentation.

Carbofuran, α -BHC, γ -BHC, β -BHC, chlordane, and DDT were separated by capillary ($6\text{ m} \times 50\text{ }\mu\text{m}$) SFC and detected with the use of a double focusing mass spectrometer. The interface developed was a direct heated probe. Spectra were collected in the negative-ion chemical ionization mode with methane as the reagent gas. The mass on column per compound was in the subnanogram range.

Chlordane was examined by capillary SFC and RFP detection using the emission wavelength for chlorine. The capillary SFC conditions are the same as those outlined in the organophosphorus section for methidathion and chlorpyrifos and a carbamate insecticide, carbofuran. The presence of DDT in milk was examined similarly. Using FID, milk extracts yield a complex chromatogram due to the triglycerides. Triglycerides are not detected by RPD, and a single peak for DDT is easily detected in milk. α - and β -BHC, chlordane, and methoxychlor were also separated and detected by RPD in the chlorine mode. Nitrous oxide was used as the mobile phase in this separation. Detection limits changed with the pressure of the capillary SFC system; higher detection limits were seen at higher pressures. Sulfur detection limits of 60 pg s^{-1} were obtained at 100 atm, while this limit rose to 178 pg s^{-1} at 400 atm.

Phthalimide Fungicides

Capillary SFC with electron-capture detection was unsuccessfully attempted for captafol and captan, although these compounds had been previously detected in SFC/FID experiments. This failure was attributed to the inability of these high melting compounds to be vaporized in the detector cavity of the ECD. The chromatographic mode is not the cause of this failed attempt as much as is the choice of detector.

Carbamoyloxime Insecticides

Aldicarb and methomyl, two carbamoyloxime insecticides, diflubenzuron, a benzoylurea and phenmedipham, a dicarbamate herbicide were separated on capillary columns ($15\text{ m} \times 50\text{ }\mu\text{m}$ ID) with a nitrogen-phosphorus detector. Similar separations of the four compounds were obtained when carbon dioxide and nitrous oxides were used as the mobile phase. Upon the addition of 1% THF as a modifier, changes in retention were observed, with the later eluting peaks, diflubenzuron and phenmedipham, showing larger changes in retention.

These same four pesticides were separated by capillary ($10\text{ m} \times 100\text{ }\mu\text{m}$) SFC with FTIR (Fourier transform infrared) detection. The flow cell interface used was connected to the chromatographic column and to the restrictor by lengths of $100\text{ }\mu\text{m}$ fused silica capillary tubing, the same ID as the capillary separation column. 200 nL injection volumes of 5 mg mL^{-1} of each component yielded spectral quality that was sufficient to provide structural information for these compounds. A 22:1 split ratio was utilized. 'Gram-Schmidt Plus' reconstruction techniques removed interference caused by changing density of the carbon dioxide with pressure programming. Spectral subtraction techniques were used to remove CO_2 features from the obtained IR spectra.

The use of dual-flame photometric detector with capillary SFC for the detection of the sulfur and phosphorus containing compounds: Oxamyl, parathion, chlorpyrifos, and Larvin. Modifications were made to the detector to make it compatible with supercritical mobile phases. The capillary SFC column was a $15\text{ m} \times 75\text{ }\mu\text{m}$ i.d.. Detection limits were superior in the phosphorus mode, only slight baseline disturbance with pressure programming was noted over the range 50 to 200 atm (700 to 2900 psi). The detection limit of 0.5 ng ($S/N = 2$) was reported for parathion. In the sulfur mode more significant baseline disturbances were observed over the same pressure range. A baseline correction programme was used; even with this only a detection limit of 25 ng ($S/N = 2$) for benzo[b]thiophene was observed.

Pyrethrins

Six naturally occurring pyrethrin insecticides isolated from chrysanthemums were separated by capillary SFC. The pyrethrins were: cinerin I and II, jasmolin I and II, and pyrethrins I and II. Separation by a biphenyl column provided baseline resolution of the six compounds insecticides followed by on-line FTIR analysis. The separation of the six compounds by GC resulted in the degradation of pyrethrins I and II; therefore SFC/FTIR provided a way to analyse these

compounds without degradation. The SFC/FTIR spectra were able to distinguish between the structurally similar pyrethrins continuing to maintain the structural information provided by GC/IR analysis.

Future Developments

The future of SFC in pesticide and environmental analysis is not predictable. Currently more work is being reported in supercritical fluid extraction than in chromatography. However, research continues in a few locations with a few select individuals. The future of SFC seems to lie with chiral separations and pharmaceutical analysis and not with the environmentally oriented work presented in this review. This is not to suggest that the work presented here is without value. Advances into enhanced fluidity chromatography were most likely initiated from the work in SFC. As with other analytical techniques, success in one area leads to attempts in others.

Low waste generation in SFC is not enough to carry the technique into the arena where it can compete equally with LC and GC, the investment in training and equipment is too large a barrier to be overcome with what has fallen into the category of being a 'niche' technique. Liquid and gas chromatography are well cemented into environmental analysis. SFC of pesticides will continue to go beyond academic exercises to solve real problems, but most like

ly only when LC and GC do not yield a satisfactory result.

Introduction

Pesticides are a group of chemicals designed for killing weeds, pest control and plant growth regulation. They are poisons by design. Some of them also demonstrate carcinogenic potential and/or teratogenic activity. Pesticides (or products of their transformation in the environment) can penetrate soil, water, air and also food and fodder. As a result, pesticides are currently present in all parts of the environment. Many of them undergo degradation, but others are persistent and may accumulate in the food chain.

Development of residue analysis for pesticides is driven by toxicological purposes or by the need to

identify residues. In the first case, the compounds are identified as being potentially hazardous to human health or to the environment. In the second case, the determination of residues is mainly aimed at inspecting and monitoring of food or environmental samples. Thin layer chromatography (TLC), including its modern developments (high-performance adsorbents, application of new, automatic techniques of spotting and development of chromatograms, spray-on technique of sample application), is still used for such analyses, especially in combination with selective biochemical detection methods or multidimensional methods although gas chromatography and high-performance liquid chromatography with selective detectors (ECD, NPD, AED or MS) are more important.

There is now a considerable literature describing pesticide analysis by TLC, with environmental and food monitoring, generally being the main aim in such

research (see Fodor-Csorba in Further Reading). There are also numerous works of cognitive character, concerning investigation of the most advantageous chromatographic systems, separation techniques and methods of visualization and quantification. Assessment of physical and chemical properties of pesticides, e.g. their mobility, bioaccumulation and biotransformation, is also an important area of TLC study.

General Principles of Pesticide Analyses

The high selectivity, high detectability and reliability of analysis under fairly simple conditions contribute to the effective use of TLC for pesticide applications. Unfortunately, in the great majority of cases, pesticides need to be determined in complex matrices at extremely low concentrations over a wide polarity range. Therefore the analysis of samples without some preliminary preparation is almost impossible. Separation of pesticides in such samples to determine chemical identity and achieve detection and quantification should be followed by obtaining representative samples, sample clean-up and analytes enrichment.

Sample Preparation

Sample preparation techniques for analysis of pesticide residues by TLC are similar to those applied in the analysis of other pollutants. In the case of liquid matrices (water, milk, oil), liquid-liquid extraction (LLE) and, more recently, solid phase extraction (SPE) are most often used. For instance, C_{18} cartridges are useful for the extraction and purification of phenylurea herbicides, N-methylcarbamate and organophosphorous insecticides from water. For solid matrices (soil, meat, fruit and vegetable) liquid extraction is the most effective, although SPE has also been used after liquid extraction. Nowadays there is an increase in the application of supercritical fluid extraction, especially for the isolation of pesticides from solid matrices. This technique is useful for the trace analysis of pesticides because of much reduced amount of co-extracted interfering material.

It should be emphasized that TLC has no limitations in the scope of solvents that can be used for sample preparation, since solvent is removed and does not take part in the chromatographic process. The choice of TLC solvent is limited only by the physico-chemical properties of particular groups of pesticides. For example, carbamates are relatively labile chemicals so that during their extraction, strong bases are to be avoided to prevent losses due to chemical reaction. Extraction is usually carried out with acetonitrile or methanol (solubility in petroleum

solvents is limited). A small amount of water often allows actively absorbed pesticides to be released into the solvent. Strongly retained pesticides may be removed by elution with a mixture of water and methanol (1 : 4, v/v) and then partitioned into methylene chloride or eluted directly with ethyl acetate if the extract is clean. Extraction of organophosphorous or organochlorine pesticides is similar. These substances are much less labile than the carbamate pesticides and may, therefore, be retained on more active sorbents.

The solvent chosen to extract residues of pesticides depends not only on the solubility of the chemical, but also on the nature of the information required. This feature has special meaning in the analysis residues of pesticides from plant tissue. For example, the determination of residues for the purpose of establishing of safe re-entry times of workers after crops have been sprayed, requires a surface extraction of residue. On the other hand, determination of pesticide residues in fruits or vegetables to ensure the safety of food for consumers usually requires homogenization of the whole sample to extract the total impurities.

The goal of clean-up is to remove as much interfering, co-extracted substances and to lose as little of the pesticides as possible. Clean-up of samples depends on the type of matrix, detection limits required and the visualization technique employed. Usually about 80% of water samples had not been cleaned, but almost all analyses of pesticides in soil and food samples requires at least some clean-up. Selective methods of pesticide visualization such as fluorescence or enzymatic methods may minimize the need of clean-up.

Development Techniques

The majority of pesticide separations are performed on un-modified sorbents such as silica gel, cellulose aluminium oxide and polyamide. Modified sorbents (amino- NH_2 octyl-RP- C_8 , and octadecyl-RP- C_{18} or impregnated silica gel) are also used (Table 1).

The composition of the mobile phase is the second parameter, defining the conditions for chromatographic separation. During pesticide analysis in normal phase systems, mixtures of organic solvents are often applied. In reversed-phase systems mixtures of polar solvents (e.g. methanol, acetonitrile) with water, organic acids (e.g. acetic or formic acid) or ammonia are used. In some cases, organic salts or ion exchangers are dissolved in the mobile phase to improve the selectivity of the system.

All works concerning research into the best chromatographic systems are commonly named 'behaviour'. An investigation of the relation between pesticide structure and retention provides informa-

Table 1 Examples of chromatographic systems and techniques of development used in pesticide analyses

Analytes	Chromatographic systems		Technique of development
	Stationary phase	Mobile phase	
Pesticides of different classes	HPTLC silica	Gradient based on <i>tert</i> -butylmethyl ether + 5% acetonitrile, hexane, formic acid and ammonia	AMD
Pesticides of different classes	HPTLC silica	Gradient based on acetonitrile, dichloromethane and hexane	AMD
Pesticides of different classes	Silica gel impregnated by paraffin oil	Aqueous sodium chloride solution modified by β -cyclodextrin polymer	Classical TLC
Triazine herbicides	HPLC silica	Chloroform : ethyl acetate (1 : 3)	OPLC
Carbamates	RPC-18	Acetonitrile : water (17 : 3) or chloroform : acetonitrile : acetone (4 : 1 : 1)	Classical TLC
Cyanophenyl herbicides	Silica bonded β -cyclodextrin	Water : methanol (7 : 3) or glycine : methanol	Sandwich DS chamber

tion about the character of interactions in the chromatographic system and the possibility of prediction of their separation. Such works concern the behaviour of different groups of pesticides on silica gel, impregnated silica gel, reversed-phases, water insoluble β -cyclodextrin polymer, etc. Perišić-Janjić and co-workers have carried out research on the chromatographic behaviour of four groups of *s*-triazine derivatives on aminoplast (a carbamide-formaldehyde polymer) and cellulose. Chromatograms were developed with three aqueous mobile phases. The basic aim of the investigation was the evaluation of aminoplast (cellulose was used as comparative adsorbent) for the separation of triazines. Because the *s*-triazines are weak bases, the influence of mobile phase pH on the chromatographic retention was also examined. The authors demonstrated that retention behaviour of *s*-triazine derivatives on aminoplast and cellulose is similar. The greatest changes in R_F values occur in the pH region of protonation and dissociation of the triazine derivatives. It was also shown, that changes in retention factor, k , with pH allows the determination of ionization constants of the analytes.

One-dimensional ascending or horizontal techniques have usually been applied for the separation of pesticides in a closed chamber; multiple and two-dimensional development techniques have been rarely used. The new instrumental techniques such as forced flow planar chromatography (FFPC), automated multiple development (AMD) and gradient

development techniques are being used more frequently. The work of Mazurek and Witkiewicz is an example of the investigation of good separation techniques for pesticides. The direct aim of the work was the analysis of organophosphorous warfare agents, but they were analysed in the presence of 22 pesticides. The main features of the work are the application of the Prisma model for the mobile phase optimization, two-dimensional development, a biochemical method of visualization and separation by overpressure TLC (OPLC). The authors demonstrated faster separations in pressure chambers compared with classical TLC. It leads to a decreased spot diffusion and an increase in the number of theoretical plates. It was also shown that complete separation of all components of the mixture is possible only by two-dimensional OPLC (Figure 1). Examples of pesticides separation using automated multiple development (AMD) and gradient development technique are presented below.

Detection, Identification and Quantification

Pesticides are visualized using chemical or biochemical, physicochemical and physical methods. Chemical methods are based on wetting the adsorbent by solvents or aerosols of different agents, which react with the pesticides, resulting in coloured products. Fluorescence and enzymatic methods are particularly useful in pesticide investigations. They are dis-

tinguished by high sensitivity and specificity and allow the analysis of pesticides in the presence of background impurities that do not interfere. In enzymatic detection chromatograms are first sprayed with

an enzyme solution, then, after appropriate incubation, components altered by enzyme are detected by reaction with a suitable reagent. This method is characterized by very low detection limits and sometimes it allows analysis of pesticides without resorting to enrichment of the sample. Radiometric visualization methods are used for detection of radiolabelled pesticides. Radiometric methods are mainly applied to studies of pesticide metabolism in plants and animals, the uptake of pesticides by plants from soil and the fate of pesticides in the environment. The principal methods for the detection and quantification of radiolabelled pesticides separated on TLC plates are autoradiography, scraping followed by scintillation counting, and direct measurement using radiation detectors. The common pesticide visualization methods are presented in Table 2.

Lawrence, Frei, Mallet, and their co-workers focused attention on the visualization and quantification of pesticides by fluorescence methods. A comprehensive account of their works was presented by Hurtubise (see Further Reading). Most fluorescence analyses of pesticides require pre-treatment of the compounds to convert them to a fluorescent species. Certain organophosphorous pesticides fluoresce after just heating others (e.g. carbaryl or benzomyl) form fluorescent anions as a result of hydrolysis, and others (e.g. organothiophosphorous compounds) can be quantified in the presence of metal chelating compounds. Sulfur-containing pesti-

cides are determined quantitatively by pH-sensitive fluorescent reagents. The best fluorogenic reagents are dansyl chloride and fluorescamine. Fluorescence allows detection of certain pesticides at the level of 10 ng and linearity in the range 10 ng to 10 µg.

In the review articles written by Sherma, several new spray reagents, recently introduced for the selective detection of pesticides, are presented. For instance 20% sodium hydroxide, 5% cupric acetate, 1% phosphomolybdic acid followed by 0.1% *o*-toluidyne in acetic acid was proposed for the determination pyrethroid insecticides containing a nitrile group. These form blue spots with a detection limits of 1 µg without interference from organophosphorous, organochlorine and carbamate insecticides. Synthetic pyrethroids (fenvalerate, cypermethrin, fenprothrin) can be visualized as pink-coloured spots at 1 µg by their alkaline hydrolysis to liberate HCN, which reduces 2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyl-tetrazonium chloride to formazan in the presence of phenazonium methosulfate. Organophosphorous, organochlorine and carbamate insecticides do not interfere. Another example is the application of 2-trichloromethylbenzimidazole to determination pesticides containing either an azine or anazole ring. Excellent detection limits (20 ng to 10 µg) and very high selectivity makes this agent as very useful chromogenic agent for identification as well as for detection of these compounds.

Quantitative analyses of pesticides are performed mainly by UV-VIS densitometric measurement or by fluorescence. Quantitative analyses of pesticides can also be performed by combining TLC with other analytical techniques, e.g. TLC/HPLC, TLC/GC, TLC/MS, etc. Theoretical considerations, the correct approach to multidimensional methods development, instrumental requirements and contemporary applications of these approaches have been reviewed by Poole *et al.*

Applications

The agricultural use of pesticides gives rise to most analysis. Instrumental TLC has been applied for sensitive and fully quantitative analyses of environmental samples and control of food. Applications in forensic toxicology are less common. A feature of these analyses are investigations of pesticide residues in very completed matrices. Samples of vegetables, meat, food or biological material (for forensic toxicology) are analysed identically (Table 3).

Monitoring of the Environment

Butz and Stan have demonstrated the application of the AMD technique for the monitoring of environmental samples and the strategy of the whole proced-

ure, which has become a German Standard (DIN 38407 part II). Pesticides isolated from water are spotted on the layer with standards, and separated using gradient elution. Gradient elution allows the separation of pesticides belonging to different classes of compounds such as phenylureas, carbamates, triazines, phenoxy-carboxylic acids, and others. In total, 283 pesticides were analysed and only eighteen of them give detection limits of more than 100 ng and can therefore not be analysed from one litre of drinking water without further treatment. Two examples of drinking water spiked at the 100 ng L⁻¹ level are presented to demonstrate the merits of the method. Further research confirmed that the AMD technique can be easily applied to screen for pesticide residues in drinking water and ideally supplements other analytical techniques (Figure 2).

In the AMD technique in the first ten isocratic development steps, the starting zones are focused into sharpened bands. The elution gradient starts with an alkaline solvent mixture and ends with an acidic solvent. In this way it is possible to move or fix particular compound classes, such as acids or amines. The pH change provides better peak shapes and improves separation performance. Figure 3 shows a densitogram of a pesticide mixture separated using a gradient (UV absorption measurement with multiple wavelength scan). The limit of detection of most pesticides was 10 ng. However, it should be emphasized that in real samples the resulting spectra of the peak may be altered by overlapping matrix compounds, so that a pesticide, although present may not be recognizable. In such cases the authors recommend another gradient to confirm positive results.

TLC/AMD and SPE have been used for the analyses of pesticide residues in strongly contaminated samples of soil (Figure 4). Chromatograms were developed in a normal-phase system by AMD gradient elution. Limitations of detectability were compensated for by the application of relatively large volumes (by use of a spray-on technique) of analysed solutions. Quantitative assessment (linear relationship $A = f(c)$, where A is densitometric peak area, c mass of pesticide in band formulated in ng) was achieved by UV absorption measurement scanning of the chromatograms by a 'zig-zag' technique (Table 4).

Recovery and error of the method was estimated; the recovery level was 80% and the R.S.D. was less than 9%. The result presented confirm the advantages of modern TLC, which result principally from equipment development. It was demonstrated that the greatest benefits in the trace analysis of pesticides are achieved by the use of the 'spray-on' technique of sample application.

Table 3 Examples of TLC application to pesticide analysis in different matrices

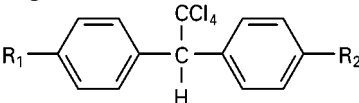

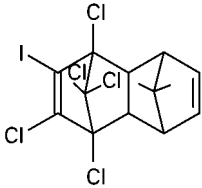

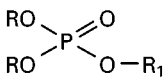

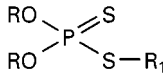

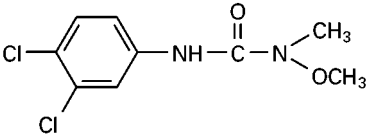

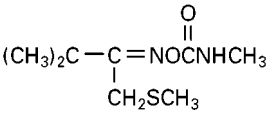

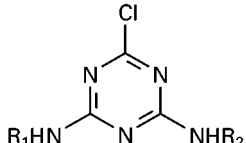

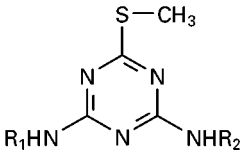

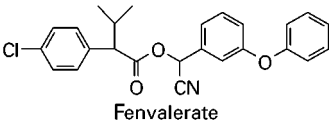

Class of pesticide and examples of its structure	Analyte	Matrix	Chromatographic system	
			Stationary phase	Mobile phase

Investigations of Pesticides in the Environment

In environmental research not only the level of pesticide residues is controlled but also their behaviour in different matrices. In such research TLC is used for the measurement of the mobility of pesticides, their bioaccumulation and biodegradation.

Residues of pesticides introduced into the environment are adsorbed onto soil particles and may end up as sediments at the bottom of lakes and rivers. Therefore, knowledge of the mobility of pesticides in soil is an essential element of environmental investigations. Measurements of pesticide mobility are usually performed using STLC (soil thin-layer chromatography). In this technique a stationary phase is prepared from a soil sample, in which the mobility of pesticides is to be determined. Solutions of persistent pesticides (sometimes radiolabelled pesticides) are spotted onto

the prepared layer and then developed with water as the mobile phase. STLC is also used for the evaluation of the influence of exogenous organic matter on the mobilities of pesticides in the soil. For example, examination of the mobility of diazinon and linuron demonstrated that simultaneous addition of organic compounds and other pesticides to the soil in agricultural practice may alter the mobility of sparingly soluble pesticides.

In another example researchers exposed Bluegill Sunfish to [¹⁴C] metolachlor at a concentration of 1 mg L⁻¹ for 34 days in a flow-through system. After that time all the fish were removed from the tank and dissected into tissues. After extraction and clean-up, eluates were spotted (together with unlabelled standards) onto layers, and then separated by two-dimensional development. Radioactive zones were detected using X-ray film. The non-radiolabelled

Figure 3 Multi-wavelength of a pesticide mixture separated according to the gradient in Figure 2. 1 = hydroxyatrazin, 2 = formetant, 3 = triadimenol, 4 = matalaxyl, 5 = isoproturon, 6 = diuron, 7 = dimethylaminosulfanilide, 8 = methidathion, 9 = 2,4-*p*-isobutyl ester, 10 = endrin, 11 = 2,2-*bis*-(4-chlorophenyl)-1,1-dichloroethane. (Reproduced from Morlock, 1996 with permission from Elsevier Science.)

standards were visualized with UV light. Detection of known metabolites was performed by the removal of radioactive zones and scintillation counting (in this case TLC was used as a clean-up technique). Unknown metabolites were identified using FAB/MS and NMR. The result showed that the pathways of the transformation of metolachlor by Bluegill Sunfish are very similar to those observed in animals, soils, and plants. In a similar way, examinations of bioaccumulation of pesticides may be performed.

TLC as a Clean-up Technique

An application of TLC as a clean-up technique is based on the separation of components of analysed mixture on TLC followed by layers introduction of analytes directly to the detector of other analytical instrument (on-line technique) or the removal of the analytes together with adsorbent and its elution with appropriate solvent (off-line technique). Identification of pesticides or their metabolites is performed

Table 4 Parameters of quantification

Type of pesticide	λ_{max} (nm)	Calibration curves			Detection limits		
		$A = f(c)$	Correlation coefficient	Max. range of linearity (ng/band)	In band (ng)	RSD (%)	In soil ($\mu\text{g kg}^{-1}$)
Oxamyl	220	$A = 3939c + 183$	0.9932	1200	150	6.1	7.7
Carbaryl	265	$A = 21793c + 1561$	0.9961	800	70	5.6	3.3
Pirimicarb	220	$A = 92115c + 1010$	0.9993	200	25	9.0	1.2
Malathion	200	$A = 5556c + 9970$	0.9958	4000	400	3.1	20.0
Phosalone	210	$A = 11695c + 1420$	0.9964	2000	200	4.4	10.0
Methoxychlor	220	$A = 63653c + 1955$	0.9991	500	50	8.7	2.4
Tetradifon	220	$A = 75175c + 580$	0.9994	500	50	8.0	2.5
Fenitrothion	280	$A = 84782c + 1821$	0.9981	500	50	9.0	2.6

(Reproduced from Błażdek, 1996 with permission from Elsevier Science.)

mainly by GC/MS, FTIR or NMR. The work in Bluegill Sunfish mentioned above is an example of such an application of TLC in pesticide analyses.

Conclusions

In the history of applications of TLC for pesticide analysis two periods (pre- and post- 1980s) may be distinguished. Within the first period, analyses were performed on home-made layers using equipment allowing for detection of substances at the μg level. During that period most chromatographic systems and methods of visualization of pesticides were developed. The second period is mainly connected with development of instrumental TLC which has enabled application of the technique for analysis of pesticides at the desired level, appropriate to the needs of food and environmental analysis.

It has not been possible to cover all applications of TLC in pesticide analysis extensively and therefore, only the demonstration of the method's abilities are presented here. TLC can be used for the clean-up of samples, for performing simple semi-quantitative screening analyses and, in the case of instrumental TLC, for the full quantitative analyses of pesticides.

PETROLEUM PRODUCTS

Gas Chromatography

J. P. Durand, Institut Français du Pétrole,
Cedex, France

Copyright © 2000 Academic Press

Introduction

Gas chromatography (GC) is an analytical technique that is widely used for characterizing hydrocarbons, and numerous advances in this method have originated in petroleum industry laboratories. Moreover, its use has markedly increased in the last few years with the progress in instrumentation and the relatively low cost of the equipment.

Its applications cover the exploration, production and refining of crude petroleum. These have developed around four major types of methods: analysis of gaseous hydrocarbons, analysis of liquid hydrocarbons, analysis of traces of heteroatomic compounds, and simulated distillation.

Advances in Instrumentation

Since the 1980s, while there has been little progress in the theory of chromatography, the instrumentation has constantly evolved. There have been major improvements in the reliability of equipment and columns, new specific detectors have been developed, and increasingly powerful computers have been used for data processing and controlling the equipment. The use of electronic pressure and flow rate regulators with increasingly stable capillary columns has made it possible to produce chromatograms that are much more reproducible. Microcomputing has simplified the analyst's work (in some cases a little too much, up to the point of forgetting the basics) and has opened the way to automation, standardization of complex methods and the development of correlation methods. Detailed analysis of gasoline and simulated distillation are the two methods that have undergone the greatest evolution. In the analysis of gaseous hydrocarbons, the most important step has been the replacement of packed columns by porous layer open-tubular columns with far greater efficiency and stability. In addition to improvements in the sensitivity and stability of the major types of selective detectors (flame photometry and electron capture),

two others – atomic emission and chemiluminescence – are now commercially available.

In the last two to three years, the new advances in technology have been in the fields of rapid analysis and equipment miniaturization. With microcolumns (100 μm i.d.) or multimicrocapillaries with very fast flow rates and programmed temperatures, gaseous hydrocarbon analysis times can be reduced to 1–2 min. However, such conditions do not allow sufficient resolution for analysing heavier hydrocarbons; here rapid chromatography is used as a screening tool, or to decrease the analysis time for simulated distillation. All these methods are now in the development stage. The recent commercial availability of portable and compact chromatographs meets the need for on-site analyses, giving reduction in sampling problems.

Gaseous Hydrocarbon Analysis

The analysis of gaseous hydrocarbons is generally carried out with porous layer capillary columns (gas–solid chromatography). These efficient columns are now very stable and are used in control laboratories. The most widely employed adsorbents are alumina and adsorbent polymers. Alumina capillary columns provide good resolution for the most difficult separation encountered in petrochemical laboratories, that of isobutene and butene-1.

Molecular sieves are used to separate the permanent gases (O_2 , N_2 , H_2 , CO , etc.). To analyse these and hydrocarbons with a single injection, multi-column chromatographs with switching valves have been developed. Natural gas, gases from crude petroleum and refinery gases are the main applications for which methods have been developed and standardized (ASTM D1945-81, IP 345/80, IP 344/88, ISO 6974-84). Gas analysis has considerable economic importance, both for natural gas, allowing the determination of the calorific value from chromatographic analysis (ISO 6977-84), and for the petrochemical feeds from the steam cracking process (ethylene, propylene and butadiene), owing to the large volumes of these gases now on the market.

Liquid Hydrocarbon Analysis

Detailed Analysis of Light Hydrocarbons

Although the separation of several hundred constituents of gasoline has been carried out for more than

Figure 1 Chromatogram of a commercial gasoline following the NF N07-086 standard. Operating conditions: column, 50 m × 0.20 mm i.d.; stationary phase 0.5 μ m OV1; oven, 35°C for 10 min, then 1.1°C min⁻¹ up to 114°C, and 1.7°C min⁻¹ to 250°C, held 5 min; detector, 280°C; carrier gas, helium at a constant flow of 0.8 mL min⁻¹.

30 years, the methods have been standardized only relatively recently (ASTM D5134-90, NF07-086). The chromatogram of a commercial gasoline, obtained as specified in the French standard NF M07-086, is shown in **Figure 1**. By using a procedure standardizing a number of parameters and specifications, capillary chromatographic methods with temperature programming are reproducible from one chromatographic system to another and identification of complex chromatograms can be automated. This automation has led to the development of numerous applications in the petroleum field. The large amounts of data supplied by the detailed analysis are normalized, after processing, to determine the physical properties (molecular weight, gross calorific value, octane number, etc.), to optimize the thermodynamic or kinetic models, and to predict the quality of the conversion products.

In refining, the two main processes, reforming and catalytic cracking, require increasingly detailed information regarding the gasoline range fraction. The complete detailed analysis data for the naphtha feed and effluents from the reforming units make following and modelling the conversion and optimization of the control of the units possible. A major application field for automated capillary chromatography is in the use of micro-pilot plants involving small amounts of feeds and effluents. The methods developed for the catalytic cracking micro-pilot plants allow detailed analysis of the gasoline cut and determination of octane numbers directly on the total effluent (final boiling point 580°C) by using a pre-column to eliminate the heavier compounds.

Commercial gasolines are formulated using around 10 petroleum basestocks. New environmental con-

straints mean that the resulting mixtures require more rigorous optimization. With all the constraints concerning benzene, other aromatics and olefins, together with the additional octane number requirements brought about by the progressive elimination of lead from fuels, there is an increasing demand for the detailed characterization of basestocks and mixtures. Analyses are now carried out on a regular basis in control laboratories.

One of the main causes of errors in modelling the behaviour of fluids in petroleum reservoirs has been the lack of reliable analytical data. Using a thermodynamic model based on an equation of state for calculating the properties of these fluids requires accurate knowledge of the molecular weights and their distribution. The large amount of information provided by the detailed and direct analysis of the fraction up to C_{20} with the molecular weight distribution has modified the methodology of describing reservoir fluids.

Characterization of the C_3 – C_{15} fraction of oils and extracts from source rocks is an important parameter for studying the origin and migration of hydrocarbons. Until recently only a profile or fingerprint was available, but now this fraction can be quantified by automated capillary methods. Various parameters (paraffin, aromatic numbers, etc.) have been obtained from the detailed analysis to follow variations in chemical composition and show biodegradation or leaching phenomena. Soil pollution by hydrocarbons, particularly fuels, requires pollutant monitoring. The replacement of global methods, like solvent extraction, by detailed analysis of the fuel, can provide a better follow-up of the decontamination operations. Figure 1 shows a chromatogram of commercial gasoline following the NF N07-086 standard.

Hydrocarbon Type Analysis of Light Hydrocarbons

Hydrocarbon type analysis (Paraffins/Isoparaffins/Aromatics/Naphthenes/Olefins (PIANO)) can be obtained from detailed analysis with a data system that identifies each of the peaks and combines them into their respective groups. Because there are some co-elutions, this analysis may not be accurate with gasolines containing significant amounts of olefinic and naphthenic constituents eluted before *n*-octane.

Some methods of type analysis have been developed with the multidimensional GC technique; these are commonly referred to as PIANO analysis. A four-column system with automatic valve switching and cold traps has been utilized to determine normal paraffins, isoparaffins, naphthenes, olefins and aromatics. A polar column separates aromatics and non-aromatics, a 13X molecular sieve column

separates paraffins and naphthenes, while a 5A molecular sieve column separates normal paraffins and isoparaffins. The unsaturated components are retained in an olefin trap, released by heating the trap and then hydrogenated. These separations allow determination of the distribution by hydrocarbon type and carbon number.

Heavy Hydrocarbon Liquid Analysis

The high resolution of capillary columns, which provides separation of a major fraction of the hydrocarbons with boiling points up to 200°C, is not sufficient for the heavier petroleum cuts owing to their increasing complexity. Although detailed information is not directly available, GC is nevertheless very extensively used. The chromatogram can serve as a qualitative plot for determining the presence of specific compounds or classes of compounds. Quantification of normal paraffins in crude petroleum (compounds that are clearly distinguished from the unresolved material) and waxes can be made. However, the most important applications concern the characterization and quantification of the fractions in hydrocarbon types, obtained, in particular, by liquid chromatography (LC). In most cases, the compounds are identified by mass spectrometry (see below). The development of online coupling of high performance liquid chromatography (HPLC) and GC has led to several petroleum applications: measurement of aromatics in gas oils, and measurement of polyaromatics in diesel engine exhausts and mineral oils.

GC/MS Coupling

Mass spectrometry (MS) coupled with GC (GC-MS) is now the main identification technique. From bench equipment (increasingly numerous) to more sophisticated systems providing high resolution measurements, the identification is facilitated by computer processing of libraries containing thousands of mass spectra. This technique has made an essential contribution to analysis of hydrocarbons, in particular for the detailed analysis of fuels and their bases, geochemical studies and pollution problems. Up to around 1000 compounds have been identified in oils. For two decades numerous data for different columns, retention times or indices of hydrocarbons identified by GC-MS have been published for compounds in gasolines and kerosenes. For the medium distillates, where direct detailed analysis is not possible, the distribution per carbon number of the MS analysis can be obtained by combining the separation by boiling point and carbon number from GC

with the analysis of hydrocarbon type from MS. Methods have been developed specifically for monitoring hydroprocessing treatments in order to provide evidence of mechanisms and to have access to the reaction kinetics. The use of GC-MS in geochemistry has been a major step in the study of the transformation of organic matter during sedimentation: this has involved going from comparison of chromatograms to the identification of molecular structures and the search for biochemical markers. This has become a standard method for following these markers in oils.

Heteroatomic Compounds Analysis

The elements most often looked for in petroleum products are sulfur, nitrogen, oxygen and the halogens. The analyst has available several single- or multi-element detectors.

Sulfur

The most widely used detector for many years has been the flame photometric detector (FPD). In spite of its limitations (non-linearity, variable response, quenching), methods have been standardized for the light petroleum cuts. The recent development of a more sensitive chemiluminescence detector for sulfur without these limitations has allowed extension of the application field to heavier cuts, such as gas oils and crude oils. The chromatograms of sulfur compounds from a catalytically cracked gas oil before and after hydroprocessing obtained with this detector are shown in Figure 2. Comparison of the two chromatograms shows the changes in the sulfur compounds during the hydroprocessing.

Nitrogen

The situation is identical to that of sulfur, the nitrogen-phosphorus detector (NPD) also having limitations (variable response, relatively low selectivity). The arrival of a chemiluminescence detector for nitrogen has provided access to semi-quantitative analysis of nitrogen compounds in gasoline and gas oil cuts from conversion processes.

Oxygen

The development of a detector specific to oxygen (O-FID) has met the need for the measurement of oxygenated compounds such as methyl *t*-butyl ether in commercial gasolines. Several methods have been standardized (EN 1601-96, ASTM D5599-93). Due to its low sample capacity, this detector cannot be used for measuring traces of oxygen.

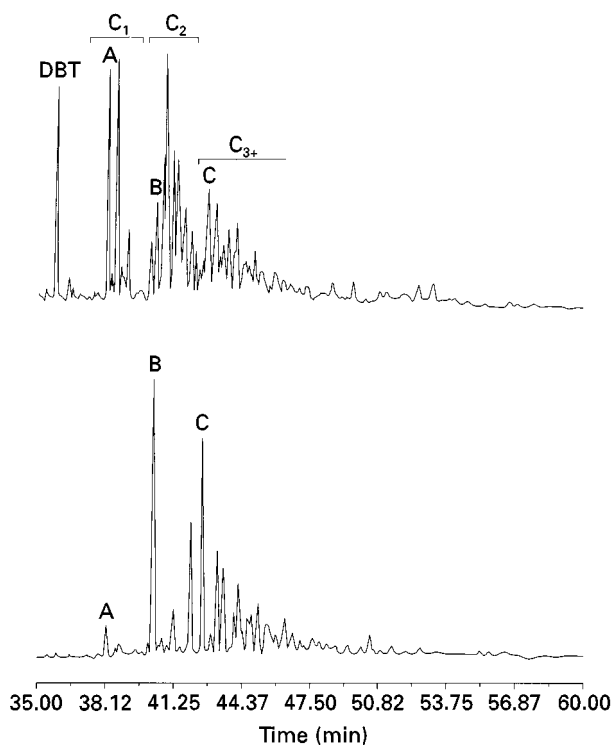

Figure 2 Chromatogram of sulfur compounds from a catalytic cracking gas oil (LCO) before and after hydroprocessing obtained with a chemiluminescent detector. Operating conditions: column, 30 m × 0.32 mm i.d.; stationary phase 4 μm SPB-1; oven, 60°C to 320°C at 5°C min⁻¹. DBT, dibenzothiophene; C₁, methyl; C₂, dimethyl or ethyl; C₃₊, three or more branched carbons.

Halogens

The electron-capture (ECD) and electrochemical detectors are used to determine the halogens. The ECD is very sensitive when the molecule is poly-halogenated; sulfur hexafluoride, used as a tracer, can be directly detected at the p.p.b. level. The main applications concern chlorofluorocarbon gases, chlorinated solvents and polychlorinated biphenyls (PCBs).

Multielement Detectors

While all the specific detectors mentioned above can detect only one element at a time, the atomic emission detector is multielement, with some restrictions concerning the number of elements that can be detected per analysis and the sensitivity to some of these elements. This is a powerful identification tool (complementary to MS). The main applications are measurement of oxygen compounds in gasolines, multielement simulated distillation (H, C, S), and the determination of nickel and vanadium in crude oils.

Simulated Distillation

Simulated distillation (SD) by GC has been the subject of numerous studies for 30 years. It is a technique that advantageously replaces traditional distillation methods for rapid checking of product yields. The principle is simple: the sample is injected into a column, which separates hydrocarbons according to their boiling points; using a mixture of normal paraffins with known boiling points, the correspondence between the retention time and boiling point is established and then the weight %–boiling point curve can be constructed. However, the implementation is more difficult. The first problem concerns the choice of the stationary phase to obtain good agreement with the real distillation curves; the second is the stability of this phase at the maximum temperatures used. There are many interdependent parameters involved in these two problems. Although several methods have been standardized (ASTM D3710-90, ASTM D2887-93, ASTM D5307-92), their applications give rise to a number of difficulties in routine use. Operating conditions, column performance, frequency of calibration runs and blanks, quantification, and raw data processing are the parameters to be controlled to achieve the level of precision given by the standard methods. Column performance is affected by noneluting residues. The problem can be resolved by installing a pre-column with a backflush and calculating sample recovery with an internal standard.

The arrival in the last few years of very stable metal columns and the use of electronic pressure and flow regulators have provided better control of the experimental parameters. These advances have extended the final determined boiling point up to 650°C with

conventional methods and to 720°C with high temperature simulated distillation (HTSD). The chromatogram of a light crude oil with a final boiling point of 650°C, obtained with a metal column, is shown in **Figure 3**. The range of boiling points of petroleum products is thus almost completely covered by using two methods, since HTSD can operate only with cuts having boiling points above 150°C. Consequently, for samples containing light compounds, heavy compounds and non-recoverable residues, a fractionated distillation yielding two cuts is necessary.

Simulated distillation can be used to determine gasoline dilution of used engine oils (ASTM D3525), to analyse the oil-soluble fraction of particulates emitted by diesel engines (estimation of the proportion attributable to the fuel and lube), and to estimate engine oil volatility (ASTM D5480).

Conclusion

The high resolving power of GC makes it a major analytical tool for characterizing the very complex mixtures that constitute petroleum products. The recent development of correlation methods in near-infrared spectroscopy (NIR) for characterizing light hydrocarbons could challenge the dominant position of chromatography in this field because of the speed of the NIR techniques. However, GC will always remain the method giving the most detailed information. With the present evolution of fast chromatography, its disadvantage of a longer analysis time is disappearing. Although GC is not as fast as spectroscopic methods, analyses in a few minutes with microequipment will ensure that it continues to be

Figure 3 Chromatogram of a light crude oil with a final boiling point of 650°C. Operating conditions: column, 10 m, deactivated metal; stationary phase 0.5 μm OV1; oven, 35°C for 1 min, then 10°C min^{-1} up to 390°C, held 14 min; detector, 400°C; carrier gas, helium at a constant flow of 10 mL min^{-1} .

a powerful tool for the detailed analysis of hydrocarbons.

Introduction

Techniques based on liquid chromatography are used in the petroleum industry for process monitoring, compliance with environmental regulations, the evaluation of product quality, catalyst performance and feed processability, as well as for determining hazardous compounds, and understanding and solving basic research problems.

Chromatographic techniques and methods used for analysing petroleum products are chosen depending on their boiling point range, which is related to their carbon number. In order to simplify the further discussion, classification of petroleum products into light, middle and heavy distillates is considered throughout this work.

Techniques based on capillary gas chromatography (GC) can perform molecular characterization of some light distillates, such as gasolines and others. However, this technique has limitations when it comes to analysing heavier distillates. As the complexity of petroleum products rapidly increases with the increasing boiling range of distillates, liquid chromatographic techniques play a crucial role in the analysis of middle and heavy distillates. They are also complementary to GC for analysing light distillates. Most of the applications of liquid chromatography to petroleum products include separation, identification and, in some cases, quantification of individual components; separation, quantification, and, sometimes,

preparative isolation of hydrocarbon types; in addition to molecular size distribution and average molecular weight determination.

In general, complete molecular separation of the components of petroleum distillates is not possible using liquid chromatography owing to their complex nature and the limited resolution of current techniques. As the boiling range of the product to be analysed increases, the greater its complexity due to the increase in the number of isomers and the broader variety of compound types present. Furthermore, the concentration of polar compounds (e.g. heterocyclic compounds) increases as the products become heavier. Therefore, the heavier the product, the poorer the chromatographic resolution obtained, and the more difficult it is to achieve good separations. In most cases, extensive separations are meaningless in the petroleum industry, but determination of particular target compounds in various distillates is sometimes useful.

Determination of hydrocarbon types (which includes separation and quantification) of all types of distillates is usually carried out by liquid chromatography. Hydrocarbon types in petroleum products can be roughly summarized into saturates (n-paraffins, branched paraffins, and cycloalkanes or naphthenes), olefins (alkenes and cycloalkenes), aromatics (hydrocarbons containing one or more rings of the benzenoid structure), and polars (which include heterocycles and/or high molecular weight material). This simple scheme becomes more complicated with increasing sample boiling range because of the many possible combinations of compound types (e.g. alkylaromatics, aromatic olefins, etc.). Therefore, separation designs may vary depending on nature of the sample and information required by the analyst.

Liquid chromatographic techniques used for the above-mentioned purposes are based on open-column liquid chromatography (LC), high performance liquid chromatography (HPLC), size-exclusion chromatography (SEC), and thin layer chromatography (TLC), as well as multidimensional techniques.

Open-column Liquid Chromatography (LC)

Liquid chromatography has been used for many years to carry out gravimetric determination of hydrocarbon types. This usually consists of separation on normal adsorption phases such as silica gel or alumina. This technique has also been used for preparative isolation of hydrocarbon types, either to carry out further characterization of isolated fractions, or to use the isolated fractions as external standards for calibrating other instrumental techniques (e.g. HPLC), which are in turn employed for hydrocarbon-type determination.

LC-based standard tests for hydrocarbon-type analysis were developed for use by the petroleum industry at a time when other instrumental chromatographic techniques were not yet available. The main advantage of these was that simple glassware was used. Some of these standard tests are still in common use because product specification analyses and referee methods require basic testing procedures (Table 1). For research purposes, low pressure to medium pressure LC is used rather than open-column LC in order

to increase separation efficiency to some extent. Other modifications to standard tests may involve the use of detectors to monitor eluents or the use of different stationary phases depending on the analytical objective.

In general, all open-column or low pressure LC methods are lengthy, labour intensive, expensive (they require high solvent consumption), and the columns need to be repacked for each determination.

Light distillates The fluorescent indicator adsorption (FIA) method (ASTM D1319) has been in use for a long time (Table 1). Light distillates are separated, using silica gel as stationary phase in a precision bore column and isopropyl alcohol as eluent, into saturates, olefins and aromatics. The use of fluorescent dyes, previously added to the gel, makes it possible to calculate the volume percentage of each hydrocarbon type from the length of each zone in the column, without eluting the zones out of the column. It must be taken into account that uncontrolled losses of some light hydrocarbons may be produced during elution, and samples containing C₃ or lighter hydrocarbons and/or more than 5% v/v C₄ and C₅ hydrocarbons must be depentanized (see ASTM method D2001).

There are many drawbacks to the FIA method. Apart from the operational ones (related to improper packing of the column and incomplete elution of hydrocarbons by isopropyl alcohol), it provides poor precision, especially for olefins at concentrations typi-

Table 1 Examples of standard tests based on open-column liquid chromatography

<i>Standard method</i>	<i>Scope</i>	<i>Boiling range (°C)</i>	<i>Comments</i>
ASTM D1319 ^a ; IP 156 ^b	Hydrocarbon types in liquid petroleum products by fluorescent indicator adsorption	< 315	Displacement development. Use of fluorescent dyes. Silica gel (100–200 mesh), isopropyl alcohol. Vol % of saturates, olefins, aromatics.
ASTM D2002	Methods for isolation of representative saturates fraction from low-olefinic petroleum naphthas	< 232	Displacement development. Use of fluorescent dyes. Silica gel (100–200 mesh), isopropyl alcohol.
ASTM D2003	Methods for isolation of representative saturates fraction from high-olefinic petroleum naphthas	< 221	Displacement development. Use of fluorescent dyes. Silica gel (100–200 mesh), isopropyl alcohol.
ASTM D2007	Method for characteristic groups in rubber extender and processing oils by the clay-gel adsorption chromatographic method	< 260	Applicable to samples with < 0.1% asphaltenes. Clay gel and silica gel. Elution using n-pentane and toluene/acetone (50/50)
ASTM D2549	Method for separation of representative aromatics and non-aromatic fractions of high boiling oils by elution chromatography	232–538	Bauxite and silica gel. Elution using n-pentane, diethylether, chloroform and ethanol

cally found in gasolines and it does not detect oxygenated compounds blended into gasoline (they are in the aromatic zone).

Middle and heavy distillates The ASTM D2007 standard is used and is still the reference when a hydrocarbon-type determination is developed using other techniques. This method provides sample separation into saturates, aromatics, resins, and asphaltenes or uneluted (SARA). It consists of the elution of n-pentane and toluene/acetone (50 : 50, v/v) through a double column which contains clay in its upper section and clay plus silica gel in its lower section. Its application requires a previous removal of n-pentane insolubles (asphaltenes). In general, the use of chromatographic columns for these kinds of product may produce irreversible adsorption of the heaviest and/or more polar compounds on to the stationary phase, which affects quantitation.

LC-based methods have also been used for a long time for determining and isolating nitrogen, sulfur and oxygen compounds in different types of petroleum distillates. Apart from silica gel, procedures include successive separations using alumina and cation exchange phases, as well as complexation packings.

Standard methods based on LC usually work using fixed volumes of eluent for the various fractions. Therefore, possible cross-contamination of fractions and errors in quantification of hydrocarbon types may occur. Conventional detection provides poor information because of column overloading. Monitoring of the eluent can be carried out using offline analytical techniques (e.g. TLC-FID).

High Performance Liquid Chromatography (HPLC)

HPLC gives a much better resolution than LC. It is a less time-consuming technique, and requires a smaller amount of sample. Percentages of peaks are usually quantified after calibration, without the errors associated with solvent evaporation and sample manipulation. However, in all column-based methods, some heavy and/or polar compounds can be irreversibly adsorbed, producing column deterioration and, therefore, incomplete elution. This can be mitigated by an adequate choice of stationary and mobile phases, and the proper use of backflushing.

Applications of HPLC include hydrocarbon-type determination (separation and quantification) and preparative isolation of hydrocarbon types: separation, identification and, in some cases, quantitative determination of single components (usually one or several target compounds).

Hydrocarbon-type Determinations

Typical analytical and preparative HPLC normal-phase columns are mostly used for hydrocarbon-type separations.

Light distillates Separation into saturates, olefins and aromatics is of most interest, and classical adsorbents, such as silica gel or alumina have been used. This analysis has been carried out on gasolines using a silica gel column, a fluorocarbon as mobile phase and refractive index (RI) detection. The low polarity of the eluent used allows the separation of saturates from olefins. Aromatics are backflushed from the column (Figure 1).

The use of silica containing bonded groups capable of forming charge transfer complexes has allowed the

Figure 1 Chromatogram of a heavy gasoline distillate with and without flow reversal. additional resolution of naphthenes from paraffins to be achieved in light distillates.

Middle distillates Separations according to number of aromatic rings (mono-, di- and polyaromatics), typically of more interest for middle and heavier distillates, have been carried out using silica gel and also the above-mentioned charge-transfer stationary phases. For this purpose, three groups of silica-bonded acceptors have been mostly utilized: nitroaromatics (e.g. commercially available dinitroanilinopropyl silica, DNAP, and 8-(2,4,6-trinitroanilino)octyl, TNAO), tetrachlorophthalimido groups, and caffeine and related compounds. Polar amino- or cyano-bonded silica have also been used extensively in the petroleum industry (e.g. IP391 standard) for this separation, using heptane or hexane as mobile phase and RI detection. Thus, saturates, mono-, di- and polyaromatics are separated using backflushing and the three last groups quantified. Likewise, the content of saturates, olefins and polyaromatic hydrocarbons (PAHs) in a variety of light and middle distillates has been successfully determined by argentation chromatography using both coated and bonded stationary phases.

Heavy distillates Besides analysis of saturates, aromatics and polar compounds, other hydrocarbon-type determinations which involve PAHs have been performed on practically all types of heavy distillates using both nitroaromatic phases and tetrachloroph-

thalimidopropyl-bonded silica. However, in all these cases, resolution is not very good and quantitative analysis is only possible in a few cases. In spite of this, these methods are useful for process monitoring or comparative purposes (e.g. determination of PAHs in used lubricating oils before and after oxidation treatments).

Determination of Individual Compounds

Individual carcinogenic PAHs have usually been determined in almost all types of distillates, after a previous cleaning-up step, using reversed-phase columns, taking advantage of the selectivity and sensitivity of fluorescence detection. Electrochemical detection has also been used for this purpose, by Ce(IV) oxidation of PAHs to quinones.

Other representative applications of HPLC are summarized in Table 2. Reversed-phase HPLC has been used as an alternative to GC in order to quantitatively determine benzene and toluene, and various oxygenates (ethanol, MTBE, ETBE, TAME) in gasolines (Figure 2). Other determinations of targeted compounds in light distillates include silica gel normal-phase separations (coumarin in kerosenes, 2,4-dimethyl-6-t-butylphenol antioxidant in light distillates), and charge-transfer HPLC (determination of ppm amounts of aniline, quinoline, pyridine and isoquinoline in kerosene and diesel).

Where middle distillates are concerned, both normal phase and reversed phase have been used to separate a broad variety of compounds, which

include dyes and coloured diesel markers, alkyl nitrate cetane diesel improvers, phenalenones, aza-arenes and alkylaromatic amines. In the case of lubricants, more than 50 additives which include antioxidants and antiwear agents, ashless dispersants,

and viscosity improvers have also been separated using the above-mentioned phases and quantified using UV, refractive index (RI) and evaporative light scattering (ELS) detection.

Detection and Quantification

Problems in detection come from the lack of a system which provides uniform response factors for all hydrocarbon types. Moreover, response factors for a given family vary from fuel to fuel. For this reason, hydrocarbon types from the sample to be analysed are usually preparatively isolated, and used as external standards for calibration.

UV cannot detect saturates, and responses of compounds are strongly dependent on chemical structure. RI is mostly used in the petroleum industry in spite of its technical disadvantages of baseline drift, slow stabilization, influence of temperature changes, negative peaks, and impossibility of using gradient elution. In general, variations in response factors for compounds are lower for RI than for UV. The use of RI (e.g. IP 391 standard for saturates, mono-, di- and polyaromatics) is justified because it uses pure aromatic compounds for external calibration. In effect, since the refractive index of each aromatic family varies over a much narrower range than that of the total aromatic fraction, the response of each family is quite well matched using several pure standards (*o*-xylene, 1-methylnaphthalene and phenanthrene). However, saturates are not accurately determined because of the large variation of refractive index possible for saturates and the small difference between saturates RI and that of the commonly used mobile phases (e.g. hexane).

The use of ELS detection is becoming more frequent in petroleum HPLC. It presents practical advantages over RI, better performance and the possibility of using gradient elution. However, it is not a true universal detector and some small volatile aromatics (e.g. methylnaphthalenes) are not detected even under mild working conditions. ELS working parameters can be optimized to obtain, in some cases, uniform responses of different compounds. However, responses depend in part on solute densities.

The dielectric-constant detector (DC) and FID have been reported to provide uniform response factors for hydrocarbon types. However, for the former, contradictory results have been published, and, in the case of FID, technical problems do not yet appear to have been solved. Mass spectrometry (MS) detectors, using different types of HPLC interfaces, have also been used although their application seems, at the moment, to be limited to a more in-depth characterization of separated fractions and to the identification of individual compounds.

Size-exclusion Chromatography (SEC)

SEC is a molecular sieving technique that separates molecules according to their selective permeation into the pores of a gel stationary phase on the basis of differences in their size in solution. Solute permeation into the gel increases with decreasing molecular size, resulting in longer elution. However, not only size but also chemical effects are present in the elution of petrochemical samples and related molecules.

Molecular size distributions SEC is a low resolution technique that allows qualitative or semiquantitative molecular size distributions (MSD) of high molecular weight heavy fractions (e.g. lubricant base oils, paraffin waxes, heavy petroleum fractions, asphalts, etc.) to be obtained in order to assess the effects of process variables. Conversion of MSD into molecular weight distributions (MWD) is usually determined by calibration using narrow polystyrene standards or fractions from the petroleum samples themselves. To cover low molecular weight ends, normal paraffins or PAH are also used. However, these determinations carry a high degree of uncertainty. Likewise, SEC has been used for obtaining estimates of average molecular weight of oil products. In general, molecular weights of petroleum constituents can vary between 30 000 and 100 Da.

Columns and mobile phases SEC is usually carried out using a series of relatively small pore size (100–1000 Å) polystyrene–divinylbenzene (PS–DVB) polymers. Among other packings, poly(divinylbenzene) and Sephadex (a dextran-based polymer) columns are also popular. The use of small particle size (3 µm) packings, and of mixed pore distribution in single columns has been recently introduced. Preparative SEC columns, using either open-column or HPLC technology, have also been used for sample clean-up to remove small molecules from high molecular weight materials or vice versa.

Inter- or intra-association of sample molecules or their interaction on the column should be minimized by selecting an appropriate solvent. The most common mobile phases are tetrahydrofuran, toluene, chloroform, pyridine and quinoline.

Detection Semiquantitative profiles of size distribution have been obtained using differential RI, ELS, UV diode-array, fluorescence, and FID detection. SEC coupled with atomic absorption or emission such as inductively coupled plasma atomic emission (ICP–AES) or atomic emission detectors (AED) has been applied to obtain elemental profiles (for Fe, Ni, V or S) from petroleum samples.

Figure 3 Evidence for the presence of elemental sulfur in hydrotreated cracked naphtha and gas oil obtained from pilot unit runs. (Reprinted from *Journal of Chromatography A* 740. Barman BN (1996) Determination of elemental sulfur by size-exclusion chromatography. Optimization and petrochemical applications, 237–244. With kind permission from Elsevier Science-NL.)

Use of non-size effects These can be used for particular separations; interesting applications relative to light and middle distillates have been developed. Thus, water and C₁–C₃ alcohols can be determined in gasolines using a series of PS–DVB columns. With the same type of stationary phase, determination of pericondensed PAHs in different distillates, and of elemental sulfur in naphthas and gas oil, have been developed which take advantage of elution beyond the total permeation limit of SEC (Figure 3).

Thin Layer Chromatography (TLC)

TLC is a simple, rapid, robust and inexpensive technique but it is not usually considered as quantitative or sufficiently sensitive. However, progress in plate manufacture (including small-sized HPTLC plates), in sample application devices, in development instrumentation, and in automated UV and fluorescence scanning densitometers, should allow improvements in separation and quantification of petroleum-derived samples to be achieved. Advantages of TLC for petroleum analysis are high sample throughput, simultaneous processing of standards

and samples, and the possibility of analysing the whole sample without previous fractionation or deasphalting.

Planar Chromatography

Conventional TLC silica gel and alumina plates (with development using solvents of increasing polarity) have been mostly used for qualitative or semiquantitative hydrocarbon-type analysis, and also for preparative isolation of hydrocarbon families in heavy distillates for further analysis or gravimetric determination of collected fractions.

In general, non-quantitative analyses have involved visual detection of colourless substances using inspection under UV illumination (if they absorb in the UV region or they exhibit fluorescence by UV excitation) or the use of chromogenic or fluorogenic spray reagents. Thus, semiquantitative adulteration of gasolines with kerosenes can be detected using silica gel plates and n-heptane as eluent.

Quantitative hydrocarbon-type analysis is possible using UV fluorescence scanners although there are only a few papers on this in the literature. Aromatic and polar peaks of petroleum bitumens have been quantified using UV scanning, and saturates using fluorescence scanning after impregnation of the plates with berberine salts. Modern scanners present the advantage of providing structural data of peaks (UV spectra). The possibility of a future growing application of TLC to the analysis of light and middle distillates depends on the control of vaporization of compounds during development and drying steps.

TLC-FID

This technique combines the advantages of TLC with the possibility of quantitation using an FID. TLC-FID has been quantitatively applied to hydrocarbon-type determination (e.g. SARA, saturates, aromatics, resins and asphaltenes) of all types of heavy distillates (lubricants, residua, asphalts, heavy oils, etc.). In these cases, FID responses are quite uniform although calibration cannot be discarded *a priori*.

Separations are carried out on Chromarods which consist of reusable quartz rods sintered with 5 μm silica gel or alumina. Saturates, alkylaromatics, aromatics, polars or resins, and asphaltenes have been separated. Olefins have also been separated in some heavy distillates by impregnating silica rods with AgNO_3 . Solvent development is carried out as in planar chromatography.

However, TLC-FID presents several disadvantages with regard to planar chromatography such as the destructive nature of FID, the impossibility of obtain-

ing structural data from FID detection, and the possible influence of sample volatility in quantification which makes it difficult to apply this technique to light and some middle distillates.

Multidimensional Liquid Chromatographic-based Techniques

A multidimensional system generates its resolving power mainly from the selectivity differences of the separating modes used. The most important multidimensional systems in petroleum chemistry are based on HPLC-HPLC and HPLC-GC.

HPLC-HPLC

Separation schemes include combinations of two or more columns. Normal-, reversed-, charge-transfer, argentation- and size-exclusion phases have been used to separate fractions of specific polarity or size in a broad variety of distillates. Hydrocarbon-type determinations of all types of distillates have been carried out. It is very common to use a polar normal phase as a first column. Thus, polar compounds (resins, asphaltenes) are retained on the packing and recovered using backflushing. Selection of the second column depends on the particular families to be separated (e.g. olefins from saturates, aromatics from saturates). Automated column selection and switching systems can improve method development and sample analysis.

HPLC-GC

GC is the most desirable final chromatographic step after HPLC fractionation in order to carry out either the analysis of selected separated fractions of hydrocarbons (e.g. by normal-phase HPLC), or the analysis of low molecular weight components in high molecular weight samples (SEC-GC). However, the final boiling point determines whether or not GC can be applied to the entire sample.

Packed capillary HPLC columns or conventional 4.6 mm i.d. HPLC columns are equally viable as long as the correct transfer method is chosen. Both loop-type and on-column interfaces have been used for analysis of saturates and aromatic fractions in gasolines, kerosene and diesel; for analysis of PAHs in light distillates, middle distillates and lubricating oils; and for determination of chlorinated benzenes in fuel oil. The loop-type interface involves complete evaporation of the HPLC eluent during its introduction in the GC. It allows a transfer of large LC fractions (100–1000 μL), and an easier internal standard quantitation (using an extra loop) to be carried out. It is

especially suitable for nonvolatile samples. A better approach to qualitative and quantitative analysis of volatile samples is through methods based on an on-column interface. However, the retention gap method uses long uncoated pre-columns and only allows modest volumes of HPLC fractions to be transferred. The partially concurrent evaporation method, where only a part of the HPLC eluent is evaporated, works with larger fraction volumes (approx. 200 μL) and with shorter uncoated precolumns.

Future Trends

The development of new, more accurate techniques based on liquid chromatography (especially HPLC, TLC, and new multidimensional or hyphenated techniques) will be increasingly important owing to legislation calling for the reduction of aromatic content in fuels. Therefore, these techniques will continue to play a crucial role in the petroleum industry for the choice of process conditions and the evaluation of fuel quality.

Introduction

Thin-layer chromatography (TLC) has strengths not applicable to other chromatographic methods. These can be summarized as cheapness of materials, low volume requirement for solvents, the ability to use any mixture of solvents, and, most important, the intractable materials of a complex sample are re-

tained within the surface area of the chromatographic plate and may be recovered. In addition, chromatographic failures can be disposed of without damaging the budget. Such considerations do not apply to gas chromatography or liquid chromatography, where involatiles (in GC) or insolubles (in LC) are lost on the column or inlet system with the possibility of permanent damage to the column performance. The difference in cost of thin-layer plates and chromatographic columns ranges from a factor of 100 for GC capillary columns, up to a factor of 1000 for preparative HPLC columns. Whereas TLC has most often

been used to examine individual compounds, it has found use (as TLC with flame ionization detection using silica rods) in the examination of crude oils and more recently as a preparative method to separate the high molecular mass fractions of coal and biomass liquids and petroleum vacuum residues for examination free from the smaller, more volatile components.

Uses of Thin-Layer Chromatography

Thin-layer chromatography has been applied to tars and oils in three ways: (1) to identify individual compounds or groups of compounds such as polycyclic aromatic hydrocarbons (PAHs); (2) to measure types of compounds such as oils, maltenes, asphaltenes and preasphaltenes in crudes by the TLC-FID method; and (3) as a fractionation method for examination by other techniques such as NMR or laser ionization mass spectrometry. These uses are considered in more detail below.

Identification of Individual Compounds or Groups of Compounds

Analytical TLC of coal tar has been achieved using silica gel plates and development by a manual method using the series of solvents – tetrahydrofuran, chloroform/methanol (4 : 1 v/v), toluene and pentane. The separated components have been recovered and examined by probe mass spectrometry directly with no prior extraction from the silica. A typical analytical separation is shown in **Figure 1**. The standard compounds on the plate included pyrogallol, perylene and rubrene, with a coal extract produced in a bomb with tetralin solvent. Mass spectra of recovered fractions are shown below.

Measurement of Compound Types

The separation and quantification of compound types – oils, maltenes, asphaltenes and preasphaltenes (terms derived from solvent solubility fractionation)

Figure 1 (See Colour Plate 109) Analytical development of coal tar pitch, tetrahydrofuran solubles, on silica developed in tetrahydrofuran, chloroform/methanol (4 : 1 v/v), toluene and pentane. – in oils and coal derived liquids may be achieved using the combination of TLC on rods with flame ionization detection (FID). The normal equipment used for this is the Iatroscan Chromatograph with Chromarods to effect the separation. Rods are cleaned and prepared by passage through a hydrogen/air flame, sample is deposited near one end of the rod and development proceeds as for a plate, using an appropriate solvent sequence. The developed and dried rod is passed through the flame detector to evaluate the separated fractions; calibration of the response factors of the different types of fraction is essential to give quantitative information. The sample is destroyed by the detection method but, as only small quantities of sample are used, several developments can be made at the same time to allow repeatability checks. Figure 2 shows details of different development sequences to obtain adequate separation of a coal tar pitch. The initial sequence was not satisfactory owing to the aromatic character of the pitch. The final sequence indicated that the hexane development had no effect on the separation of the pitch, since hexane would separate aliphatics, which are absent from the pitch.

Separation of Fractions for Examination by Other Techniques

In this mode, TLC has opened a route to the isolation of fractions of coal-derived liquids and tars from biomass as well as petroleum vacuum residues. The essence of the method is the application of sample either in solution or as a suspension or slurry in a volatile solvent. Pyridine has been used for slurring or dissolving all of these sample types; 1-methyl 2-pyrrolidone (NMP) is capable of dissolving coal and biomass tars, but is involatile (boiling point 202°C) and cannot be removed easily from the plate. After addition to the longer edge of a plate as spots or as a band along the bottom of the plate, usually 10 cm × 20 cm coated with silica gel, the pyridine is allowed to evaporate. Figure 3 shows a typical preparative development of a synthetic naphthalene mesophase pitch using tetrahydrofuran and toluene, with application of sample in a pyridine slurry. After separation the colours of the bands were black (immobile), brown (mobile in tetrahydrofuran but immobile in toluene) and orange (mobile in both solvents).

Development solvents used include pyridine followed by acetonitrile, pyridine followed by *N,N*-dimethylformamide and tetrahydrofuran followed by toluene. In each case, the first solvent used is the more polar of the two and development is not more than half way up the plate, less than 5 cm. After drying, the

Figure 2 TLC-FID chromatograms corresponding to the following development sequences: (A) 38 min *n*-hexane, 3 min toluene, 30 s dichloromethane (DCM)-MeOH; (B) 38 min *n*-hexane, 20 min toluene, 5 min DCM-MeOH; (C) 45 min *n*-hexane, 20 min toluene, 3 min DCM-MeOH; (D) 35 min toluene, 3 min DCM-MeOH. Numbers correspond to area percentages. (TLC-FID reproduced with permission from Cebolla VL, Vela J, Membrado L and Ferrando AC (1996) *Chromatographia* 42(5/6) March 1996, © Friedr. Vieweg & Sohn Verlagsgesellschaft mbH.)

plate is developed in the second solvent to a distance approximately twice that of the first, but less than 10 cm. In some cases, the development has been achieved using a manual multiple development technique in which the plate is removed from the tank after the solvent front has passed the sample application zone (or the solvent front of the previous solvent), dried and reinserted into the same solvent to continue the development. By this method, the possibility of the mobile material being partially retained by the immobile fraction is reduced.

To avoid contamination of the tar fractions, the plates are usually washed before use with the first

Figure 3 (See Colour Plate 110) Preparative development of a synthetic naphthalene mesophase pitch applied in pyridine slurry and developed in tetrahydrofuran and toluene.

solvent to be used in the development, either pyridine or tetrahydrofuran. This is achieved by placing the fresh plate into a development tank containing the solvent and allowing the solvent front to rise almost to the top of the plate. In the subsequent preparative or analytical development, the final solvent front is not allowed to reach the washing-solvent front and, in consequence, the height of the plate used for the separation is probably not more than two-thirds of the available plate height, with allowance for the sample application zone being above the initial level of the solvent when first placed into the development tank.

As indicated earlier, after development three zones are normally visible (black, dark brown and orange or yellow). These zones are recovered by scraping the coated silica into a glass vial and extracting with NMP at room temperature, with ultrasonic agitation if necessary. The extract may be recovered either by decanting the solvent from the silica, using a syringe, or by adding the slurry to a glass syringe equipped with a filter tip (0.6 μm). In this case, the physical pressure necessary to force the solvent through the filter may cause the filter to be blown off the syringe, with loss of sample. The complete removal of black, low mobility material from the silica is difficult to achieve and the residual silica may be dark in appearance; however, the recovered material is unlike the other fractions in molecular mass and spectroscopic behaviour (see below). The solutions derived by solvent extraction may be concentrated by vacuum evaporation or used as recovered. NMP is a difficult solvent to remove completely, but water washing of the almost dried fraction may achieve removal since NMP is very soluble in water.

Instrumentation

For TLC on plates as described here, the equipment needed is minimal: simple development tanks lined with absorbent paper to produce an atmosphere in the closed vessel that is in vapour equilibrium with the solvent pool in the tank, to reduce evaporation from the advancing solvent front on the plate. The plates themselves may be used as commercially supplied, requiring only a solvent wash to remove impurities from the area of the plate to be used for the separation.

More complex automated chromatographic development instruments may be used but the simple separation of tars into three fractions can be achieved without them.

TLC-FID requires specialist equipment since the chromatographic rods require passage through the detector flame by a controlled mechanical technique. The Iatrosan Chromatograph with Chromarod silica rods has been developed for this analysis.

Analyses by Other Methods

Material from analytical spots or bulk fractions recovered from thin layer plates may be analysed by a variety of analytical techniques. In particular, mass spectrometric methods can be applied since they require very little sample. Also, several different mass spectrometric techniques can be applied to either one recovered spot or a bulk fraction. In this section, the analysis of fractions obtained by preparative TLC by probe mass spectrometry, matrix-assisted laser desorption mass spectrometry (MALDI-MS), size exclusion chromatography (SEC) and UV-fluorescence spectroscopy (UV-F) are discussed.

Probe Mass Spectrometry (Probe-MS)

This method can be used without extraction of the fraction from the silica. The range of molecular mass achieved depends on the volatility of sample in vac-

uum and the probe temperature; for fractions of pitch an upper mass of around m/z 600 is possible. The examination of spectra of spots in combination with R_F values of standards can permit the identification of compound types – aromatics, pyridinic and pyrrolic nitrogen heterocyclic aromatics. The absence of signal for the material left at the origin indicates that

it contains large, involatile molecules rather than aggregates of small polar molecules.

Figure 4 shows mass spectra for some spots recovered from an analytical separation of a coal tar, following a separation similar to that shown in Figure 1. Fractions 1 (mobile in pentane) and 2–4 (mobile in toluene close to toluene front) gave molecular ions for polynuclear aromatic hydrocarbons ranging from fluorene (m/z 166) to m/z 482, corresponding to a dimethyl tetrabenzobinaphthyl type. Fractions 5, 6 and 7 correspond to the range of mobility between aromatics in the toluene zone and the chloroform/methanol solvent front and show evidence of the presence of nitrogen-containing heterocyclics. Fractions 8–11 were taken from material

mobile in chloroform/methanol but not mobile in toluene and correspond to basic nitrogen heterocyclic aromatics. The probe mass spectra of thin-layer fractions have allowed the identification of isomer classes rather than individual isomers but have extended the mass range of identified nitrogen PAH to nearly m/z 500. The identification of neutral and basic nitrogen components can be achieved during one rapid, simple and inexpensive separation with the use of standards to define the separation. Also, interference from the ^{13}C isotope peak of the more abundant polycyclic aromatics which have molecular masses one unit less than the nitrogen heterocyclics, is avoided, as opposed to the situation in GC-MS where both types elute together.

Matrix Assisted Laser Desorption Mass Spectrometry (MALDI-MS)

The application of MALDI-MS to coal-derived fractions is at an early stage. Much of the published work corresponds to laser ablation MS, where the fractions are examined with no added matrix but with the small molecules of the sample itself acting as the matrix. In the absence of small molecules (indicated by SEC) to form an effective matrix for kerogen extracts, no significant mass spectrum can be generated for the large molecules; addition of suitable matrix materials allows the generation of mass spectra, however. The upper limits observed for coal-derived materials by MALDI are in excess of 100 000 u but so far, it has not proved possible to generate mass spectra from the TLC-immobile fractions containing the largest molecules. Similarly, the techniques and matrix materials used to generate spectra for coal-derived fractions have not proved successful with immobile fractions from either biomass tars or petroleum vacuum residues.

One essential requirement for producing good mass spectra is the reduction of polydispersity (ratio of mass average to number average molecular mass) of fractions. **Figure 5** shows the MALDI-mass spectra of coal tar pitch fractions from development in pyridine and acetonitrile: (A) immobile fraction; (B) fraction mobile in pyridine only; and (C) fraction mobile in pyridine and acetonitrile. Increasing the mobility leads to shifts of molecular masses to smaller values and to changes in the shapes of spectra; the spectra become narrower and sharper with increasing mobil-

ity. Comparing relative intensity scales, intensities of immobile fraction spectra were only 1–4%, whereas the spectra of mobile fractions gave signal at full scale (100%). Smaller-mass molecules appear to be preferentially ionized and desorbed, thus skewing the molecular ion distribution in favour of the smaller molecules.

Size Exclusion Chromatography (SEC)

Size exclusion chromatography has been used extensively for the examination of oils and tars from coal, biomass and petroleum. Until recently, tetrahydrofuran (THF) was the solvent most used, for example for asphalts for road tars. In work with coal tar, we have shown that the use of THF gives erroneous results since the high-mass portion of the tar is lost to the guard column, which gradually blocks. It can be

cleaned using 1-methyl-2-pyrrolidinone (NMP) and restored to a usable state. In addition, THF does not completely dissolve the coal-derived materials. In the work described here, NMP has been used to dissolve tars and as an eluent for SEC. Although NMP dissolves coal tars and biomass liquids completely, it is

a poor solvent for alkanes and therefore petroleum-derived materials may be only partially soluble. However, the use of TLC fractionation allows the removal of alkanes from the aromatics by applying a final development of pentane. If UV absorbance is the method of detection for SEC, then alkanes are not observed.

SEC chromatograms of coal tars, biomass tars and petroleum vacuum residues are shown in Figures 6–10. All of the chromatograms show at least two major peaks, the first near the exclusion limit of the column and the second corresponding to material resolved by the column. The signal for the excluded material is thought to correspond to material the column is unable to resolve. If resolved, this material will appear as a long trailing distribution of apparently larger-mass material. More important though is the increasing proportion of excluded material in the TLC fractions with increasing immobility. This indicates that the TLC separation is on the basis of molecular size and not just polarity. Indeed, the definition of polarity for the fractions of tars described as oils, maltenes, asphaltenes and preasphaltenes on the basis of solubility or insolubility in particular solvents may apply equally well as a measure of increasing molecular

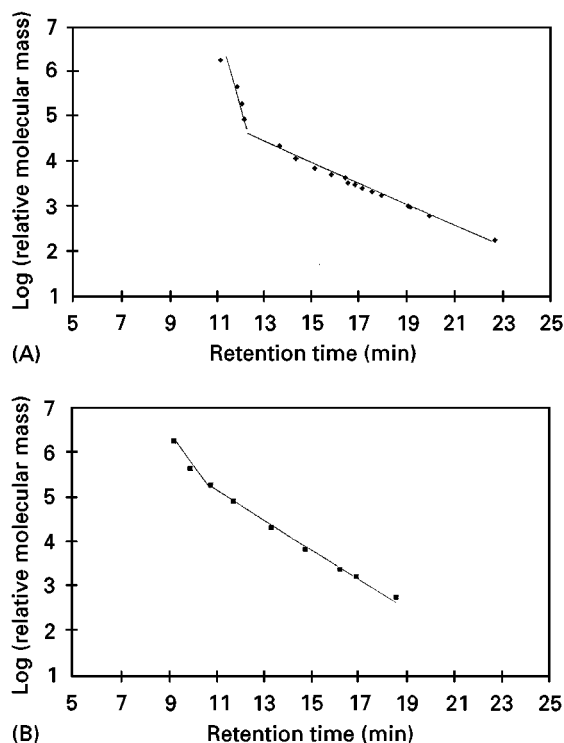

Figure 11 Calibration graphs for two SEC columns using polystyrene standards; \log_{10} molecular mass versus elution time. (A) Mixed E column and (B) Mixed D column from Polymer Laboratories Ltd, Church Stretton, UK.

mass or size. In SEC, the sequence of solvent-derived fractions shows a trend towards increasing molecular size from oil to preasphaltene. The combination of evidence from SEC, TLC, solvent solubility and MALDI-MS indicates that the immobile fractions do contain the largest molecular masses present in the tars from different sources. The SEC profile of the

whole pitch shows a relatively smaller peak of excluded material compared with the immobile fractions. This points to the masking effect of the greater concentration of smaller masses and more mobile material, and emphasizes the utility of the planar chromatographic separation.

Calibration of the column separation is normally achieved using polymer standards; in this work polystyrene standards have been used. The calibration then appears to apply to polycyclic aromatic hydrocarbons and their N, S and O derivatives up to masses of approximately 1000 u. At higher masses, two problems apply: (1) there are no standard PAH available; and (2) the structures of the tar molecules are totally unknown. Calibration curves based on polystyrenes up to relative mass 1.84 million are shown in **Figure 11** for two columns. The linear regions from low mass (A) 20 000 u or (B) 200 00 u correspond to

the working region in which solute molecules penetrate the pores of the column packing and separate by size. The linear relation for larger polystyrenes at shorter elution times may correspond to separation in the space between the particles of the packing and molecules eluting in this region are described as excluded from the porosity; the discontinuity is described as the exclusion limit of the column.

UV-Fluorescence Spectroscopy (UV-F)

UV-fluorescence spectroscopy does not measure molecular size directly, but shifts of fluorescence maximum intensity to longer wavelengths indicate an increasing aromatic cluster size since the fluorescence originates from the largest aromatic system within a molecule, fed by energy absorbed by the smaller pendant aromatic groups. Such shifts to longer wavelengths point to increasing molecular size. Decreasing fluorescence quantum yields are a consequence of increased molecular size and complexity since there are more pathways for the electronic exci-

tation to progress to vibrational and thermal energy rather than being lost as fluorescence.

UV-F spectra of coal- and biomass-derived liquids and petroleum residues are shown in Figures 12–14. In coal-derived tars, the fluorescence intensity of the materials showing reduced mobility in TLC (and being largely excluded from the SEC porosity) decreases and the maximum shifts towards red wavelengths, indicating that these fractions contain large molecules. With biomass tars, immobile fractions do not show any fluorescence at all, indicating the presence of very high molecular mass material.

The fractions mobile in both solvents showed relatively strong fluorescence intensities, the position of the peaks at lower wavelengths suggesting the presence of relatively smaller polynuclear aromatic ring systems and probably also the presence of lower molecular mass material. Similarly fractions mobile in one solvent gave less intense fluorescence than fractions mobile in both solvents. TLC fractions of petroleum vacuum residues show no similar shift to red wavelengths with increasing immobility, or markedly reduced quantum yield but tend to cover the same range of wavelengths with shifts of intensity of peaks within that range. However, SEC of the immobile fractions indicates that the lack of mobility results from molecular size.

Conclusions

Several examples of the fractionation by TLC of coal- and biomass-derived liquids and petroleum residues have been shown. TLC improves the isolation and characterization of large molecular mass fractions in oils and tars for examination by other techniques such as probe mass spectrometry, MALDI-MS, SEC and UV-F. The separation is relatively rapid and inexpensive and requires only small volumes of solvents. The fractionation has led to structural information not readily available by direct characterization of the original mixture. Molecular-mass distributions, determined by SEC and MALDI, increase with decreasing mobility of the fractions in thin layer chromatography. UV-F spectroscopy has distinguished structural features by showing the presence of large polycyclic aromatic systems that increase in proportion to decrease in mobility of fractions. Detailed structures of the largest molecules remain unknown. Probe mass spectra have allowed the identification of isomer class and extended the mass range of identified nitrogen PAH to nearly m/z 500, allowing the identification of neutral and basic nitrogen types as well as the major components through one rapid, simple and inexpensive separation.

Copyright © 2000 Academic Press

Introduction

High performance liquid chromatography (HPLC) is the most important technique for the separation, analysis and quantification of a wide range of drug types. Although there are a variety of approaches available for the chromatography of basic drugs, analysis of these compounds is still one of the main challenges for the practising chromatographer in the pharmaceutical industry. The general approaches have remained the same since the early days of HPLC, but there have been many refinements and developments since the late 1960s. In the main these have involved modification and improvements to the stationary phase, which are still continuing today.

This article focusses on the main methods of separation and analysis of basic drugs that are currently in use. Consideration is given to the relative pros and cons of the different approaches, as well as the development and evolution of the techniques.

Liquid–Solid Chromatography

Liquid–solid, or normal-phase chromatography (LSC) was one of the first approaches employed for the separation of bases in modern LC. Its use, however, has decreased dramatically since the 1970s and it is now rarely employed for the routine separation of basic drug molecules.

LSC was originally carried out using native silica or alumina, with the former being preferred for the separation of bases. Recently, there has been a gradual shift towards the use of polar bonded phases such as cyanopropyl, amino or diol, the last two showing preferential retention of bases compared with cyanopropyl. These bonded materials overcome some of the problems associated with silica phases such as deactivation by water and long equilibration times. The problem of deactivation is particularly acute in the area of bioanalysis, where it can be difficult to obtain extracts that are totally dry. To a certain degree this problem can be overcome by the inclusion in the eluent of a small amount (1% v/v) of water or a short-chain alcohol.

Eluents for LSC typically consist of mixtures of a nonpolar hydrocarbon, such as hexane or iso-octane, and a polar modifier, e.g. dichloromethane, 2-propanol, methyl *t*-butyl ether or ethyl acetate. Frequently, the addition of an amine modifier such as triethylamine may be necessary to give satisfactory peak shapes.

LSC does complement reversed-phase separations, in that the selectivity is very different, with the order of elution usually being reversed. Unlike the more widely used reversed-phase HPLC (RP-HPLC; see below), it is particularly suited to the separation of geometric isomers.

Reversed-phase HPLC

RP-HPLC for pharmaceutical analysis took off in the early 1970s with the introduction of commercially available microparticulate bonded packings. Although it rapidly became the dominant mode of chromatography in the pharmaceutical area, it quickly became apparent that the chromatography of basic compounds was not a straightforward matter. Despite this, RP-HPLC still figures prominently in both literature and pharmacopeia methods.

The analysis of basic solutes using RP-HPLC methods presents a number of problems, principally because the analyte is retained by a number of retention mechanisms (some of which are poorly understood) in addition to the expected hydrophobic interaction. These include: hydrogen bonding, π - π interactions, ion exchange, ion pair formation and salting out. It is the multiplicity of these retention mechanisms that often leads to poor chromatographic performance, characterized by low peak efficiencies, tailing or asymmetric peaks and retention times that are dependent on the mass of compound injected.

Many of these phenomena can be traced back to the presence of unreacted silanols on the bonded silica surface. Despite the use of forcing conditions during the bonding process, there always remains a significant number of unreacted silanols, around 60% of the total. Silanols are acidic and if ionized can function as ion exchange sites. They are also polar and are able to interact with solutes via hydrogen bonding. While hydrogen bonding is not considered to be a serious problem, ion exchange can be particularly troublesome. From an energetics point of view this is easy to understand since the energy involved in coulombic or ionic interactions is around 20 times greater than that of hydrophobic interactions. Much of the development of RP-HPLC phases has been directed at minimizing the number (or type) of silanols, or at least minimizing their influence.

The interaction of a basic solute with the residual silanols is dependent on the pK_a of the base and the stereochemistry around the basic centre. The higher the pK_a and the lower the steric hindrance around the basic centre, the greater the interaction with silanols. Thus pyridine, which is a relatively weak base (pK_a

5.25), is also probably the smallest and least hindered aromatic base and can be particularly difficult to chromatograph on reversed-phase materials.

A number of general strategies involving both changes to the mobile phase and the stationary phase have been employed to improve the chromatography of bases. Each of these is discussed below.

Stationary Phase Modifications

End-capping

For many years manufacturers attempted to eliminate the residual silanols through a process known as end-capping. Following the primary bonding procedure, the stationary phase is further reacted with a small silylating reagent such as trimethylchlorosilane (TMCS) or hexamethyldisilazane, both of which generate trimethylsilyl groups ($(\text{CH}_3)_3\text{Si}-$). The rationale for their use is that the small size of the trimethylsilyl group should allow access to the silanols, which are inaccessible to bulkier primary reagents such as octadecyldimethylchlorosilane. However, this approach has never been fully successful, and even after exhaustive end-capping, unreacted silanols always remain. It is also believed that some silanols are so reactive that although they can be end-capped, they rapidly hydrolyse in aqueous organic mobile phases (especially at acid pH) to regenerate the silanol.

Polymer-coated Phases

In this approach a polymer coat is formed over the surface of the silica. If desired this can be further modified by the addition of C_{18} groups, for example. Although partially successful in blocking access to the silanols, this approach also leads to reduced efficiency, presumably through poor mass transfer caused by blocking of the silica pores. Although packings based on this approach are commercially available, they are not widely used.

Sterically Protected Phases

Another approach to minimizing silanol interactions is through the use of sterically hindered silylating reagents, such as diisopropyloctadecylchlorosilane. The rationale here is that the bulky isopropyl groups (in contrast to the more commonly employed methyl groups) should result in steric occlusion of any residual silanols. This approach has only been partially successful in reducing analyte-silanol interactions and has not been widely adopted. However, it would appear to be more successful in stabilizing the bonded phase and allowing the use of a wider range of pH.

Base-deactivated Phases

In the mid-1980s it was demonstrated that it was the type, rather than the number of silanols that was responsible for the secondary interactions. A poor silica is characterized by an uneven distribution of silanols with varying and strong acidity – so-called Type A materials. In contrast, good silicas (Type B) are characterized by a large population of hydrogen-bonded, low-acidity silanols.

This discovery led to the development of the so-called base-deactivated phases, which were claimed to be superior to standard materials for the separation and analysis of bases. Figure 1 presents three chromatograms showing the separation of a series of basic drugs using three reversed-phase packings. The first is a standard C₁₈ material, the second is partially deactivated (typical of end-capped materials), and the third is a modern base-deactivated material. The improvement in peak shape and efficiency across these three types is clearly evident.

The purity of the silica that is used to make the bonded-phase material is also considered to be important in the analysis of basic drugs. Silicas with high purity and very low metal content, particularly aluminium and iron, have been shown to give improved performance. These metallic impurities can

act in one of two ways: directly as centres for chelation, or indirectly through their polarization of silanols, thereby increasing their acidity or activity.

Much of the technology that has gone into the development of modern reversed-phase materials is proprietary. However, most of these stationary phases are probably made by employing one or several of the following approaches: fully rehydroxylated silicas with an even distribution of low acidity silanols; high purity silicas; sterically hindered silylating reagents; or more recently silylating reagents incorporating a polar linkage (e.g. carbamates). It is important to note that a column that gives particularly good performance with one compound may be totally unsuited to the analysis of another compound. This is clearly seen from the data in Table 1, which compares the performance of four commercial columns based on the tailing observed for a series of basic drugs. All the columns were claimed to be suitable for the analysis of bases. For example, column I is clearly the worst with atenolol and chlorpheniramine, giving rise to the most severe tailing peaks. With amiloride, however, column I is almost as good as column IV, the best, and column II stands out as being quite different. With pyridine as a simple test marker, all the columns give a similar poor performance. Before selecting a column, therefore, it is

Figure 1 A comparison of the chromatography of a range of basic compounds on three C₁₈ reversed-phase packings: (A) a conventional material, (B) a semi-deactivated material and (C) base-deactivated material. Eluent: methanol/KH₂PO₄ (25 mmol L⁻¹, pH 6.0) (80/20). Flow rate: 1 mL min⁻¹. Identification: 1, norephedrine; 2, nortriptyline; 3, toluene (neutral test marker); 4, imipramine; 5, amitriptyline. Table 1 The tailing factor for a range of basic compounds on four base-deactivated reversed-phase columns

Compound	Tailing factor on different columns			
	I	II	III	IV
Atenolol	2.6	1.7	1.3	1.2
Pyridine	2.2	2.5	2.1	2.7
Pindolol	1.7	2.2	1.4	1.3
Amiloride	1.2	1.7	1.2	1.1
Cycloguanil	2.2	1.9	1.4	1.2
Chlorpheniramine	6.8	3.1	3.1	1.6

Eluent methanol/water, containing ammonium acetate (0.1 mol L^{-1}), pH approximately 7.1. (Reproduced from Law *et al.*, 1998, with permission from Elsevier Science.)

important to try it out with the given analyte using a variety of conditions, since some columns seem to perform better with acidic eluents while others work best at neutral pH. The use of a number of parameters such as retention, efficiency and peak tailing are necessary if a true measure of column performance with regard to a particular analyte is to be gained.

Most manufacturers and distributors of HPLC materials supply base-deactivated materials.

Polymeric Phases

In an attempt to eliminate the effects of silanols totally some manufacturers moved away from silica completely and developed polymeric phases based on styrene-divinylbenzene. These materials are claimed to offer pure reversed-phase chromatography devoid of the secondary interactions that so bedevil chromatography on silica-based materials. They also offer a significant advantage in that they are fully stable over the pH range 1–14. This allows chromatography of basic drugs in the unionized form at high pH, which is impossible with standard silica-based materials.

These materials, however, were not without disadvantages. Some of the early materials underwent swelling when moving from high aqueous to high organic eluents, resulting in back-pressure changes and column blocking. Surprisingly, however, they also suffered from secondary interactions that resulted in poor performance. It has been claimed that the grafting of alkyl chains (typically C_{18}) onto the polymer phase is a useful method of minimizing these undesirable interactions. The major disadvantage of these materials for most analytes, including basic drugs, is the poor peak efficiencies attributed to slow mass transfer. These materials have not found widespread general use, although they are used for some particular applications, such as the analysis of quater-

nary amines, where their high retentivity compared with comparable silica phases is particularly useful.

Eluent Modifications

Organic Modifier

It is a generally observed phenomenon that of the three commonly used organic modifiers – methanol, acetonitrile and tetrahydrofuran – the first gives the most symmetrical peaks with basic compounds. This is usually explained by the fact that methanol has both hydrogen bond acceptor and donor properties, in contrast to the other two solvents, which have only acceptor properties. Thus, methanol is able to interact and effectively block residual silanols to a greater extent.

Eluent Buffers

Phosphate buffers are commonly used in HPLC eluents, especially for reversed-phase work. Of the two counterions mainly used, potassium has greater affinity for the silanol ion exchange sites than sodium. Thus the use of potassium phosphate is recommended, since this will result in a small but significant improvement in peak shape. It follows also that the use of stronger buffers (100 mmol L^{-1}) should be more effective than buffers of lower concentration.

Eluent pH

The eluent pH can also have a marked effect on peak shape. Since the undesirable interactions are ionic, then an improvement in chromatographic performance should be achieved by suppressing the ionization of either the base or the silanol. Because many basic compounds of pharmaceutical interest are relatively strong bases ($pK_a > 8.5$), an eluent pH of around 10.5 would be required to suppress their ionization. Since many silica-based stationary phases undergo dissolution at $pH > 7.5$ –8, this approach is impractical. More commonly, therefore, the eluent pH is reduced to around 2 to 3 through the addition of trifluoroacetic acid or phosphoric acid in an attempt to suppress the ionization of the silanols. This approach is not always fully successful because a small population of silanols are often quite acidic with pK_a values < 1 . Acidified eluents, however, do complement the use of silanol-blocking and ion pair reagents (see below).

Silanol-blocking Agents

Silanol-blocking agents, which normally take the form of a lipophilic amine, can be considered as a special type of eluent additive. They are usually

included in the eluent at a concentration of around 25 mmol L^{-1} . If secondary or tertiary amines are used, then the eluent pH needs to be adjusted to ensure full ionization of the amine. Where quaternary amines are used the eluent can be at any pH, although a slightly acidic eluent would be recommended to minimize the number of ionized silanols.

The large excess of the protonated amine in the eluent effectively blocks or masks the residual silanols, making them less accessible to interaction with the basic analyte. A number of systematic studies have been carried out on the use of silanol-blocking agents. From these a number of general conclusions can be drawn. First, the silanol-blocking properties of alkylamines decreases in order primary < secondary < tertiary \leq quaternary. Compounds of the type $(\text{CH}_3)_3\text{N}^+\text{R}$ or $(\text{CH}_3)_2\text{N}^+\text{HR}$, where R is a long alkyl chain, are the most effective. There is no consensus as to the optimal length of the alkyl chains; some workers recommend triethylamine ($30\text{--}50 \text{ mmol L}^{-1}$) while others prefer dimethyloctylamine ($5\text{--}10 \text{ mmol L}^{-1}$). As well as improving peak shape and efficiency, the use of masking agents can also lead to a significant reduction in retention for basic solutes. Silanol-blocking agents can also be used with base-deactivated materials, where significant improvements can be observed with some basic drugs.

Dynamically Modified Silica

Introduced by Hansen in the early 1980s, this approach involves the creation of a dynamic reversed phase. A bare silica column is used with an aqueous/organic eluent containing a long-chain quaternary ammonium compound. Initially the eluent is passed through the column until equilibrium is reached, and the quaternary ammonium compound forms an adsorbed monolayer on the silica surface. This approach has been shown to give good peak shapes for strong bases (Figure 2) and to give separations difficult to achieve using base-deactivated materials. A major and somewhat surprising attribute of the system is the excellent reproducibility in selectivity, even when changing from one brand of silica to another. Thus this approach is particularly suited to those assays where long-term reproducibility is essential, such as in pharmaceutical quality control. Despite these advantages this method has not become widely used, possibly due to the limitations with respect to UV detection, particularly at short wavelength. The lack of compatibility with mass spectrometry, currently the favoured means of detection in the pharmaceutical industry, probably means that it will never become popular.

Figure 2 The separation of imipramine and metabolites under three sets of conditions. (A) Column, LiChrosorb RP-18 ($120 \text{ mm} \times 4.6 \text{ mm}$); eluent, methanol/water/phosphate buffer (0.2 mol L^{-1} , pH 4) (60 : 35 : 5). (B) As for (A) but with the addition of dodecyltrimethylammonium bromide (2.5 mmol L^{-1}) and sodium dodecanesulfonate (5 mmol L^{-1}). (C) Column, LiChrosorb Si 60 ($120 \text{ mm} \times 4.6 \text{ mm}$); eluent, methanol/water/phosphate buffer (0.2 mol L^{-1} , pH 7) (55 : 40 : 5) with the addition of cetyltrimethylammonium bromide (2.5 mmol L^{-1}). Identification: 1, imipramine-*N*-oxide; 2, desipramine; 3, imipramine. (Reproduced from Hansen SH, Helboe P and Thomsen M (1987) Separation of basic drug substances by reversed-phase high-performance liquid chromatography on dynamically modified silica and on bonded-phase materials. *Journal of Chromatography* 409: 71–80, with permission from Elsevier Science.)

Ion Pairing HPLC (IP-HPLC)

This is an approach developed during the early 1980s and pioneered by Schill and co-workers. It is parti-

Figure 3 Recommended maximum mobile-phase concentrations of alkyl sulfonate pairing ions and their application range as a function of the mobile-phase methanol concentration. (Reproduced from Bartha A, Vigh G and Vorga-Puchony Z (1990) Basis for the rational selection of the hydrophobicity and concentration of the ion-pairing reagent in reversed-phase ion-pair high-performance liquid chromatography. *Journal of Chromatography* 499: 423–434, with permission from Elsevier Science.)

cularly useful for the separation and analysis of polar bases such as drugs containing quaternary amine groups, which are usually difficult to analyse under standard reversed-phase conditions because their high polarity leads to poor retention. Because of the general improvement in the quality of reversed-phase materials (end-capped, base-deactivated) the use of IP-HPLC has declined somewhat. Typical ion pair reagents are perchlorate or more commonly alkyl sulfonates (e.g. pentane, heptane or dodecane). The organic ion pair reagents are normally added at concentrations of around 10 to 100 mmol L⁻¹ and, to ensure full ionization of the basic drug, the eluent is normally acidified to a pH of around 2–3. The longer the alkyl chain of the pairing ion, the greater the retention. Excellent control of selectivity with respect to other bases, as well as neutral or acidic compounds, is possible. This flexibility can also make optimization of the system complex, since as well as organic modifier type, modifier concentration and eluent pH, the nature and concentration of the ion pair reagent, as well as the concentration of the buffer, all have an effect on the separation. The optimization of such systems have been extensively studied. **Figure 3** shows how the nature and concentration of the pairing ion are dictated by the methanol concentration in the eluent.

In a number of applications, a quaternary ammonium ion has also been added to the eluent to further improve the peak shape of the basic analytes.

Ion Exchange HPLC (IE-HPLC)

Ion exchange is a useful, if under utilized, mode of chromatographing basic solutes. With this form of

chromatography the ionic interactions, which prove so troublesome in RP-HPLC, are actually employed as the major retention mechanism. Two general approaches are available, the first employing native silica as the stationary phase and the second utilizing bonded phases bearing a specific ion exchange group.

Ion Exchange Using Native Silica

As stated earlier, the silanol groups on the surface of silica gel are weakly acidic with a bulk pK_a of around 4. Consequently at pH values greater than 4 the silanols become ionized and they are able to act as ion exchange sites. Silica is typically used with eluents consisting of a mixture of an organic modifier (methanol or acetonitrile) and an aqueous buffer at a pH > 7. A variety of buffers have been employed, but ammonium acetate is particularly useful since it has low UV absorbance, high volatility and is noncorrosive. A good general purpose eluent is methanol/ammonium acetate buffer (9:1 v/v, pH 9.1). When employed with Spherisorb S5W silica this system shows excellent performance for the analysis of strongly basic drugs with pK_a values > 8. Most bases, including some quaternary ammonium compounds, give excellent peak shapes (< 1.2) asymmetry and high efficiencies (N = 50 000 plates m⁻¹). Despite the use of a high eluent pH the silica stationary phase shows excellent stability and the columns can be used for many months with no loss in performance. This unexpected stability of the silica is attributed to the use of a high proportion of organic modifier in the eluent and ammonia as the base, rather than sodium, potassium or a strong organic base, which are generally more aggressive.

This approach is particularly good for drug screening since a wide range of drug types elute in a relatively narrow retention range (**Figure 4**). Thus gradient elution, which would be needed to chromatograph a similar set of compounds under RP-HPLC conditions, is avoided. Retention is found to be dependent on the solute pK_a with the more basic compounds being more highly retained. Since the pK_a of basic drugs often does not change radically when the drug is metabolized, the system is useful for the analysis of metabolites in biological fluids. To a certain degree the retention of the metabolites is predictable, with most metabolites eluting after the parent compound in contrast to RP-HPLC.

The major limitation of this approach is its restriction to the analysis of strong bases with pK_a values > 8. The column-to-column reproducibility can also be a problem as 'ageing' of the silica, whether in the dry state or packed into a wet column, can result in significant selectivity differences.

Figure 4 The separation of a range of bases using a Spherisorb S5W column (100 mm \times 4.6 mm) and an eluent consisting of methanol/ammonium acetate buffer (9 : 1, v/v) with an apparent pH of 9.1. Identification: 1, tetracaine; 2, tamoxifen; 3, diphenhydramine; 4, amiloride; 5, thioridazine; 6, chlorpheniramine; 7, *N*-methylamphetamine; 8, debrisoquine; 9, 4-hydroxydebrisoquine; 10, quinacrine; 11, strychnine; 12, betahistine; 13 benzethonium; 14, pyrantel. (Reproduced from Law, 1990.)

Ion Exchange Using Bonded Phases

Although introduced not long after hydrocarbon-bonded phases, these materials have never really caught on for the separation of drugs. To a degree this may be due to the perceived complexity of ion exchange as a mode of separation, with the need to control the ionization of both analyte and stationary phase. However, the use of strong cation exchanger (SCX) materials, such as propylsulfonic acid, which are highly acidic ($pK_a < 1$) and effectively ionized at all pH values, makes the development of separations relatively straightforward.

Recently there has been renewed interest in bonded phase ion exchange materials with a number of reports appearing on applications of the propylsulfonic acid phases. To ensure full ionization of both weak and strong bases, acidic eluents should be employed, and to give good efficiencies and good selectivity, a high organic modifier concentration is recommended. Using a Spherisorb 5 μ m SCX column with an eluent consisting of methanol/water/trifluoroacetic acid (800 : 200 : 2.3 v/v) containing ammonium formate (20 mmol L⁻¹) it has proved possible to chromatograph a very wide range of basic drugs. The system shows acceptable retention for strong bases such as the β -blockers ($pK_a \sim 9.5$) through to weak bases such as diazepam with a pK_a of only 3.4 (Figure 5). Like the silica-based system described

above, this approach also gives very good performance with high efficiencies (up to 70 000 plates m⁻¹) and good peak symmetries. The retention is controlled in the main by the concentration of the ammonium formate buffer. Furthermore, through systematic modification of the eluent pH or organic modifier concentration, it is possible to change selectivity in a predictable manner.

One advantage of both the above ion exchange approaches is that the eluent constituents are relatively volatile ensuring compatibility with mass spectrometric detection.

Future Developments

RP-HPLC, utilizing silica-based materials, is likely to continue as the dominant technique for the analysis of pharmaceuticals including basic drugs. Despite their problems and limitations, silica-based materials are still able to outperform polymeric phases. Although the development of polymer-based materials is likely to continue, our knowledge and understanding of silica – despite its use in HPLC for over 30 years – is still growing. A number of academic groups and chromatography companies are actively researching silica. Although major breakthroughs in the

Figure 5 The separation of a range of basic drugs using a Spherisorb 5SCX column (100 mm \times 4.6 mm) and an eluent consisting of methanol/water/trifluoroacetic acid (TFA) (800 : 200 : 2.3, v/v) containing ammonium formate (0.02 mol L⁻¹), with an apparent pH of 2.45. Identification: 1, halofantrine; 2, minoxidil; 3, haloperidol; 4, reserpine; 5, cimetidine; 6, verapamil; 7, clomipramine. (Reproduced from Law and Appleby, 1996.)

methods of production and quality of silica are unlikely, a process of refinement can be expected, leading to even better deactivated materials.

While it would be encouraging to believe that the benefits of some of the other approaches will be recognized and exploited, the conservative nature of the pharmaceutical analyst – partially driven by the heavily regulated nature of the industry – and the dominance of reversed-phase methods make this unlikely.

Capillary Electrophoresis

K. D. Altria and S. M. Bryant, GlaxoWellcome Research Centre, Hertfordshire, UK

Copyright © 2000 Academic Press

Introduction

In recent years the analysis of pharmaceuticals has been predominantly performed by high performance liquid chromatography (HPLC), which offers a number of advantages over other alternative techniques. These advantages include automated and precise sample injection devices, sensitive detection and high capacity autosamplers. HPLC is supported by other techniques such as thin-layer chromatography (TLC) and gas chromatography (GC). In the late 1980s a further technique, that of capillary electrophoresis (CE), became recognized as a viable alternative and complementary technique to HPLC. Modern CE instruments offer some of the same features as HPLC in terms of automation and autosampler capacity, although precision and sensitivity are not as good.

The wide range of application areas for CE within pharmaceutical analysis mirror well those of HPLC. These areas include the determination of drug-related impurities, chiral separations, main peak assay, stoichiometric determinations and the analysis of vitamins. The majority of pharmaceuticals are synthetic organic molecules that are well suited to analysis by HPLC or CE. There is an increasing move in pharmaceutical companies to the development of new pharmaceuticals that are based on biomolecules such as peptides and DNA. Traditionally these biomolecules have been analysed using electrophoretic techniques; for this reason CE has been widely applied to the analysis of biomolecule pharmaceuticals.

One of the attractive features of CE is that method development can be relatively simple for uncomplicated separations of ionizable pharmaceuticals. For example the majority of pharmaceuticals are basic drug salts. Use of a low pH electrolyte causes these basic drugs to protonate and become cations, and thus allows separation by CE. There are also a number of drugs with acidic functionalities that can

be separated by CE as anions using high-pH electrolytes. Neutral solutes require the use of micellar electrokinetic chromatography (MEKC) methods. Water-insoluble drugs can be separated in CE using traditional aqueous-based electrolytes but there is an increasing tendency towards the use of nonaqueous solvent systems in CE. The ease of method development is also a key feature in the use of CE for chiral separations, as a range of chiral additives can be quickly and effectively assessed in automated unattended injection sequences.

The use of indirect UV detection for the detection of small inorganic and/or organic cations and anions is widespread. These applications include determination of metal ion contents and inorganic anions such as sulfate and chloride. Traditionally determination of these species is performed by ion exchange chromatography but CE offers specific advantages in terms of ease of operation and reduced time and cost of consumables.

In this article the various application areas of CE in drug analysis are covered with some illustrative examples of reported applications. The discussion also includes some details regarding the analytical performance levels described for these analyses.

Determination of Drug-related Impurities

Capillary electrophoresis is increasingly being viewed as an alternative, complementary technique to HPLC for the determination of drug-related impurities. A number of applications have been reported, many with detection of the impurities at the 0.1% level or lower. Often low UV wavelengths (190–200 nm) are used to improve the detection limits obtained. The ability of CE to give a different selectivity to HPLC and/or TLC provides a further means to characterize the impurity content and profiles in drugs.

The separation of structurally similar drug-related impurities is difficult as the drugs and the related impurities often have very similar electrophoretic mobilities. Therefore the separation conditions must be optimized to enable a good resolution to be obtained, especially as low detection limits are generally required for the related impurities in the presence of a large drug peak. The pH of the separation is the most important optimization factor for separation of ionic species. However, the concentration and type of surfactant used is the most important factor for resolution of neutral and/or charged species by MEKC. Other factors that can be optimized in method development include the addition of ion-pair reagents and cyclodextrin and the ionic strength and type of electrolyte. These factors influence the shape of the main

peak and appropriate optimization may allow resolution of a closely existing impurity. For instance, various types and concentrations of ion-pair reagent have been employed in conjunction with cyclodextrin in the optimization of the separation of remoxipride and related impurities. **Figure 1** shows the separation achieved of remoxipride and eight related impurities using a relatively complicated pH 3 phosphate buffer which contained 40 mM hydroxypropyl beta cyclodextrin and 20 mM tetrabutylammonium bromide.

Many examples of the use of CE for the analysis of drug-related impurities have been published that have shown CE to be a useful complementary technique to support HPLC. These methods have been validated and are in routine use in many pharmaceutical companies. These include a CE method that has been used to monitor the stability of a cephalosporin in solution. Validation included specificity, linearity and repeatability by different analysts on different days. Migration time precision was less than 1% RSD (relative standard deviation). Injections were performed from sample solutions every 30 min to monitor the solution stability online. The cephalosporin (Roche compound RO 23-9424) was found to be twice as stable in an L-arginine/sodium benzoate/saline solution than when prepared in water.

Chiral Separations

Undoubtedly the most frequently used selectors in free solution CE are cyclodextrins (CDs). Other possibilities include crown ethers, carbohydrates, proteins and chiral antibiotics. The majority of pharmaceutical applications have involved the use of CDs. The most widely used approaches in MEKC are mixtures of sodium dodecyl sulfate (SDS) and CDs or bile salts, which are naturally occurring chiral surfactants.

There have been many quantitative applications of CE to the separation of drug enantiomers and these have included several reports of the validation of these methods. Method validation for chiral CE methods is similar to that undertaken for validation of an HPLC method. In the validation of a CE method, aspects such as the precision of injection, detection limits, and method repeatability on different capillaries using different operators and reagents are important. As in other separative techniques, comigration of related impurities with either of the enantiomer peaks is possible. Therefore it is necessary to establish the migration position of all available related substances in method selectivity studies. This procedure has been performed in a number of chiral CE methods including the chiral separation of a cholesterol-lowering agent (**Figure 2**). The ability of the

Figure 1 Effect on resolution of remoxipride analogues by variation of the tetrabutylammonium ion (TBA^+) concentration (0.1 mmol L^{-1}) in the presence of hydroxypropyl- β -cyclodextrin (HP- β -CD; 40 mmol L^{-1}) using a phosphate buffer at pH 3.0. The TBA^+ concentrations were (A) 10 mmol L^{-1} and (B) 20 mmol L^{-1} . The peaks are: 1, FLA 708; 2, FLA 739; 3, FLA 83; 4, FLB 526; 5, FLA 731 (remoxipride); 6, NCR 513; 8 = FLA 740; and 9, FLA 797 (*x*-scale in min). (Reproduced from Stalberg O, Brotell H and Westerlund D (1995) *Chromatographia* 40: 697–704, with permission from Elsevier Science.)

method to quantify accurately the enantiomeric impurity is also an important part of method validation and is often demonstrated by recovery experiments in which accurately known amounts of the impurity are spiked into standards of reference material. **Table 1** shows recovery data obtained during validation of a method for enantio-purity determination of a cholesterol-lowering drug.

Main Component Assay

The use of CE for main component assay is possible as commercially available instruments offer a high degree of automation and are capable of unattended injection sequences by use of PC-controlled autosamplers. The injection precision demands in many pharmaceutical companies is stringent for separative

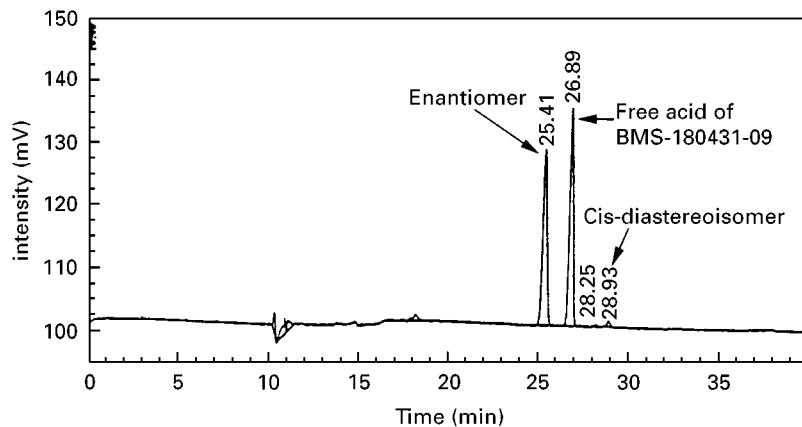

Figure 2 CD-MEKC of a racemic mixture of BMS-180431-09 with some trace *cis*-diastereoisomer added. Conditions: 0.01 mol L^{-1} ($1.5 \text{ g per } 100 \text{ mL}$) hydroxypropyl- β -cyclodextrin, 0.1 mol L^{-1} sodium borate, 0.03 mol L^{-1} SDS, pH 9.3, 20 kV, current $\sim 65 \mu\text{A}$, 50 cm effective capillary length, $50 \mu\text{m}$ capillary width, UV adsorption detection at 200 nm; sample was 0.3 mg mL^{-1} in water. techniques such as HPLC and CE and figures such as 1–1.5% RSD are common practice. This can be routinely obtained by HPLC but this is not always the case for CE as the injection volumes are very small (1–20 nL) and can be variable. The use of internal standards to eliminate injection volume-related errors can dramatically improve the precision in CE and allow the required precision requirements to be achieved. For example internal standards were used in the validation of a simple pH 2.5, 25 mmol L⁻¹ phosphate buffer for assay of a wide range of basic drugs. The method was shown to have good sensitivity, linearity (correlations > 0.999) with RSD values of 0.3–2.0% for peak area ratios. The robustness of the method to deviations in the method settings was satisfactorily assessed using an experimental design. Shelf-lives of electrolyte and sample solutions were assessed (3 months and 14 days, respectively). Good precision was obtained using either aminobenzoic acid or imidazole as the internal standard. Good agreement between CE data and the label claim for tablets was obtained (Table 2).

An MEKC method was successfully validated according to US Pharmacopoeia guidelines for analysis of hydrochlorothiazide and chlorothiazide. The

method involved use of a 20 mmol L⁻¹ borate buffer containing 30 mmol L⁻¹ SDS. A 100 µm capillary was employed to give large peak areas in order to minimize integration-related errors. Careful control of the method settings such as injection time, temperature and sample concentration enabled values below 1% RSD to be routinely obtained with no internal standard. Recoveries ranged from 99.5–100.6% absorbance unit full scale (AUFS) for hydrochlorothiazide over the range 50–150% of target concentration. Detector linearities were greater than 0.998. Analyses were successfully repeated on different days by different analysts using different capillaries to demonstrate robustness.

Stoichiometric Determinations by CE

During development of a new drug, a range of different salts may be synthesized to compare pharmaceutical properties such as solubility, stability and crystallinity. The ratio of the drug to counterion is known as the drug stoichiometry and this needs to be characterized analytically. The typical stoichiometry is a 1 : 1 drug : counterion mixture; however, 2 : 1 and 1 : 2 compositions are frequently manufactured, depending upon the ionic nature of the drug and/or counterion. There is a clear analytical need to quantify drug : counterion levels to demonstrate that the correct salt version has been manufactured and that the required stoichiometry can be reliably achieved batch-to-batch when the final drug salt has been selected.

The counterion of basic drugs include inorganic ions such as sulfate and chloride or organic ions such as maleate, fumarate, acetate or succinate. Cations analysed involve a range of metal ions including Na⁺, K⁺, Mg²⁺, Ca²⁺ and simple low molecular weight amines. Since these analytes possess little or no chromophore, indirect UV detection is generally necessary. However, some larger anionic counterions such as benzoates and simple organic acids can possess sufficient UV absorption to allow direct UV detection. Alternatively, metal ions may be complexed on-capillary to form metal chelates, which can then be detected by direct UV measurement.

The quantitative aspects of a CE method for the determination of calcium in calcium acamprosate has been validated. Standard solutions of calcium carbonate and test solutions of calcium acamprosate containing 100 ppm of Ca²⁺ and Mg²⁺ (internal standard) were determined by indirect detection at 214 nm. Table 3 shows the determination of calcium in calcium acamprosate and the results compare favourably with the theoretical content.

Table 3 Comparison of CE and titration results for the calcium content in calcium acamprostate drug substance

Batch	Theoretical content	CZE	EDTA titration
C110	10.01% m/m	10.01% m/m (10.00, 10.04)	9.98% mass/mass
OTA 37	10.01% m/m	9.98% m/m (9.96, 10.01)	10.08% mass/mass

Levels of chloride and sulfate have been determined using electrolyte containing chromate and tetradecyltrimethylammonium bromide (TTAB). Sample solutions were prepared to give 100 ppm of chloride as sulfate as appropriate. AnalaR grade salts such as NaCl were used as reference standards. **Table 4** shows the good agreement between the average CE results, microanalysis data and the theoretical content. Peak areas were used to calculate % w/w in samples of three different drug substances. Improved data for injection have been obtained using an internal standard. A detection limit of $0.5 \mu\text{g mL}^{-1}$ was reported for standard anions.

Separation and detection of a range of organic acids is possible using phthalate as the background absorber (Figure 3). The method has been validated for the quantitation of both succinate and maleate content in drug substance batches.

Vitamin Analysis

The majority of vitamin determinations are currently performed by HPLC with UV detection. These HPLC methods involve gradient elution and often extensive

sample work-up prior to analysis to remove matrix interferences. The majority of vitamins are water-soluble acidic compounds and can be readily determined by free solution CE using high pH electrolytes. Water-insoluble and neutral vitamins require the use of MEKC. Many of the vitamins are acids or contain groups that ionize at high pH and therefore borate or phosphate buffers in the pH range 7–9 have been used extensively.

The CE and MEKC methods have been compared with the USP HPLC method to determine various B group vitamins in capsules, tablets and syrups. **Table 5** shows the data obtained by the three techniques to be equivalent. The use of an internal standard (paracetamol) improved the CE and MEKC precision from 7–10% RSD to 1%. Accuracy and repeatability of the MEKC method was demonstrated by spiking appropriate levels of the vitamins into artificially prepared mixtures of the tablet excipients.

Figure 3 Separation of a selection of organic acids using phthalate as the background absorber. Separation conditions: fused silica capillary 27 cm \times 75 μm ; buffer, 50 mmol L⁻¹, 4-morpholineethanesulfonic acid (Mes), 0.5 mmol L⁻¹ TTAB and 5 mmol L⁻¹ phthalate adjusted to pH 5.2; voltage – 3.0 kV; wavelength 254 nm indirect detection (detector signal reversed); temperature 30°C. n/a, not analysed. Reproduced with permission from Boonkerd S, Detaevernier MR and Michotte Y (1994) *Journal of Chromatography A* 670: 209–214.

Six replicate samples were analysed on each of four separate days and acceptable data were obtained for average recovery and precision from the pooled assay results.

Figure 4 shows the separation of a range of common vitamins in a pharmaceutical preparation. The components are separated using a micellar electrolyte containing the surfactant SDS with acetonitrile and cyclodextrin modifiers. Detection is at 200 nm.

Levels of vitamins B₁, B₃, B₆, B₂, and C in injection solutions have been determined using an MEKC method with ethylaminobenzoate as an internal standard to give RSD values for precision of less than 2%. Agreement with label claims ranged from 98.8% to 104% for the five components.

Regulatory Aspects

The acceptance of CE methods by regulatory authorities has been highlighted in a confidential survey of a number of major UK and US pharmaceutical companies. All CE methods submitted had been accepted without technical query. The companies surveyed indicated that they had no reluctance to submit appropriate CE data in submissions. The survey was conducted in mid 1994 and the number of submitted methods has certainly increased since then. For example, a stability indicating MEKC method for the analysis of BMS-188484 has been successfully included in a regulatory submission from Bristol-Myers-Squibb.

Pharmacopoeia have also recognized the advancing application of CE within pharmaceutical companies

Figure 4 Separation of a range of vitamins.

and a draft USP general chapter on CE has been published (*Pharm Forum* 1996) in anticipation of future monographs containing CE analytical methods.

Conclusions

The use of CE in the analysis of pharmaceuticals is now becoming firmly established as a useful complement and alternative to the more widely employed technique of HPLC. The major attractions of CE are that considerable cost and time savings are possible, especially in the areas of chiral analysis and in the determination of solutes having limited or no chromophore. The recent advent of the use of nonaqueous solvents in CE should extend further the application range of the technique. Routine CE methods have been established in many industrial laboratories and CE methods have been successfully submitted to regulatory authorities.

Introduction

Between the mid-1980s and the mid-1990s great advances were made in the development of commercially-available methodologies for the separation of enantiomers. These developments were undoubtedly catalysed by the need to determine the enantiomer content of chiral drug substances, chiral drug products and samples of chiral drugs in biological fluids in the pharmaceutical research and development environment. It had long been recognized that, since it is possible to distinguish between enantiomers in a chiral environment, enantiomers might be expected to have different effects on the body which contains potential chiral 'selectors' such as proteins, peptides, carbohydrates and enzymes. The action of a drug on

the body or of the body on the drug involves many processes including the following:

- active transport
- plasma binding
- tissue binding
- receptor protein binding
- drug metabolism
- active secretion.

These and many of the other processes involve or may involve mediation by a protein or enzyme so that there is no shortage of opportunities for chiral discrimination to take place. As a consequence it is actually quite rare for enantiomers to have very similar pharmacological and toxicological properties. They must therefore be treated as if they were different drugs, and their use in combination in a drug product in a fixed 50 : 50 ratio as the racemate must be justified to the governmental regulatory bodies which issue licences to companies to produce and market drugs. Not only is this usually not justifiable,

but also when it is justifiable the burden of justification might be such that it is even conceivable that it might be more convenient to proceed with a single enantiomer in any case.

The classic case of thalidomide, developed as a non-addictive alternative to barbiturates, is frequently cited as an illustration of the extreme case, where the desired pharmacological activity resides in one enantiomer and the other enantiomer has all the undesirable toxic effects. This is in fact an oversimplification of the true situation and the emphasis on this one case does nothing to allude to the wide range of other possible cases that might arise. There is no doubting though that the thalidomide case served not only to highlight the potential problems inherent in developing racemic drugs but also it triggered off the greater awareness of drug safety that led to the extensive regulatory frameworks that today control the production and sale of pharmaceuticals. Just as there was a time lag before there was a readily available capability to resolve enantiomers, so there was a time lag before single enantiomer chiral synthetic drugs were being brought onto the market.

Application Areas

Many of the naturally-occurring chiral drugs and chiral drugs derived from naturally-occurring subunits contain multiple chiral centres. Penicillin antibiotics and steroids are cases in point. For such compounds it would be exceptional for there to be a need to determine the enantiomer of the drug as an impurity as this would involve inversion of the stereochemistry at all chiral centres. What is more likely to be an impurity is an epimer where there is inversion at one of the chiral centres only. Since the chiral drug and one of its epimers are diastereomers they may be separated by high performance liquid chromatography (HPLC) on an achiral column.

For a different reason a chiral separation is also not usually required for the drug substance of a chiral drug marketed as the racemate, a 50 : 50 mixture of the enantiomers. If there is no chiral intervention in the synthesis there would be little reason to suspect that anything other than a 50 : 50 mixture was present. Accordingly in pharmacopoeial monographs it is usually sufficient to establish for the drug substance that e.g. the optical rotation lies between $+0.15^\circ$ and -0.15° . Chiral LC would only be required if 'chiral switch' were being contemplated. This might happen if it was thought that a significantly better drug could be had by substituting a single enantiomer for the racemate in cases when the racemic drug had been developed and licensed before the significance of

chirality in drugs had been fully appreciated and before chiral resolution had become commonplace. The first step in the chiral switch decision making process, even before resolving, isolating and testing the individual enantiomers, would often be to study the fate of the individual enantiomers in the body following dosing with the racemate. It is therefore necessary to have a method capable of determining low levels of each enantiomer in biological fluids. To study the enantiomers in this way in the presence of the other enantiomer does not necessarily give a close approximation to the pharmacokinetics of the enantiomers when they are dosed on their own, but it does give an early indication as to whether there is a major difference in the way each enantiomer interacts with the body.

The main area in which enantiospecific LC methods are called for is in the research, development and production of synthetic single enantiomer drugs. This category mainly consists of drugs which arise directly from the selection of the most suitable enantiomer of a new chemical entity but will also include those which arise from a chiral switch. The actual applications of chiral LC which are important and most commonly carried out are described below.

Preparative Resolution of Individual Enantiomers

Clearly the individual enantiomers need to be isolated before they can be tested for their pharmacological action. This is very often done by semi-preparative LC since often only milligram quantities are needed. Preparative even up to Kg scale is an option for the actual production of a drug substance but most often a stereospecific synthetic route is more commercially viable.

Trace Enantiomer Determination in a Drug Substance

The trace enantiomer must be treated like any other related substance and therefore must be quantified down to levels of 0.1% w/w. This is usually carried out as a separate exercise from the determination of other related substances.

Chiral Drug Bioanalysis

As already indicated, a chiral method for the determination of enantiomers plays an important role in the decision on which enantiomer should be developed as a drug candidate. For a new chemical entity this will take place in the discovery phase of pharmaceutical research and development but a few studies might still be needed in early development to ensure that there is no interconversion between enantiomers taking place in the body.

There are a few other instances where a chiral assay might be needed but, for example, the determination of trace enantiomer in a formulated product would only be needed if it were known that it was a potential degradant.

Method Development

Now that the current scenario involves a strong preference for the development of single enantiomer drugs, the types of chiral analytical methods that are required has changed. However the first step in method development is as always to achieve chiral resolution. This has never been a matter of trial and error. By the late 1980s there was already a large number of chiral stationary phases (CSP) available for direct resolution by chiral LC. Despite this it was possible to group these together in classes by their mode of action and from this deduce which types of enantiomeric drugs might be separable using each class. For example, the acidic drug ibuprofen is highly protein bound in plasma and it is therefore no surprise that its enantiomers may be separated on a column containing an albumin CSP since albumin is the major binding plasma protein for acidic drugs. As CSP became more effective and more sophisticated by incorporating multiple modes of interaction, such simple predictions were no longer possible.

Fortunately there were 'intelligent' approaches that could be used to address this paradoxical situation. These are outlined below.

NMR Modelling

If splitting of the signals for the analyte is observed when its ^1H NMR spectrum in the presence of the chiral selector that is used in the chiral HPLC column is recorded, then if the solvent used in ^1H NMR is the same or similar to that which might be used in HPLC then it might be expected that chiral resolution will be observed in HPLC.

Molecular Modelling

The molecular orbitals involved in the transient diastereomeric complexes formed between the individual enantiomers and the chiral selector determine whether there is a large enough energy difference for the selector to be able to distinguish between the enantiomers at ambient temperature. While it is one thing to simulate selector approaching select and in a vacuum, it is an altogether more difficult matter to construct a meaningful simulation that incorporates mobile phase molecules, neighbouring chiral 'strands' on a CSP and the supporting stationary phase.

Databases

The most well known of these is *Chirbase*. Whether or not a separation will take place may be predicted by comparing with information on similar selector-selectand situations held on the database. This approach is reliant on the quality of the information held on the database and suffers from the weakness that it might be a subtle difference between the chiral drug being studied and a similar one described on the database that might be responsible for a quite marked difference in behaviour towards the chiral selector being considered.

Expert Systems

These systems are more versatile than databases in that they make decisions and learn from experience with each problem encountered. Again, each new problem might be subtly different from the one that has gone before and it might be this subtle difference that is critical with respect to which is the best chiral selector to use.

While these approaches have remained popular in academic circles, screening approaches have been more widely adopted in pharmaceutical research and development. This might typically involve the LC of the racemate being studied on three or four different chiral columns in a column-switching manifold, using a range of different mobile phases. Ideally in one overnight run the racemate would be analysed on each column using each of the mobile phases. The conditions which had shown the best resolution would then be identified by the computer controlling the system in order that they be further refined, if necessary, using mobile phase optimization so that by the morning the chiral method development would be complete. The increasingly widespread use of such screens may be attributed to the fact that the CSP used in them are now more effective to the extent that the screens are usually highly successful, with 'hit rates' for chiral resolution in the range 80–100% being quite common. Their acceptance in drug development in particular arises also because of the availability of highly automated instrumentation and the fact that in this environment, the purchase of a range of chiral LC columns which would generally be regarded as expensive is cost effective in the context of the benefit derived and the overall costs involved in pharmaceutical research and development. Modelling and database approaches have been overtaken because now it is just as quick to do the actual experiments.

Derivatized cellulose CSP with organic mobile phases usually play an important role in such screens. For example the use of ChiralCel OD, ChiralPak

AD, ChiralPak AS and the Whelk-O CSP with *n*-hexane-propan-2-ol (85 : 15, v/v) containing 0.5% triethylamine and *n*-hexane-propan-2-ol (85 : 15, v/v) containing 0.5% trifluoroacetic acid as the mobile phase is highly effective. Remarkable though the success rate of such a screen might be it would be the complete answer to all chiral method development problems, since it would not be ideal for giving optimum conditions for very polar compounds and would not be suitable in practice for samples presented as salts or as aqueous solutions. For these cases a screen using a cyclodextrin CSP and different macrocyclic antibiotic CSP with polar organic and aqueous-organic mobile phases would likely be more appropriate. Such a screen is often as effective as the type involving organic mobile phases and, for the polar organic mobile phase in particular, the final optimization can be quite simple.

Of course, achieving the chiral separation is not the end of the story. There are additional difficulties peculiar to each type of application.

Preparative Resolution of Individual Enantiomers

An additional difficulty in preparative resolution is the issue of time and money. Therefore as high as possible a sample load will be applied to the column. This leads to loss of efficiency and subsequent loss of resolution. Although loss of baseline resolution can be compensated for by collecting or 'shaving off' a leading part of the first peak and the second part of the second peak with the portion collected where the peaks overlap being recycled later, it is a general rule that it is better to start off with very high chiral resolution before commencing with scale-up.

The range of approaches to preparative chiral LC is dealt with elsewhere in this Encyclopedia. However the approach of choice will depend on the circumstances. In the 'drug discovery' phase of pharmaceutical research and development it will often be sufficient to obtain mg-quantities of each enantiomer for pharmacological testing or perhaps g-quantities if preliminary information on pharmacokinetics or toxicology is required before proceeding to early 'development'. Under these circumstances chemists are usually prepared to put up with the cost of using a semi-preparative (~7 mm i.d.) or preparative (16–22 mm i.d.) derivatized polysaccharide column, as this works out more economical than taking the time that might be needed to develop a 'cheaper' method.

The economics in a Pilot Plant or Production environment are entirely different. Conventional preparative chiral LC on scaled-up versions of analytical columns would be too expensive in terms not only of

money but also time (which of course is money!). In this scenario the simulated moving-bed approach to preparative work, in which the mobile phase is cycled round a closed system of connected preparative chiral columns and resolved enantiomers are periodically drawn from the system at set points, is becoming increasingly popular. However, old habits die hard and if organic chemists cannot devise a stereoselective synthesis they may then still revert to a fractional crystallization to isolate the large quantities of one enantiomer that are required.

Trace Enantiomer Determination in Drug Substance

As for preparative chiral LC, there are additional problems that need to be dealt with over and above simply achieving chiral resolution. Generally it will be necessary to be able to determine down to 0.1% of the trace unwanted enantiomer in the bulk drug substance. Since peaks in HPLC are more often than not slightly asymmetric with a degree of peak tailing, this determination of enantiomeric impurity is more difficult when the impurity peak elutes after the main peak. As with the problem with scale-up in preparative chiral LC, one approach is to attempt to obtain a separation that is significantly better than baseline resolution. In this way the impurity peak is well clear of the tail of the main peak with the result that its area may be more accurately integrated. An alternative approach is to use the chiral stationary phase or chiral mobile phase based on the antepode of the chiral selector enantiomer used initially. Under these circumstances the enantiomeric impurity peak will elute first and will be much easier to determine. Switching the chirality of the selector in this way may be carried out for small molecule chiral selectors such as ligand-exchange, synthetic multiple interaction or Pirkle-type, ion-pair and crown ether selectors. However it is a weakness of the broader spectrum chiral selectors based on larger molecules, e.g. proteins, cyclodextrins, derivatized polysaccharides and macrocyclic antibiotics, that such a simple reversal of retention order is not possible.

Another difficulty is that the enantiomeric impurity must also be resolved from other structurally-related impurities. In general this is possible but it is more difficult to separate all structurally-related impurities from one another with a method using a chiral stationary phase or mobile phase additive. It is for this reason, and the fact that it is not prudent to use expensive chiral stationary phases more than is absolutely necessary, that the determination of trace enantiomeric impurity is almost always performed as a separate test.

Chiral Drug Bioanalysis

The difficulties over and above that of achieving a chiral separation are much more apparent for chiral drug bioanalysis than for the other two application areas that have been discussed. In any determination of drugs in biological fluids, problems arise because the levels of drug are invariably low and the matrix is invariably complex. Often also, for example in clinical trials to assess the safety and efficacy of a drug on patients, sample numbers may be very high. However this latter issue does not normally apply to chiral drug bioanalysis since, as has already been indicated, a method which is not stereoselective may be used if it can be shown in early development that the drug does not racemize or invert to its opposite enantiomer when in the body. Accordingly, some of the complex, automated methods involving column switching mooted in the early days of chiral drug bioanalysis when there were still many racemic drugs in the development phase are no longer appropriate. What is needed is simple methods that don't take too long to develop. As it is not sensible to load 'dirty' samples from biological fluids onto expensive chiral columns, the most common approach is to use extensive sample pre-treatment. This would involve concentration as well as clean-up so that the levels of drug loaded onto the column would be well above the limit of quantitation.

While the use of chemical derivatization is another approach that may be adopted to ensure that the chiral drug and its enantiomer, if present, are easily detected, chiral derivatization followed by achiral LC is an approach that needs to be used with caution. There is now greater awareness of potential difficulties such as racemization during the derivatization reaction, kinetic resolution caused by different reaction rates for the enantiomers and differing detector responses for the diastereomeric products. Apart from the racemization issue and the fact that an extra step is involved in the analytical procedure, there are no such drawbacks when achiral derivatization is used followed by chiral LC. Further, when the derivatizing agent contains a π -electron rich aromatic ring system and the chiral stationary phase used is a synthetic multiple interaction or Pirkle-type containing a π -electron deficient aromatic ring system in the chiral selector, then very good chiral resolution as well as easy detectability may be anticipated.

A more recent approach to chiral drug bioanalysis that fulfils all the requirements is the use of solid phase extraction (SPE) followed by direct injection of a large volume of the SPE eluate onto a microbore LC containing the porous graphitic packing material Hy-

percarb^R with a mobile phase containing a chiral mobile phase additive. Low limits of quantitation are ensured by the focussing effect that takes place because the eluate from a C-18 or phenyl-SPE cartridge is less strongly eluting than the mobile phase in the microbore LC column. Hypercarb^R is used because it is both highly retentive, thereby requiring a mobile phase that is more strongly eluting than that required to elute the analyte from the C-18 or phenyl-SPE cartridge, and is a very effective achiral support for use in methods that use a chiral mobile phase additive. The latter property is also at least in part due to its high retentivity.

Future Perspectives

Chiral LC of drugs is one of the scientific success stories of the late 20th century. It is now a mature area of research even although it only really began in the 1980s. While it would be useful to have more economical preparative chiral LC methods and to be able to determine enantiomeric and other structurally-related impurities simultaneously, it has to be said that these are not critical needs and that the major advances have almost certainly already taken place.

Overview

Pharmaceutical analysis is traditionally defined as analytical chemistry dealing with drugs both as bulk drug substances and as pharmaceutical products (formulations). However, in academia, as well as in the pharmaceutical industry, other branches of analytical chemistry are also involved, viz. bioanalytical chemistry, drug metabolism studies and analytical biotechnology. The development of drugs in the pharmaceutical industry is a long-term process, often taking more than a decade from the start of a research project to the appearance of a drug on the market. That process involves several decision points, such as the choice of the candidate drug after the preclinical screening phase, the investigational new drug (IND) application before testing the compound for the first time in man, and finally the new drug application (NDA) which summarizes the data obtained from all the studies needed for marketing approval of the drug as a medicine. In all these steps, especially the IND and NDA, the amount of data generated is enormous. Analytical chemists take part in many of the studies that constitute this documentation. Substance quality and its specifications are based on substance analysis, and that knowledge is later used for quality control during full-scale production. Product analysis involves dealing with the various formulations and starts after the IND has been approved. The results from such work lead to specifications that form the basis for the quality control of the product. For both substances and formulations there is an increasing interest in the introduction of process analytical chemistry.

Biomolecules, i.e. macromolecules such as proteins or hormones, either produced by isolation from biological sources or by means of biotechnology, must also be subjected to careful analytical control. Thus

whilst the analytical tasks required for biomolecules are somewhat different from those of ordinary pharmaceuticals when it comes to regulation and documentation of their quality and properties they definitely belong to the same group.

There are a number of regulations that have to be followed in the development of pharmaceuticals as well as in their production. Regulatory approval is required prior to the IND and before marketing is licensed (NDA). Today clinical trials also undergo scrutiny by the authorities.

An important part of the development process is safety evaluation, primarily the toxicology tests, which run from 6 to 24 months in different species. During this time bioanalytical studies are performed as well as control of the formulations used in the tests. After approval for marketing, the authorities exercise control of products on the market and require post production stability data. Public interest in the quality of drugs is also reflected in the compilation of substance monographs in compendia that are known as pharmacopoeias. In addition to collections of substance monographs these pharmacopoeias contain general analytical methods and some also contain monographic requirements on the formulation of the substances.

This article provides an overview of mainly substance and product analysis (traditional pharmaceutical analysis), as used in the pharmaceutical industry. The support of other branches of analytical chemistry will be mentioned.

Bulk Drug and Pharmaceutical Products

Common Features

Identity testing Identity testing is used to verify that the drug substance is what it is stated to be or that the formulation contains the correct compounds. Infrared (IR) spectra are used quite extensively in industry, whereas the pharmacopoeias often have a set of alternative tests. These can be colour reactions, melting point of a compound or derivative, optical

rotation values or ultraviolet (UV) spectral data such as maximum wavelength and absorptivity. Today chromatographic data are also used to support identity tests.

Impurities Impurities or degradates require separation methods and are usually studied at the level from 0.1–2% (purity patterns) or 0.1–5% (stability profiles). This means that the analytes have to be quantified in up to a 1000-fold excess of the major compound. In practice qualitative work is performed at still lower levels. This sometimes creates problems in the chromatographic methods as minute amounts of related substances may be hidden under the peak of the drug itself. This is the background for the interest in peak purity tests. With the advent of diode-array detection in liquid chromatography (LC) compounds with different chromophores may be differentiated, either through spectral comparison or by absorbance ratioing at selected wavelengths. However, a peak impurity present at below 1% may be difficult to detect. The use of mass spectral data for the verification of peak purity is still better and has been practised in gas chromatography–mass spectrometry (GC-MS). However, peak purity tests are inferior to the use of complementary separation systems.

Selected analytes Selected analytes sometimes have to be analysed at ppm levels. Typical examples are aromatic amines, nitrosamines, reactive intermediates left from the synthesis, or certain solvent residues, i.e. all components that are known to be noxious and thus must be controlled separately.

Compendial analysis Pharmacopoeias are the official collections of drug standards. They all include requirements for drug substances but only a few have monographs for products (formulations). Harmonization efforts between the compendia for the three big markets, Europe, Japan and the US, have recently been started. There is an agreement now that the major pharmacopoeias are in principle intended for the pharmaceutical industry and the authorities and not for community pharmacies.

Bulk Drug Analysis

Physicochemical characterization Physicochemical characterization yields a number of important parameters that can be used in the control of the quality of a substance. Typical properties are melting point and other thermal data, acid-base behaviour with pK_a values, redox potentials, polymorphism, solubility and spectral information.

Purity tests Purity tests are in particular focused on related substances such as homologues, analogues, by-products from the synthesis or degradates. Enantiomeric purity has been a more common test since the early 1980s. Chromatography has revolutionized our ability to determine substance purity and is currently the most important check, giving essentially the finger-print of a synthesis. An example of a separation of some potential impurities that have been added to a metoprolol sample is given in **Figure 1**. For qualitative studies LC-MS is beginning to establish its role as the primary on-line analytical tool for the elucidation of unknown structures among the impurities. From a toxicological point of view the impurity profile of the substance batch used in safety studies should form a reference for the full-scale production material. This means that in later batches impurities in amounts that deviate from those found in the batches used for toxicology should be avoided. The high standard and good reproducibility required of the purity profile is clearly evident from that perspective. There are some other tests that also contribute to the general impression of the quality of a substance, i.e. tests for protolytic impurities, content of chloride, sulfated ash or residue upon ignition that gives the inorganic content. These tests reflect the performance of the purification process in general, but their importance will probably diminish in the future. For inorganic ionic analytes the older methods can be replaced by ion chromatography.

Heavy metals and arsenic Heavy metals are routinely determined, often with one or other form of sulfide precipitation. These tests are performed from the viewpoint of safety and the general limits ($1\text{--}30\ \mu\text{g mL}^{-1}\ (\text{g}^{-1})$) are now more often related to the dose. For metals such as mercury, lead, cadmium or nickel, atomic absorption spectrometry or other instrumental methods are often prescribed. Copper and other transition metals can act as catalysts in certain degradation reactions and thus require special attention. Surprisingly, arsenic tests that were important at the beginning of this century are still considered necessary.

Potency assay Common for all bulk drugs is an assay of potency. This can be an aqueous or nonaqueous titration based on protolytic properties or on some other property. Many compounds lack functional groups suitable for titration and here chromatographic methods (LC in particular) are often used. However, titrations are preferable as their precision is, in general, superior.

Biomolecules Biomolecules such as proteins represent a special type of bulk drug. Depending on the

Figure 1 (A) Separation by LC of metoprolol and some of its potential impurities that have been added in amounts from 0.01 to 0.4% to a pure sample. Peak 6, Metoprolol; peak 7, an unknown purity. Peaks 1–11, see structures in (B). Column: 125 mm long and 4 mm i.d. filled with 5 μm C-8 particles (Li Chrospher RP-Select B). Mobile phase: Acetonitrile, 17% in ammonium phosphate buffer 0.05 mol L⁻¹, pH 3.2. Detection at 280 nm. (With thanks to Lars A. Svensson, Astra Hässle, Sweden.)

source, various chromatographic tests are used to show the absence of contaminating proteins remaining from the purification process. The separation methods used have a more biochemical character and differ from those for compounds of synthetic origin. Immunochemical techniques are very often used as complements. Typical tests include separation of dimers, trimers etc. from the biomolecule itself. Molecular size determination by size-exclusion chromatography is common and will probably be supplemented by mass spectrometry in the future.

Biotechnological products have some advantages over products from human or animal origin with respect to the risk of transferred diseases, but they have some special requirements. In particular, when parenteral use is intended, the absence of host proteins has to be guaranteed as well as DNA residues from the vector used for expression. Such matters often need the attention of specialist laboratories.

Bioassay Many biomolecules have, over the years, been assayed using methods where biological activity in an animal, organ or receptor is assessed, i.e. a bioassay. The traditional opinion has been that such bioassays cannot be replaced by physicochemical methods as the latter do not reflect the biological activity. Bioassays, no matter how well characterized they are, have certain disadvantages with respect to precision, time and cost compared to instrumental methods. The pharmaceutical industry has therefore been able to show that, for several of its biotechnological products, e.g. insulin and human growth hormone, chromatographic methods (LC in particular) can give the same information. Moreover, proteins from different species can be chromatographically separated and degradation products well quantified. This is not possible in quantitative bioassays where only the sum of activities is obtained. A similar paradigm shift has also taken place for antibiotics, where LC methods give information not

available from microbiological assays. However, it should be noted that for many biomolecules there are, as yet, no alternatives to bioassay.

Excipients

There are a great number of materials that are used to transform a substance from an active compound to a medicine useful for a patient in a therapeutic situation. These compounds, or excipients, are becoming more and more important in the construction of modern drug delivery systems. Many excipients are macromolecules and have been used for decades in traditional remedies. With modern drug delivery systems the old requirements may not always fit those necessary for the technologically advanced products of today. This has become increasingly evident in recent years. Moreover, the requirements on excipients in the various pharmacopoeias are not always consistent with each other and are often rather vague. This has been recognized at an international level and efforts at harmonization are proceeding. Polymeric excipients are generally characterized by some average physicochemical property such as viscosity. Studies of the distribution of relative molecular mass are rarely performed on such excipients due to the lack of suitable methods. The majority of the excipients used today, however, have relative molecular masses in the same range as the active compounds. The tests for safety and purity are similar to those of the drugs.

Excipients could usefully be classified or tested according to their properties at three levels, viz. molecular, particular and bulk properties. Those are tested for by the manufacturer of a dosage form. It is not clear which of those properties should be covered by the official compendia. Testing of functionality, i.e. at particulate or bulk level, does not seem to be possible yet. Typical tests are bulk density, specific surface area, flowability and particle size distribution. However, the standardization of methodology in compendia, without specification limits, would probably be of help for both vendor and buyer. As excipients are becoming more and more complex, their analytical characterization will be more important. Interesting opportunities lie ahead, particularly with macromolecular separation, MS and spectrometric methods such as near-infrared (near-IR) spectrometry.

Pharmaceutical Products

A medicine is much more than simply a drug substance, and huge efforts are put into the development of biopharmaceutically optimized drug delivery systems. Analytical chemists contribute to that process by analysing the experimental formulations with re-

spect to various properties such as homogeneity, content, stability and release of the active agent in dissolution testing but also through bioanalysis to create data for *in vitro* – *in vivo* correlations.

Solid dosage forms Solid dosage forms, e.g. tablets and capsules, are by far the most common for several reasons. The production of relevant doses is easy to accomplish, and scale-up is usually a standard technological process. All divided dosage forms have strict requirements for uniformity of content, i.e. a statistical sampling of the batch should show a uniform distribution of the active component. This requirement is especially important for units with very small amounts of the active component, i.e. from a few μg per dose to 50 mg. This has often led to automated analytical methods to cope with the large number of samples.

The pharmacokinetic performance of a drug influences the construction of a formulation. This has nowadays led to a dominance of drug delivery systems that provide a controlled or modified release of the drugs, defined as extended or delayed release. Release-controlling polymers are used to build up a barrier that prevents immediate release of a compound. In this way high peak plasma concentrations of drugs are avoided and usually only one dose per day is necessary. The characteristic properties of the formula are evaluated in *in vivo* tests where blood samples are analysed often by extremely sensitive bioanalytical methods.

However, for routine quality control it is usual to rely on *in vitro* models, which obviously have to be correlated with the *in vivo* data. Dissolution testing has been standardized in the pharmacopoeias for a long time with respect to release media, apparatus and other conditions. However, in modified release formulations the prescribed conditions might have to be changed. This is the responsibility of the analytical chemist, whilst still having the routine testing conditions in mind, i.e. quality control (QC) methods should also be practically feasible.

Parenterals Parenterals are dosage forms intended for injection into the body. Water is normally used as the solvent. The special tests for parenterals include sterility and absence of particles as well as endotoxins that can give fever reactions. The old test that was performed on rabbits is nowadays often replaced by a test based on the reaction of endotoxins with a lysate from *Limulus amoebocyte* (LAL-test) that is less time-consuming and more exact. Sterility testing is complicated from a sampling point of view because of the random appearance of microbial contaminants. A thorough in-process validation is the best way to

ensure that the products are sterile. In large volume parenterals' requirements on limits for particle contamination have created a need to analyse for particles down to the size of a few micrometres, usually by light-blocking or by conductivity techniques. For compounds which are sparingly soluble in water other solvents or co-solvents can be used creating problems of quite a different kind for both formulator and analyst, such as evaluation of precipitation phenomena and interactions with packaging materials.

Other dosage forms Other dosage forms are needed for topical administration such as creams, ointments and patches. The latter should usually deliver the drug over an extended period of time and thus require reliable *in vitro* release testing and as a consequence also *in vivo* data.

Sometimes other routes of administration are necessary. Thus suppositories are used for rectal delivery and sprays for the nasal route. Sublingual delivery can be advantageous, e.g. for nitrate esters. For asthma the use of inhalators has increased considerably as reliable hi-tech delivery systems have been developed. Here the uniformity of the inhaled dose (usually a few μg), as well as the narrowness of the particle size distribution, must be safeguarded.

The analytical problems of these dosage forms have to do both with the type of excipients used and their characterization and quality as well as the function of the delivery system.

Toxicological formulations Toxicological formulations appear in the early project work in short-term toxicology tests performed before testing in humans (pre IND) and later on during long-term carcinogenicity studies before approaching the authorities for marketing approval (pre NDA). The reason for mentioning them here is that at this early stage a full understanding of the properties of a drug is not always available, and most important, the animal feed into which the drug may be blended is a very difficult matrix in which to analyse a drug. Yet, the analyst has to determine the homogeneity and the stability of such formulated animal feeds during the use of the material. Here the rules of Good Laboratory Practice (GLP) are emphasized with careful validation of analytical methods.

Packaging materials Packaging materials are also part of the medicine presented to the patient. They are usually polymers that have properties chosen to give drug the product protection during storage and handling. Usually multilayer materials are used, as in blister packages for tablets, with some layers being a barrier towards moisture penetration.

Plastic bottles are becoming more common now. For many products, particularly parenterals, there is a risk of interaction between the polymeric material and the active component, especially if the latter has a lipophilic character. Rubber stoppers in parenterals are likewise prone to trap organic molecules from, and also leak stabilizers into the solution. Biomolecules in solution may adsorb onto these surfaces and this may be especially significant if the amounts in solution are minute. From these comments it is clear that stability testing must also be performed in the consumer package under appropriate conditions of temperature, humidity and light.

Stability studies Stability studies constitute a major task for the analytical chemical laboratory. The aims of initial physicochemical studies and investigations of incompatibilities, i.e. preformulation studies, are to identify the weak points of a compound, in order to avoid vulnerable conditions in the formulation. An example of an incompatibility reaction in a formulation containing three active ingredients and stored under accelerated conditions is given in **Figure 2**. The structure of the degradate was elucidated with electrospray LC-MS and verified as shown in **Figure 3**. Heat, moisture, oxygen and light may all influence stability.

Tests have to be performed under standardized conditions with respect to temperature and humidity. Accelerated tests can be used to isolate the weak points, but in the documentation submitted to the authorities long-term stability data under normal conditions are required. In these studies stability indicating assays are important and usually LC is the method of choice as the measurement of the drug content should not be disturbed by interfering components. Early degradation is, however, more reliably monitored through the degradates as the precision in the determination of a degradate is less demanding than the measurement of the corresponding decrease in the parent compound.

Full-scale production Full-scale production is the final step in the research process. Scaling up from the pharmaceutical development laboratory via the pilot plant to full-scale production is not without problems. This is one of the reasons for the requirement by the authorities that stability studies should be performed and reported for the first three production batches. The transfer (scaling up) can be facilitated by thorough process controls that give an understanding of those parameters which must be controlled. As pharmaceutical formulations are more complicated today than ever before it is clear that process analytical chemistry will play an important role in the

Figure 2 Separation by LC of degradates from a formulation containing hydralazine. After storage at accelerated conditions components A and B started to grow the peaks. They were both the result of an incompatibility with lactose. The structure of B was elucidated by LC-MS as shown in Figure 3. (With thanks to Rose-Marie Janson, Astra Hässle, Sweden.)

future. In this way it will hopefully be possible to control the process by feedback reactions before severe deviations occur. Noninvasive techniques such as near-IR and ultrasonic methods provide interesting possibilities in this context.

Specifications and Quality Control (QC)

Specifications

The quality requirements of a substance in bulk and those of a pharmaceutical formulation are compiled

in specifications. In these documents the requirements on the various quality parameters are given as minimum or maximum limits or ranges. Formulations often have requirements on technical properties such as dissolution rate, disintegration and hardness for tablets. All those requirements are the result of comprehensive studies in the R&D phase, where the knowledge of the properties of the drug is gathered, resulting in the optimized formulation of the active component. The analytical and technical test methods that are linked to the specifications will have evolved during the R&D process and can, at the NDA stage, be transferred to QC laboratories.

Figure 3 Mass spectra of degraded B in Figure 2. Electrospray LC-MS was used with a 0.5 m fused silica capillary column, i.d. 250 μm . The packing material was 5 μm C-18 Chromasil and the mobile phase was 60% acetonitrile in 5 mmol L^{-1} ammonium acetate with a flow rate of 1.5 $\mu\text{L min}^{-1}$. The left-hand panel mass spectrum was obtained with the mobile phase consisting of water and the right-hand panel with the use of heavy water (deuterium oxide) instead. The mass number difference is due to nine hydrogen atoms exchanged with deuterium plus the ion charge H^+ being changed to D^+ . (With thanks to Karl-Erik Karlsson, Astra Hässle, Sweden.)

It is important to bear in mind that what is used in clinical trials should be reproduced in full-scale production. Of special importance is the particular batch, or so-called biobatch, which is studied *in vivo* and compared with *in vitro* properties as in dissolution testing to establish a correlation *in vivo* – *in vitro*. This batch is of critical importance for the future and its documentation has to be thorough. The bioavailability, as documented in the biobatch, is the foundation for the coming market presentation. Equally important are the substance batches used in safety studies, and requirements on the knowledge of their quality are very exacting. Also, there is a distinction between release and check specifications. The requirements at the release usually are somewhat tighter than those at a control performed any time during the entire lifetime of a medicine (check specification). In order to be aware at an early stage of deviations from the intended range of a quality parameter in a process the industry works with internal specifications that are tighter than the external ones.

Reference Substances

Most methods require some form of chemical reference substances (CRS), which have already been characterized in an IND more thoroughly than in normal specifications, for example, by adding thermo analytical data and spectrometric data for structural evidence, e.g. infrared, nuclear magnetic resonance and ultraviolet. Compendial methods have official CRS, which are available for customers all over the world. It is important to remember that a reference substance can be used for different purposes, not all of them requiring extensive testing. So a CRS for identity testing is less demanding from a purity point of view. For daily work a less expensive working standard can be calibrated vs. a CRS.

Quality Control (QC)

Full-scale production is checked in the QC laboratories according to the specifications and test methods approved by the authorities. Decisions by QC management cannot be overruled by any person in the organization, which puts a particular onus on the competence and judgement of the person in charge of QC. In addition to the chemical and biological tests that comprise QC the organization can introduce preventive measures to avoid quality impairment. This activity is defined as integrated or total QC and is further outlined in Good Manufacturing Practice (GMP) (see Regulatory Aspects). It cannot be emphasized enough that chemical control at the end of

a process can never replace high standards in the process itself. This is sometimes so evident that release in certain cases can be given based on the documentation and control in the process steps. This is called parametric release. Parametric release has been accepted by the authorities in those cases where end control does not fully reflect failures in the production. This has been most evident in many biotechnological processes, where the absence of host proteins, DNA residues or virus particles has been approved through a thorough validation procedure where the purification step is challenged. The analytical methodology is not adequate in this situation at the end control.

Process analytical chemistry may, in the near future, play a similar role in showing that a process does not run beyond prescribed limits. This not only gives better quality in products, but also fewer failures and thus reduced costs. Verification of identity is required at several stages during the process, not only at the end. This can be done in many ways and it is important to remember that the sum of the tests performed during a process also contributes to that verification. Biotechnological products are a special case in that the identity of the recombinant protein with that of the native one has to be established. Thus, it is important that the correct order of the sequence of amino acids is verified. Peptide mapping provides one way of showing this by comparing the chromatographic pattern of peptide fragments obtained after enzymatic cleavage. Capillary electrophoresis (CE) complements LC in this role. In this area there are new and interesting possibilities with mass spectrometric techniques that allow molecular ions to be determined up to and above 200 kDa.

Regulatory Aspects

Good Manufacturing Practice (GMP) was mentioned above and has been a cornerstone of pharmaceutical production and control since the 1970s. These regulations state clearly what has to be done to safeguard quality from the beginning of the production process to the end, viz. documentation, staff qualifications, standard of facilities, technical standards, handling of material, labelling, etc. Control guidelines are mentioned but not in the same detail as in Good Laboratory Practice (GLP). These rules state that all documentation of analytical methods should fulfil certain performance criteria, that instruments should have maintenance records and that their performance and those of the method should be documented. Every analyst should in principle document an analytical method and its aims.

Validation of Analytical Methods

Validation of an analytical method establishes in laboratory studies that the performance characteristics of the method meet the requirements for the intended application, thus the method does what it is expected to do. In the *United States Pharmacopeia (USP)* the following items are listed: precision, accuracy, limit of detection, limit of quantification, selectivity, range, linearity and ruggedness. Of these, accuracy is probably the most difficult to document or obtain, at least for solid formulations. This has to do with the fact that recovery experiments are difficult to design in such a way that they resemble the process conditions. The reactions there can create interactions which are not obtained in an experiment where the analyte has only been mixed or spiked to the sample.

Selectivity is another factor in the validation process that is much discussed. Many authorities require a selective method in a product release specification and mean that a chromatographic procedure has to be carried out even if a simple UV method is free from interferences. Here cost effectiveness should be the guide and analysts should therefore use their scientific arguments to justify using the simpler method. Validation procedures are equally important in the documentation of bioanalytical methods.

International harmonization Harmonization efforts are now being made at an international level. Of special importance is the possibility of having the same guidelines worldwide on how stability studies should be performed and reported. The same is true of guidelines on how to study impurities, especially where the limits should be set and at what level identification is needed. Similar efforts are seen for dissolution testing and how to correlate *in vivo* and *in vitro* data. The question of bioavailability and bioequivalence is an important one and a common view on these issues would be welcome, even if recommendations on how to perform a bioanalytical method will probably never appear in a pharmacopoeia. In recent years the interest in chiral drugs has increased and we can now also see an interest in harmonization for these compounds.

Emerging Techniques in Pharmaceutical Analysis

Analytical chemistry is one of the disciplines most frequently involved in the R&D work performed in the pharmaceutical industry. This makes the industry very analysis intensive, which explains the high level of interest in testing new methods in order to get further information. It is also clear that this interest in

Figure 4 Separation by LC and SFC of omeprazole and some related compounds. Conditions for LC: column 100 mm long and 4.6 mm i.d. filled with 3 μm C-18 (Chrompak Microsphere). Mobile phase: acetonitrile, 26%, in phosphate buffer 0.01 mol L⁻¹ and pH 7.4 containing tetrabutylammonium 1.0 mmol L⁻¹. Flow rate: 1.0 mL min⁻¹. Conditions for SFC: column 125 mm long and 4 mm i.d. with 5 μm Li Chrosorb NH₂. Mobile phase: carbon dioxide 2.0 mL min⁻¹ with methanol containing 1% triethylamine at 120 μL min⁻¹. Temperature: 40°C. Pressure: 175 bar. Test compounds: O = omeprazole (a sulfoxide); S = reduced form, a sulfide; SO₂ = oxidized form, a sulfone, and M = two isomers of *N*-methylated omeprazole (only separated by SFC). (With thanks to Mats Josefson, Astra Hässle, Sweden.)

learning, and using the latest techniques, stems from a desire to obtain reliable information more quickly, or to obtain complementary data.

The research process is a long-term commitment and requires high standards in the results from the very beginning. The quality of the results relies

on competent analytical chemists, but also on the availability of good instrumentation, which is often evident in the laboratories of the research intensive pharmaceutical industry. Separation techniques, especially LC, have had an enormous impact on pharmaceutical analysis. The combination of LC with MS has further extended the possibilities of the techniques as qualitative data can very often be obtained on-line. Can we foresee a similar development in years to come? The development of new techniques usually proceeds in a stepwise fashion and, at present, mass spectrometric techniques are taking a giant step towards the analysis of macromolecules in a reliable way. This revolutionary process has just begun to show promising results with relative molecular masses of more than 200 kDa being determined using time of flight drift tubes. Whether or not these instrumental possibilities can be combined on-line with separation methods, especially CE, remains to be seen. These MS extensions will have great impact on biotechnology products and macromolecular compounds used as excipients.

Another area where rapid development is taking place is Raman spectrometry. New technology has opened interesting possibilities for this old technique. Many opportunities lie ahead both in regular and in process analysis.

Separation methods will see continued growth, particularly the capillary techniques. Capillary chromatography is particularly useful when expensive mobile phases are used. A good example of LC-MS using packed fused silica columns 250 μm in diameter is given in Figure 3. Here heavy water was used interchangeably with an aqueous phase. Hydrogens bound to heteroatoms (O, N, S) were then replaced with deuterium, which was easily revealed in the mass spectrometer. This tells the analyst how many labile hydrogens the molecule has (in the case of the example this was 10). For macromolecules up to particles, the use of field flow fractionation (FFF) techniques can be expected to increase. Complementary information to LC will come from CE and supercritical-fluid chromatography (SFC). The latter technique will probably find a place in product analysis, especially in the packed column version, where polar compounds can be analysed. Packed column SFC is an interesting complement to LC, showing more rapid and efficient separations. An example is given in Figure 4, where omeprazole and some related compounds are separated. The sulfide form is eluted at about 25 min in LC, i.e. twice the retention in SFC. Capillary electrophoresis has recently become

a useful separation method in the pharmaceutical industry, not least for biotechnological applications.

Chemometric methods will have an impact on many types of technique, particularly in areas where properties which are not easily measurable (such as taste, texture, etc.) have to be correlated with physicochemical parameters. In this context, near-IR has started to gain prominence within the pharmaceutical industry. An example from the analysis of a number of cellulose ether samples with reflective near-IR is shown in Figure 5. The individual spectra do not show much in the way of differences. The spectra were corrected for different light penetration depths by multiplicative signal correction (MSC). Then the entire spectra were projected by principal components analysis (PCA) as points on a plane. The samples could be grouped into two clusters in this plane, one for each vendor. The calibration of this technique is entirely dependent on multivariate analysis or chemometrics and this combination will grow in use. In the same way process analytical chemistry is going to proceed based on multivariate data. Many noninvasive approaches rely on near-IR and multivariate calibration. New approaches combined with techniques that will stand harsh process conditions will also be introduced. Clearly, in the future new principles of measurement may also be necessary and the analytical chemist will have much to contribute here.

Crystallization

W. Beckmann and U. Budde, Schering AG,
Berlin, Germany

Copyright © 2000 Academic Press

Two decades ago, crystallization was called both an art and a science. However, the field is improving quickly. The crystallization of pharmaceuticals is still sometimes regarded an art and rather a mystery. However, crystallization processes are widely used throughout the production processes of the active ingredient of a drug product, and a lot of knowledge is nowadays available.

For the crystallization of drug substances several aspects have to be considered, as the crystallization process is the last step in the chemical manufacture of pharmaceuticals. The crystallization determines a number of important properties of the drug substance, namely the purity and residual solvent content, the polymorphic form, crystal size and size distribution, and it affects downstream processes such as drying, ease of comminution and formulation of the final drug product.

The crystallization of all drug intermediates have the same goals and follows the same procedures as for other organic substances and thus will not be discussed here separately.

General Considerations for the Development of the Crystallization Process

In general, the demands on the crystallization of a drug substance differ according to the final use, e.g. if the product is used in oral dosage forms, in ointments or in liquid formulations. However, for the sake of simplicity, it is assumed here that the crystallized drug substance is to be used in an oral dosage form.

Figure 1 shows a typical crystallization process of a drug substance and the downstream processes up to the formulation of the drug product. The crystallization and the properties of the product have a great influence on all the following steps.

Impurities

Foreign and related compounds The requirements on the purity of a drug substance are strict; guidelines require a purity of typically >98%. Individual impurities with a known structure have to be below 0.5% and unidentified impurities have to be below 0.1 or

0.05%. In addition, the toxicological effect of all impurities must have been assessed in the first toxicological tests, i.e. no new impurity is allowed that has not been present in the batch used for toxicological experiments.

The purification of a drug substance via crystallization cannot be predicted easily. While foreign impurities can mostly be easily reduced, related substances like impurities stemming from side reactions in the synthesis behave in an unpredictable way. In general, the purification via crystallization will decrease with an increase in the yield, especially if the yields are >90–95%.

Residual solvent content Beside obvious solvent properties such as a certain solubility for the drug substance and an appropriate purification to yield ratio, the choice of the solvent for the crystallization of a drug substance is governed by the permissible limitations placed on the residual solvent content of the drug substance. All typical solvents have been classified according to their toxicity and tolerated daily uptakes of a solvent have been established, that are not to be exceeded by the drug product.

Three classes of solvents are distinguished: (i) those that should be avoided; (ii) those that have a limit to their daily uptake; and (iii) those for which no limits have been set up so far. Examples are benzene and dichloroethane for class 1, methanol and dichloromethane for class 2 and ethanol, ethyl acetate and acetone for class 3. In addition, good manufacturing practice (GMP) requires the manufacturer to limit the residual solvent to the lowest content possible.

Figure 1 Typical crystallization and downstream processes up to formulation.

Table 1 Productivity, yield and development prerequisites for the separation of isomers via crystallization, enzymatic resolution and chromatography

Parameter	Crystallization	Enzymatic resolution	Chromatography
Productivity	High	Low	Medium
Selectivity	Varies	High	Very high
Prerequisite	High	High	Low
Development time	High	High	Low to medium

Two types of limits for the residual solvent content of a drug are distinguished. Case 1 is a dosage-independent concentration limit and Case 2 is a limit for the total uptake through the drug product, that must not be exceeded by the solvent content of the drug substance and the excipients.

The mechanisms of incorporation of solvent into the crystals can be described as follows:

- The solvent is incorporated into the lattice at fixed positions during the crystallization (solvate formation). In this case, the incorporation cannot be avoided directly. In some cases, a solvent of crystallization is removed or replaced by water.
- The solvent is incorporated into the lattice as three-dimensional inclusions. The formation of inclusions is facilitated by the speed of crystallization, thus, the amount of residual solvent can be decreased by lowering the rate of crystallization. For some systems, the tendency to form three-dimensional inclusions of solvent increases with the crystal size.

If a problem with the residual solvent content of a drug arises, the clear remedy is a change of solvent.

Separation of isomers An increasing number of pharmaceutical active ingredients are either isomers or enantiomers. Typically, different isomers of a chemical compound exhibit different biological or

therapeutic activities, with one of the isomers being the carrier of the activity. In some cases, the second isomer can even have an adverse biological activity. In any case, the inactive isomer constitutes an unnecessary load to the body. Thus, a separation of isomers is almost a prerequisite for the production of a drug.

Isomers can be separated by enzymatic resolution, chromatography or crystallization. **Table 1** summarizes and compares productivity, yield and development prerequisites of the three separation techniques.

The success (or possibility) of the separation of isomers via crystallization depends on the phase diagram of the two compounds.

Figure 2 shows typical phase diagrams of isomers, i.e. eutectics, solid solutions and partial solubility in the solid state. A separation of isomers in a single step is only feasible for eutectic systems. Systems forming solid solutions have to be purified in multiple steps, as for example in zone refining which is only feasible if the substance is stable in the molten state. For systems exhibiting partial miscibility in the solid state, the separation cannot be better than the partial miscibility concentrations.

In principle, isomers forming eutectics can be separated directly via crystallization. However, without using special techniques, the crystallization can only be carried out until the concentration of the mother liquor has reached the composition of the eutectic mixture. To improve the yield two ways are often pursued:

**Figure 2** Typical phase diagrams for isomers: eutectics, complete miscibility in the solid state and partial miscibility in the solid.

- Forming diastereomeric salt derivatives of the isomer will often direct the eutectic composition towards one of the isomers. This will increase the yield and productivity of the crystallization process considerably.
- The desired isomer is enriched via preparative HPLC followed by crystallization. The chromatographic technique achieves a high degree of enrichment but the amount of solvent to be handled is considerable. Crystallization is carried out at high concentrations and thus more effectively. Attempts have been made to find the optimal cost effective division between the separation via preparative HPLC and crystallization.

Solid-State Forms

Polymorphism Before a crystallization process is developed, the solid-state polymorphism of the substance has to be elucidated. Less than 50% of the drug substances described in monographs crystallize in a single polymorphic form; the majority form polymorphs, pseudomorphs, or both. The polymorphic form of a drug can influence a number of its properties such as the following:

- The solubility and the dissolution rate and consequently the bioavailability. Although typical differences in solubility between polymorphs are of the order of ≤ 2 , the differences in solubility between pseudomorphs are somewhat higher. The largest differences exist between amorphous and crystalline material.
- The habit (the external appearance) of the crystals which in turn influences the mechanical properties of the drug during further processing such as the ease of comminution.
- The chemical stability.

Thus the regulatory agencies ask for the reproducible production of the specified polymorphic form. In the case that a drug can form more than one polymorph, a choice of the polymorphic form must be made.

Amorphous compounds Amorphous solids are a metastable form of the drug substance that can crystallize at any instant. In this respect, an amorphous form can only be second choice as solid-state form for a drug substance.

The stability of amorphous material can be characterized by its glass-transition temperature T_g , which can be determined by differential scanning calorimetry (DSC). Below the glass-transition temperature, the molecules are practically frozen; above it they have a finite mobility making the conversion into a crystalline form possible.

The glass-transition temperature and thus the stability of amorphous materials can be decreased by residual solvent.

Salts A number of properties of the chemical compound can call for the use of a salt as the drug substance. An insufficient chemical stability of the parent compound can be overcome by the formation of a salt, e.g. amines sensitive to oxidation can be stabilized by forming a hydrochloride. Other properties calling for salt formation include low melting points or unfavourable solid-state properties such as a tendency to form amorphous material or too many polymorphs.

Finally, in case of an insufficient solubility in water or gastro-enteric fluids it is sometimes tried to avoid this problem by the formation of salts.

Salts of sparingly-soluble parent compounds can lead to the precipitation of the parent compound when the salt is dissolved in water. This poses considerable problems if it occurs during formulation like wet granulation.

Salts are typically formed by precipitation or reaction crystallization, i.e. by adding an acid or a base to a solution of the drug substance. Of course, each salt constitutes a new drug substance, that has to be treated accordingly as a new chemical entity.

Clathrates Chemical instability of parent compounds can also be overcome by the formation of clathrates typically of α -, β - or γ -cyclodextrin. The parent molecule partially enters the large voids of the cyclodextrin (see Figure 3). It is thus shielded from the environment, especially the excipients.

The clathrate is typically formed by precipitation i.e. by adding the parent compound dissolved in a water-miscible organic solvent to an aqueous solution of the cyclodextrin.

Choice of solid-state form The selection of the optimal solid-state form is an important step in the

Figure 3 Schematic picture of the clathrate formation of a steroid by two β -cyclodextrin molecules.

Figure 4 Properties of the different solid-state forms of a drug to be considered when choosing the optimum form to be used in the final product.

development of the crystallization process of a drug. The form, once decided upon, has to be used in all relevant clinical and pharmaceutical tests and it must be certain that this form can be crystallized in a reproducible way, and that it can be formulated into the drug product.

A number of basic physico-chemical and pharmaceutical properties of the different forms that are considered for selection are listed in **Figure 4**, and can be tested and used in the process of decision making.

A drug substance that occurs only in a single polymorphic form is preferred; if not available, the stable polymorph is preferred. The techniques to infer the relative stability of polymorphs include solubility measurements, storage in suspensions and DSC experiments to construct enthalpy–temperature diagrams.

Crystal size and habit

Crystal size and habit of a drug can vary considerably. Thin needles, platelets and rhombohedral crystals are found. The crystal habit can influence all processes after crystallization

- during work-up, the de-watering in the centrifuge, the washing of the filter cake and the drying are affected;
- in the formulation, behaviour during micronization or flow during direct tableting are affected.

Micrographs of the drug substance and crystal size distributions can help in understanding the behaviour of the product crystallized under different conditions.

Habit The external appearance of crystals is called habit. The crystal habit can be influenced by the growth conditions. For example, crystals of the A modification of Abecarnil, a β -carboline derivative, grown after spontaneous nucleation at high supersaturations exhibit an avicular habit, while those grown at moderate supersaturations after seeding are still needle like but thicker and more rod-like (**Figure 5**).

Other factors determining the crystal habit are the solvent and the impurity profile of the material to be crystallized. The impurity level that influences the habit – and other properties – can be as low as ppm. **Figure 6** shows the habits of a steroid crystallized from two different solvents, one more protic (solvent I) and the other more aprotic (solvent II). Of course, the different habits lead to a different behaviour in downstream processing.

Crystal size distribution For the formulation of oral dosage forms, the desired crystal size distribution is

Figure 5 (See Colour Plate 111) Habit of Abecarnil grown from methanol after spontaneous nucleation at relatively high supersaturations (left) and grown at moderately low supersaturations after the addition of seeds (right).

Figure 6 (See Colour Plate 112) Habit of a steroid crystallized from two different solvents.

mainly imposed by the demands for blend and content uniformity. For low-dosage formulations, such as steroids in contraceptives, the maximum crystal size is $\leq 10 \mu\text{m}$. These crystal sizes cannot be attained via classical crystallization techniques. Thus, the standard procedure is crystallization and drying followed by a comminution, e.g. via jet-milling. It has been reported that the milling process is also dependent on the crystal size and the homogeneity of the crystal size to ensure a homogeneous milling process.

The size distribution obtained in a jet mill is decisively determined by the cut size of the cyclone of the mill. When the drug substance is to be used without comminution, the crystal size distribution will typically be broader. Small crystals, $\leq 10\text{--}100 \mu\text{m}$, can only be achieved via precipitation, larger crystals by evaporative or cooling crystallization. If large crystals are desired, the best way to control the process is via seeding. Here, care must be taken not to destroy the crystals during the crystallization process through the power input of the stirrer or during work-up, especially in agitation dryers.

Care must be taken to avoid agglomeration during crystallization and drying, as this process is erratic and in precipitation processes agglomeration is almost unavoidable. For the formulation of liquid dosage forms, the dissolution rate can limit the permissible crystal size, although the requirements are not really strict.

Development of the Crystallization Process

In most cases, a drug substance will be crystallized from solution in a batch process. The techniques most often employed are cooling, evaporative, drowning-out and reaction crystallizations. Glass-lined as well as stainless-steel vessels are used. These classical crys-

tallization techniques and their implications will be discussed in detail. Certain properties of the drug substance may call for a crystallization from the melt, via spray drying or through the use of novel techniques for particle formation. These techniques will be discussed more briefly later.

Laboratory Development of Crystallization Technique

Supersaturation, nucleation and growth The crystallization involves two basic steps, nucleation and growth. The driving force for both processes is the relative supersaturation, typically defined as $\sigma = \Delta c / c_{\text{sat}}$, where $\Delta c = c - c_{\text{sat}}$, the difference between the actual concentration c and the saturation concentration c_{sat} . Depending on the magnitude of the supersaturation, at which the nucleation occurs, nucleation and growth will have different importance:

- at high supersaturation, nucleation will be the dominant process, the number of nuclei formed is large so that the increase in size via growth and thus the particles found are small;
- at low supersaturation, the number of nuclei is small so that growth dominates and coarse crystals will be obtained.

The first process is usually called precipitation, the second one crystallization. In both processes, nucleation can either be deliberate by seeding or involuntary by primary, spontaneous nucleation. As far as spontaneous nucleation concerned, heterogeneous nucleation by foreign particles in the solution will dominate. In case of easily or moderately soluble substances secondary nucleation caused by addition of the parent crystals in general dominates the nucleation process, once crystals of a sufficiently large size are present.

Figure 7 Typical solubility and metastability curves for a drug substance.

Solubility and metastability Two basic pieces of information on the system are necessary for a successful development of a crystallization process, the solubility curve and degree a solution can be supersaturated before spontaneous nucleation occurs.

The solubility defines the equilibrium state of the substance dissolved in the mother liquor, and the metastable zone is a concentration region, where a supersaturated mother phase can exist for a certain period of time without spontaneous nucleation. This latter region has typically a width of the order of 10°C and owing to the relatively large metastable zone, the amount of material coming out of solution under spontaneous nucleation without further cooling can be of the order of 10–30% of the entire mass, which is a considerable value. **Figure 7** shows typical solubility curves and metastable lines. The left-hand system lends itself to cooling crystallization, the right hand one to an evaporative crystallization because of the slope of the solubility curve.

For a drowning-out crystallization, a primary solvent in which the drug substance has a high solubility and a secondary, or anti-solvent, which has a negligible solubility are needed. **Figure 8** shows three typical curves for the mixing.

If the solubility has a concave curvature, i.e. the secondary solvent acts as an anti-solvent a drowning-out crystallization is feasible as shown in curve B. For curves A and C, crystallization by addition of an anti-solvent is not possible.

For precipitation by mixing of reactants or the formation of salts, the solubility is given by the solubility product, i.e. $a + b \rightarrow \text{product} \downarrow$ and $K = [a][b]$ (**Figure 9**).

For moderate formation constants, the solubility at $[a] = [b]$ is quite low. This implies high to very high supersaturations upon mixing, which can lead to small or very small crystals, which in turn can cause

problems in downstream processes, $\sigma = \Delta c/c_{\text{eq}}$. If c_{eq} is very low, σ will become very high. But this on its own has nothing directly to do with small crystals. Small crystals result from the lack of growth limits in the solution (even at high σ values). Apart from that abundant nucleation also leads to small crystals, but this is also true for easily soluble compounds.

Influence of impurity and purity of material An often underestimated effect is caused by changes that may be made during the lifetime of the synthesis and its implications for the crystallization process. Variations in the impurity profile can influence both the width of the metastable zone and thus the degree of supersaturation at which spontaneous nucleation occurs, and the polymorph obtained during via spontaneous nucleation. It can also influence the rate of polymorphic transformation during work-up and the habit and crystal size. Although the effects of a changing impurity level on the behaviour of a drug substance are difficult to anticipate during the first stages of development, there is a need for a careful investigation of these effects.

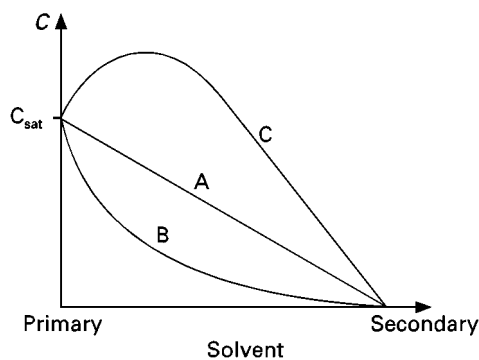

Figure 8 Typical solubility curves for a drug substance in a mixture of a primary and a secondary solvent.

Figure 9 Solubility for a ionic reaction crystallization such as the formation of the salt. The supersaturation at moderate formation constants reaches a high value.

Choice of solvent and of the crystallization technique The choice of solvent for the crystallization of a drug substance is governed by (i) the need to use a Class 3 or Class 2 solvent and (ii) a solvent that does not interact with the drug substance. These considerations limit the solvents allowed to very few, preferably such as ethanol, ethyl acetate and water.

A cooling crystallization is the first choice, if the temperature dependence of the solubility permits it. It is the most straightforward technique for the crystallization, as the temperature, is easily controlled. In most cases, the temperature dependence will be such, that >90–95% of the material dissolved will crystallize upon cooling from a temperature close to the boiling point down to ambient temperatures. Final temperatures down to -10°C can easily be handled; lower temperatures may significantly increase production costs.

If the solubility changes only gradually with temperature, evaporative crystallization, either at ambient or at reduced pressure may be chosen. To increase yield it is often followed by a cooling step.

If the solubility of the drug in the organic solvent is high, and if the solvent cannot be changed and it is

miscible with water, anti-solvent precipitation with water can be used. Since a drowning-out crystallization leads to solvent mixtures that have to be treated afterwards, this technique should be avoided when possible.

Rate of crystallization The rate of crystallization should not exceed values that cause too much uptake of solvent via inclusions. For a cooling crystallization, natural cooling profiles should be avoided, as most of the material crystallizes too fast. Linear cooling rates are a first approximation. The rates can be classified as slow, realistic, fast and crash cooling for rates of < 5 , < 10 , < 15 and $> 15^{\circ}\text{C h}^{-1}$, respectively.

Instead of linear rates, a controlled rate of crystallization should be used where possible; this is especially important for drowning-out crystallizations, for neutralization reaction crystallizations or for the formation of salts. In these cases, even a moderate dosage of the anti-solvent or the acid or base can lead to very high supersaturation which in turn can cause the formation of oils or amorphous material. Often most of the yield is produced during the addition of the first amount of the secondary solvent.

Thus either a very slow dosing or when exactly stepwise dosing with time interval between are appropriate tools to avoid too high supersaturation and the adverse effects usually observed for nucleation and growth at high supersaturation.

At the point of addition, high local supersaturation is generated so that mixing has to be optimized (see **Figure 10**).

Programmes for cooling, evaporative and drowning-out crystallization are derived by requiring the crystallization to proceed with a constant rate of deposition of mass or with a constant linear growth rate. **Figure 11** presents curves for a drug substance having a temperature dependence of the solubility of 40 kJ mol^{-1} . The solubility decreases by a factor of 10 with a change in temperature from 70 to 20°C . However, the calculations yield only the profile, the absolute times are not given.

Figure 10 Mixing schemes for precipitation. Dosing of the anti-solvent into the primary solvent (left) is to be avoided. A parallel dosing of both solutions (middle) is better and even better is a dilution scheme (right).

Figure 11 Suggestion for a cooling programme for a drug having a high solubility dependence on temperature. The lower curve is for a constant flux of mass, the upper for a constant rate of crystallization. —○— Constant growth rate; --- Constant flux of mass.

Seeding is more likely to succeed for cooling and evaporative crystallizations but rather difficult in drowning-out crystallizations, or in precipitation because these processes are dominated by primary nucleation around the inlets that can hardly be avoided.

Scale-up Crystallization parameters arrived at in the laboratory have to be scaled up for production and this must always be borne in mind. In the laboratory, typically glassware or small crystallization vessels are used. In production, vessels are either glass or glass lined, or are made of stainless steel. The vessels are equipped with a cooling/heating jacket and a distillation device. Stirrers are normally impellers or of the anchor type. Few vessels are baffled, the only device acting in this respect is often the temperature probe.

The scale-up factors from laboratory to production are in the order of $100\text{ mL}^{-1}\text{ L}$ to several 100 L or 1000 L, factors considered high for crystallization operations. The stirrer action can be scaled up using either constant tip velocity or constant power input, as is the case for all crystallization operations.

A problem often encountered in production but seldom in the laboratory is the formation of encrustation during distillation. This is to be avoided, as it can create hot spots and can act as a source of seeds. In this case, the outcome of the crystallization is entirely unpredictable. Encrustations during distillations can be avoided using reflux schemes.

Work-up The classical procedure for the work-up of the crystallized drug substance is centrifugation and washing followed by drying on a tray dryer. This procedure involves a number of transfer steps, where the product can be contaminated or where the product can contaminate the environment.

The number of transfer steps can be minimized by using the filter type dryer shown in **Figure 12**. The device is used for the solid-liquid separation, washing and finally drying. The heat is transferred both through the outer wall and the stirrer. The stirrer facilitates the washing and the drying. However, if this stirrer is used inappropriately, it can act as a milling device and can generate fines down to $<10\ \mu\text{m}$.

Other Crystallization Techniques

Direct contact cooling (DCC) In the direct contact cooling (DCC) process a solution of the drug substance in a primary solvent at a temperature close to saturation is mixed with a liquid coolant, rapidly creating supersaturation, consequently followed by crystallization of the drug substance. Coolants include immiscible as well as miscible liquids and liquidified gases. Recently, solid CO_2 at -60°C has been used as coolant. Coolants that are gaseous under ambient conditions offer the advantage that they can easily be separated from the mother liquor. Depending on the heat capacities and the ratio of mixing very high supersaturations and thus fine particles can be obtained. **Figure 13** shows a SEM micrograph of Abecarnil crystallized by using solid CO_2 coolant.

Spray drying In spray drying, a solution of the drug substance in an appropriate solvent is sprayed into

Figure 12 Schematic drawing of a filter dryer, in the states (i) solid-liquid separation, (ii) washing and (iii) drying. The heating is via both the surface of the dryer and the stirrer and (iv) product discharge.

Figure 13 SEM image of Abecarnil obtained by using solid CO₂ as direct contact coolant.

a hot stream of gas that carries the heat both for the evaporation of the solvent and the drying of the product. Although the temperature of the gas stream lies between 200 and 300°C, the maximum temperature that the drug substance is exposed to is close to or less than the boiling point of the solvent. The short residence times also limit the thermal stress.

The particle size attained through spray drying is of the order of micrometres. The habit of the particles obtained strongly depends on the system, typical particle shapes are shown in **Figure 14**. The left micrograph shows well-defined spherical particles, that are fully separated. The right micrograph shows felted needles obtained with a different substance.

Figure 14 (See Colour Plate 113) Shape of particles obtained via spray drying. The left micrograph shows well-separated spherical particles typically obtained. Note the indentations on one side. The right micrograph shows felted needles that are in addition interwoven. Both products are fully crystalline.

In most cases, spray drying will be from organic solvents. In these cases, safety against explosions can be achieved either by keeping the amount of solvent in the stream of air below the explosive limit or by using nitrogen as an inert drying gas.

The solid-state form obtained can be amorphous or crystalline depending on the substance and the drying conditions. The fast evaporation of the solvent can lead to amorphous material. However, if the glass transition temperature of the drug substance is less or equal to the temperature regime in the dryer, a transformation into a crystalline product may occur. This transformation may be facilitated by residual amounts of solvent.

Melt crystallization Melt crystallization techniques are rarely applied for the crystallization of drug substances, as many have a high melting point, typically $\geq 150^\circ\text{C}$, a temperature at which these compounds have a tendency to become unstable if exposed to these temperatures for prolonged periods of time.

Techniques of particle formation The requirement to produce small particles of a drug substance has led to the development of alternative processes of particle formation via a precipitation technique. These processes are as follows:

- RESS: the Rapid Expansion of Solutions of the drug in Supercritical CO₂, or other fluids. This technique is hampered by the low solubility of most drug substances in supercritical fluids. Although modifiers can increase the solubility, they have to be removed effectively to prevent agglomeration or ripening.

- PCA: the precipitation of the drug substance from a solution in a primary solvent with the aid of a Compressed Anti-solvent, namely CO₂.
- SEDS: Supercritical solution Enhanced Dispersion of Solutions. A solution of the drug in a primary solvent is mixed in a nozzle with a stream of supercritical CO₂ that acts both as dispersant and anti-solvent. The particles form immediately and are collected on filter plates. This technique offers a number of very intriguing advantages such as very small particle size, very low residual solvent contents, or a low surface charge of the particles facilitating the formulation process.

It has been reported, that proteins or peptides crystallized via this technique fully retain their biological activity.

With these processes, crystal sizes down to and below 1 µm can be attained. So far, all these processes work in batch mode with small batch sizes, although attempts are being made to increase the batch size.

The particle formation, nucleation and growth, in all three techniques is rapid. Information on the nucleation and growth process are only emerging and more work needs to be done. Due to the nucleation and growth under very high supersaturations, the polymorphic form obtained might not be the stable one.

Introduction

Although the general topic of the high performance liquid chromatographic (HPLC) analysis of neutral and acid drugs encompasses a broad range of com-

pounds that include antibacterial agents to vitamin supplements, many of the more common acid compounds are therapeutically active as analgesics, antipyretics, and antiinflammatories (e.g., aspirin, diclofenac, flurbiprofen, ibuprofen, indomethacin, ketoprofen, meclofenamic acid, mefenamic acid, naproxen, tolmetin and other compounds shown in Table 1). In many cases, this group of compounds are relatively small molecules and are structurally simple, containing only one or two aromatic rings and a single ionizable carboxyl group. Many of the common

Table 1 Recently published HPLC methodology for common acid drugs

Analyte	Procedure
General	<p>The simultaneous analysis of twelve common nonsteroidal antiinflammatory drugs has been carried out by reversed-phase chromatography on a C18 column using acetonitrile–phosphate buffer as the eluent and detection at either 230 or 320 nm. The method has been used to evaluate the level of the analytes in human urine samples [5].</p> <p>A fully automated on-line dialysis sample preparation procedure has been developed for assaying several nonsteroidal antiinflammatories in human plasma. In addition different strategies for improving analyte loss due to drug–protein binding are discussed [6].</p> <p>A systematic investigation of the enantioselective separation of 28 α-alkylarylcarboxylic acids on an amylose tris(3,5-dimethylphenylcarbamate) chiral station phase has been carried out and the resulting retention data correlated to a series of molecular descriptors [7].</p> <p>A [2.2.2]-bicyclooctane-based stationary has been developed for the chiral resolution of various profen enantiomers which functions via combination of hydrogen bonding, π-π face-to-face stacking, π-π face-to-edge interactions [8].</p>
Aspirin	<p>A high performance liquid chromatographic (HPLC) method has been developed for the simultaneous determination of aspirin and salicylic acid in transdermal perfusates. The compounds are separated on a C8 column 65 : 35 water–acetonitrile containing 0.2% phosphoric acid. For certain samples, a gradient was introduced by increasing the acetonitrile content of the mobile phase after the salicylic acid had eluted [9].</p> <p>Aspirin and salicylic acid have been determined in skin and plasma samples by an isocratic reversed-phase method that uses a C18 column and 75 : 25 pH 2.5 phosphate buffer–acetonitrile as the eluent [10].</p> <p>Gradient elution reversed-phase methods have been developed for measuring aspirin and warfarin in combination tablet formulations and in the presence of potentially related impurities that uses a C8 column operated at 40°C. In the first instance the starting conditions, which are maintained for 11 minutes, are 68 : 17 : 15 water adjusted to pH 2.6 with formic acid–methanol–acetonitrile. This is followed by a linear gradient over 15 minutes to 56 : 17 : 27 of the respective solvents and a hold time of an additional 38 minutes. When assaying for possible related substances, a second gradient step is used to 13 : 17 : 70 [11].</p> <p>An isocratic reversed-phase assay has been reported for measuring aspirin, salicylic acid, and warfarin sodium. The separations are carried out on a C18 column using 23 : 5 : 5 : 67 acetonitrile–tetrahydrofuran–glacial acetic acid–water as the eluent with UV detection at 282 nm. The method has been used to study tablet dissolution [12].</p> <p>An alternate isocratic reversed-phase method has been developed for measuring the analyte in model solution aerosols. It uses a C8 column with 44 : 5 : 5 methanol–THF–1 M phosphoric acid qs to 100 with water as the eluent and UV detection at 275 [13].</p>
Diclofenac	<p>An isocratic reversed-phase method has been reported for measuring the analyte and flurbiprofen in plasma. It uses a C18 column and 35 : 65 acetonitrile–0.1 M sodium acetate adjusted to pH 6.3 with glacial acetic acid as the eluent and detection at 278 nm [14].</p> <p>The analyte has been detected fluorometrically as its photodecomposition product, carbazole-1 acetic acid, after on-line post column UV irradiation. Excitation and emission wavelengths of 286 nm and 360 nm are used respectively. The photoderivative is formed via loss of both chlorine substituents and ring closure [15].</p> <p>Solid-phase extraction in combination with isocratic reversed-phase chromatography has been used to measure the analyte as well as indomethacin and phenylbutazone in human urine. The separations were performed on a C18 column using 42 : 58 acetonitrile–10 mM pH 4 acetate buffer as the eluent and detection at 210 nm [16].</p> <p>The analyte has been assayed in the presence of oxybuprocaine in human aqueous humor by reversed-phase HPLC-EC using a C8 column coated with a hydrophilic polyoxyethylenepolymer. The detection limit for the analyte is 500 pg [17].</p> <p>Pharmaceutical formulations containing the analyte, cyanocobalamin, and betamethasone have been assayed on a C18 column operated at 34°C employing 60 : 40 acetonitrile–water adjusted to pH 3.45 with acetic acid as the eluent and detection at 240 nm [18].</p> <p>See general methodology above [5].</p>
Felbinac	See general methodology above [5].
Fenbufen	See general methodology above [5].
Fenoprofen	See general methodology above [6].

Table 1 *Continued*

Analyte	Procedure
Flurbiprofen	See general [5,6] and diclofenac [14] methodology above.
Ibuprofen	<p>A reversed-phase method has been developed for studying the analyte and five metabolites that uses a 1.5 mm i.d. semi-microcolumn and a linear gradient over 70 minutes from 2:98 acetonitrile–phosphate buffer (pH 2.5 0.05 M) to 60:40 of the respective components. Both UV and EC detection were used to obtain information about glucuronation [19].</p> <p>The analyte has been assayed in erythrocytes and plasma by an isocratic reversed-phase procedure following its liquid–liquid extraction with methylene chloride. The separation is carried out on a C18 column with 22:10 methanol–water acidified with perchloric acid to pH 3 as the eluent and UV detection at 222 nm [20].</p> <p>Two cellulose-based chiral phases (Chiralcel OD and Chiralcel OJ) have been evaluated for their ability to resolve various aliphatic ibuprofen esters and the latter material in combination with nonaqueous eluents provided effective resolution of most of the esters [21].</p> <p>The retention properties of a molecularly imprinted 4-vinylpyridine/ethylene glycol dimethacrylate polymer for (S)-ibuprofen have been evaluated using aqueous eluents. The novel packing, which is prepared via a multi-step swelling and thermal polymerization method, also has been used to partially resolve the enantiomers of ibuprofen metabolites, 2-hydroxy- and 2-carboxyibuprofen [22].</p> <p>Both zonal elution and high-performance affinity techniques have been used to characterize the interaction of enantiomers of ibuprofen with immobilized human serum albumin [23].</p> <p>The stereo specific analysis of two major metabolites of ibuprofen (hydroxyibuprofen and carboxyibuprofen) in urine has been carried out using a sequential achiral–chiral HPLC approach. The achiral separation was carried out under normal-phase conditions using a silica column and 98.2:1.8 hexane–ethanol with 0.05% trifluoroacetic acid (THF) as the eluent. The fraction containing the two metabolites is collected, evaporated to dryness, and redissolved in 92:8 hexane–ethanol with 0.05% THF (i.e. the chiral eluent). Subsequently, the chiral separation is performed on a Chiralpak AD CSP column [24].</p> <p>A method has been reported for simultaneously determining the four major metabolites of the analyte in biological fluids. It uses a silica column and N-cetyl-N,N,N-trimethylammonium hydroxide dissolved in the eluent to dynamically modify it [25].</p> <p>A column-switching system has been developed for measuring ibuprofen directly in plasma that employs three sequential separation steps: (1) the deproteinization and fractionation of 100 mL plasma samples with a polymer-coated mixed-function phase column, (2) concentration with an intermediate column, and (3) a final analytical separation. The reported dynamic range for the analyte is 0.1–250 mg mL⁻¹ with intra-day and inter-day variation of less than 5.6% and 6.5% respectively and a detection limit of 25 ng mL⁻¹ [26].</p> <p>See general methodology above [5,6].</p>
Indomethacin	<p>The analyte has been assayed in plasma samples on a C18 column operated at 50°C in combination with 50:50 acetonitrile–6 mM phosphoric acid as the eluent and detection at 205 nm [27].</p> <p>A study has been carried out to examine the loss of the analyte as well as ibuprofen and flufenamic acid in valve injectors for samples in non-eluting solvents [28]. Likewise, the assessment of injection volume limits when using on-column focusing with microbore LC has been evaluated [29].</p> <p>See general methodology [5] as well as methodology for diclofenac [16] above.</p>
Ketoprofen	<p>An isocratic method has been developed for measuring the analyte in tissue samples following a two-step extraction procedure which involves an initial extraction into methylene chloride and back extraction following acidification with HCl into 95:5 isooctane–isopropanol. Subsequently, HPLC separation is carried out on a C18 column using 43:57 acetonitrile–water containing 0.1% glacial acetic acid and 0.03% triethylamine [30].</p> <p>Zonal elution in combination with a novel mathematical approach has been used to characterize the mechanisms involved in the stereoselective binding of ketoprofen enantiomers to immobilized human serum albumin [31].</p> <p>A stereospecific HPLC assay has been reported for the analyte in human plasma and urine that employs an amylose carbamate column and 80:20 hexane–isopropanol with 0.1% trifluoroacetic acid as the eluent [32].</p> <p>See general methodology above [5,6].</p>
Loxoprofen	See general methodology above [5].
Mefenamic acid	See general methodology above [5].

Analyte	Procedure
Naproxen	Recently uniform-sized molecularly imprinted polymers for (S)-naproxen have been prepared using 4-vinylpyridine and ethylene glycol dimethacrylate as functional monomer and cross-linker respectively [33]. Subsequently, this material was modified further with a hydrophilic external layer via treating it with a 1 : 1 mixture of glycerol monomethacrylate and glycerol dimethacrylate. Likewise, molecularly imprinted polymers for the analyte have been prepared using 4-vinylpyridine and ethylenedimethacrylate [34]. In this latter study two different polymerization approaches were tested and materials prepared by the thermal route were found to have better chiral selectivity. See general methodology above [5,6].
Piroxicam	See general methodology above [5].
Sulindac	See general methodology above [5].

profens and compounds like ibuprofen and xenbucin fit this general description as illustrated in **Figure 1**. However in some cases, with compounds such as indomethacin, caprofen, tolmetin, and zomepirac, additional functional groups are present which influence the chemical equilibria of the solutes and hence make generalization about separation conditions more difficult.

The most common of the non-steroidal analgesic/anti-inflammatories is aspirin, which is sold throughout the world as an over-the-counter (OTC) product and in combination with other non-acid analgesics as well as various other cough-cold agents. However in more recent years, compounds like ketoprofen and ibuprofen, which were first introduced as prescription products for the treatment of arthritis and related inflammatory disorders, are now available in OTC dosage forms and popular for their analgesic properties. When considered as a group, the number of pharmaceutically important acid analgesics/antiinflammatories is relatively small, but because of their widespread therapeutic usage, hundreds of assay procedures have been reported for these compounds, many of which are HPLC based.

In terms of the neutral drugs, perhaps the most common of these are hormones/steroids, certain vitamins (e.g. A, D and E), the pharmaceutical co-additives (e.g. alkyl parabens), and other miscellaneous compounds like the anticoagulant, warfarin, the coronary vasodilator, visnadine, and the antineoplastic agent, carubicin. Some of the more common examples of non-ionizable pharmaceutically active compounds are listed in **Tables 2** and **3** along with the accompanying analytical methodology that has appeared more recently. A number of these have been assayed by HPLC in combination with either mass spectrometry or an alternate detection technique to more commonly used UV monitoring. Also, unlike ionizable drugs that typically require buffers to obtain sufficient solute phase interaction, the neutral

drugs are often separated using neat binary hydroorganic eluents in combination with either a C8 or C18 stationary phase. However, unlike the acid drugs, which contain at least one aromatic ring and are easily detectable using standard UV monitoring at 254 nm, a large number of them (i.e. the steroids) contain only a carbonyl group(s) (λ_{max} about 210 nm) and are less favourably detectable by UV monitoring.

Because of the very large number of HPLC procedures that have appeared for neutral and acid drugs, as well as for the related metabolites and degradation products of these, it is not possible to do an extensive review of them in the space limitations of the current chapter. Rather, a more general discussion of important principles and strategies in developing HPLC methods is presented, accompanied by representative analytical procedures for a number of the more important compounds that have appeared in the recent literature. However, for additional information the reader is referred to the comprehensive biennial reviews, *Pharmaceutical and Related Drugs*, that have appeared in *Analytical Chemistry*.

General Trends and Considerations

Over the last three decades HPLC-based methods have become increasingly popular and currently are the most widely used procedures for assaying pharmaceutical compounds. Their growing acceptance has resulted from the inherent versatility and reliability of the methodology, improvements in hardware, and ease of use and automation. Likewise, fundamental sample considerations such as thermal instability, low volatility, and matrix complexity have been important contributing factors.

The selection of the appropriate separation mode is dependent on the solubility and size of the analyte. Since most of the acid and neutral drugs are relatively small analytes that can be dissolved in either water or hydroorganic solvents, and are either neutral or their

Figure 1 Examples of some common acid drugs.

chemical equilibria can be favourably controlled, reversed-phase (RP) procedures dominate the literature. However, in cases where structural differences are small (e.g. certain steroids, closely related impurities, or degradation products that result in only very minor changes to the analyte hydrophobicity) normal-phase conditions may provide better selectivity. In addition, if the intended application is to measure the level of a single active ingredient and to assure that it is

within acceptable standards during manufacture of the formulated product, then simplicity, reliability, speed, and cost become important factors in selecting the overall approach. Typically in this situation, assays based on the use of isocratic eluents are more effective than those based on gradient elution conditions since they are easier to carry out by the less trained practitioner. Alternatively, if the analytical problem involves more complex samples or less

Table 2 Recently published HPLC methodology for steroids

Analyte	Procedure
General	<p>Several reversed-phase HPLC methods have been developed for assaying a variety of corticoid alcohols and their corresponding esters and acetals derivatives. All are carried out with a C18 column in combination with several aqueous–acetonitrile eluents, either deoxycorticosterone or methylprednisolone as internal standards, and UV detection. In addition to the parent analytes studied (i.e. fluorocortisone and fluorocortisone acetate, triamcinolone and triamcinolone acetonide, dexamethasone and dexamethasone phosphate, 21-hydroxydeflazocort and deflazacort, betamethasone and betamethasone valerate), the methods have been used to examine the hydrolysis of the analytes in aqueous media at different pH and temperature conditions [35].</p> <p>Several conjugated and unconjugated estrogens and related impurities have been assayed by reversed-phase chromatography in combination with postcolumn online photochemical derivatization via UV irradiation (254 nm) of the column effluent prior to fluorescence detection (excitation 280 nm; emission 410 or 312 nm). The photo induced modifications were useful for the identification of the various estrogens. The method has been used to evaluate raw materials and pharmaceutical formulations [36].</p> <p>The influence of temperature on the high-performance chromatographic separation of steroids using eluents containing β-cyclodextrin has been studied [37].</p> <p>The analysis of several binary drug mixtures have been carried out using either C18 or cyano bonded phases in combination with on-line post-column photochemical derivatization [38]. In another study, the simultaneous determination of glucocorticoids in plasma and urine using HPLC in combination with precolumn fluorimetric derivatization with 9-anthroyl nitrile has been considered [39].</p> <p>The quantitative structure-chromatographic retention relationship of underivatized equine estrogens have been investigated [40].</p> <p>The feasibility of using a combined liquid chromatographic–thermospray mass spectrometric–isotope dilution approach for measuring corticosteroids in human plasma has been evaluated. The selection of the eluent composition and its effect on the MS results are discussed [41].</p> <p>The use of particle-loaded membranes to extract steroids prior to their HPLC analysis has been considered in terms of improvements in analyte stability and detection [42].</p>
Beclomethasone	<p>Metered-dose inhalers containing the analyte have been studied a simple isocratic method that uses a C8 column and 50 : 50 acetonitrile–water as the eluent [43].</p> <p>HPLC methodology as well as other related assay procedures have been evaluated as a means of measuring the active ingredients and excipients found in commercial nasal sprays. The samples studied were highly viscous and contained a large number of particles in suspension. As such, special emphasis was paid to sample cleanup prior to analysis. Of the techniques examined, liquid chromatography was found best in terms of reproducibility and speed for assaying beclomethasone dipropionate, fluticasone dipropionate and benzalkonium chloride [44].</p>
Betamethasone	<p>Different hyphenated liquid chromatographic (LC) and mass spectrometric (MS) techniques have been evaluated for their use as fast direct analytical methods of measuring betamethasone in hydrolysed and non-hydrolysed urine. Following both the LC, thermospray, and mass spectrometric parameters separately several combined approaches were examined which included LC in combination MS–MS, coupled-column LC (LC–LC) combined with single quadrupole MS, and LC–LC–MS–MS. Neither of the three-step configurations (LC–MS–MS and LC–LC–MS) did not give satisfactory results. However, LC–LC–MS–MS analysis was found to meet the requirements of high sample throughput speed, selectivity, and sensitivity [45].</p> <p>See general methodology above [35].</p>
Cortisol	See general methodology above [41].
Cortisone	<p>Electrochemically modulated HPLC, a technique developed by Deinhammer and co-workers, has been used to assay four common steroids including the analyte. The separations were carried out using a stainless-steel column containing both a tubular Nafion cation-exchange membrane and packing of porous graphitic carbon spheres, a mixture of 50 : 50 acetonitrile–water containing 0.1M-HClO₄/0.1M-LiClO₄ as the eluent, an open-circuit potential of + 0.44 V vs. Ag/AgCl/saturated NaCl and detection at 258 nm. The unique aspect of this technique is the ability to adjust analyte retention by manipulating the applied column potential [46].</p> <p>See general methodology above [41].</p>
Deflazacort	See general methodology above [35].
Dexamethasone	<p>On-line coupled immunoaffinity chromatography-reversed-phase high-performance liquid chromatography particle beam interfaced quadrupole ion trap mass spectrometry has been used to measure dexamethasone and flumethasone [47].</p> <p>See general methodology above [35].</p>

Table 2 *Continued*

Analyte	Procedure
Fluorocortisone	See general methodology above [35].
Fluticasone	The purity of batches of bulk drug substance has been evaluated via a combination of directly coupled HPLC–NMR spectroscopy and HPLC–MS. The separations are carried out on a C18 column using a multilevel gradient produced with D ₂ O and acetonitrile [48]. High-performance liquid chromatography/atmospheric pressure chemical ionization mass spectrometry has been used to quantify fluticasone propionate in human plasma. The eluent was 50:50 water–ethanol and the mass spectrometer was set to monitor masses of 473.2 and 501.2 <i>m/z</i> , which correspond to the internal standard (i.e. the 22R epimer of budesonide) and the analyte respectively [49]. This same analyte also has been measured in plasma using an automated solid-phase extraction liquid chromatography tandem mass spectrometric approach [50]. See methodology for beclomethasone above [44].
Hydrocortisone	The analyte has been assayed in gel formulations by a reversed-phase isocratic procedure using a C18 column and 60:40 methanol–pH 7.5 0.02 M phosphate buffer as the eluent [51]. A normal-phase procedure has been developed for simultaneously measuring prednisolone and hydrocortisone in human serum. A silica column is used in combination with 266:120:26:0.8 n-hexane–dichloromethane–methanol–acetic acid as the eluent [52]. See methodology for cortisone above [46].
Lenonorgestrel	The orally active, progestational agent, levonorgestrel (I) in transdermal patches has been extracted with methanol and separated isocratically on a C18 column with 55:45 acetonitrile–water as the eluent and detection at 225 nm. The average recovery of 1 mg of the analyte from patches was 99% with an RSD of 0.4% [53].
Prednisolone	See general methodology [41] as well as methodology for cortisone [46] and hydrocortisone [52] above.
Prednisone	See general methodology [41] and methodology for cortisone [46] above.
Triamcinolone	An isocratic reversed-phase method has been reported for measuring triamcinolone acetonide in ointment preparations. The separations are carried out with a C18 column and either 35:65 acetonitrile–water or 55:44:1 methanol–water–acetic acid [54].
Triamcinolone	See general methodology above [46].

routine usage such as that encountered during drug discovery and product development, then specificity, versatility, and flexibility are the most important factors and gradient and multilevel elution, combination column, and novel detection approaches may not only be more convenient, but necessary. Additionally, gradient elution and alternate detection approaches may provide an important advantage in the detection and identification of trace impurities, especially if they vary significantly in their structures and polarity.

As noted above, an important trend in drug discovery and development has been the ever expanding usage of HPLC and the development of separation procedures that are based on reversed-phase conditions. An inspection of the recent pharmaceutical literature reveals that by far the most typical set of RP conditions used to measure neutral and acidic drugs employ either 150 or 250 mm conventional bore columns packed with either octadecyl or octyl 5 to 10 μm porous silica-based stationary phases in combination with either water–methanol or water–acetonitrile as eluents. Typically, octyl bonded phases

are used for more hydrophobic analytes or if the analyte is easily resolved on an octadecyl phase, to reduce the amount of organic co-solvent in the hydroorganic eluent. An alternate approach to reducing the chain length of the bonded groups is to use shorter columns. For the neutral drugs, other retention modifying agents (i.e. those that are added to the eluent to suppress unfavourable equilibria) are not needed and for many of the common acid drugs, such as the non-steroidal analgesics/antiinflammatories (see Table 1), the most common eluent modifiers are simple buffers added to minimize ionization.

Chemical Equilibria and Methods Development

In the case of neutral drugs, pH control of the eluent is unnecessary. The reason for this is theoretically illustrated in Figure 2 by the series of dashed lines labeled 1', 2', 3' and 4' (i.e. constant $\ln k'$ vs. eluent pH) for a homologous series of alkyl esters, such as

Table 3 Recently published HPLC methodology for miscellaneous acid and neutral pharmaceutical agents

Analyte	Procedure
Ascorbic acid	<p>The stability of the analyte as well as ascorbyl palmitate and magnesium ascorbyl phosphate have been studied using an amino column and either 40:60 acetonitrile–pH 4 phosphate buffer or 70:30 methanol–pH 3.5 phosphate buffer as the eluents [55].</p> <p>A review with 70 references has been published that considers the use of different detection methods as well as other HPLC conditions for assaying L-ascorbic acid, its dehydro oxidation product, D-isoascorbic acid, and its dehydro oxidation product [56].</p>
Etoposide	<p>A reversed-phase method, which uses a phenyl column, 23:77 acetonitrile–25 mM citric acid–50 mM sodium (pH 2.4) buffer as the eluent and electrochemical detection, has been developed for simultaneously assaying etoposide and its <i>O</i>-demethylated metabolite, etoposide catechol in human plasma. Prior to carrying out the chromatographic separation, the samples are extracted using chloroform and methanol. In addition, the long term stability of etoposide and etoposide catechol in human plasma containing ascorbic acid and stored at 27°C has been demonstrated and the procedure has been used to study the analytes pharmacokinetics in plasma following etoposide administration [57].</p> <p>Several combined HPLC–fluorimetric detection procedures have been developed for measuring the analyte and related compounds in physiological media [58–61].</p>
Parabens	<p>Alkyl esters of <i>p</i>-hydroxybenzoic acid have been separated on a C18 column using 60:40 methanol–water as the eluent and detection at 254 nm [62].</p>
Retinoic acid	<p>A gradient elution method has been developed for measuring 9-<i>cis</i>-retinoic acid and its major metabolite, 4-<i>oxo</i>-9-<i>cis</i>-retinoic acid in human plasma. The analytes are first extracted with methyl-<i>tert</i>-butyl-ether and then separated on a C18 column by employing a multilevel gradient approach. The gradient components are pH 2.7 acetate buffer and methanol and detection is at 348 nm. The method is selective against endogenous compounds and potential metabolites (retinol, all <i>trans</i>-, 13-<i>cis</i>-, and 4-hydroxy-9-<i>cis</i>-retinoic acid) [63].</p> <p>Normal-phase liquid chromatography/mass spectrometry has been used to study the photo degradation of retinoic acid. The chromatographic separations were performed on a silica column using 96.5:3.5 hexane–tetrahydrofuran containing 0.015% acetic acid as the eluent. Isomerization to form 5,6-epoxides occurred more readily in solution than in the solid form and 13-<i>cis</i> retinoic acid oxidized more readily than the all-<i>trans</i> isomer [64].</p>
Vitamin A	<p>UV, electrochemical, and particle beam mass spectrometry have been evaluated for use in assaying vitamins A and E in infant formula and related samples. Separations were carried on both a standard and micro bore C8 columns using hydroorganic eluents [65].</p>
Vitamin E	<p>See methodology for vitamin A above [65].</p>

alkyl esters of *p*-hydroxybenzoic acid (i.e. methyl, ethyl, propyl, and butyl paraben). Shown in **Figure 3** is a representative chromatogram of the separation of this series of analytes carried out on a short column containing an octyldecyl reversed-phase packing using a simple binary hydroorganic eluent. Likewise, this separation demonstrates how retention is influenced by simple hydrophobic changes in the molecule and a plot of $\ln k'$ vs. carbon number is linear with a slope related to the incremental methylene selectivity. The addition of a polar substituent (e.g. a hydroxyl group) will result in a shift to shorter retention.

For many of the more common acid drugs, the most often used eluent modifiers are simple buffers that are added to control the protonation/deprotonation of the ionizable carboxyl group and hence to alter the reversed-phase retention properties of the analyte. A simple rule for reversed-phase separations

is that by decreasing the extent of dissociation of the analyte one increases its interaction with the stationary phase, hence increasing its retention and the possibility of resolving like compounds. This also is illustrated in **Figure 2**, which shows how eluent pH influences the retention of a series of homologous acids with the general structure RCOOH, where R would be the alkyl chain in fatty acids or it would include all structural features in the molecule except the carboxyl group (e.g. as shown in **Figure 1** where the basic structure of ibuprofen is compared to the structure of ibuprofen which contains an additional methyl group). In the deprotonated form (RCOO⁻), the acid drug elutes quickly from the column, whereas in the protonated form (RCOOH), it is retained to an increasing degree based on the hydrophobicity of the molecule. As in the case of the neutral compounds, the incremental addition of carbons to R results in a predictable incremental increase in

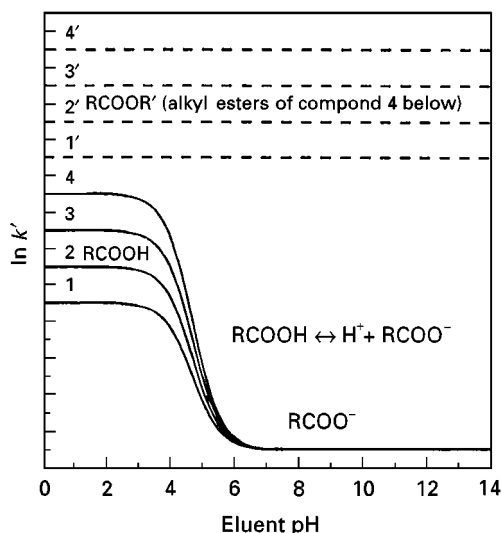

Figure 2 Influence of eluent pH on the retention properties of neutral (dashed lines) and simple monoprotic acid (solid lines) drugs. Curves 1–4 show the incremental change in $\ln k'$ as a function of incremental addition of carbon to simple ionizable solutes, and 1'–4' show the continued incremental change when carbons are added to the alkyl ester portion of monoprotic compounds represented by solid line 4.

retention. This is illustrated by the family of retention curves in **Figure 2** (solid lines labeled 1–4). In the fully protonated form, as in the case of the neutral compounds, the relationship between retention and size (i.e. carbon number) of the aliphatic portion of the homologue is logarithmic.

Typically, the preferred set of conditions for the separation of simple acid drugs (i.e. monoprotic compounds) is in the plateau region of the curves shown

Figure 3 Reversed-phase separation of paraben homologues. Solutes: (A) unretained peak, (B) methyl paraben, (C) ethyl paraben, (D) propyl paraben, and (E) butyl paraben.

in **Figure 2**. Experimentally, this is accomplished by adjusting the pH of the eluent to about 1 to 1.2 pH units below the pK_a of the carboxyl group which is approximately 4.7. When the eluent is buffered to about 3.5, the solute exists predominately in its uncharged form and its retention is governed by the hydrophobic interactions between the nonpolar portion of the molecule and the immobilized alkyl chains of the bonded phase. However, once the eluent pH is adjusted to this region, further adjustments to lower pH will have little effect on the quality of the separation, but will lead to increased chances of phase instability and decreases in the long term performance of the column. A working range for most silica-based bonded phases is 3.0 to 8.5 which is within a useful range for resolving most acidic drugs without the addition of more exotic eluent additives.

As the analyte becomes more complex in terms of the presence of multiple functionality and other structural features, it is often not possible to predict in advance many of the subtleties controlling retention. Considering some of the related non-steroidal analgesic/anti-inflammatories appearing in **Figure 1**, it is possible to predict that ibuprofen will elute before ibuprofen, since the molecules are structurally very similar except ibuprofen contains an additional methyl carbon. However, it is much more difficult to predict how long indomethacin will be retained compared to tolmetin or the elution order of ketoprofen, fenoprofen, and flurbiprofen. Nevertheless for the latter set of compounds, since they are structurally similar, it is reasonable to suggest that an assay developed for ketoprofen might be a useful starting point for fenoprofen. Additionally, it is reasonable to suggest that the pH of the eluent for separating the first six compounds in **Figure 1**, which are all monoprotic acids should be in the 3.5 range, since the only important structural feature requiring eluent buffering, is the carboxyl group.

Representative Methodology

Summarized respectively in **Tables 1–3** are HPLC methods that have appeared recently for assaying some of the more common (1) non-steroidal anti-inflammatories/analgesics, (2) steroids, and (3) other miscellaneous neutral and acid drugs. These represent only a fraction of the numerous analytical procedures that have appeared and many of them are useful for measuring the analyte in biological materials as well as in formulated products. Shown respectively in **Figures 4–7** are representative separations of common non-steroidal anti-inflammatory drugs, aspirin and salicylic acid, several important steroids, and the fat-soluble vitamins A, D and E. In all cases the

Figure 4 Reversed-phase separation of common nonsteroidal antiinflammatory drugs. Conditions: C_{18} column using 42:58 acetonitrile–phosphate buffer (pH 5.0) as the eluent. Solutes: (A) sulindac, (B) loxoprofen, (C) ketoprofen, (D) naproxen, (E) felbinac, (F) fenbufen, (G) flurbiprofen, (H) diclofenac, (I) indomethacin, (J) ibuprofen, and (K) mefenamic acid. (Chromatogram redrawn from Hirai, Matsumoto and Kishi, 1997.)

Figure 6 Reversed-phase separation of common steroids. Conditions: C_{18} column using 20:80 acetonitrile–phosphate buffer (pH 3.0). Solutes: (A) hydrocortisone, (B) corticosterone, (C) 11- α -hydroxyprogesterone, (D) unidentified compound, (E) 11-keto progesterone, (F) deoxycorticosterone, (G) 17- α -hydroxyprogesterone. (Chromatogram redrawn from *J. Chromatogr. Sci.* 1995, 33: 411.)

chromatograms were obtained under reversed-phase conditions using either an octyl or octadecyl column. In the first three examples standard bore columns were used in combination with UV detection and in the latter vitamin assay the separation was performed on a narrower 2.0 mm i.d. column using both UV and electrochemical detection.

In addition to the relatively common approaches in terms of separation mode and operating conditions

discussed above, other important considerations have been addressed in the literature. These include analyte-cleanup prior to carrying out the HPLC separation, evaluation of optical purity, and the development of novel phases such as molecularly imprinted polymers as well as the use of alternate detection techniques like mass spectrometry and fluorescence to improve sensitivity and selectivity. In the latter instance, post-column photo-decomposition/derivatization has been used in methods developed for simple acid drugs such

Figure 5 Reversed-phase separations of aspirin and salicylic acid. Conditions: left: C_8 column using 35:65 acetonitrile–water containing 0.2% orthophosphoric acid, centre: C_{18} column 25:75 acetonitrile–phosphate buffer (pH 2.5), right: C_{18} column 23:5:5:67 acetonitrile–tetrahydrofuran–glacial acetic acid–water. Solutes: (A) aspirin and (B) salicylic acid. (Chromatograms redrawn from McMahon, O'Connor, Fitzgerald, leRoy and Kelly, 1998, Pirola, Bareggi and DeBenedictus, 1998, McCormick, Gibson and Diana, 1997, respectively.)

Figure 7 Reversed-phase separation of fat-soluble vitamins. Conditions: C_8 column using 92:8 methanol–water. Solutes: (A) vitamin A, (B) vitamin A acetate, (C) vitamin D_3 , (D) vitamin E, (E) vitamin E acetate, and (F) vitamin A palmitate. (Chromatogram redrawn from Andreoli, Careri, Manini, Mori and Musci, 1997.)

as diclofenac, conjugated and unconjugated estrogens and related impurities, and binary drug mixtures containing either betamethasone, hydrocortisone, desonide, dexamethasone, or triamcinolone.

Supercritical Fluid Chromatography

W. H. Wilson, Hewlett-Packard Co., Wilmington, DE, USA

Copyright © 2000 Academic Press

Introduction

The role of supercritical fluid chromatography (SFC) for the pharmaceutical scientist is based on its enhanced performance compared with high-performance liquid chromatography (HPLC). These advantages are speed, selectivity, and efficiency. Since diffusion is faster in a fluid than a normal liquid, SFC typically is five to ten times faster than HPLC. The mobile phase is less polar than the stationary phase in most SFC analyses so that the separation mechanism is similar to normal-phase HPLC. Thus, SFC can serve as a powerful complement to the vast majority of reversed-phase HPLC analyses. In terms of efficiency, SFC does not necessarily make the column more efficient.

However, the tenfold lower viscosity of the mobile phase allows columns to be joined together. As many as eleven 20 cm × 4.6 mm 5- μ m packed columns have been linked to yield over 250 000 theoretical plates. Packed capillary columns have been made even longer.

In order to demonstrate the utility of SFC for pharmaceutical analysis, the range of SFC in this field needs to be understood. A brief review of mobile phases, columns, and solutes (see the SFC instrumentation section) will suggest the current limits. The modes of application are summarized, indicating current and future usage. Finally, a thorough but by no means exhaustive listing of successful solute-specific applications serve as a reference for more detailed investigation.

Range of SFC

Mobile Phases

Carbon dioxide is by far the most popular choice as the primary mobile phase component. Since most

compounds of pharmaceutical interest are more polar than carbon dioxide, a polar component will be needed in the mobile phase. Organic modifiers such as methanol, ethanol, and acetonitrile have been added to carbon dioxide to increase its elution strength. For strongly polar analytes such as amines or acids, a third component, called an additive, is needed to improve peak shape. Typical additives are primary amines for bases and trifluoroacetic acid for acids.

Solutes

SFC can separate a wide range of pharmaceutical solutes. From nonpolar fatty acid methyl esters to multifunctional acids and bases; SFC overlaps the application 'spaces' of gas chromatography (GC) and HPLC. Pharmaceuticals that are soluble only in aqueous solutions are not likely candidates for SFC. For example, purines and pyrimidines can be eluted from packed column SFC. These building blocks of DNA and RNA are polar, basic moieties but can be chromatographed, although DNA itself, has not been eluted by SFC. Similarly, amino acids can be readily analysed but proteins are not typically feasible. Recent work, however, suggests that short peptides can be eluted; further studies are in order.

Columns

The diffusivity of analytes in supercritical fluids is sufficiently high to allow both capillary and packed columns to be used. Both column types have strengths and weaknesses (refer to the instrumentation chapter). For most pharmaceutical applications, capillary columns do not offer sufficient retention time and area reproducibility to be implemented in routine use. However, some enantiomer separations are well suited to capillary SFC and warrant consideration of the technique.

Packed columns have been the predominant mode of operation for most pharmaceutical analyses. Column diameters from 50 μm up to preparative scale have been used. Particle diameters as small as 1.5 μm have found a use in packed column SFC. Since the mechanism for analyte retention is akin to normal-phase HPLC, typical stationary phases are cyanopropyl, aminopropyl, and diol-functionalized supports. Less polar columns such as octyl and octadecyl are also used. Support materials of silica, alumina, zirconia, and polymeric materials have been employed with successful results. Perhaps the most prominent application of packed column SFC is chiral separations. The majority of chiral stationary phases have been used in packed column SFC with beneficial results (refer to the chiral separations chapter).

Detectors

Numerous detectors have been modified and developed for SFC. The most prominent condensed phase detector is UV-Vis. Other condensed phase detectors are fluorescence, FTIR, radiometric, and electrochemical. Gas phase detectors such as mass spectrometry, flame ionization, and others have been interfaced to SFC.

Pharmaceutical Applications

Achiral Separations

The fundamental advantages of SFC are a normal-phase retention mechanism, rapid analysis times, tunable selectivity, and high efficiency. Since the stationary phase is more polar than the mobile phase, SFC is most similar to normal phase HPLC. Solute separation is based on their polarity and functional groups rather than their hydrophobicity. Consequently, it is an excellent complement to reversed-phase HPLC. In addition, retention time stability is similar to reversed-phase HPLC. The effects of trace amounts of water in the mobile phase are essentially insignificant for SFC when compared with normal-phase HPLC, particularly for polar pharmaceutical compounds. For example, a mixture of steroids shows the elution profile from a silica column (Figure 1). The steroids elute based on the number of polar functional groups in the structure. For example, estrone (one ketone, one alcohol) elutes before estradiol (two alcohols) which elutes before estriol (three alcohols). Note the rapid speed of analysis. The column is run at 2.5 mL min^{-1} . In HPLC, the column would be run at five to ten times lower flow rate. As

Figure 1 Steroid analysis by packed column SFC. Column 2.1 \times 250 mm Lichrosphere Si-60 (5 μm particles); oven 70°C; flow rate 2.5 mL min^{-1} ; outlet pressure 200 bar; modifier 20% methanol in carbon dioxide; UV detection at 210 nm. Elution order: progesterone, methyltestosterone, testosterone, estrone, estradiol, cortisone, hydrocortisone, and estriol. Courtesy Dr TA Berger, Berger Instruments.

cited previously, columns can be linked to increase efficiency or tune selectivity. In the latter case, columns of different stationary phase can be joined to change selectivity. An example of this appears in the chiral section.

Table 1 contains a summary of achiral pharmaceutical separations. Where practical, the actual sol-

utes chromatographed are listed. The majority of these separations have been done on packed columns. SFC easily analyses basic compounds such as phenothiazine antipsychotics, tricyclic antidepressants, and stimulants. Nevertheless analysis of acids is also possible. Berger has demonstrated the elution of benzene derivatives with up to six carboxylic acid functional

groups. A ternary mobile phase of carbon dioxide, methanol, and trifluoroacetic acid was required to elute these strong acids.

An extremely valuable application of SFC is as a compound purity measurement tool. Gyllenhal *et al.* demonstrate the utility of SFC on four separate pharmaceuticals. All four examples indicate that SFC either equalled or improved the existing HPLC methods. For instance, packed column SFC was able to separate two impurities from metoprolol that HPLC was unable to achieve. Once again, the complementary nature of a reproducible, normal phase-like separation enhances the more traditional reverse phase HPLC results.

Chiral separations

Perhaps the most important role SFC currently plays in pharmaceutical analysis is as a chiral resolution technique (refer to Chiral Separations/Supercritical Fluid Chromatography). In this arena, the normal-phase retention mechanism is a tremendous asset. Since most chiral separations rely on polar solute-stationary phase interactions, a normal-phase environment is much more conducive to chiral recognition. Normal-phase HPLC chiral separations typically can be replaced by packed column SFC and enjoy the benefits of faster analysis times, lower solvent consumption, and more reproducible retention times. SFC also offers greater efficiency by allowing columns to be coupled.

Similar and dissimilar stationary phases can be coupled together to permit selectivity tuning.

Figure 2 shows an achiral/chiral column pair used to separate ibuprofen enantiomers in a urine matrix. The sample is initially injected onto the cyano column. The large peak at approximately 1 min is ibuprofen. When this peak has passed into the switching valve, the valve is turned and the loop contents are injected into the chiral column. The advantage of this approach is that on the achiral column, both enantiomers will coelute. With the valve arrangement used, the more polar urine components are never introduced into the chiral column. The peaks at approximately 7 min are the ibuprofen enantiomers. Note that ibuprofen is sold as the racemate of the enantiomers. The larger second peak is the S form of ibuprofen, while the barely visible first peak is the R form. In the body, the R form is inverted to the S form. Sandra *et al.* investigated a 'universal' chiral column by coupling three different chiral columns in series. In 90% of the successful separations on a single phase, the column triad was able to perform as well.

Preparative Separations

A natural extension of SFC is as a preparative separation technique. The column capacity is a function of the packing material and is essentially equivalent to liquid chromatographic systems. Consequently, scale-up procedures are similar. A major advantage for SFC is the solvent. Upon expansion, the mobile phase becomes gaseous or gaseous with a small amount of liquid phase, simplifying the recovery of analytes. The bulk of the mobile phase is nontoxic

Figure 2 Chiral separation of ibuprofen in a biological matrix. Columns 4×125 mm Lichrosphere CN ($5 \mu\text{m}$ particles) and 4.6×250 mm Chiralpak AD ($10 \mu\text{m}$ particles); oven 35°C , flow rate 2 mL min^{-1} ; outlet pressure 150 bar; modifier 5% methanol in carbon dioxide, UV detection at 210 nm; injection volume $5 \mu\text{L}$. Courtesy Dr TA Berger, Berger Instruments.

(carbon dioxide) and, at large enough scale, can be recycled.

The differences between using normal liquids and supercritical fluids for preparative separations present advantages and disadvantages in both cases. For isocratic mobile phases, HPLC is probably easier in terms of mobile phase handling (e.g. no back-pressure regulator required). Mobile phase recycling is straightforward in HPLC since the column effluent is merely redirected to the pump inlet reservoir. SFC requires some repressurization apparatus at the outlet of the back-pressure regulator in order to recycle the mobile phase. However, SFC can use pressure as a separation variable whereas HPLC cannot. Although pressure programming in SFC is not as powerful as composition programming, it still affords the user an additional degree of flexibility. Recovery to initial chromatographic conditions from a pressure programme in SFC is very rapid. For composition programming or in HPLC terms, 'gradient programming', HPLC is more difficult to use. The time for column recovery is substantially longer in HPLC than in SFC, particularly for normal-phase separations. In addition, mobile phase recycling is complicated in gradient HPLC. The mobile phase depressurization actually benefits SFC in this scenario. By depressurizing the mobile phase, the concentration of modifier can be reduced to some low, reproducible value. This fluid can then be repressurized and fed to the pumping system with the modifier added to restore the desired initial composition. Column re-equilibration is very fast in SFC, thus minimizing recovery time.

Jusforgues *et al.* have described three applications of preparative SFC which demonstrate some of the merits of this approach. The excellent retention

time and area reproducibility possible with SFC is demonstrated with an insecticide. For the discrete peaks, the retention time reproducibility ranges from 0.17% to 0.19% relative standard deviation. In terms of peak area, the range is 1.17–1.54% relative standard deviation. An additional example given by these authors shows the separation of enantiomers by preparative SFC. The separation cycle takes less than 5 min and the yield of > 99% purity compounds is 29 g day⁻¹.

Laboratory-scale preparative separations, typically in the milligram range, are attractive in conjunction with combinatorial chemistry. The aforementioned rapid analysis time, simple mobile phase elimination, and loading capacity make SFC an attractive option for small-scale purification.

Rapid Screening

The extensive growth of combinatorial chemistry has brought about significant changes in pharmaceutical analysis. Synthetic production is now discussed in terms of thousands of compounds per year. With this explosion of organic syntheses, the companion techniques must also develop to handle the load. Parallel synthesis must be met with rapid, parallel analysis to maintain the pace. SFC is well suited for interfacing with this demanding need.

The current workhorse for combinatorial analysis is still reversed-phase HPLC. As discussed previously, packed column SFC is both complementary to reversed-phase HPLC and potentially an order of magnitude faster. Not only is this speed apparent in the analysis times but more importantly, in the total cycle time on the system. **Figure 3** illustrates the impressive speed of gradient elution by packed column SFC. The

Figure 3 High-speed packed column SFC for combinatorial screening. Column 4 × 125 mm Lichrosphere CN (5 μm particles); oven 35°C; column flow 4 mL min⁻¹; outlet pressure 120 bar; 15–65% modifier (methanol + 0.4% isopropylamine) programmed at 45% min⁻¹ in carbon dioxide, UV detection at 230 nm; 10 μL injection from a 96-well plate. Courtesy Dr TA Berger, Berger Instruments.

column is a 125 mm × 4 mm × 5 μm Lichrosphere cyano (these are typical column dimensions for a standard HPLC separation). The sample is drawn directly from a titre plate and injected. The modifier is programmed from 15% to 65% at 45% min⁻¹. The analysis takes 1.2 min to complete and an additional 0.68 min to re-equilibrate. Consequently, the system is able to run over 760 samples per day. On a similar column by reversed-phase HPLC, the system is capable of two to three runs per hour or at best, 72 samples per day.

Note that the chromatogram shows several peaks in the sample. Since the goal of this synthesis was a single component, there are some obvious complications. With the column used, the system has sufficient peak capacity to separate the seven components identified. For a similar speed of analysis by HPLC, the column would have to be substantially shorter or have much smaller particles. In either case, the peak capacity would not be the same at the SFC separation. As a result, the HPLC system may be unable to resolve all of the peaks. The speed and efficiency of SFC is better suited to these high volume analyses than HPLC.

Summary

The rapid analysis speed, complementary selectivity, and achievable high efficiency of SFC make it a valu-

able technique for pharmaceutical analysis. Because of its normal-phase-like retention mechanism, SFC affords users of reversed-phase HPLC an orthogonal separation system. In addition, chiral separations are clearly a strong application for SFC. The renewed interest in SFC for laboratory-scale purifications and combinatorial screening has breathed new life into this technique.

A valid point raised by Wilson *et al.* is that the current literature still demonstrates the potential of SFC rather than fully developed methods. This situation has begun to change. Although the literature may not reflect it yet, more and more pharmaceutical workers are using SFC as a routine technique.

Thin-Layer (Planar) Chromatography

B. Renger, Byk Gulden, Konstanz, Germany

Copyright © 2000 Academic Press

In 1938, Izmailov and Schraiber used aluminium-coated plates to separate coloured plant extracts. Further development of thin-layer chromatography (TLC) as a semiquantitative analytical technique and a tool for identity testing took place in the mid-1950s, especially by Stahl. Soon after this pioneering work, TLC found its way into pharmaceutical analysis.

Surveys of the analytical literature from the late 1980s to the mid-1990s show that approximately 25–30% of all articles published in the field of TLC described pharmaceutical applications. These figures may give some idea about the status of TLC in pharmaceutical analyses.

The rapid development of liquid chromatography (LC, especially high performance liquid chromatography (HPLC)) in the mid-1970s has made LC the

predominant analytical method in pharmaceutical analysis. Nevertheless, even today TLC must be considered the most widely used pharmacopoeial chromatographic technique.

TLC in the Pharmacopoeias

An early example of pharmacopoeial use of TLC (Table 1) was for impurity testing of corticosteroids in the *British Pharmacopoeia* (BP) addendum 1966 and as a general method featured in the BP of 1968. A typical specification for an active pharmaceutical ingredient until then would require verification of identity and then rely on a usually nonspecific assay supplemented by traditional limit tests, e.g. for heavy metals and chloride. For most organic substances a reasonably sharp melting point was a crude but generally accepted measure of purity. The introduction of TLC to the BP 1968 had great expectations of this technique, as it refers to 'greatly increased

Table 1 TLC in the pharmacopoeias

1964	DAB 7 – GDR: general method
1966	BP addendum: corticosteroids
1968	BP: general method
1980	DAB 8 – add. – FRG: general method
1985	DAB 9 – FRG: 'quantitative' determination of glycyrrhizic acid in liquorice root
1998	DAB – 1998 monograph 'soja lecithin': assay of phosphatidylcholine via quantitative TLC
1999	EP addendum 1999: revised general monograph TLC including quantitative TLC

DAB, German Pharmacopoeia; FRG, Federal Republic of Germany; GDR, German Democratic Republic; EP, European Pharmacopoeia.

emphasis placed on detection and control of impurities [from] manufacture or degradation ... made possible by the rapid development of TLC as a reliable means of detecting and assessing small quantities'.

In its basic form, as developed then, TLC is simple, rapid, robust and inexpensive and can be performed in nearly every analytical environment. Therefore it is still widely used in national and international pharmacopoeias for identity testing of active pharmaceutical ingredients and excipients, especially of compounds of natural origin like plant extracts or herbal preparations. In its semiquantitative mode, where spots of reference test solutions are usually visually matched against the impurity spots in the chromatogram of the undiluted test sample, it is still the widest used chromatographic technique to con-

trol impurities in either active pharmaceutical ingredients or drug products.

High performance TLC (HPTLC), with layers composed of particles with smaller diameters and narrow particle size distributions, gives greater separation efficiency and improved detection limits. Automated scanning densitometers have led to instrumental quantitative TLC, but neither of these developments has found its way into the national and international pharmacopoeias until recently.

Today, most of the TLC procedures included in pharmacopoeial monographs must be considered to represent an obsolete form of this technique, leading to the misconception that TLC *per se* is merely a qualitative or at best semiquantitative technique lacking in accuracy and sensitivity (Figure 1).

But even when performed under state-of-the-art conditions, separation power and sensitivity are generally lower for TLC than for HPLC. As a consequence, there is a general shift away from semiquantitative TLC to quantitative HPLC for the control of impurities in new or revised pharmacopoeial monographs. This development is especially justified by the requirement of the guidelines of the International Conference on Harmonization (ICH), to control unknown impurities down to a threshold limit of 0.1% – originally intended for new chemical entities only – but today also applied to well-known active pharmaceutical ingredients, listed in pharmacopoeias. This general shift away from TLC to HPLC for the control of impurities and related substances must be considered irreversible.

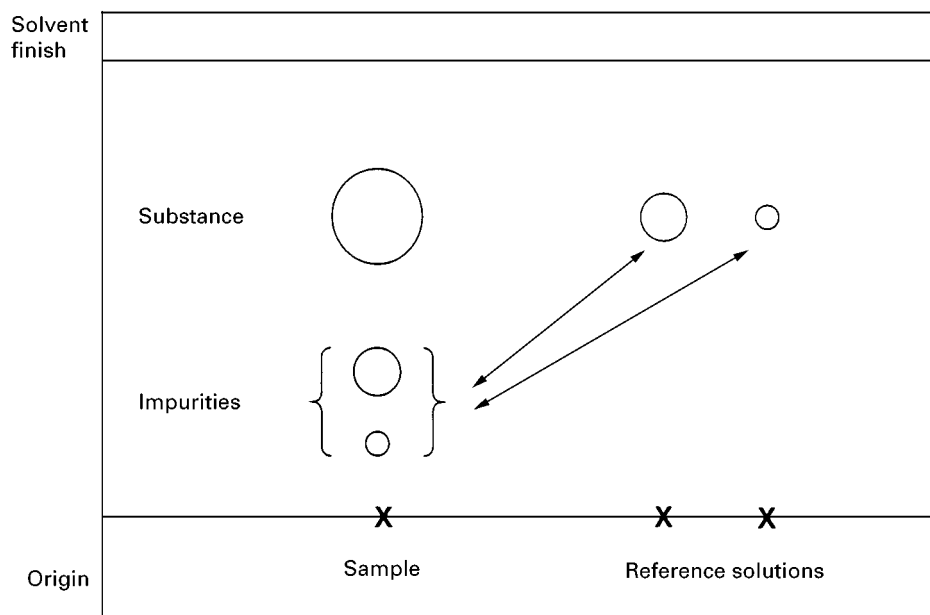

**Figure 1** Pharmacopoeial use of TLC: testing for related substances.

Table 2 Quantitative TLC in the general monograph TLC of the Addendum 1555 of the European Pharmacopoeia: features

Plates	Laboratory-prepared plates abandoned; commercially available plates referred to in reagent section
Performance test	Plates are tested using a mixture of Sudan red, methyl orange, bromocresol and methyl red for separation efficacy and/or with benzoic acid for fluorescence quenching
Preconditioning	Washing or impregnating of plates, if appropriate
Development	Vertical and horizontal development described
Visual estimation	Described for related substances tests and identification
Verification of separation power	Described for related substances tests and identification
Verification of detection power	Described for related substances tests
Quantitative measurement	Described for substances responding to UV-visible irradiation (remission or fluorescence) or containing radionuclides using three-point calibration (approx. 80, 100, 120% of expected value) and scanning densitometry
Resolution factor	Results are only valid if the resolution (R_s) between measured peak in the chromatograms is greater than 1.0
Signal-to-noise ratio	Described for determination of the detection limit (DL)

However, the progress in quality of sorbent materials, pre-coated plates and instrumentation that has led to a remarkable improvement in the reliability of instrumental quantitative TLC, has led to its recent introduction as a general pharmacopoeial method. The revised general monograph 2.2.27 *TLC* of the addendum 1999 of the *European Pharmacopoeia* for the first time includes a description of quantitative TLC via automated scanning densitometry and lists the required performance parameters *resolution* and *limit of detection* (Table 2).

The first example of the pharmacopoeial use of fully automated quantitative TLC is the assay for phosphatidylcholine in the monograph *Soya Lecithin* of the addendum to the *German Pharmacopoeia DAB* (1998).

Potential Applications of TLC/HPTLC

For many years TLC was not considered to be a reliable quantitative technique and it was displaced by the techniques of gas chromatography, introduced as a general method in the *BP* of 1968 and, in the mid-1970s by LC, especially HPLC, which today is the most popular technique for assays and purity testing (Table 3).

It must be emphasized that only approximately 20% of analytical work in the pharmaceutical industry is controlled by pharmacopoeias. The remaining 80% of analytical problems, such as analytical work in research and development, reaction and process control, stability testing, analytical control of cleaning and its validation may be solved by every available analytical technique, assuming that the corresponding validation and performance data prove that it is suitable for the intended use.

When used with plates containing fluorescence indicators that allow detection of UV-active substances

by UV irradiation for identification, the existence of more than 1000 specific derivatization agents represents a major advantage of TLC over other chromatographic techniques.

Hyphenated techniques, or combinations of TLC with spectrometric techniques like Fourier transform near infrared spectroscopy (FT-NIR), Fourier transform infrared spectroscopy (FTIR), diffuse reflection infrared Fourier transformation (DRIFT), Raman/surface enhanced Raman spectroscopy (SERS) or mass spectrometry (MS) with different ionization techniques, are reserved for special applications and are not as commonly used as simple visualization.

For fast, rough quantifications – either in purity and related substance testing or for assays – TLC coupled with visual examination and/or with the emerging technique of video densitometry must be considered the most flexible and economic alternative of all chromatographic techniques.

But TLC is no longer the traditional, uncomplicated but less reliable technique. Reliable, technically mature automated instruments are available for individual steps like sample application, development, derivatization, scanning and quantitation.

For assays and content testing, TLC with scanning densitometry must be considered a realistic alternative to other chromatographic techniques concerning analytes with problematic detection characteristics. Also it is suitable with crude or dirty sample matrices, especially when particulate impurities like plant extracts of finished pharmaceuticals raise problems with other analytical techniques.

Sometimes the weakness of TLC – its lower separation power – can be an advantage: when components consisting of mixtures of oligomers or having different chain length distributions have to be assayed in different matrices.

Table 3 Potential applications of TLC/HPTLC in pharmaceutical analysis

Type of analytical procedure	Field of application	Principle(s)
Qualitative/identification (API)	Quality control of components, active pharmaceutical ingredients (API), finished pharmaceuticals Single container identification Quality control of herbal/vegetable drugs and fermentation products At-site and port-of-entry testing Forensic and drug of abuse screening	Parallel chromatography of sample and reference standard or reference sample, evaluation and comparison of R_F values, spot size and colour (after derivatization) Evaluation and comparison of R_F values using different mobile-phase systems with data from libraries, specific derivatization if required, <i>in situ</i> or offline spectroscopy of selected spots/bands
Semiquantitative purity test (limit test)	Quality control of components, API, finished pharmaceuticals Quality control of herbal/vegetable drugs and fermentation products At-site and port-of-entry testing: check for adulterations and contaminations	Parallel chromatography of sample and diluted (1 : 50, 1 : 60, 1 : 200) test solution or solutions of potential impurities. Visual match of spot size and intensity (after derivatization if required) with following estimation of impurity/related substances content. Increased reliability and precision using video densitometry.
Semiquantitative assay/content testing	Reaction/process/cleaning control or optimization in: API synthesis Pharmaceutical manufacturing Fermentation Plant/herbal extraction Assay of herbal/vegetable drugs and extracts	Parallel chromatography of reaction mixture or rinse solution and eluent/starting materials/previous sample/previous rinse solution. Visual estimation and/or video integration and estimation of process reaction/cleaning progress Parallel chromatography of sample and different concentrations of lead component/reference sample. Visual evaluation and/or video integration after derivatization if required.
Quantitative assay/content testing/impurity/related substances testing	Quality control of APIs and finished drugs Quality control of herbal drugs/extracts and fermentation products Assays and purity testing in stability studies (development, ongoing, follow-up) Bioanalytics: bioavailability studies, pharmacokinetic studies Reaction/process control or optimization: impurity profiles	Parallel chromatography of sample and different concentrations of reference standard and/or dilutions of main component and/or reference sample. Pre- or postchromatographic derivatization if required, preferred: automated spotting, development under controlled conditions, quantitative evaluation via calibration function using peak area or peak height after scanning densitometry (or video integration if applicable)

Validation and Performance Characteristics

Like any other analytical technique, TLC used in pharmaceutical quality control or in stability studies and later stages of pharmaceutical development (clinical trial batches) has to be validated in line with the latest guidelines of the ICH. As planar chromatography allows the simultaneous analysis of up to 24 samples on one plate, the time and effort required to validate a procedure are distinctly lower than for other chromatographic techniques.

Performance data verify that, under optimized conditions, quantitative TLC or HPTLC results are comparable to those of LC. A prerequisite is parallel testing of two sample weightings with double-spotting (resulting in four spots for every unknown) and – mandatory according to the monograph in the *European Pharmacopoeia* – a three-point calibration (e.g. 80, 100, 120% of label claim in assays) for linear and preferably four-point calibration for nonlinear calibration models. Except for fluorescence measurements, calibration functions in TLC are generally nonlinear. Narrow specification limits and working

Table 4 Comparison of performance characteristics of TLC, HPTLC and HPLC

Separation power	Technique	Performance
Separation number	TLC	~ 10
	HPTLC	~ 15–20
	HPLC	~ 150
Sensitivity		
Detection limit (UV absorption)	TLC	~ 1–5 µg
	HPTLC	~ 0.2–0.5 µg
	HPLC	~ 0.05–0.3 µg
Precision		
RSD interm. precision (assay)	TLC	~ 1.5–3.0%
	HPTLC	~ 1.0–2.0%
	HPLC	~ 0.8–1.5%

RSD, random standard deviation; interm. precision, day-to-day variability.

ranges in pharmaceutical analytical chemistry however often make it possible to use quasi-linear calibration functions over the limited concentration ranges to avoid calibration via higher polynomial functions.

Generally, selectivity, separation power and sensitivity (expressed as quantitation limit) are lower for TLC or HPTLC than for LC. For assays, measurement uncertainty and precision data from validation experiments are comparable, whereas for quantification of impurities and related substances, the higher variability and measurement uncertainty and the resulting higher quantitation limit normally make HPLC the preferred analytical technique. TLC may be the method of choice if the detection characteristics of the analyte does not encourage the use of LC, e.g. for phospholipids that require light-scattering detection in LC.

Table 4 gives a rough estimation of selected performance characteristics of TLC–HPTLC.

Features and Advantages of TLC

There is a general shift away from TLC to HPLC for the control of impurities in new or revised pharmacopoeial monographs. Planar chromatography has a number of features and advantages (**Table 5**) so that, for some of the applications listed above, this technique must be considered to be at least an alternative to other chromatographic methods.

Actual Use of TLC in Pharmaceutical Analyses

As outlined in **Table 3**, TLC may theoretically be used for nearly every analytical task in the pharma-

ceutical industry. However, the general lower performance characteristics compared to LC on one hand and the special features (outlined in **Table 5**) on the other hand have resulted in some specifically traditional applications of TLC. These are identification, especially for port-of-entry testing, single container testing and for samples of natural origin like plant extracts or fermentation products. In its semiquantitative mode it is used for fast on-site testing. Applications in pharmacokinetic or bioavailability studies as well as quantitative determinations of impurities or related substances and assays of active pharmaceutical ingredients are still exceptions, mostly limited to cases where the matrix or the detection features of the compounds are to be determined, or the matrix excludes or limits the use of other chromatographic techniques.

Table 6 lists the main applications of TLC in pharmaceutical analysis today. For most of these applications, TLC is either mandatory or at least recommended by the respective pharmacopoeias and compendiums or encouraged by regulatory authorities.

Economic and Environmental Considerations

Most separations by TLC are performed in a normal-phase mode, using unmodified silica gel pre-coated layers, whereas HPLC in pharmaceutical analysis is nearly always used in the reversed-phase mode. Therefore, **Table 6** lists predominantly examples where the straight-phase mode of TLC must be considered more appropriate than reversed-phase or examples where normal-phase TLC acts as a supple-

Table 5 Advantages and features of TLC/HPTLC

Simplicity of handling, easy to learn technically
Flexibility, short preparation time needed prior to analysis
Broad choice of mobile-phase systems
Numerous (> 1000) sensitive and selective reagents for detection and/or visualization
No obligation for elution of the analyte
Whole chromatographic information is stored on the plate and can be (re)evaluated
Detection and/or quantitation steps can easily be repeated using different parameters
Simultaneous yet independent analysis/samples of several samples and reference standards on one plate offers a high sample throughput and an increased reliability of results (in-system calibration)
Procedures are generally robust, allowing easy transfer and adoption
The single use of the plates offers the ability to handle crude, complex or dirty samples, even those with particulate impurities
Modular structure

Table 6 Main applications of TLC in pharmaceutical analyses (qualitative, semiquantitative and quantitative)

Identity testing of raw materials, components and drugs in quality control, on-site or at port-of-entry
Single container identification if spectroscopic techniques (e.g. near infrared (NIR)) not suitable or available
Identity, purity testing and assay of herbal/vegetable material, extracts and drugs
Single, rapid on-site/port-of-entry testing for adulterated and faked drugs
Purity and related substance testing or assays if analyte has problematic detection characteristics (polyglycol derivatives, quaternary ammonium salts, phospholipids) and/or the materials require laborious and error-prone sample workup steps in other chromatographic techniques
Additional straight-phase technique parallel to RP-HPLC or other techniques for proving procedure selectivity in validation, for second assays of reference standards, in stability testing to prove that primary technique indicates stability and in forced degradation studies to give better mass balance

mentary or additional technique run in conjunction with reversed-phase HPLC (Figure 2).

There is a main field of application, however, where TLC and HPLC may be regarded as competing techniques. These are assays and content determinations of finished pharmaceutical products. HPLC has been the most popular analytical technique for these determinations for many years (and, like TLC, the most popular compendial technique for impurity and related substances testing) within the last few years. But papers dealing with TLC in pharmaceutical analysis are focusing more and more on final product assay and content testing, especially on content uniformity testing of tablets.

This application combines the technique's inherent advantages, its ability to accept complex or dirty sample matrices without requiring time-consuming sample clean-up steps, and its ability to run several samples on one plate in parallel and to be readily available without requiring system set-up and equilibration times.

In addition, TLC generally requires fewer solvents and chemicals than HPLC procedures.

Reports on the costs of performing multiple drug analyses conclude that cost reductions using TLC or HPTLC instead of LC (HPLC) can be significant. This is especially the case when many repetitive analyses have to be performed at one time and automated HPLC systems are not economic, as the total number of batches is too low or manufacturing is not evenly distributed throughout the year. If the obtainable separation performance parameters are considered sufficient, that is, if the TLC procedures have precisions within the required limits and a random standard deviation (RSD) of 2%, as required by the USP,

then planar chromatography offers an alternative that costs less, is faster and has less impact on the environment. In addition, this type of TLC can in certain cases be performed even in hospitals, pharmacy laboratories or ports of entry, warehouses or

Figure 2 Comparison of HPLC and HPTLC analyses of phospholipids. (A) HPTLC, copper (II) sulfate/phosphoric acid derivatization and scanning densitometry. (B) HPLC, light-scattering detection. (B) DSPA, phosphatidic acid; lyso LPG, lyso phosphatidyl glycerol; main component, 1,2-distearoylphosphatidyl glycerol (DSPG).

small control laboratories. However, although most of the published applications in the field have their origin not in the highly HPLC-oriented first world, the approach must not be considered to be only valuable and suitable for simple control laboratories with very limited assets.

Pharmaceutical analytical laboratories work under enormous economic and time pressure. Sample throughput has to be increased and lead times decreased, both without any consequence to the reliability of the results and at best without increase in personnel and operational costs. Therefore it must be recommended that TLC is considered as a possible replacement or substitute for compendial or noncompendial HPLC assays and content uniformity testing, especially for tablets.

Future Perspectives

A shift away from the traditional, semiquantitative TLC compendial purity testing of active pharmaceutical ingredients must be expected. Instead, a higher level quantitative TLC will be recommended and promoted by various national/international regulatory agencies for on-site and port-of-entry testing of pharmaceuticals. This development will be stimulated by the development of modern video imaging systems. Originally developed for documentation, modern closed-circuit device cameras are now combined with powerful software to collect the information stored on a plate in a very short time. Although not yet generally as precise and accurate as scanning densitometry, latest published results indicate that at least in the UV-region, video imaging can produce assay results that are equivalent to those derived by scanning densitometry. The lower price of video integration systems makes them the ultimate choice for rapid quantitative TLC applications.

The use of scanning densitometry will be limited to more delicate analytical tasks like stability or quality

control testing procedures such as assays or content testing of finished pharmaceuticals, especially tablets, where TLC will expand because of its economical and environmental advantages, compared to HPTLC.

Highly sophisticated hyphenated techniques or combinations of TLC with spectrometric techniques such as FT-NIR, FT-IR, Raman or MS with different ionization mechanisms and MS-MS will be improved, but they will remain special technical solutions to special problems and must not be expected to become routine methods.

PHENOLS

Gas Chromatography

Phenolic compounds are extensively used in the chemical industry. Some simple phenolic species are known to be products of vascular plant metabolism, and also contribute to the polymeric structures of tannins and lignin. In addition to their use as intermediates in industry and in the production of dyes, plastics and pharmaceuticals, chlorophenols have

been extensively utilized as preservative agents, pesticides, antiseptics and disinfectants. Chlorophenols can also be obtained by hydrolysis, oxidation and microbial degradation of chlorinated pesticides, and can be produced when phenol-contaminated water is chlorinated for purification. The US Environmental Protection Agency (EPA) listed 11 phenols as priority pollutants, including phenol, 2-nitrophenol (2-NP), 4-nitrophenol (4-NP), 2-chlorophenol (2-CP), 2,4-dinitrophenol (2,4-DNP), 2,4-dichlorophenol (2,4-DCP), 2,4-dimethylphenol (2,4-DMP), 2-methyl-4,6-dinitrophenol (2-M-4,6-DMP), 4-chloro-3-methylphenol (4-C-3-MP), 2,4,6-trichlorophenol (2,4,6-TCP) and pentachlorophenol (PCP). Several phenolic compounds are also listed in the European Community (EC) Directive 76/464/EEC regarding dangerous substances discharged into the aquatic environment. For drinking purposes, EC Directive 75/440/EEC states that maximum levels of phenolic compounds in surface water should be within the range 1–10 ng mL⁻¹. Therefore, rapid and reliable methods must be developed to analyse these compounds.

Owing to its high sensitivity and resolving power, chromatography is the most commonly used analytical technique to determine phenols. Previous investigations have developed gas chromatography (GC), high performance liquid chromatography (HPLC), capillary electrophoresis (CE) and supercritical fluid chromatography (SFC) to monitor these pollutants. Government-approved analytical methods, e.g. US EPA 604 and 625 (acid-extractable section), are based on gas chromatography using electron capture or mass spectrometry detection.

Gas chromatography is the most widely used technique in analytical chemistry. The merits of gas chromatography include its speed, precision and accuracy. Gas chromatography is appropriate for separating and analysing nonpolar volatile materials but it is limited in application to materials that exert vapour pressures of at least 10 mmHg at the column operating temperature. Also, owing to their high polarity, phenols tend to produce broad-tailed peaks, and this effect increases as the column ages. In order to obtain more favourable chromatographic peaks, less polar derivatives of phenols are often prepared. When GC is applied to determine trace amounts of phenols in water or other samples a pre-concentration or extraction step is frequently required. Proper sampling largely determines the validity of an analytical sample for trace analysis. Various pre-concentration techniques have been developed for phenol analysis. The sensitivity of GC for phenol analysis depends markedly on the detector used. Sample preparation methods, including various types of extraction tech-

niques and derivatization procedures, are described below. The effectiveness of the techniques is demonstrated by investigations on real samples.

Sample Preparation

As many investigations have confirmed, determining phenolic compounds in water or other matrices in the range below 1 ng mL⁻¹ is extremely difficult. The extraction and preconcentration of a mixture of phenols present difficulties owing to their wide range of polarities. In addition, volatilization may cause losses in preconcentration because of their relatively high vapour pressure. The conventional preconcentration technique is liquid-liquid extraction (LLE) for aqueous samples. The US EPA method for the analysis of phenols in water (EPA 604 and 625, acid-extractable section), consists of acidification of the sample to pH 2, followed by dichloromethane extraction. Merits of LLE include its simplicity and the need for inexpensive equipment. Nevertheless, despite its extensive use, LLE has many drawbacks, such as emulsion formation and different extraction efficiencies for different compounds. In addition, the method requires a large amount of solvent, and is slow and laborious. It is also hazardous to health since it uses toxic organic solvents that are also relatively expensive in terms of disposal. Solid-phase extraction (SPE) protocols are more commonly used than conventional LLE procedures, thereby reducing loss of analytes and the use of large amount toxic solvents. The complete extraction is performed in a series of stages, including washing, conditioning, eluting and drying. Many SPE materials are used in the preconcentration of phenols from aqueous samples including Empore disks, cartridges or small precolumns. Sorbents, including C₁₈, C₁₀, C₈, C₂, CH, CN and RLRP-S (styrene-divinylbenzene copolymer), have been used to investigate the extraction efficiency of phenols in water. The C₁₈-based sorbents have the property of low breakthrough volume of the more polar analytes and are therefore inappropriate for the simultaneous preconcentration of polar and nonpolar compounds. Notably, the breakthrough problem occurs for catechol, phenol and 4-NP extracted with C₁₈ sorbent. According to a previous investigation, a polymeric material such as Amberlite XAD-2 or XAD-4 or PRP is the most appropriate sorbent, yielding recoveries of up to 80% for most phenolic compounds; however, the breakthrough problem for some phenols still occurs. To overcome this problem, polymeric phases with high cross-linking have been proposed, e.g. by using the packing materials based on styrene-divinylbenzene copolymer, such as Isolute ENV⁺, Lichrolut EN,

Envi-chrom, PLRR-S and Porapak RPX. However, SPE can be expensive because the cartridges are normally discarded after one extraction. Moreover, the extraction still uses organic solvents that potentially threaten health and the surrounding environment.

Solid-phase microextraction (SPME) does not require the use of an organic solvent. The mechanism of SPME is based on an equilibrium of analytes between the sample and the solid phase coating on a quartz fibre. The analytes are directly determined by thermal desorption from the fibre into a GC. SPME has been extensively applied to extract trace organic compounds from aqueous samples owing to its solvent-free methodology, simplicity and rapidity. The feasibility of applying SPME to extract phenols from a complex matrix with polyacrylate (PA)- or poly(dimethylsiloxane) (PDMS)-coated fibres has been thoroughly evaluated. Extraction optimization procedures have been systematically studied, involving the pH of the sample, the desorption time and salting-out. Supercritical fluid extraction (SFE) and Soxhlet extraction techniques have been used for the solid samples. The extraction of 11 phenolic compounds from a river sediment by methanol-CO₂ mixtures under supercritical conditions and Soxhlet extraction with methylene chloride have been evaluated.

In the GC analysis of high polarity and vapour pressure phenols, a derivatization step is frequently executed to provide the mixture with better chromatographic characteristics. Until now, the derivatives used for this purpose have been based on the formation of esters, ethers and silyl derivatives. The derivatizing agents used are acetic anhydride, diazomethane, 2,4-dinitrobenzene, heptafluorobutylimidazole, pentafluorobenzoyl chloride, pentafluorobenzoyl bromide and silanizing agents. Acetylating agents have been widely used for the derivatization of phenols. Phenols can be acetylated in the aqueous organic sample or after extraction. EPA method 8041 recommends the derivatization of phenols to methylated phenols using diazomethane but diazomethane gas is extremely toxic, irritating and carcinogenic, so derivatization must be handled in a hood and with safety equipment.

Environmental Applications

Analysing phenol residues in environmental samples by GC has been the subject of extensive investigations. A novel means of determining eight chlorophenols in tap water was reported: it involved the direct acetylation of the chlorophenols with acetic anhydride in the presence of K₂CO₃. A graphitized carbon cartridge was used for extraction and precon-

centration. Chlorophenols were quantitatively measured by a microwave-induced plasma atomic emission detector at the sub-p.p.b. level in tap water. A methylphenylsilicone capillary column was used for separation.

The purge-and-trap technique and laboratory-made pulsed-spray techniques to extract five chlorophenols in water have been evaluated. The absorbent tubes were packed with 100 mg Tenax TA (0.2 µm). The absorbent tubes were attached to the injector port of a GC and heated to 200°C for 3 min to desorb the trapped analytes. GC separation was followed by MS detection and quantitation in the selected ion monitoring (SIM) mode. **Figure 1** depicts the gas chromatogram of spray-and-trap GC-MS of a water sample containing 100 µg L⁻¹ chlorophenols and 20 µg L⁻¹ internal standard (2,4,6-tribromophenol). Low ng L⁻¹ levels of detection were obtained for the studied chlorophenols.

The optimization of SPME conditions for the determination of phenols was investigated. The SPME method, based on a polyacrylate-coated fibre, gave a detection limit at 32–0.01 µg L⁻¹ level for GC-flame ionization detector (GC-FID) and GC-mass spectrometry (GC-MS) using saturated sodium chloride solution at pH 2. Applying the method to analyse a sewage sample indicated that the matrix significantly influenced the extraction of heavier chlorinated phenols. The feasibility of SPME-GC-MS was examined for detecting phenolic compounds in waste water and the effects of humic acid and surfactants on recovery were studied. SPME using pencil lead as a sorbent for analysis of 2-CP in water was also investigated. The detection limit for the determination of chlorophenols by GC-ECD (electron-capture detection) was 1 ng mL⁻¹. According to their results, the dissolved humic substances (10 mg L⁻¹) did not affect the analysis. Analysis of chlorophenols from an aqueous sample by GC-MS following SPME and reaction with diazomethane has been studied. A silica fibre coated with polyacrylate yielded good extraction efficiency. **Figure 2** displays the mass chromatogram of chlorophenols derivatized with diazomethane after SPME, with detection limits at the level of ng L⁻¹.

The direct determination phenols in water using headspace-gas chromatography (HS-GC) has been developed. A method has been proposed based on the GC headspace analysis of phenols in solids as acetate derivatives. The acetate derivatives were directly prepared in the wet solid samples by acetic anhydride in the presence of KHCO₃ and separated on a diisodecylphthalate capillary column with FID. The detection limit ranged between 0.03 and 0.08 µg g⁻¹. We have evaluated SPME with a polyacrylate fibre

Figure 1 Chromatogram of pulsed spary-and-trap GC-MS of a water sample containing $100 \mu\text{g L}^{-1}$ chlorophenols and $20 \mu\text{g L}^{-1}$ internal standard (2,4,6-tribromophenol).

coupled with GC-MS (electron impact ionization and negative chemical ionization) to determine chlorophenols in landfill leachates and soil. The chlorophenols were analysed without any derivatization.

The method is precise and can be used over a wide linear range, with detection limits of 1 ng L^{-1} levels of chlorophenols in water. The chlorophenols were determined in soil contaminated with PCP from

Figure 2 Chromatogram of $100 \mu\text{g L}^{-1}$ chlorophenols by post-derivatization following SPME with diazomethane produced using GC-MS (SIM).

Figure 3 Mass ion chromatogram (TIC) of a real soil sample. (Reproduced from Lee MR (1998) *Journal of Chromatography A* 806: 323, with permission from Elsevier Science.)

a chemical manufacturing plant. **Figure 3** depicts the mass ion chromatogram of a real soil sample. Chlorophenols detected were 2,4-DCP, 2,4,6-TCP, 2,3,4,6-tetrachlorophenol (2,3,4,6-TeCP) and PCP. The internal standard was 2,4,6-tribromophenol. The PCP detected in the soil was estimated to be $534 \mu\text{g g}^{-1}$.

Biological Fluid Analysis

The monitoring of phenols in human urine and other biological samples is used as an indication of occupational exposure or exposure to environmental contamination. The efficiency of extracting analytes from complex matrices, particularly urine samples, affects the detection level. Selecting the optimum sample preparation method is a prerequisite for trace analysis of phenols in urine. Many methods of extraction combined with chromatographic techniques have been proposed to determine phenols in urine. One method determined the urinary chlorophenols as acetyl derivatives after hot acid hydrolysis, then extracted them using LLE with toluene. The chlorophenol derivatives were then determined by GC-MS using selected ion monitoring. The method was used to monitor the urine of sawmill workers who are still

occupationally exposed to chlorophenols because of a contaminated work environment. The limit of quantification was in the level of $3.6 \mu\text{g g}^{-1}$ creatinine for all the studied chlorophenols. A sensitive and selective method was developed for the quantitation of total *o*-phenylphenol (free plus conjugates) found in human urine samples. Conjugates of *o*-phenylphenol were acid-hydrolysed to free *o*-phenylphenol, extracted into toluene and derivatized to the pentafluorobenzol ester derivative. The analysis was performed via negative ion chemical ionization-GC-MS (NCI-GC-MS). In this case, the lower limit of quantification was 1 ng mL^{-1} urine.
