Mantled karst is wholly or partly covered by a relatively thin veneer of post-karst rock or sediment and is part of the contemporary landscape.

Cooper (1998) defined 16 sinkhole variations in the gypsum subsidence belt at Ripon, all are types of ^{7.4}entrenched, subjacent and mantled karst. Changes in karst style are caused by; the type of gypsum, the nature and thickness of the overlying deposits, presence or absence of consolidated layers overlying the gypsum and the size of voids/caverns within the gypsum.

To the west of Ripon, the gypsum of the Edlington Formation lies directly beneath glacial drift. These unconsolidated drift deposits and the loose residual marl atop the dissolving gypsum gradually subside into a pinnacle or suffusion (mantled) karst. But between Ripon city and the River Ure, the limestone of the Brotherton Formation overlies the Edlington Formation. There the karst develops as large open caverns beneath strong roof spans (entrenched karst). Ultimate collapse of the roof span creates rapid upward-stopping caverns in loosely consolidated sediment. Slopes break through to the surface as steep-sided collapse dolines or chimneys with sometimes catastrophic results. A similar entrenched situation is found east of the Ure River but there karstified gypsum units of both the Edlington and the Roxby formations are involved.

When a chimney breaks through, the associated surface collapse is very ^{7.5}rapid. A recently documented example of one such subsidence crater, which opened up in front of a house on Ure Bank terrace on 23rd and 24th April, 1997, is documented by Cooper (op. cit.) as follows (Figure 7.43a).

“The hole grew in size and migrated towards the house, to measure 10m in diameter and 5.5m deep by the end of Thurs-

day. Four garages have been destroyed by the subsidence. This collapse was the largest of one of a series that have affected this site for more than 30 years. The hole is cylindrical but will ultimately fail to become a larger, but conical, depression. As it does so, it may cause collapse of the house, which is already damaged, and the adjacent road. The house and several nearby properties have been evacuated and the nearby road has been closed. The gas and other services, which run close to the hole, have also been disconnected in case of further collapse.”

Problems with Miocene gypsum, Spain

Karstification has led to numerous problems in areas of subcropping Miocene gypsum in the Ebro and Calatayud basins, northern Spain. Areas affected are defined by subsidence or collapse in Quaternary alluvial overburden and include; urban areas, communication routes, roads, railways, irrigation channels and agricultural fields (Soriano and Simon, 1995; Elorza and Santolalla, 1998). There can be a reciprocal interaction between anthropic activities and sinkhole generation, whereby the ground disturbance engendered by human activity accelerates, enlarges and triggers the creation of new sinkholes. Subsidence is particularly harmful to linear constructions and buildings and numerous roads, motorways and railways have been damaged. Catastrophic collapse in roads and buildings

^{7.5}A. H. Cooper in a lecture to the general public has recently argued that the collapse dolines breaching the landscape between Ripon and Darlington were the inspiration for the rabbit hole in Alice in Wonderland. In Chapter 1, Lewis Carroll wrote.

“The rabbit-hole went straight on like a tunnel for some way, and then dipped suddenly down, so suddenly, that Alice had not a moment to think about stopping herself, before she found herself falling down what seemed a deep well. Either the well was very deep, or she fell very slowly, for she had plenty of time as she went down to look about her, and to wonder what would happen next”

Charles Lutwidge Dodgson, who later adopted the Lewis Carroll pseudonym, was born in Cheshire and spent his early days at Croft, near Darlington. There, a trio of ponds called Hell’s Kettles were believed by locals to be bottomless. The pits are now known to be gypsum collapse features only 22ft deep but they may have inspired this passage from the first chapter. In 1852 Carroll moved with his parents to Yorkshire when his father became Canon Dodgson of Ripon. Here, he first met Mary Badcock. Carroll, a keen mathematician, scientist and photographer, took pictures of Mary that were later adapted by Sir John Tenniel into illustrations in the first edition of Alice in Wonderland.

can have potentially fatal consequences. For example, several buildings have been damaged around the towns of Casetas and Utebo. In the Portazgo industrial estate some factories had to be pulled down due to collapse-induced instability. A nearby gas explosion was attributed to the breakage of a gas pipe caused by subsidence. The local water supply is also disrupted by subsidence and pipe breakage so that 20,000 inhabitants periodically lose their water supply. The most striking example of subsidence affecting development comes from the recently built village of Puilatos, in the Gallego Valley. This was severely damaged by subsidence and abandoned before it could be occupied.

Collapse affects irrigation channels in the countryside with substantial economic losses (Elorza and Santolalla, 1998). In 1996 a doline collapse cut the important Canal Imperial at Gallur village. New dolines often form in close proximity to unlined irrigation canals. The ongoing supply of fresh irrigation waters to field crops can also encourage sinkhole generation in the fields. Though not directly visible, natural sinkholes also form in the submerged beds of river channels cutting regions of subcropping gypsum. On December 19th, 1971, a bus fell from a bridge into the Ebro River at Zaragoza, near where the so-called ‘San Lazaro well’ (a submerged gypsum sinkhole) is located. Ten people lost their lives in this accident, nine of them where never found. Locals suggested that bodies were carried into the sinkhole and sank into the caverns fed by this losing stream.

Variation in the water table level, induced by groundwater pumping, is another anthropogenic trigger for dolines. As the watertable declines it causes a loss of buoyant support to the ground, it also increases the flow gradient and water velocity, which facilitates higher rates of crossflow and deeper aquifer recharge in subsequent floods and so reduces the geomechanical strength of the cover and washes away roof span support. Dolines can also be associated with groundwater quality issues. Collapse dolines or sinkholes are frequently used as areas or sumps for uncontrolled dumping industrial and domestic waste. Because of the direct connection between them and the regional aquifer, uncontrolled dumping can cause rapid dispersion of chemical and bacterial pollutants in the groundwater.

Sometimes even well-intentioned attempts to remediate culturally significant buildings under threat of karst collapse can exacerbate collapse problems. Gutiérrez and Cooper (2002) cite two examples from the city of Calatayud, Spain (Figure 7.44a, b). Subsidence-induced differential loading drives the tilting of the 25 metre high tower of the San Pedro de los Francos church, which leans towards and overhangs the street by about

Figure 7.44. Gypsum karst, Calatayud region, Spain. A) View from the town of Calatayud toward the retreating front of Miocene gypsum and the encroaching floodplain of the Río Jalón. B) Mantled steep edge of a collapse doline exposed in a highway cut on the approach to Calatayud. Bedded gypsum makes up the right half of the exposure, alluvium the left.

1.5 metres. In places, the brickwork of the church indents the pre-existing tower fabric, which probably dates from the 11th Century or the beginning of the 12th Century. This indentation and the non-alignment of the church and the tower walls indicates that most of the tower tilting occurred prior to the construction of the church. In 1840, the upper 5m of the tower was removed and the lower part buttressed for the safety of the Royal family, who visited the town and stayed in the palace opposite. On 3rd June 1931, San Pedro de los Francos church was declared a “Monument of Historical and Artistic value.” Due

to its ruinous condition, the church was closed to worship in 1979. Micropiling to improve the foundation was started in 1994, but this corrective measure was interrupted when only half of the building was underpinned. Very rapid differential settlement of the building took place in the following year, causing extensive damage and aggravating the subsidence problem.

Colegiata de Santa María la Mayor was constructed between the 13th and 18th centuries, it has an outstanding Mudéjar (a 72 m high tower) and numerous Renaissance features; it is considered the foremost monument in the city of Calatayud. As with the San Pedro de los Francos Church, recent micropiling work, applied to only one part of the cloister, has been followed by alarming differential movements that have drastically accelerated the deterioration of the building. Large blocks have fallen from the vault of the “Capitular Hall” and cracks up to 150 mm wide have opened in the brickwork of the back (NW) elevation, which has now been shored up for safety. The dated plaster tell-tales placed in these cracks to monitor the displacement demonstrate the high speed of the deformation produced by subsidence in recent years. On the afternoon of 10 September 1996, the fracture of a water supply pipe flooded the cloisters and the church with 100 mm of muddy water. Ten years earlier a similar breakage and flood had occurred. These breaks in the water pipes are most likely related to

karst-induced subsidence. Once they occur, the massive input of water to the subsurface may trigger further destruction via enhanced dissolution, piping and hydrocollapse (Gutiérrez and Cooper, 2002).

Gypsum karst beneath Mosul, Iraq

A similar quandary of multiple areas of structural damage from gypsum-induced subsidence affects large parts of the historic

section of the city of Mosul in northern Iraq (Jassim et al., 1997). The main part of its old quarter is over a century old and some buildings are a few hundred years old. Mosul lies on the northeastern flank of the Albu Saif anticline and near to its northern plunge. It was built on the western bank of the Tigris River on a dip slope of Miocene limestone that is directly underlain by bedded gypsum and green marl (equivalent to Fars Formation). Houses in the old city were built on what seemed to be at the time a very sound rock foundation.

In the early part of last century water distribution in the city was done on mule back and the estimated water consumption did not exceed 10 litres per person per day (Jassim et al., 1997). Discharge from households was partly to surface drainage and partly to shallow and small septic tanks. The modern piped system of water distribution did not start until the 1940s, resulting in a sudden increase in water consumption (presently around 200 litres per person per day) and it was not associated with a complementary sewer system. Increased water consumption meant larger and deeper septic tanks were dug at the perimeter of buildings (which never seemed to fill) resulting in a dramatic increase in water percolating downwards, water which was also more corrosive due to the increased use of detergents and chlorination. This water passes through the permeable and fractured limestone to the underlying gypsum. On its way through the limestone it enlarged and created new dissolution cavities, but eventually found its way into the older gypsum karst maze, which is then further widened as water drains back into the Tigris. Caverns in the gypsum enlarge until the roof span collapses. Since the 1970s more and more buildings in the old city have fractured and many were subject to suddenly collapse. The problem was further intensified due to the expansion of the city in the up-dip direction (west and southwest) including construction of industrial, water-dependant centres. Water draining from the up-dip areas eventually passes under the old city before discharging in the Tigris river. The process was slightly arrested in the 1980s by the completion of a drainage system for the city, but the degradation of the old city continues.

Solving the problem?

Throughout the world, be it in the UK, Spain, eastern Europe, or the Middle East, it is a fact that weathering of shallow gypsum forms rapidly expanding and stoping caverns, especially in areas of high water crossflow, roof beams and unconsolidated overburden. Formative processes and mechanism are commonplace and widespread (Table 7.8). It is fact that natural solution in regions of subcropping evaporites is always rapid,

and even more so in areas where it is encouraged by human activities, especially increased cycling of water via groundwater pumping, burst pipes, septic systems and uncontrolled storm and waste water runoff to the aquifer.

Typically, the best way to deal with a region of an evaporite karst hazard is to map the regional extent of the shallow evaporite solution front and avoid it. In established areas with a karst problem the engineering solutions are largely short term and local. Problems will be ongoing as subsidence and occasional, but rapid, catastrophic collapse are both natural processes. If man-made buildings of significance are to be restored and stabilized, perhaps it is better to wait until funds are sufficient to complete the job rather than attempt partial stabilization of the worst-affected portions of the building. In the words of Nobel prizewinner, Shimon Peres; "If a problem has no solution, it may not be a problem, but a fact - not to be solved, but to be coped with over time."

Sulphuric acid speleogenesis

Historically, most carbonate karst networks have been interpreted as epigenic (surface-driven) responses to vadose/shallow-phreatic leaching of carbonate bedrock, in a hydrology driven by throughflowing fresh to brackish meteoric waters. Leaching and cavern/joint enlargement is seen as a response to waters enriched in carbonic acid. Carbonic acid is derived from CO₂ in the atmospheric and soil zones. Most vadose cave ornamentation is a response to CO₂ degassing at or above the watertable and precipitates are dominantly calcite, with lesser volumes of other carbonate minerals (aragonite, magnesite) and rare sulphates.

We have just seen how gypsum maze caves do not fit neatly into this epigenetic meteoric/watertable dominated template. Telogenetic gypsum karst in an evaporite basin starts much deeper (hypogenic), typically in water crossflows driven by deep artesian circulation or escaping basinal fluids. In the last two decades the importance of similar hypogene leaching of carbonates has been recognised in systems driven by the ascent, mixing and cooling of H₂S and CO₂ rich basinal brines. Examples are now documented in what were once considered classic regions of meteoric leaching (Table 7.9; Davis, 1980; Egemeier, 1981). Caverns can form in carbonate hosts well below the water table where there is frequently a calcium sulphate association in the deeper parts of the hydrology, both in basinal generation of H₂S and in the typical byproducts of cavern creation.

Table 7.9. Active and inactive sulphuric cavern systems, not all are related to evaporite dissolution, but all accumulate gypsum.

Bathypneatic caves are still classified by some carbonate sedimentologists as a form of hydrothermal karst with an implication of hot hydrothermal waters. There certainly are some bathypneatic caves developed as carbonate karst that do have an association with hot circulating waters, especially those caves forming host cavities to some MVT deposits (Warren and Kendall, 1997). But many sulphuric acid groundwaters that form caves and cavern gypsum, such as those of the Carlsbad system, were probably not all that hot. The term hypogene (formed at depth) is more appropriate than hydrothermal (waters with elevated temperature) in classifying caves formed by cooling and mixing of hydrocarbon-rich basinal waters, which have encountered deeply buried beds of sulphate evaporites on their way to the surface.

Hypogene caves in carbonate hosts can contain substantial volumes of gypsum precipitated as cavern fills and limestone replacements at scales ranging from microcrystalline crusts on the cave wall to cavern-filling accumulations of phreatic gypsum crystals deposited either as pelagic laminites or as spectacular crystal-clear prisms that can be metres long and wide (Buck et al., 1994). The accumulation of large volumes of cave-fill gypsum, independent of the climate at the landsurface, does not fit well with older notions of surface-driven meteoric circulation and arid cave atmospheres for gypsum speleothems. Hypogene caverns and their gypsum fills can develop wherever oxygenation of rising H_2S -laden hypogene waters occurs, this typically first occurs at bathypneatic depths, and can be hundreds of metres below the meteoric water table.

Early stages of hypogenic caves display no relationship to meteoric recharge conduits in their overburden. This is typically an epigenic overprint that forms during later uplift. Hypogenic cave passages typically follow ramiform, network, or spongiform patterns (Palmer and Palmer, 2000). Time and ongoing exhumation brings a hypogene cave closer to the land surface and moves it out of its formative bathypneatic hydrology. By the time hypogene caves are accessible to speleologists the evidence of the formative hydrology is largely overprinted by classic meteoric-driven karst textures and precipitates. H_2S needed to drive hypogene cavern formation is carried by escaping basinal waters that have experienced biochemical or thermochemical reduction of sulphate evaporites and petroleum. Less commonly, they are derived by groundwater oxidation of pyrite, or they entrain volcanogenic waters. As anoxic, H_2S -enriched basinal water rise along fractures in the limestone host, it cools and mixes with the underside of a layer of meteoric pore water, which typically is oxygenated. As sulphide-rich waters mix and become oxidized, the most aggressive byproduct of their oxidation is sulphuric acid, which can be biologically-mediated by sulphur-oxidising bacteria. This aggressive water leaches and dissolves the surrounding carbonate aquifer so that hypogene caverns tend to have large chambers with narrow connections and deep shafts along fracture or joint avenues where the sulphide-rich waters rose (inverted tear-drops). As the acid is spent the concentrations of calcium and sulphate in the cave waters build to gypsum saturation and the resulting gypsum ornamentation can be spectacular.

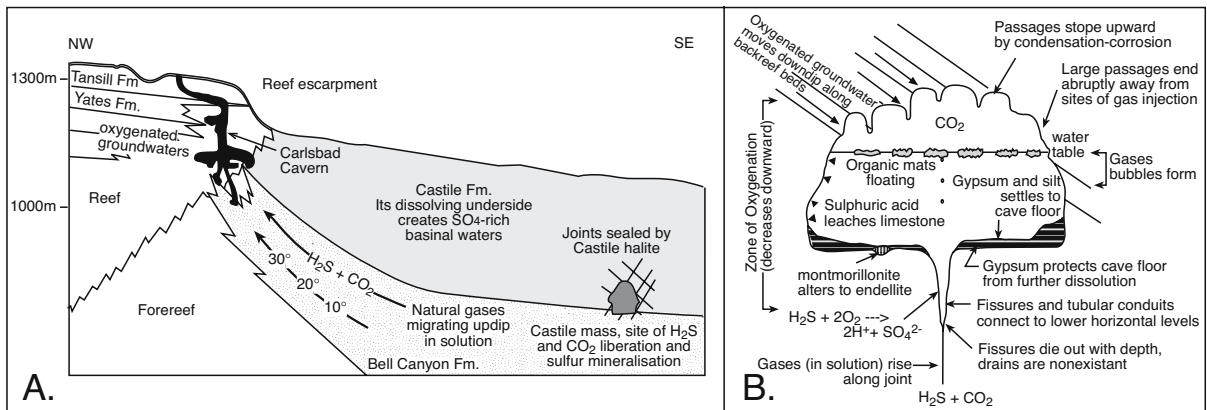

Figure 7.45. Sulphuric acid speleogenesis. A) Schematic section of Delaware Basin. Escape of natural gas from hydrocarbon kitchen in the basin centre is focused along the dissolving underside of the laminated anhydrite of the Castile Formation. It reacts thermochemically with the sulphate ions to produce H₂S, CO₂ and calcite replacement of the anhydrite (this forms the characteristic Castiles when later exhumed). H₂S and CO₂ continue their focused escape through the Bell Canyon Formation toward the basin margin where they enter limestones of the Capitan and Goat Seep Reefs. There the gases mix with oxygenated groundwater, hydrogen sulphide in solution and dissolved oxygen combine to form sulphuric acid, which then leaches the host limestone, especially along the more permeable joints and fissures. B) Hydrogen sulphide reacts with dissolved oxygen to form sulphuric acid which leaches a cavern. The sulphuric acid is neutralised by the limestone so that caverns tend to terminate abruptly away from zones of gas injection. Oxygenation and hence the acidic reaction die out with depth so that large rooms do not extend far below the horizontal extent of the cavern. With successive lowering of base level, driven by uplift and climatic change, new horizontal levels became connected with older horizontal levels by spring shafts and joint chimneys (after Hill, 1990; Forti et al., 2002). The gas-filled cavern top and an associated water table is only present during the more mature stages of exhumation. The process of mixing of H₂S-rich and meteoric waters that creates the hypogene cavern is a totally phreatic system and is largely unrelated to the presence or absence of a water table.

The best documented example of sulphuric acid speleogenesis in the western literature is the Carlsbad-Lechuguilla cavern system in Permian reefal limestones of the Guadalupe Mountains, USA (Figure 7.45a; Hill, 1990; Palmer and Palmer, 2000). Although meteoric processes now form calcitic speleothems in these caves, the early host caverns were etched bathyphreatically by sulphuric acid and walls were free of calcite speleothems. Sulphuric acid caverns created by mixing of H₂S waters with oxygenated phreatic waters began to form in the Carlsbad system some 10-12 Ma and as much as 200 metres below the water table. Remnant blocks of pelagic gypsum, a widespread byproduct of sulphuric acid leaching, still cover the floor of the now largely inactive and exhumed Carlsbad Cavern.

Room” level of Carlsbad Cavern formed 3.9 to 4.0 Ma, while the upper level of Lechuguilla Cave formed 5.7 to 6.0 Ma (Figure 7.46). Other older and now more elevated hypogene caves in the Guadalupe Mountains formed at various times from 6.0 to 11.3 Ma (Polyak et al., 1998). Alunite ages increase with,

Figure 7.46. Age versus elevation for several cave levels in the Guadalupe Mountains (after Polyak et al. 1998). 1 = Cottonwood Cave and Virgin Cave; 2 = Endless Cave and Glacier Bay (Lechuguilla Cave); 3 = Lake Lebarge (Lechuguilla Cave); 4 = New Mexico Room, Big Room, and Green Clay Room (Carlsbad Cavern); 5 = present water table.

⁴⁰Ar/³⁹Ar dating of fine-grained alunites that were formed during hypogene leaching, and still present in residual clays, show that the “Big

and are strongly correlative to, cave elevation, indicating an 1100-metre decline in the water table tied to ongoing Neogene uplift and tilting (Figure 7.46).

The cavern forming process is driven by chemical changes in oil- and gas-rich basinal waters moving up dip from the evaporite-sealed Delaware Basin (Figure 7.45a). Rising waters derive much of their sulphate content by dissolution of the underside of Castile anhydrite. Some of this sulphate undergoes thermogenic and biogenic sulphate reduction to form H₂S and CO₂, with bacteriogenic “Castile” calcite precipitated as a sulphate reduction byproduct along the contact between the underlying aquifer and the Castile Fm. SO₄. H₂S-enriched basinal waters then enters the Capitan and Goat Seep strata via crosscutting joints, typically along local aquifers created by the steeply dipping fore reef beds, or via lenses of sandy equivalents to Bell Canyon siliciclastics.

Rising basinal waters carry large volumes of H₂S, CO₂ and methane in solution. As it rises it depressurizes and releases the various dissolved phases as gas bubbles (degasses). By

Figure 7.47. Maximum depth at which degassing of H₂S, CO₂, and CH₄ can take place below the unconfined water table. Partial degassing occurs at depths well below the respective lines, but no degassing will occur above the line (after Palmer and Palmer, 2000).

the time the water comes to within a few metres of the water table it has released almost all of its gas as bubbles (Figure 7.47; Table 7.10; Palmer and Palmer, 2000). We shall focus on the H₂S because of its role in precipitating hypogene gypsum fills, but released CO₂ and methane released as gas bubbles from ascending brines also play a role in hypogene caves. Like H₂S, they can create chemosynthetic ecosystems in the deep phreatic, systems which function independent of energy input from the surface (Chapter 9).

On arrival in the shallower phreatic levels of the basin, the H₂S reacts with oxygenated groundwater to form sulphuric acid:

Once formed, the sulphuric acid immediately attacks the limestone host and etched out the Carlsbad caverns via the reaction:

This adds further sulphate to the already sulphate-enriched cave waters. If the dissolving carbonate host is dolomitic, then significant magnesium is also added to the cave water. Expanding horizontal benches in such hypogene caverns reflect intervals of most intense phreatic mixing between H₂S and SO₄ saturated basinal waters. They are located in the lower portion of the oxygenated active phreatic system and may not necessarily be tied the presence of a water table.

Sulphuric acid caves have spongelike edges and no calcitic speleothems ornamenting the growing cavity. Cave walls tend to end abruptly in the horizontal plane as the acidity of the cave waters is quickly quenched away from fissures supplying H₂S. Likewise, since the level of dissolved oxygen in cavern waters decreases with depth, the fissure passages and pits tend to terminate vertically via a rapid narrowing downward channelway. This forms an inverted “tear drop” cavern, a shape less seen in epigenic carbonate karst (Figure 7.45b).

Ongoing leaching means calcium and sulphate levels continue to build in cavern waters, which are already near or at gypsum saturation from earlier leaching of the Castile Formation. Gypsum starts to precipitate in the cave water column and on the cave walls. Fine laminated and layered pelagic gypsum builds up beneath the water-covered parts of the cave floor, typically atop endellitic silts. Huge centripetal splays (metres long and decimetres wide) of ice-clear prismatic gypsum precipitate in

stable phreatic portions of the cavern system. Alabaster crusts can coat vadose areas of the cave walls often in association with the growth of acidophilic archaea and sulphur-oxidising bacteria.

Smectitic clays, released by the leaching of the carbonate bedrock settle through the quiescent cave waters, along with the gypsum crystallites forming in the supersaturated cave waters, to form a pelagic (“rain-from-heaven”) unit of laminated gypsum and silt on the cave floor (Figure 7.45b). Acidic cave waters convert some of the accumulating smectite to endellite ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4 \cdot 2\text{H}_2\text{O}$), a brightly coloured clay indicative of acidic conditions in hypogene caves. Two other low-pH, sulphuric-acid indicator minerals, alunite and natroalunite, also occur in association with the endellite (Cunningham 1992; Hill 1995). The same sulphuric acid environment facilitates the formation of secondary late-stage, uranium-vanadium minerals tyuyamunite and metatyuyamunite at redox boundaries in the caves and their presence helps explain elevated levels of radon that typify the modern cave air in the various Carlsbad caverns (Hill, 1995).

Even though further uplift has now drained the waters from the caverns, relicts of the gypsum spar and blocks of layered granular pelagic gypsum remain. Such blocks are sporadically scattered over the deeper parts of the floor of the “Big Room” in Carlsbad Cavern as remnants of a former gypsum layer that was up to 10m thick. Internally, the blocks and rinds of the pelagic units show a laminated or microfolded fabric indicative of its subaqueous origin (pers. obs). In Lechuguilla Cave, phreatic spar gypsum ornamentation forms “chandeliers” or “ferro di lancia” accumulations of ice-clear gypsum crystals, which now, with subsequent water table lowering, protrude from the exposed and accessible areas of the cave.

Even more widespread and spectacular examples of gypsum chandeliers line the Cupp-Coutum and other now inactive hypogene sulphuric acid caves of Kugitangtau Ridge, Turkmenistan (Maltsev and Malishevsky, 1990). The phreatic calcium sulphate textures record a phase of hydrothermal activity within a pre-existing karstic groundwater conduit system (Bottrell et al., 2001). Hydrothermal fluids entered the caves through fault zones and deposited sulphate, sulphide and carbonate minerals under phreatic conditions. Locally, intense alteration of limestone wall rocks also occurred at this stage. Elsewhere in the region, similar faults contain economic quantities of galena and elemental sulphur mineralization. Comparisons between the Pb and S isotope compositions of minerals found in cave and ore deposits confirm the link between economic

mineralization and hydrothermal activity at Cupp-Coutum. The predominance of sulphate mineralization in Cupp-Coutum implies that the fluids were more oxidized in the higher permeability zone associated with the karst aquifer.

Following the hydrothermal phase, speleothemic minerals were precipitated under vadose conditions (Bottrell et al., 2001). Speleothemic sulphates show a bimodal sulphur isotope distribution. One group has compositions similar to the hydrothermal sulphates, whilst the second group is characterized by higher $\delta^{34}\text{S}$ values. This latter group may either record the effects of microbial sulphate reduction, or reflect the introduction of sulphate-rich groundwater generated by the dissolution of overlying evaporites. Oxygen isotope compositions show that calcite speleothems were precipitated from nonthermal groundwater of meteoric origin. Carbonate speleothems are relatively enriched in ^{13}C compared to most cave deposits, but can be explained by normal speleothem-forming processes under thin, arid-zone soils dominated by C_4 vegetation. However, the presence of sulphate speleothems, with isotopic compositions indicative of the oxidation of hydrothermal sulphide, implies that CO_2 derived by reaction of limestone with sulphuric acid (‘condensation corrosion’) contributed to the formation of ^{13}C -enriched speleothem deposits.

Blocks composed of white, fine-grained, pelagic (phreatic) gypsum cover large floor areas (over 1000m^3) of the upper cave level of the Grotta Grande del Vento, Italy (Galdenzi, 1990; Galdenzi and Maruoka, 2003). In this case the gypsum does not form the spectacular “ferro di lancia” found in New Mexico and Turkmenistan, although there are some coarsely crystalline aligned prisms that are interpreted to have grown in the cave mud. Today’s gypsum textures in the Frasassi caves are much less diverse and more localised than when sulphate precipitation was at its peak in the hypogene phreatic caverns of the early Pleistocene (Galdenzi and Maruoka, 2003). What makes Grotto Grande so interesting is that the process of gypsum formation is still active in some accessible parts of the cave where H_2S -rich waters mix with oxygenated ground waters. Hollow vaterite spherules have been precipitated in the laboratory from bacterial cultures collected from such caves in Italy and Spain (Sanchez-Moral et al., 2003).

Native sulphur can be found in sulphidic caverns of New Mexico either admixed with gypsum in the remnant pelagic blocks or as canary-yellow sulphur crystal coats on the undersides of dipping beds of the foreereef or the siliciclastic Bell Canyon Formation. $\delta^{34}\text{S}$ values are as low as -25.8‰ (CDT) in this cave sulphur. Similar values in the cave gypsum (-25.6‰) and the

Figure 7.48. Range of sulphur isotope values for various H_2S associated cave deposits in the USA, Italy and Mexico (after Hill, 2000; Hose et al., 2000; Polyak and Güven, 1996; Galdenzi and Maruoka, 2003; Garcia-Guinea et al., 2002; Sancho et al., 2004). Cave gypsum and sulphur in the Delaware Basin are significantly enriched in the light isotopes compared to the Castile Formation. Their isotopically light composition within the basin (H_2S gas, native sulphur) and in the reef (sulphides and sulphur/gypsum cave deposits) reflect bacterial sulphate reduction where sulphate solutions mixed with hydrocarbons to produce isotopically light hydrogen sulphide. Similar products from sulphuric acid caves in Italy and Mexico also plot in the negative sulphur range and are clearly not indicative of a meteoric or marine source.

endellite, indicate that they too are end products of microbial reduction reactions metabolising escaping hydrocarbons. Their isotopic signatures are not products of meteoric diagenesis (Figure 7.48; Hill, 1990).

Throughout the various caves of the Guadalupe Mountains, sulphur isotope results have been crucial in defining its hypogenic speleogenesis (Figure 7.48; Hill, 1990, 2000). Without bacterial mediation (mostly by anoxic sulphate reducers at depth, then sulphate oxidisers near the water table), cave gypsum with such negative values could not have been derived from Castile anhydrite beds. It means inorganic models based on local brine pooling and saturation (Bretz, 1952) or the inorganic cooling of basinal water (Queen et al., 1979) are not directly applicable to Carlsbad precipitates. Such inorganic models are more relevant to the ice-clear 8 metre long, 1 metre wide,

gypsum crystals filling giant geodes in a Triassic limestone host at Pulpí in SE Spain (Garcia-Guinea et al., 2002) and to gypsum crusts in Brujas Cave, Argentina (Sancho et al., 2004). The average isotopic composition of marine-fed Castile gypsum/anhydrite is +10.3‰. If the cave gypsum had precipitated directly from cooling Castile brines, then gypsum in the cave fill should have a similar signature to the Castile Formation, clearly, it does not. Sulphur isotope data also discount sulphate derivation from a pyrite precursor, as proposed by Jagnow (1977). Metal sulphide values in the Guadalupe Mountain samples (mostly pyrites) range from $\delta^{34}S = -9.3$ to +12.6‰ (mean = -2.2‰ for 20 samples; Figure 7.48). As there is no significant isotopic fractionation involved in the subsurface leaching of sulphides (less than 1‰), it must be concluded that the isotopically lighter signatures of cave floor gypsum and sulphur (mean $\delta^{34}S = -16.8$ ‰ for 22 samples) are not derived from a pyrite source. Instead, the consistent isotopically light signature in the cave precipitates support a model of bacterial sulphate reduction acting on Castile Formation sulphate (and hydrocarbons) and ultimately creating sulphuric acid leading to caves with gypsum as a widespread precipitate.

Sulphuric acid speleogenesis is no longer active in the accessible portions of the New Mexico or Turkmenistan caves. But sulphuric acid driven cave expansion is occurring today in the Cueva de Villa Luz in Mexico (Hose et al., 2000), Grotta Grande del Vento in Italy (Galdenzi, 1990) and the Movile Cave in Romania (Sarbu et al., 1994). In all three, the cave water and cave atmosphere is enriched in hydrogen sulphide and the action is centred around the watertable (Table 7.10).

Oxidation of sulphide-rich waters seeping from the cave walls and the associated precipitation of fine-grained gypsum is largely microbially driven (Figure 7.49). It is localised to seepages at or near the water table and the precipitation chemistry is facili-

tated by sulphur-oxidising bacteria. Near identical microbial mat communities float at the air/water interface in the active sulphuric acid lake of Movile Cave, Romania, and coat the cave walls (snottites) in Cueva de Villa Luz, Mexico. In all three, the process today is vadose and tied to the watertable. Textures in the wall gypsum are not the same nor as widespread as the relict phreatic pelagics and gypsum spars we see in palaeohypogene caves in New Mexico and Turkmenistan.

Measured H_2S levels in the cave atmosphere of Cueva de Villa Luz reach 210 ppm, while SO_2 typically exceeds 35 ppm, conditions which require researchers to use masks and breathers. These gases, plus oxygen from the cave air, are absorbed by water films that gather on the cave walls via infiltration and condensation. Sulphur-oxidizing bacterial colonies in water films on cave walls and floating on cave waters facilitate the conversion of the abundant hydrogen sulphide to sulphuric acid. Microbes probably also facilitate the conversion of carbon dioxide to carbonic acid. Low pH waters (0.0-3.0, with a mean of 1.4) drip from microbial veils onto the limestone floor. Growths look like delicate stalactites made of phlegm, locally dubbed “snottites” (Figure 7.49). The acid drips form rillen and incised channels in the wet limestone walls adjacent to the main cave stream. On the cavern slopes above main stream level, the sulphuric acid reacts with the surrounding limestone to produce a pasty plastering composed of microcrystalline (alabastrine) gypsum and microbes, with surface pH values between 0.5-3.0.

Cueva de Villa Luz is fed by at more than 25 groundwater springs, with a combined flow of 200-300 l/s. Inlet water chemistry defines two categories: a) those with high H_2S content (300-500 mg/l), mean $P_{CO_2} = 0.03-0.1$ atm, and no measurable O_2 ; and b) those with less than 0.1 mg/l H_2S , mean $P_{CO_2} = 0.02$ atm, and modest O_2 contents up to 4.3 mg/l. Both water types have a similar source, as shown by their dissolved solid content. However the oxygenated water has been exposed to aerated conditions upstream from the cave inlets so that much of the original H_2S has been largely lost via outgassing and oxidation to sulphate, increasing the sulphate concentration in the waters by about 4%. Modelling of the cave water chemistry shows that it can be produced by dissolution of sulphate, carbonate, and chloride minerals, which are present deeper in the basin (Hose et al., 2000).

Two cave-enlarging mechanisms were identified in the Cueva de Villa Luz (Figure 7.49; Hose et al., 2000): 1) Sulphuric acid from oxidation of hydrogen sulphide prior to exit into the cave, which converts subaerial limestone surfaces to gypsum and

is aided by the activities of sulphur-oxidising bacteria. Most of this gypsum ends up falling into the cave stream where it is redissolved and lost via the stream exiting the system. 2) Strongly acidic droplets, formed on microbial filaments, which dissolves limestone as it drips onto the cave floor. Possible sources of H_2S in the Cueva de Villa Luz system are the evaporites of the Villahermosa petroleum basin, which is less than 50 km downdip and to the northwest, or the hydrothermal system of the El Chichon volcano located some 50 km to the west. Depletion of ^{34}S values for sulphur stabilized from H_2S in the cave atmosphere (-11.7‰), along with the hydrochemistry of the spring waters, favour an evaporite - sulphate reduction origin over a volcanogenic source.

In part, so much more gypsum occurs in the caverns at Carlsbad, compared to the amount of gypsum accumulating on cave walls in other active sulphuric acid caves of today, simply because there was so much more dissolved gypsum entering the cave system along the edge of dissolving evaporite bed. When it was active, the Carlsbad system was located in the outflow zone of a large regionally draining basin with escaping waters focused

Figure 7.49. Mechanisms for cave enlargement. 1. Conversion of limestone to gypsum crust by sulphuric acid, dissolved by the cave stream and by infiltrating freshwater. 2. Drips of sulphuric acid from the gypsum wall crust and snottites corrode limestone below. Microbial activity enhances the oxidation reactions that produce the acid. 3. Sulphuric acid seeps through the gypsum crust and dissolves the limestone at the base. Solutional rills are common (after Hose et al., 2000).

into the growing cave system by the dissolving underside of a bedded basinwide anhydrite.

But there is another key difference when comparing gypsum precipitation processes at Carlsbad to modern sulphuric acid caves. Gypsum textures in now inactive hypogene karst fills of Carlsbad and similar systems elsewhere (Table 7.9) indicate phreatic gypsum could accumulate within expanding caves situated as much as 100–200 m below the meteoric water table. Today in all the accessible parts of the active sulphuric acid caves of Mexico, Italy and Romania caves the gypsum precipitation process is a microbially-mediated seepage process, where H_2S rich waters condense and seep down cave walls. It leads to unique lithoautotrophic systems centred on the sulphate oxidisers in the vadose zone at or immediately above the water table. But how relevant are these modern biogenic gypsum products to the much more spectacular and voluminous gypsum precipitates forming in inaccessible blind and deep hypogene caverns some tens to hundreds of metres below the water table? We now can study the results of this bathypneumatic hydrology only as relicts that have survived exhumation into the vadose realm.

In terms of models of gypsum precipitation and the relative contribution of sulphur-oxidising microbes to all gypsum formation in hypogene karst systems, we have the same scale and process-comparison problems that plague all studies of ancient evaporite deposition. What we have available to use in modern sulphuric caves, such as Cueva de Villa Luz, is accessible and measurable, but how reliably can we generalise our conclusions on what forms hypogene gypsum using models of vadose cave wall products to interpret what we see in the rock record. Studies of process in active sulphuric acid caves is restricted to parts of a cave system where people can crawl, sweat, swim and sample. These accessible parts are probably not the parts of a hypogene carbonate system where most gypsum precipitates and accumulates. To interpret process for this type of gypsum we must use the textures and extent of the gypsum itself. Even if such places were accessible in some yet to be discovered part of an active cave system, the elevated levels of H_2S would make it extremely toxic to generalist lifeforms like us.

Some carbonate workers would argue that H_2S -related karstification of marine carbonates is not a widespread diagenetic process. They argue that the bulk of published karstification studies in the literature support this contention. To this I would argue that the literature on carbonate karst reflects a sampling bias. That is, most studies of modern karst process are done in caves that are accessible for study. By definition these caves are near or at the surface and so are in

settings where meteoric karst predominates. Most H_2S -related karstification takes place at greater depths. In Chapter 9 we shall see that H_2S (sour gas) is a significant fluid component in most carbonate-evaporite basins and that much of this H_2S is produced by thermochemical sulphate reduction. Evaporite-associated examples from the Gulf of Mexico, the eastern US and Canadian shelf, the Mediterranean and the Middle East will be discussed.

H_2S can even be a significant component in fluids hosted in normal marine shelf sediments. For example fluids collected during the drilling of the southern Australian continental margin (Leg 182 of the Ocean Drilling Program), showed unusually high salinities (to 106‰) in nonevaporitic Miocene to Pleistocene carbonate and siliciclastic sediments (Swart et al., 2000). At three sites (1127, 1129, and 1131), high contents of H_2S (to 15%), CH_4 (to 50%), and CO_2 (to 70%) were encountered and may be associated with H_2S dominated clathrates. These levels of H_2S are the highest yet reported during the history of either the Deep Sea Drilling Project or the Ocean Drilling Program. The high concentrations of H_2S necessary for the formation of hydrates under these conditions were provided by the abundant SO_4 caused by the high salinities of the pore fluids, and the associated high concentrations of organic material. One hypothesis for the origin of these fluids is that they were formed by evaporation of brines on the adjacent continental shelf during previous lowstands of sea level. They then sank into the underlying sediments (brine reflux) where their residuals remain today.

Mineralised breccias

As they form, or after they form, evaporite solution breccias can act as permeable foci for base metal, sulphur hydrocarbon accumulations. Where the dissolving bed contains sulphate evaporites, it can act also as a source of sulphur to base metal sulphide precipitates and so become a locus for ore deposition (Warren 2000b). This is clearly seen in the ores of the now depleted Cadjebut Mine on the Devonian Lennard Shelf, West Australia (Warren and Kempton, 1997). The Cadjebut zinc mine is situated at the southern margin of the Emanuel Range and is hosted by platform carbonates of probable Givetian age near the base of the Pillara Limestone (Figure 7.50a). The orebody lies approximately 500 m to the north of the Cadjebut Fault and trends subparallel to it over a strike length of 3 km. Surface expression of the orebody is the “No Way Gossan,” which crops out 100m to the west of the mine portal. The orebody is roughly linear in shape, trending toward the northwest and dipping with the host dolomite at 5° – 10° to the northeast.

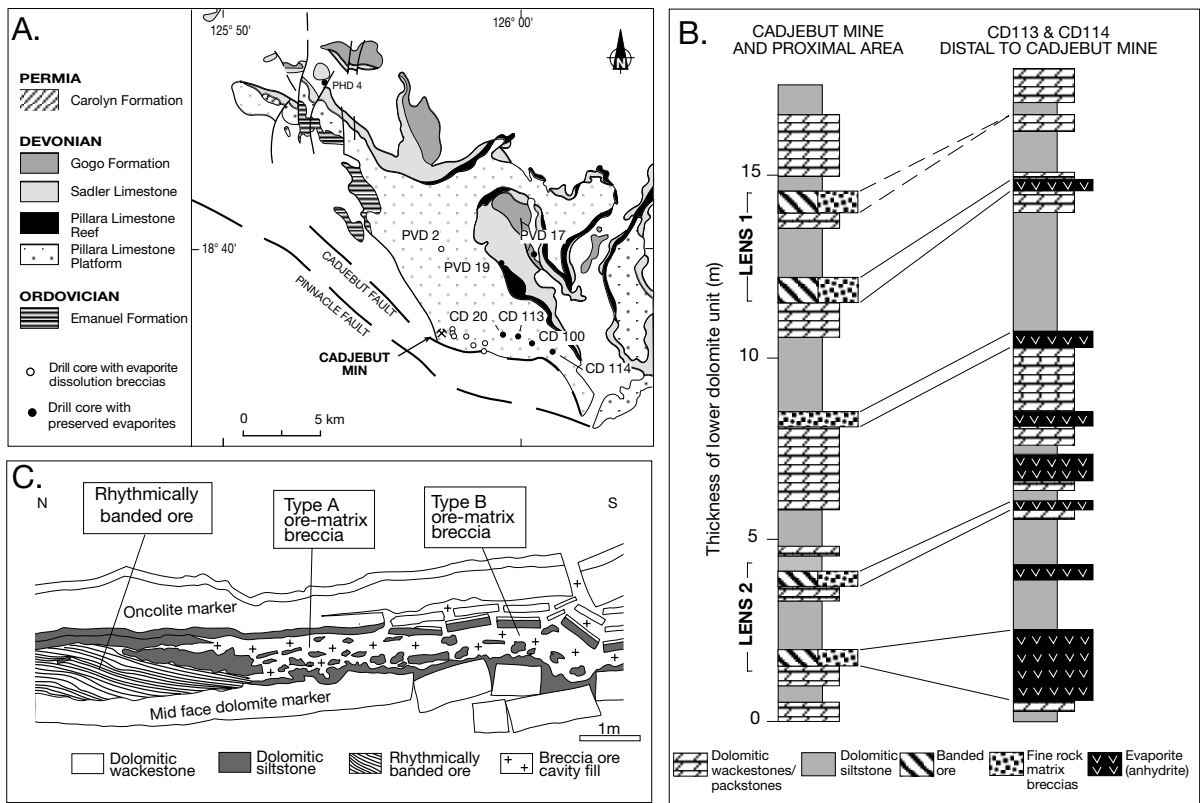

Figure 7.50. Cadjebut evaporites and mineralisation. A) Regional mine geology showing cored wells with and without evaporites. B) Correlation of ore lenses to solution breccias to evaporites in more distal positions from mine. C) Mapped ore face showing the different styles of ore texture in the mine. This ore horizon is laterally equivalent to an evaporite dissolution breccia, which in turn passes into equivalent anhydrite beds (after Warren and Kempton, 1997).

Cadjebut Mine had pre-mining reserves of 3.8 million tonnes of 17% combined zinc and lead. Ore grade mineralization (Zn-Pb) occurs as two stratabound lenses, referred to as “lens 1” and “lens 2” (Figure 7.50b), ranging in thickness from 4 to 6 metres. The width of the orebody varies from 50 to 150 m, as defined by a cut off grade of 7% lead-zinc, and is flanked to the north and south by hypogene alteration haloes of marcasite, calcite and baryte (Tompkins et al., 1994). The contact between ore grade mineralization (>7% Zn+Pb) and the alteration halo is usually abrupt over a distance of a few metres. In section, the ore-bearing lenses are stacked vertically above one another and separated by about 5 to 6m of barren or weakly mineralized dolostone (Figure 7.50b). In plan view, both ore lenses have a broad sinusoidal shape and display the same geometrical congruence.

Two dominant ore types are present (Figure 7.50c): (a) stratiform, rhythmically banded zinc-rich ore; and (b) stratiform to stratabound, lead-rich breccia-hosted cavity-fill ore. The rhythmically banded ore occurs as four stratiform horizons,

two throughout lens 2 and two in the northern part of lens 1. Rhythmically banded baryte and/or rhythmically banded marcasite form a halo around the orebody and are associated with the rhythmically banded zinc-rich ore.

There is a one-to-one correlation of sulphide-mineralised horizons in the Cadjebut Mine with evaporite dissolution breccia horizons in the immediate area around the mine, and with remnant bedded anhydrite units well away from the mine (Figure 7.50b). Evaporite beds were the precursor lithology to the sulphide ore lenses at Cadjebut. The stratabound linear nature of the Cadjebut deposit reflects a time when upwelling metalliferous basinal fluids interacted with bedded stratiform nodular anhydrite beds and trapped hydrocarbons to precipitate lead and zinc sulphides. Current structure in the mine region still preserves a gentle drape anticline, which Warren and Kempton (1997) interpret as a partial artifact of the mineralisation structure, enhanced by the sequential loss of the surrounding evaporites, after ore had locally replaced a bedded anhydrite precursor. The linear nature of the anticlinal structure

indicates some form focusing of ore fluids and hydrocarbons, either atop an active underlying fault, or within a preexisting anticlinal trap, perhaps created as a rollover drape on the edge of an evaporite-dissolving front (e.g. Figure 7.51a). Hydrocarbon residues (bitumens) are still present in the ore zones.

The rate of evaporite dissolution versus the rate of supply of mineralising fluid controlled the large scale textures within the Pb-Zn ores. Lead-zinc mineralisation in the Cadjebut Mine occurs as three distinct ore types (Figure 7.50c):

- stratiform rhythmically banded zinc-rich ore,
- stratiform Type A ore-matrix breccia ore, and
- crosscutting Type B ore matrix breccia ore.

The rhythmically banded ore formed under conditions where the potential for sulphide precipitation exceeded the rate of evaporite dissolution. This occurred in cm-sized laminar dissolution meshworks that ate their way into the anhydrite beds (Figure 7.51b). Millimetre-laminated colloform to pendulous microstalactitic sphalerites were the dominant precipitates.

Type A ore matrix breccia formed in irregular cm-dm stratabound cavities. These formed at times when the rate of sulphide precipitation was slower than the rate of sulphate dissolution. Such cavities were not sufficiently large to instigate catastrophic roof collapse. Type B ore-matrix breccia ores formed in dm-metre sized crosscutting cavities, fractures and veins. Cavern space was sufficiently large to allow the single-event roof span collapse and rotation of metre-sized roof blocks into the caverns. Type B ore-matrix breccias are lead-rich compared to the banded ore and are interpreted by Tompkins et al. (1994) to postdate the formation of banded ore. All the Cadjebut ore textures were created from sulphate supplied by the dissolving evaporites across mm-dm-sized replacement fronts or meshworks under deep bathyphreatic and typically overpressured gassy conditions (Warren and Kempton, 1997).

Evaporite solution breccias can also focus the deep meteoric flow of radiogenic groundwaters and so control the distribution of economic uranium deposits. For example, in the uranium district of southern Black Hills, South Dakota, Gott et al. (1974) showed how an extensive blanket of collapse breccia and trans-stratal breccia chimney fills were produced by the dissolution of gypsum and anhydrite beds in the upper part of the Late Palaeozoic Minnelusa Formation (Figure 7.52). Up to 83 m of evaporites

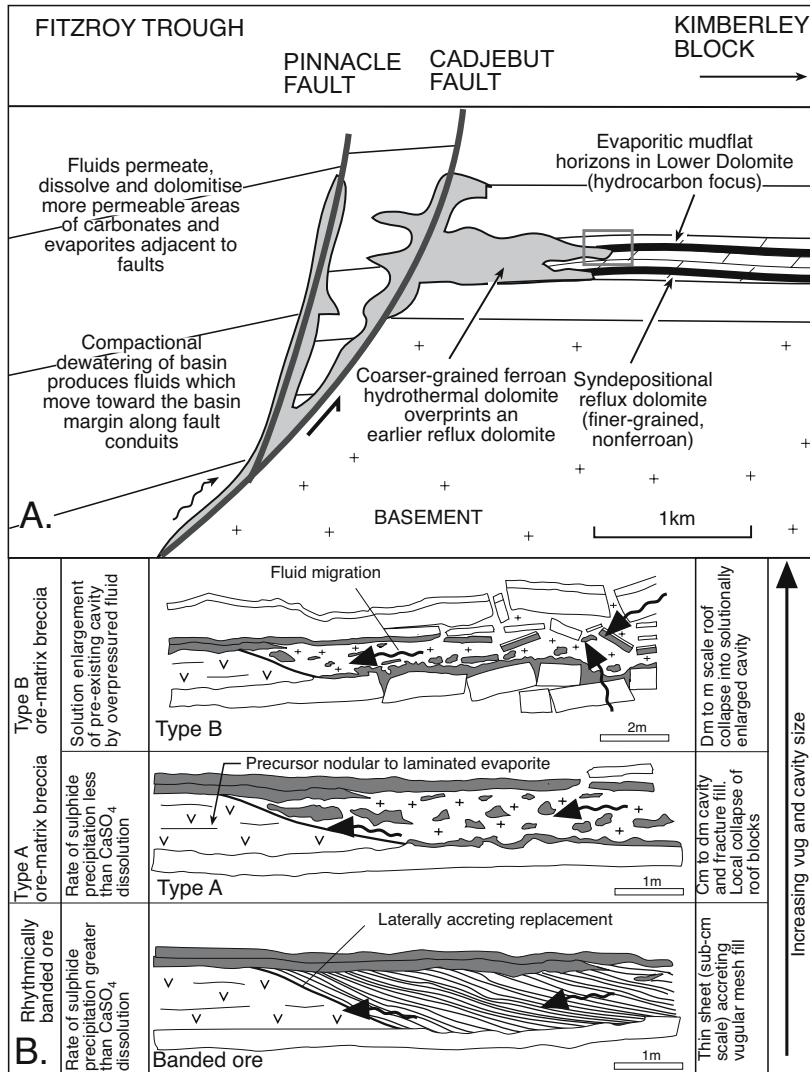

Figure 7.51. Cadjebut MVT ore, NW Australia. A) Schematic cross section showing the relationship between basal fluids moving up along regional extensional faults to act as sources for burial dolomite in the platform carbonates, and the focusing/replacement effect of sulphate beds in the evaporitic mudflat sediments of the Lower Dolomite (rectangle indicates zone of sulphide mineralisation). B) Schematic showing controls on ore texture reflect an interplay between rate of supply of metalliferous fluid and the rate of evaporite dissolution (after Warren and Kempton, 1997).

Figure 7.52. Infiltrated uranium mineralisation in the Cretaceous Inyan Kara Group sandstones, southern Black Hills (South Dakota). Solution collapse chimneys and breccias in the Late Palaeozoic Minnelusa Formation transport uraniferous groundwaters to precipitation sites (modified from Gott et al., 1974).

were removed and numerous breccia chimneys were created that extend up to 430 m vertically into Cretaceous continental sandstones of the Inyan Kara Group (Figure 7.52). The chimney fill consists of downward displaced sandstone blocks that were later cemented by calcite. Gott et al. argue that the breccia chimneys created a plumbing system through which artesian oxidised waters leached and transported uranium from deeply buried uraniferous sands and granites up into the Cretaceous section (Figure 7.12). There they encountered organic-entraining Cretaceous sands and so precipitated carnotite-dominated infiltrations along redox interfaces.

Filled vugs and nodules

Replaced nodules and characteristic vug shapes are some of the most used indicators for the former presence of evaporites in both the core and outcrop (Table 7.1). They define former crystal clusters and nodules of gypsum, anhydrite or halite in a matrix composed of mud or silt. Unlike the interiors of halite or anhydrite beds, buried evaporite nodules in a non-evaporite matrix are not isolated from the ongoing effects of crossflowing nearsurface and basinal waters. Whenever an undersaturated pore fluid flushes the matrix, it also dissolves or replaces the salts.

Resultant replaced crystals and vug fills are composed of varying combinations of silica, calcite, dolomite, celestite, baryte and strontianite. Internal textures and nodule fabrics can be spectacular and include; linings and splays of silicified and calcitised evaporite crystallites, evaporite moulds and residues, calcitised evaporitic dolomites (dedolomites), crosscutting drusy dissolution veins and solution enlargement fabrics, with late stage hydrothermal precipitates often infilling the last porosity. Despite the diagenetic complexity, most nodules and vugs mimic the shape of the evaporite parent and this typically leads to recognition of the evaporite connection. When mineralised, vug fill can weather out of the softer matrix to create dispersed surfaces of nodules or clustered piles, leading to descriptions of such outcrops as “Mendip potatoes.”

An open vug in a rock indicates that something has dissolved, while a nodule composed of chert or calcite indicates that something has been replaced or filled. Deciding whether or not that something had an evaporite forebear is frequently dependant on shape and texture. Smooth walled nodules, especially ones now composed of chert or baryte, are a commonplace replacement in normal marine sediment and need not indicate an evaporite precursor. A reliable evaporite indication of a syndepositional CaSO_4 nodule only comes if the rugose irregular surface texture and the shape of the precursor anhydrite nodule or layer remains. In other words, nodules with surfaces of irregular ridges and vugs, textured like the flowerets of a cauliflower, likely indicate an evaporite antecedent. Such nodules are usually described as cauliflower textured (e.g. cauliflower chert or cauliflower vug). If Magadi-style silicate gels were the nodule's parents, then nodule surface should show remnant crocodile-skin texture. Without this, or if only smooth walled nodules shaped like cucumbers and melons are present then a thin section of the nodule, especially of its outer portion is needed as this is where small relict crystallites or replaced lath outlines may still be visible.

Similarly, if single coarse-grained crystals or crystal clusters (desert roses) were either dissolved or replaced and now constitute open or filled moulds, then the original crystal shape

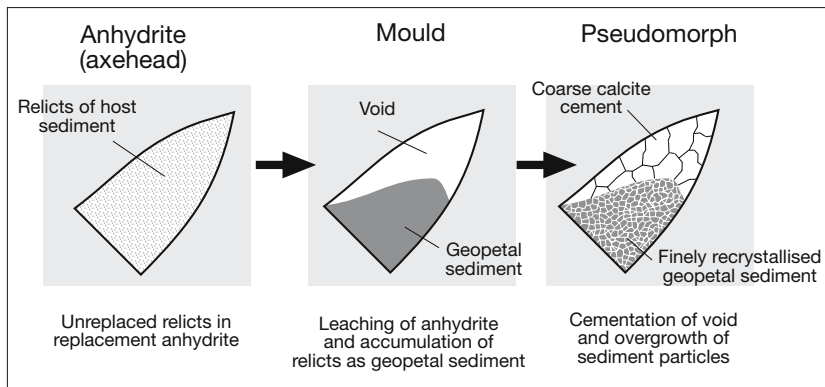

Figure 7.53. Replacement of axe-head anhydrite by carbonate spar showing how void shape needs to be preserved for reliable genetic interpretation. The fill is also a geopetal.

should be clearly discernable in order to reliably proclaim its parenthood (Figure 7.53). If lenticular gypsum was replaced, it should have the bird-beak shape of its precursor, while lenticular anhydrite replacements should be axe-head or barrel shaped (Figures 1.16, 1.26). If displacive halite clusters were replaced there should be evidence of cubes and hoppers on the outside of the vug or nodule.

Preservation of the shapes of evaporite crystals with similar outlines creates difficulties when trying to separate silicified replacements of beds of growth-aligned gypsum from beds of nahcolite/trona. Yet it is the separation of these pseudomorphs that is the fulcrum to arguments on the nature of early Archean seawater (Figure 2.31). Both gypsum and trona have a monoclinic bladed form and both can form nodules or grass-like beds of growth-aligned prisms. Once the actual salt has gone, defining original salt mineralogy and separating crystals with similar shapes using partly altered pseudomorphs can be very difficult.

Silicified evaporites

Silicified anhydrite nodules and CaSO_4 crystals are widely reported and reliably documented in sediments as old as Early Archean and as young as Holocene (Table 7.11).^{7.6} Quartzine and^{7.7} lutecite (aka length-slow chalcedony) typically infill or replace nodules that preserve characteristic cauliflower shapes of the antecedent anhydrite/gypsum nodule (Figure 7.54a; Arbey, 1980). According to Folk and Pittman (1971), rates of nucleation and crystallization are the main controls on crystal size and variety of silica precipitating in a void in a dissolving nodule. Rates in turn depend on the level of silica saturation or its concentration in the mother brine (Figure 7.54b).

High (alkaline) pH levels in the mother solution tend to ionize dissolved silica. Neutral or low pH levels favour silica crystallites made up of combined $\text{Si}(\text{OH})_4$ groups. These tend to polymerise into spiral chains at lower pH and higher concentrations. At high concentrations and high pH the silica precipitates possess a fibrous chalcedonic form reflecting their rapid rates of precipitation. High pH at the precipitation site means silica crystallites also tends to be present in solution as single ionized tetrahedra that attach themselves one by one to the growing surface, so

creating fibres of quartz with the c axes oriented parallel to the long axis of the growing fibres (length-slow). Under low pH or in non-sulphate settings the silica is polymerized into spiral silica chains that attach tangentially to the growth surface of the silica gel, with their c-axes parallel to the growing crystal surface and perpendicular to the eventual direction of the fibres (Figure 7.54c; length-fast; Folk and Pittman, 1971).

Milliken (1979) summarised the typical petrographic and hand specimen scale features of silica that replaced CaSO_4 nodules in Mississippian sediments of southern Kentucky and northern Tennessee (Figure 7.55). Such nodules typically have knobby irregular cauliflower-like surfaces. Diagnostic internal textures include: 1) length-slow chalcedony after lathlike evaporites, especially anhydrite; 2) quartzine; and 3) small amounts of lutecite associated either with megaquartz that shows strong undulose extinction, or with euhedral megaquartz (Chowns and Elkins, 1974). The megaquartz often encloses small blebs of residual anhydrite.

Many buried calcium sulphate nodules are silicified in a multistage process that involves both replacement and void filling (West, 1964; Chowns and Elkins, 1974). The process commences about the margins of a nodule (stage 1) with a volume for volume replacement of anhydrite by microcrystalline quartz. It normally ends with the growth of euhedral drusy

^{7.6} Quartzine is a form of chalcedony composed of fibres having a positive crystallographic elongation parallel to the c axis.

^{7.7} Lutecite is a form of chalcedony characterised by fibres that are seemingly elongated about 30°C to the c axis.

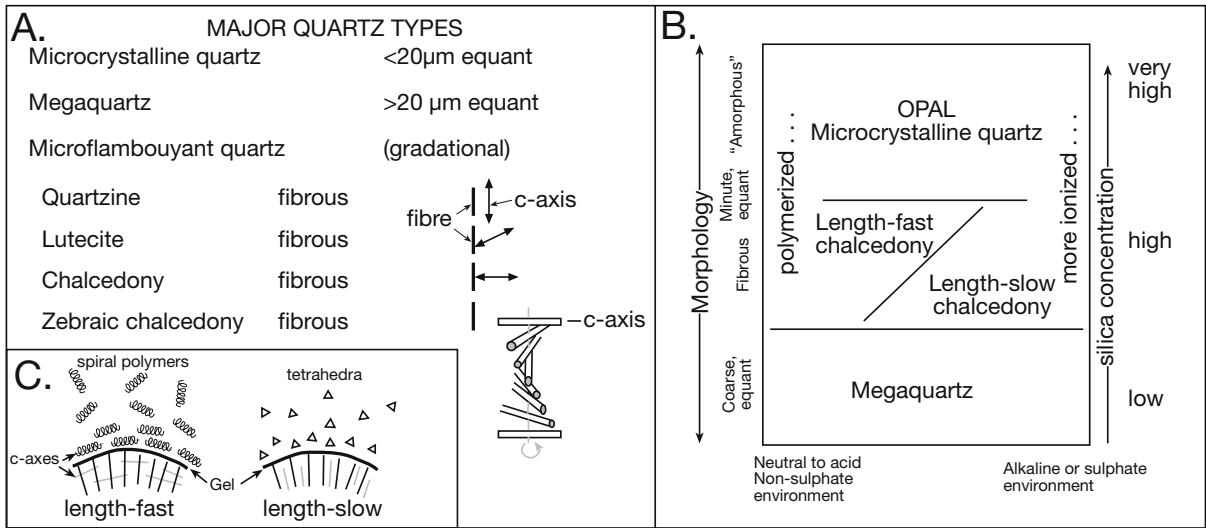

Figure 7.54. Chalcedony as an indicator of vanished evaporites. A) Major quartz types based on crystal size and orientation of chalcedony fibres with respect to c-axis (after Milliken, 1979). B) Style of chalcedony precipitate is controlled by the degree of polymerization, which in term reflects environment of precipitation. C) Crystallite orientation (single tetrahedra versus spiral polymers) with respect to growth surface controls formation of length slow versus length fast crystals - see text (B and C after Folk and Pittman, 1971).

quartz crystals into a central vug (stage 2 and 3). This mode of replacement exemplifies textures seen in texture style A in Figure 7.55.

Stage 1 chalcedony mimics or pseudomorphs the felted lath textures of the precursor anhydrite in the outer portion of the nodules. The pseudomorphs occur as radiating or decussate aggregates with a distinctive flow pattern. Identical decussate and flow textures occur in laths that make up sabkha anhydrite nodules and define their explosive mode of growth (Figure 1.26). As well as the silicified lath microtexture, outlines of larger crystals that predated anhydritisation and silicification may also be preserved by the nodule margin, these crystal outlines vary from prismatic to bladed. Many silicified nodules still retain the knobby cauliflower outline of its precursor anhydrite, other nodule edges preserve the interfacial outlines of gypsum or trona or borate precursors.

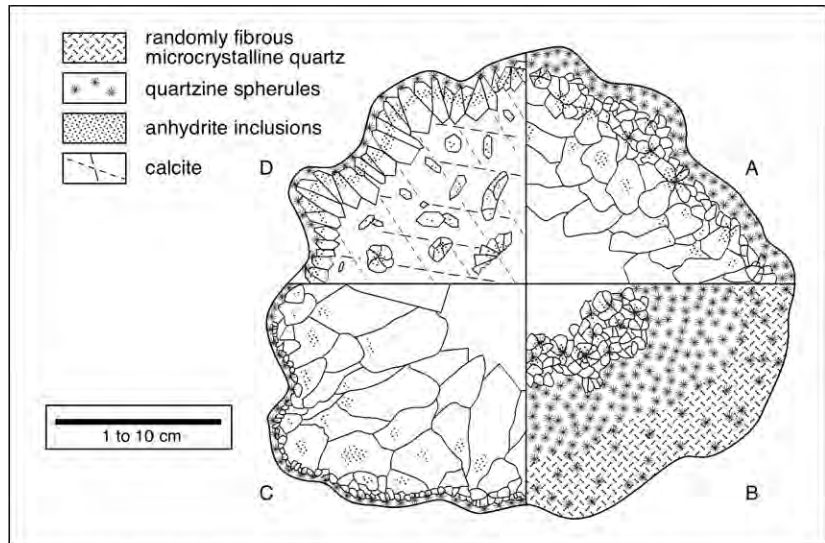

Figure 7.55. Texture in silicified-calcitized anhydrite nodules. A) Most common style of nodule with thin rim of spherulitic quartzine followed inward by megaquartz characterised by increasing crystal size and with frequent anhydrite inclusions. B) Nodule with a large proportion of fibrous quartz. Thick rim of spherulitic quartz passes inward to strongly undulose megaquartz. Some of the megaquartz has anhydritic nuclei. C) Nodule with a thin rim of spherulitic quartzine passing inward to a large proportion of megaquartz. D) Nodule with megaquartz rim and an interior filled with calcite. Calcite may have filled a cavity or replaced earlier silica. Late stage cavity-fill calcite is often defined by a thin rim of authigenic baryte or sulphide, prior to precipitation (modified from Milliken, 1979).

Occurrence and age of host	Comments	Reference
Silica precipitates in Holocene alkaline lakes along the Coorong coastal plain, South Australia. Type area for "Coorong style" chert.	Direct precipitation (?bacterially mediated) of opal-cristobalite in small mm-scale vugs in and on the surface of tepee-overprinted strandzone magnesite/dolomite crusts around the edge of Milne Lake and probably in crusts in other lakes accumulating evaporitic lacustrine dolomite, magnesite, hydromagnesite, aragonite and gypsum.	Peterson and von der Borch (1965)
Nodules and polygons of chert in diatomaceous beds of the late Pleistocene High Magadi beds, Lake Magadi, Africa. Type area for "Magadi-style" chert.	Chert in nodules and polygons is a weathering product of sodium silicate gels. Conversion involves shrinkage and induration. It creates a characteristic "crocodile-skin" texture on the surface of newly formed chert. This texture is associated with soft sediment deformation in the surrounds and sodium carbonate salts in adjacent sediments.	Eugster, 1967; Jones et al., 1967; Hay, 1968
Pleistocene nodules in saline mudflats, Lake Olduvai, Africa.	Magadi-style chert nodules (crocodile-skin) formed by replacement of a sodium silicate (magadiite) precursor.	Hay and Kaiser, 2001
Double-terminated euhedral quartz in Pleistocene sabkha dolomite, offshore Al Jabyl, Saudi Arabia (Pleistocene "Herikimer diamonds").	Megaquartz as individual crystals and clusters of crystals and overgrowths on detrital quartz. Individual crystals up to 1 mm long, many with shallow dolomite mould impressions on their crystal facies, some partly, or completely, engulf dolomite rhombohedra.	Chafetz and Zhang, 1998
Quartz geodes and nodular chert in Campanian (Cret.) marly clays and calcarenites, Basque-Cantabrian Basin, Northern Spain.	Silica replacement of cauliflower geodes and chert as spherulitic fibrous quartz (quartzine-lutecite). There are small anhydrite laths included in some of the mega-quartz crystal fills.	Gomez-Allday et al., 2002
Quartz geodes and chert hosted in Triassic red mudstones, Bristol district of the UK.	Silica replacement in open voids after cauliflower textured anhydrite. Loose euhedral double-terminated quartz crystals aggregating on bottom of some geodes after the CaSO ₄ is dissolved and are called "Bristol Diamonds."	Tucker, 1976a
Nodules developed in a single layer in Bundsandstein (Triassic) redbeds, Iberian Range, Central Spain.	Cauliflower shaped chert nodules and geodes, some are filled with concentric layers of quartz and carbonate, others are still open and partially filled and fractured. Relict anhydrite textures and rare laths, bacteria played a role in dolomitisation of some nodules.	Alonsa-Zarza et al., 2002
Chert nodules in Triassic of North Carolina, USA.	Cauliflower chert with relict anhydrite.	Wheeler and Textoris, 1978
Nodules and crystals in Lower Purbeck Beds, (Jurassic) Dorset, UK.	Silica replacement of individual and clustered gypsum bird-beaks and enterolithic anhydrite nodules (with small relics of anhydrite preserved).	West, 1964; 1973
Discrete horizons, scattered nodules in layers and individual replaced crystals in Seven Rivers, Yates and Tansill formations, Guadalupe Mountains, (Permian) Delaware Basin, USA.	Cauliflower nodule and geodes. Nodules, bird-beak gypsum, axehead anhydrite were all replaced by silica and calcite spar. Initial replacement by black megaquartz (with anhydrite, dolomite, water and hydrocarbon inclusions). This was followed by blocky calcite spar fill of voids created by late-stage dissolution of remaining anhydrite (telogenetic).	Ulmer-Scholle et al., 1993
Thin layers of chert nodules in fluvio-lacustrine muds sandwiched in acidic volcanics of the Lower Permian Bolzano Volcanic Complex, Northern Italy.	Magadi-style chert showing soft-sediment deformation and shrinkage cracks (crocodile-skin), imply a sodium silicate parentage. Transformation to quartz and concomitant (re)crystallization created a variety of silica textures, dominated by microflamboyant quartz.	Krainer and Spötl, 1998
Fist-sized nodules and geodes in layers and dispersed zones in Fort Payne Fm., Warsaw Limestone, St Louis Limestone (Mississippian) of south-central Kentucky and Tennessee, USA.	Concludes that megaquartz characterized by strong undulose, radial extinction, the existence of anhydrite laths included in megaquartz crystals with 'cubic' appearance terminations, the growth of spherulitic, fibrous-radial quartz aggregates (quartzine-lutecite), and crusts of zebraic chalcedony are all evidence of silica replacing anhydrite nodules.	Milliken, 1979
Fist-sized nodules and layers in Fort Payne Fm. and Warsaw Limestone, (Mississippian) near Woodbury, Tennessee, USA.	Silica replacement of anhydrite to form cauliflower cherts with outlines reminiscent of the nodules in the Abu Dhabi sabkha. Soft sediment deformation in the surrounding matrix argues silicification took place prior to complete induration of matrix. Silica was derived from sponge spicules.	Chowns and Elkins, 1974

Table 7.11. Selected examples of silicified evaporites.

Stage 2 microquartz and quartz fill can assume euhedral faces as they grow into voids created by the dissolution of the nodule. At the same time the quartz may continue to engulf and pseudomorph small areas of residual anhydrite or other less

common evaporite salts. Quartz crystals precipitated at this stage are commonly zoned, with more anhydrite inclusions found within the inner zone of the pseudomorph. Some quartz crystals are doubly terminated and probably grew via the support

of a dissolving meshwork of anhydrite. With the final dissolution of the supporting mesh these quartz crystals sometimes dropped to the floor of the void to create a geopetal indicator. Such highly birefringent anhydrite spots define cauliflower nodules in 2.2 Ga sediments in the Yerrida Basin, Australia (El Tabakh et al., 1999).

Stage 3, the final stage of the void fill is typified by the precipitation of coarse drusy euhedral quartz with no included anhydrite. This coarse quartz resembles coarse vein quartz.

Sometimes the processes of void fill may be arrested to leave a hollow core in the silica-lined geode. The void may be filled by a different burial stage cement such as baryte, sparry carbonate (e.g. ferroan dolomite or calcite), or even metal sulphides. This is the case with the large (up to 1 m diameter) silicified cauliflower-shaped anhydrite nodules of Proterozoic Malapunyah Formation of the McArthur Basin in Northern Australia where baryte, then metal sulphides and then sparry calcite typify the latter stages of void fill (pers. obs.). Similar fracture-filling baryte characterises the later diagenetic stages of silicified and calcitised anhydrite nodules in the Triassic Bundsandstein redbeds of the Iberian Range of central Spain (Figure 7.63; Alonso-Zarza et al., 2002). Such geodes are typically excellent indicators of burial cement stratigraphy in a mudstone matrix that otherwise preserves few indicators of the evolving pore fluid chemistry.

Cauliflower chert may retain no evidence of former anhydrite lathes mimicked in chalcedony, but can be completely filled by various styles of coarser-grained megaquartz. The resulting nodules still retain the outline of the precursor evaporite nodule (Figure 7.56). Work on diagenetic timing of numerous silicified CaSO_4 nodules (e.g. Milliken, 1979; Geeslin and Chafetz, 1982; Gao and Land, 1991; Ulmer-Scholle and Scholle, 1994) shows that most silica replacement begins with shallow burial, either in the zone of active phreatic flow or in the upper portion of the zone of compactional flow (probably at depths of less than 500-1000 m). Early silica replacement in the zone of active phreatic flow is indicated by a lack of compressional flattening of the nodule, by the preservation of delicate surface ornamentation and the preservation of

compactional drapes around replaced nodules. If replacement of an anhydrite nodule occurs later in the burial cycle, many anhydrite nodules have by then become flattened or sluggy and no longer retain a rugose surface. The result can be a series of “cucumbers” rather than “cauliflowers.”

Milliken’s (1979) isotopic evidence implies much silica replacement in the nodules she studied was relatively early in the burial cycle at temperatures that were $< 40^\circ\text{C}$. Silica was supplied by throughflushing pore fluids with compositions ranging from seawater to mixed meteoric-seawater. Of course, nodule replacement by silica or calcite does not have to happen on the way down in the burial cycle, it may also happen during uplift back into the telogenetic realm, where the strata have once again entered the zone of active phreatic flow.

Until recently, there were no documented examples of the process of evaporite replacement by quartz in Quaternary sediments. Now, autochthonous, doubly-terminated, euhedral megaquartz crystals have been observed infilling voids in a gypsum- and anhydrite-bearing Pleistocene sabkha dolomite sequence in the Arabian Gulf, as well as forming overgrowths on detrital quartz grains (Chafetz and Zhang, 1998). These siliceous sabkha precipitates are forming within metres of the present sediment surface with a silica source that is probably recycled biogenic material. Individual quartz crystals attain lengths of 1 mm. Many quartz crystals faces preserve impressions of dolomite rhombs or they partly, or completely, engulf dolomite rhombohedra. This process of replacement is early burial, to see the full suite of silica replacement textures and

Figure 7.56. Sketches showing various shapes of the quartz nodules and internal arrangements of megaquartz crystals from replaced anhydrite nodules in the Mesoproterozoic Wollgorang Formation of northern Australia and the Neoproterozoic Gaissa Sandstone/Porsanger Dolomite of Finnmark, Arctic Norway (in part modified from Tucker, 1976b).

the variations in timing of the replacement means one must study ancient evaporite sequences.

Overall, the texture of silica infill or replacement in a nodule is dependent on the rate of sulphate dissolution, timing of silica precipitation and rate of silica supply. Some nodules are dominated by the early *lit par lit* replacement textures (styles A and C in Figure 7.55), others have textures indicating silica cements growing into an open phreatic void left after the complete dissolution of the CaSO_4 . Such nodules may still retain a hollow centre where the anhydrite once resided (Figure 7.56). When a silica-filled geode did not start to accumulate silica until after all the CaSO_4 dissolved, the main evidence for an evaporite precursor comes from the shape of the replaced nodule and its stratigraphic position within the evaporitic depositional

sequence, e.g. beneath an erosional surface that defines the top of the capillary zone.

Not all the anhydrite nodules, now replaced by silica, were syndepositional. Maliva (1987) showed that nodular anhydrite, now indicated by quartz geodes in the Sanders Group of Indiana, actually precipitated in the subsurface, while its surrounding matrix of normal marine Sanders Group sediment was still un lithified (Figure 7.57). Anhydrite nodules formed in the subsurface during early burial as hypersaline reflux brines sank into the normal marine limestones of the Ramp Creek and Harrodsburg Formations. Silica subsequently replaced the anhydrite. These geodes are almost invariably associated with the development of reflux dolomite.

Figure 7.57. Precipitation of anhydrite and gypsum during St. Louis Limestone deposition formed a dense magnesium- and sulphate-rich brine that percolated downward and seaward through the then un lithified sands of the Salem Limestone. Dolomitisation of carbonate mud mounds and beds in the Harrodsburg and Ramp Creek Formations released calcium causing pore waters to become supersaturated with respect to anhydrite, resulting in the precipitation of anhydrite nodules that were later silicified (after Maliva, 1987).

Similarly, not all silica replacing anhydrite in a particular region need come from the same source or be emplaced by the same set of processes. Silicified nodules within middle-upper Campanian (Cretaceous) carbonate sediments from the Lafio and Tubilla del Agua sections of the Basque-Cantabrian Basin, northern Spain preserve cauliflower morphologies, together with anhydrite laths enclosed in megaquartz crystals and spherulitic fibrous quartz (quartzine-lutecite). All this shows that they formed by ongoing silica replacement of nodular anhydrite (Gómez-Alday et al., 2002). Anhydrite nodules at Lafio were produced by the percolation of saline marine brines, during a period corresponding to a depositional hiatus. They have $\delta^{34}\text{S}$ and $\delta^{18}\text{O}$ mean values of +18.8‰ and +13.6‰ respectively, consistent with Upper Cretaceous seawater sulphate values. Higher $\delta^{34}\text{S}$ and $\delta^{18}\text{O}$ (mean values of +21.2‰ and 21.8‰) characterise nodules in the Tubilla del Agua section and are interpreted as indicating a partial bacterial sulphate reduction process in a more restricted marine environment. Later calcite replacement and precipitation of geode-filling calcite in the siliceous nodules occurred in both sections, with $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values indicating the participation of meteoric waters in both regions. Synsedimentary

activity of the Penacerrada diapir (Kueper salt - Triassic)), which lies close to the Lafio section, played a significant role in driving the local shallowing of the basin and in the formation of the silica in the nodules. In contrast, eustatic shallowing of the inner marine series in the Tubilla del Agua section led to the generation of morphologically similar quartz geodes, but from waters not influenced by brines derived from the groundwater halo of a diapir.

The chemistry that controls the precipitation of silica as it replaces calcium sulphate in early diagenesis is not well understood. Is it a response to biogenic or abiogenic changes in pH and alkalinity? When opal cristobalite was observed filling mm-scale fenestral vugs in strandzone crusts in a Holocene dolomite/magnesite lake in the Coorong it was considered an inorganic precipitate (Peterson and Von der Borch, 1965). It formed where the pH of surface waters fluctuated between 10.2 and 8.5, and the season fall in pH was considered to drive inorganic precipitation of silica dissolved in the schizohaline lake waters. It came to be considered the type area for inorganic evaporitic precipitation of chert and a style of chert formation known as "Coorong-style." In the last decade sulphate-reducing bacteria have been shown to form dolomite in hypersaline coastal salinas in Brazil (Chapter 4) and some have applied similar notions to interpret the Coorong lake carbonates, that is, they are bacterially mediated precipitates (Rosen et al., 1988; Wright, 1999). The notion that silica precipitation in "Coorong-style" cherts is also microbially mediated is a distinct possibility.

Birnbaum and Wireman (1985) argued that bacterial degradation of organic matter must be important in forming silica precipitates in most evaporites. They demonstrated, through experiment, the strong influence of bacterial sulphate reduction on silica solubility. The ability of sulphate-reducing bacteria to remove silica from solution is related to local changes in pH and to hydrogen bonding within amorphous silica, followed by polymerization to higher weight molecules. During silica replacement of sulphate evaporites, the pore fluid becomes depleted in dissolved sulphate as it is reduced to H_2S by the action of anaerobic sulphate-reducing bacteria, which metabolise sulphate from an anhydrite or gypsum substrate. Where this selective dissolution of the sulphate occurs in the presence of amorphous silica the reaction is accompanied by the precipitation of silica. Hence the microscale mimicry of the lath outlines in the outer parts of many replaced nodules. According to Birnbaum and Wireman it reflects bacterially-mediated silica replacement of the nodule in relatively shallow burial settings where bacteria flourish.

Abiological processes, including thermochemical sulphate reduction are more important at greater burial depths where bacteria no longer survive. Providing matrix permeability is retained, silica replacement can continue into the thermobaric stage and can even persist into exhumation. Replacement under a thermobaric regime is frequently indicated by the preservation of hydrocarbon inclusions in the infilling silica cement.

Not all silicified nodules in evaporitic lacustrine sequences are replacements of $CaSO_4$ nodules, some form by transformation of sodium silicate gels. In the saline alkali lakes of the African rift valley, magadiite ($NaSi_7O_{13}(OH)_3 \cdot 3H_2O$) is a common sodium silicate associated with volcanogenic sediments (Eugster, 1969). It forms beds and nodules in sediments outcropping about the margins of many of the trona-containing lakes in the East African Rift, including Lake Magadi and Lake Natron. Other sodium silicates such as kenyaite and Na-Al silicate gels and zeolites are also present locally in the African rift lakes.

Magadiite nodules in Lake Magadi weather into cherts called Magadi-style cherts with a characteristic reticulate or "crocodile-skin" surface created by shrinkage during the transformation from sodium silicate gel to chert nodule. When buried, Magadiite rich layers in the diatomaceous host sediment pass along strike into outcrop and into beds of crocodile skin chert (Figure 4.39). Conversion of magadiite to bedded and nodular chert is thought to take place close to the sediment surface and be related either to the mobilisation and flushing of sodium by dilute waters in these shallow environments or to spontaneous conversion to chert in deeper brine-saturated zones. Eugster et al., (1967) proposed that magadiite is precipitated by diluting silica-rich, sodium carbonate brines with fresher waters. Mixing lowers the pH, and although the pH change may have been as little as 0.5, a decrease in pH from 10.3 to 9.8 lowers amorphous silica saturation by more than 500 ppm (Figures 4.38b, 7.58). Silica solubility changes very little when pH varies below a maximum of 8. Highly alkaline sodium carbonate waters containing abundant SiO_2 readily form in the Magadi rift valley via weathering and rapid subsurface hydrolysis of labile volcanic materials. Given the hydrogeochemistry needed for highly alkaline brines, evaporite minerals likely to be found in association with Magadi-style cherts are the sodium carbonates (trona, gaylussite or pirssonite; searlesite); gypsum is not present (Figure 2.12; Hardie and Eugster, 1970).

Surdam et al. (1972) listed the following textures as indicators of Magadi-style cherts that have evolved from a sodium silicate gel: 1) Preservation of the soft-sediment deformation features of the putty-like magadiite, such as enterolithic fold-

Figure 7.58. Silica solubility curves at 25°C. Solid line shows experimentally determined variation in solubility of amorphous silica with respect to pH. Dashed lines bracket the quartz solubility field (after Krauskopf, 1967 - see also Figure 4.38b).

ing, lobate nodular protrusions, casts of mudcracks and trona crystals, and extrusion forms; 2) Contraction features, such as reticulate cracks and polygonal ridges on the surface of the chert, reflect the loss of volume in the transition (crocodile skin chert). In Phanerozoic strata an ability to separate cauliflower cherts (after gypsum/anhydrite nodules) from crocodile-skin cherts (associated with silicate gels in trona/natron soda lakes) is considered important in defining marine-fed versus continental hydrologies. However, it has yet to be shown that any of these textures are unique to magadiite-chert transitions.

Ancient Magadi-style chert nodules crop out in lacustrine rocks of the Middle Devonian (Middle Old Red Sandstone) Orcadian Basin, Scotland (Parnell, 1986) and the fluviolacustrine sediments of the Permian Balzano volcanic complex in Italy (Krainer and Spötl, 1998). The Scottish cherts are replacive nodules within organic-rich laminates and are the deposits of a stratified alkaline lake. Nodules exhibit soft sediment deformation features including sediment injection along shrinkage fractures within the nodules and preserved stellate quartz pseudomorphs after an evaporite mineral, possibly trona. Nodules were nucleated about vertical cracks in the host sedi-

ment and show polygonal or parallel aligned patterns. Thus the precipitation of the magadiite precursor must have occurred from nearsurface alkaline groundwaters flushing through partially consolidated sediments.

The Italian cherts form thin layers within a fluviolacustrine succession sandwiched between acidic volcanic rocks of the Lower Permian Balzano Volcanic Complex in northern Italy. These cherts are interpreted as analogues to Magadi-style abiogenic chert (Krainer and Spötl, 1998). They show soft-sediment deformation features, shrinkage cracks, and well-preserved palynomorphs that document early diagenetic silica precipitation, volume loss by dehydration, and consolidation prior to mechanical compaction of the enclosing sediment. Similar chert layers were also noted in Triassic playa deposits of North Carolina replacing evaporite siliceous gels in 60 cm-thick siliceous beds intercalated with 20 cm-thick limestone tufa beds (Wheeler and Textoris, 1978).

But evaporite-associated chert can probably accumulate in any number of highly alkaline settings, with or without trona. White magadiite veins constitute rectilinear polygons (1-3 metres across) in playa sediments in Alkali Lake, Oregon, and in adjacent muds associated with alkali salts and brines (Rooney et al., 1969). The same beds do not host substantial volumes of sodium bicarbonate salts. Jones et al. (1967) noted up to 2,700 ppm of dissolved silica in the present-day brines from Alkali Lake playa. Such values represent a substantial supersaturation with respect to amorphous silica, even at the playa's current pH levels, which are near 10.5 (Figure 7.58). This level of supersaturation, in the absence of extensive trona suggests that these lacustrine sodium silicates precipitated directly from a hypersaline silica-saturated solution without the need for a sodium silicate precursor. The debate as to how, where and when crocodile-skin chert can precipitate continues, as yet unresolved.

In thin section, Schubel and Simonson (1990) showed that chert with a magadiite precursor has a characteristic rectilinear or gridwork orientation of quartz crystals, visible in thin section. The texture seems to be inherited, a pseudomorph after the original spherulitic magadiite structure, which shows similar extinction patterns due to presence of 10-20 μm spherical aggregates of plate-like crystals. This microscale pseudomorphing implies a direct volume-for-volume replacement of magadiite by chert. Unfortunately the level of detailed preservation needed to make such distinctions is not usually preserved in older cherts where megaquartz dominates the fill. It is useful in separating cherts from magadiite precursors versus chert from other hypersaline associations in Neogene strata, and

perhaps in a few examples it can be utilised in rocks from as far back as the Mesozoic.

As mentioned earlier, Folk and Pittman (1971) and Folk and Siedlecka (1974) concluded that length-slow chalcedony (lutecite) in chert nodules is a useful indicator of the former presence of evaporites (both anhydrite or magadiite precursors). But the occasional presence of length-slow chalcedony in nonevaporitic regimes, such as in turbidites and basalts, has shed suspicion on its absolute reliability. Heaney (1995) further refined the significance of lutecite by showing that in the early stages of its diagenetic evolution it is largely composed of a form of silica called moganite. Moganite is a polymorph of SiO_2 that is microcrystalline, fibrous and optically length-slow. Water content is $\approx 2\%$, slightly higher than chalcedony and lower than opal (6–10%). It is abundant in, but not restricted to, cherts formed in evaporitic environments. Nonevaporitic silica precipitates typically contain between 5 and 15 wt% moganite, whereas undeniably evaporitic specimens contain between 20 and 75 wt% moganite. No chert from nonevaporitic settings has been found to contain more than 25 wt% moganite. Consequently, enhanced moganite concentration (> 20 wt%) in microcrystalline silica is a valuable indicator for vanished evaporites. Heaney noted a frequent association of moganite with “Magadi-style” chert and suggested that moganite is a diagenetic alteration product of the hydrous Na-silicate magadiite. Unfortunately moganite is a metastable phase and all samples analysed by Heaney that are older than Cretaceous contain little or no moganite.

The transformation of magadiite to moganite must occur over hundreds to thousands of years in alkaline lake systems, whereas the inversion of metastable moganite to quartz requires tens of millions of years. But the moganite-evaporite association is broader than magadiite in soda lake cherts as moganite is forming as an authigenic phase in inland playas of central Australia and these Na-Cl brine systems never contained trona, magadiite or volcanoclastics (English, 2001). The source of silica is a deeply weathered granitic terrain soaked in stagnant brines.

When dealing with chert nodules, lutecite is only a reliable evaporite indicator when it occurs in suitable host lithologies, is stacked into appropriate vertical sequences and occurs in association with other indicators of “the evaporite that was.” The only undeniable single indicator that a chert has an evaporitic parentage is when relicts of the precursor salt still remain within the nodule.

Calcitisation and dedolomitisation

Calcitisation and dedolomitisation are two often-associated diagenetic processes affecting both evaporite salts (anhydrite/gypsum) and evaporitic dolomites. Calcitisation of evaporites refers to the replacement of an evaporite bed by calcite or limestone. Dedolomitisation refers to the conversion of a dolomite to a limestone. Calcium sulphate evaporites are calcitised in two settings; the meteoric, via groundwater flushing and spar fill of the resulting voids, and in the deeper subsurface, via sulphate reduction (both bacterial and thermochemical). Waters in deeper burial settings situated below the active phreatic tend toward anoxia and can carry organics as suspended or dissolved hydrocarbons.

As well as replacement, the flushing of bedded evaporites by surface-derived, low-sulphate meteoric waters also brings on evaporite rehydration, dissolution. Calcite cements typify the nearsurface, while anhydrite conversion, via slow hydration, characterises the deeper near stagnant portions of the same meteoric flow system (e.g. Figure 7.37b). Replacement is often bioepigenetic in shallower settings and thermochemical in even deeper and hotter settings. Thus the products of calcitisation tend to have diagnostic isotopic signatures.

Calcitisation of evaporites

Like silicification, the calcitisation of evaporite crystals and nodules can occur at any time in the burial cycle; whenever the throughflushing waters are undersaturated with respect to the evaporite salts and supersaturated with respect to CaCO_3 (Table 7.12). In South Australia, hollow aragonite (micrite rind) pseudomorphs after Holocene gypsum grow in the shallow subsurface about edges of coastal salinas in areas of active marine phreatic flushing (von der Borch et al., 1977; Warren, 1982a). Similar early pseudomorphs after bottom-nucleated gypsum have been recognised in the Lower Carboniferous of the Vesder region, Belgium (Figure 7.18; Swennen et al., 1981). There the process was under the influence of sulphate-reducing bacteria and the precipitates in zones of dissolved crystals are now composed of sparry calcite. Later in the burial history, compaction- or thermobaric-derived waters can leach CaSO_4 or other salts from the system to create characteristic voids that are then filled by burial-stage calcite. Examples of this other end of the burial spectrum include spectacular Au-enriched silica-rimmed dolomitic nodules after anhydrite in the Triassic redbeds of Spain (Bustillo et al., 1999; Alonso-Zarza et al., 2002).

Occurrence and age	Comments	Reference
Gypsum replacement in sub-tepee limestones in Holocene carbonate, Marion Lake, Australia.	Aragonite skins formed on dissolving gypsum prisms in the boxwork limestone forming where a prism of less saline marine seepage water interacts with the outer edge of the Holocene gypsum fill. This an excellent example of a gypsum-shaped crystal void in the midst of its creation.	Warren, 1982a
Calcitised gypsum beds in Miocene-Pliocene sediments, Calatayud Basin, northern Spain.	Early calcitization of lacustrine evaporite (gypsum, anhydrite) and/or magnesium carbonate (dolomite, magnesite) deposits driven by the encroachment of meteoric waters either at the contact of these deposits with overlying freshwater or where percolating freshwater enters at very shallow burial depth. Calcitization occurs during the interaction between magnesite and Ca-enriched waters derived from the dissolution of gypsum or glauberite.	Sanz-Rubio et al., 2001; Canaveras et al., 1998
Calcitised beds in Tertiary lacustrine dolomites, Madrid basin, central Spain.	Mineralogy of bedded carbonates is now dominated by calcite and the limestones contain moulds of gypsum. Occurrences of calcitised dolomite textures in these facies suggests the influence of fresher water during expanding lacustrine cycles or further subsurface interactions with less saline groundwater.	Calvo et al., 1995
"Gypsum-ghost" limestones adjacent to selenite lithofacies in the Miocene of northern Carpathian Foredeep, Poland.	Mass-balance chemistry shows a deficit of calcium and sulphur contents in the limestones compared to the composition of the selenitic gypsum and implies that the gypsum-ghost limestones system was open to mass transfer and cannot be related to simple and regionally extended replacement of solid sulphate rocks by limestones plus native sulphur; it is a transitional facies.	Gasiewicz, 2000
Calcitised Danian dolocretes in lacustrine beds, Provence Basin, France.	Dolocretes deposited around the palaeolake or playa margin subsequently leached and calcitised. Dolomite rhombs can be hollow. Fabric-destructive calcitization attributed to drop in the lake level, when the upper part of the dolocrete was subjected to vadose flushing, whereas the fabric-preserving calcitization (poikiliotopic) resulted from rise in lake level.	Colson and Cojar, 1996
Marbles in the Muttelbury Nappe, Jurassic Lovelock Formation, West Humboldt Range, Nevada.	Outcropping rauhwacke sheets are interlayered and interlensed with non-breccia marble slabs. The marble slabs are calcitised anhydrites from the original décollement of the thrust. They were produced biopigenetically by the action of sulphate-reducing bacteria on the CaSO ₄ antecedent.	Speed, 1974, 1975
Calcitization of the Permian Raisby/Cadeby Formation, UK.	Groundwater flushing converts nodular calcium sulphate into spar-filled cauliflower-shaped geodes. Fill is multistage telogenetic and with a consistent unroofing history outlined in zoned calcite linings of the geode fills.	Lee and Harwood 1989; Lee, 1990
Calcitization of Permian Karstryggen Formation, Central East Greenland.	Groundwater driven karstification on "the way down" created spar filled vugs after nodular anhydrite and was often associated with the precipitation of celestite.	Scholle et al., 1990, 1993
Calcitised anhydrite in Poplar and Ratcliffe beds in association with Watrous Formation, Mississippian, Williston Basin, USA.	Anhydrite calcitization occurred only after the Watrous unconformity was shallowly buried by redbeds, and replacement probably involved sulphate-reducing bacteria. Replacement calcite contains pseudomorphs and relicts of anhydrite, and pseudomorphs of secondary gypsum, indicating calcitization occurred only after original Mississippian gypsum was altered to anhydrite.	Kendall 2001
Dedolomites in the Mississippian Madison Group of Wyoming and Utah.	Two types of fracture-related dedolomites, one precedes and one postdates regional dolomitisation. The early dedolomite occurred as active groundwaters flushed anhydritic sequences during shallow burial. The later post-stylolitisation fracture-associated dedolomite records chemistries and isotopic signatures of deep tectonic-vein mineralisation.	Budai et al., 1984
Calcitised anhydrite, Winnipegosis Formation, Middle Devonian, Saskatchewan.	Calcitization of organic layers and anhydrite section occurred before compaction and was driven by the activities of sulphate reducing bacteria. It preserves characteristic structures of antecedent (lamination, nodular outlines).	Shearman and Fuller, 1969; Wardlaw and Reinson, 1971
Calcite-filled pseudomorphs in the Cambrian Parakeelya Alkali member of the Observatory Hill Formation, Australia.	Calcite pseudomorphs after trona and shortite occur in the perennial lake and saline mudflat facies of this alkaline playa. Cauliflower-shaped vugs are more commonplace in overlying marine section. Fills are composed of poikilotic calcite with dull luminescent cores and alternating dull and semiluminescent rims. Replacement occurred deep and in association with sulphate reduction.	Southgate et al., 1989; White and Youngs, 1980

Table 7.12. Selected examples of calcitization and dedolomitization in evaporitic settings.

Thus carbonate replacement of calcium sulphate is not depth specific and is driven by various hydrological processes (Pierre and Rouchy, 1988):

- 1) Sulphate dissolution during flushing by bicarbonate-rich waters derived from:
 - dissolved atmospheric CO₂,
 - oxidation of organic compounds (marine or terrestrial),
 - thermal decarboxylation of organic matter.
- 2) Bacterial sulphate reduction in organic-rich or hydrocarbon-flushed sediments. Sulphate reduction may also be later and deeper where it is abiotic and thermochemically induced (Chapter 9).

Late-stage calcite replacement of evaporite nodules postdates silicification in the Tosi Chert, Wyoming (Ulmer-Scholle and Scholle, 1994). It was thermochemically driven and was associated with hydrocarbon migration. Similar pseudomorphic replacement by calcite or dolomite of euhedral trona and shortite crystals occurs in the saline facies of the Cambrian Lake Parakeelya Member, South Australia. It was mesogenetic and took place during burial diagenesis as basinal brines flushed the system at temperatures of up to 110°C. The catabaric dissolution and removal of the sodium carbonate salts took place either coincident with or following the generation of hydrocarbons (Southgate et al., 1989).

Calcitisation of evaporite nodules is most widely documented where meteoric waters react with an evaporite bed in the active phreatic zone and not in the deep subsurface (Table 7.12). Meteoric flushing can occur soon after an evaporite unit is

deposited (early mesogenetic replacement “on the way down”) or it can occur after deeply buried evaporite units are uplifted back into the zone of active meteoric throughflow (telogenetic or “on the way back up”). And, as we have already seen, the replacement process can continue “while at the bottom” or wherever epithermal fluids flush calcium sulphate nodules. This can be as part of an active volcanogenic system (Bustillo et al., 1999) or even in association with the cycling of seawater through hydrothermal anhydrite in mid ocean ridges (Warren, 1999; Chapter 9). In hydrologically mature sedimentary basins, uplift-related meteoric flow is typically forced by head-driven circulation from high-elevation recharge areas (Figure 8.10), which can drive calcitisation and replacement to depths of more than a thousand metres.

One of the best documented examples of calcitised evaporites forming long after deposition and burial of the primary salt beds (“on the way back up”) comes from the onshore Permian Raisby Formation of the UK. There, alteration processes related to relatively recent re-entry into the zone of active meteoric flushing, can be studied both in outcrop and in core. The Raisby Formation (formerly the Lower Magnesian Limestone) is the first major carbonate unit deposited in the English Zechstein series and outcrops as escarpments and coastal cliffs along the NW coast of the UK (Figure 7.59). It is overlain by the Ford Formation (formerly Middle Magnesian Limestone), a classic wedge-shaped carbonate shelf succession, which today crops out in a north-south belt up to 5 km wide. It is interpreted as a barrier reef/shoal sequence with backreef and lagoonal facies composed of white to buff, soft, bedded oolitic and fine grained dolomite. The reef faces is buff to brown hard massive

Figure 7.59. Evaporite dissolution in the Permian Zechstein on the NW coast of England. A) Extent of the dissolution zone of the Hartlepool Anhydrite from offshore anhydrite to onshore dissolution residue. Hartlepool isopachs in metres. B) Facies patterns in the Raisby and related formations that make up the Zechstein unit formerly known as Magnesian Limestone. The cross section shows the relationship to dissolution residues of the Hartlepool Anhydrite seen in coastal outcrops where the anhydrite has dissolved.

to rubbly reef dolomite and associated talus, passing up into algal-laminated dolomite with oncoliths. Bryozoa, crinoids, brachiopods, bivalves and gastropods are abundant, except near the top of the buildups where stromatolitic and encrusting algae dominate and define the transition into more hypersaline conditions. Its slope and basin facies today consist of seaward dipping buff fine-grained dolomite. Offshore to the Raisby Formation lies the Hartlepool Anhydrite (Figure 7.59a). Onshore the former position of the Hartlepool Anhydrite is defined by a regionally extensive dissolution residue at the base of the Raisby (Figure 7.59b).

Outcropping Raisby dolomites contain nodular cavities, pores and pseudomorphic voids, which are lined or filled by calcite spar. Deep borehole cores sampling the Raisby Formation may still retain nodules and euhedral crystals of gypsum and anhydrite that are near-identical in size and shape to the cavities and pseudomorphs now seen in outcrop. This indicates that

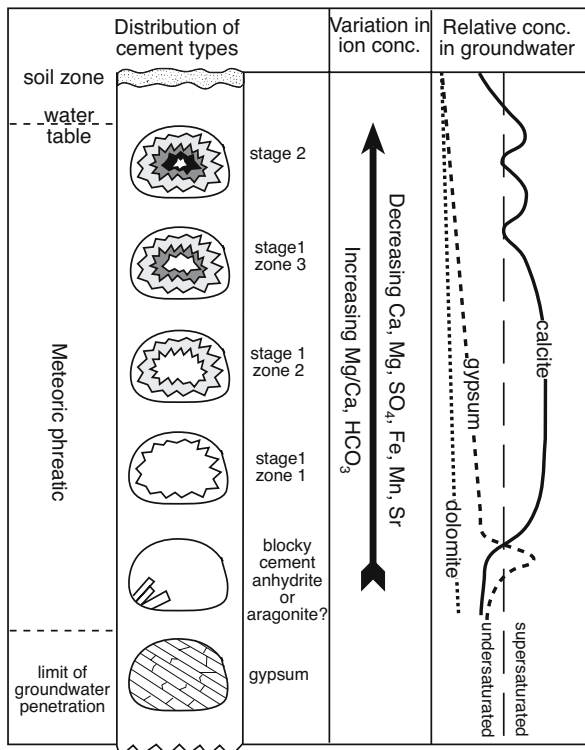

Figure 7.60. Nodule evolution in the Raisby Formation, UK. Vertical axis indicates distance from the land surface, but may also indicate evolution through time of any one cavity. The lowermost cavity is filled with gypsum derived by rehydration of buried anhydrite. Contact with meteoric water causes dissolution of gypsum followed by local anhydrite pore cement that is then replaced by calcite. Succeeding calcite fill of cavities indicates increasing oxygenation and activity of groundwater system (after Lee and Harwood, 1989).

calcium sulphate nodules were once abundant in the subcropping Raisby Formation, but almost all the original salts have since been removed by crossflows of meteoric groundwaters.

Thus calcitisation of evaporite nodules is still active in appropriate zones of groundwater flushing along much of the coastal zone of NW England (Figure 7.59, 7.60; Lee and Harwood, 1989; Lee, 1994, 1995). Much earlier in the burial history of the Raisby Formation, primary Permian gypsum was replaced by anhydrite nodules. Later, coarser replacive burial anhydrite formed, postdating both pressure-solution and any further dehydration of any residual primary gypsum. During further mesogenetic burial, some of the anhydrite in the nodules was replaced by catabaric baryte, dolomite and sphalerite. Upon uplift of the Raisby Formation during the Tertiary, any remaining nodular anhydrite was telogenetically rehydrated to porphyroblastic gypsum. With further exhumation the gypsum was then dissolved by meteoric groundwaters and multiple stages of meteoric calcite cement precipitated within the voids (Figure 7.60). All meteoric phreatic waters in this part of the UK are currently undersaturated with respect to dolomite and saturated with respect to calcite. Thus the calcite void fills in the Raisby Formation are made up of clear, inclusion-free, non-ferroan, low-magnesian telogenetic calcite.

There is an enigmatic episode of what was interpreted by Lee and Harwood (1989) as a widespread, but minor nearsurface anhydrite cement. It precipitated after regional exhumation had rehydrated all the buried anhydrite to gypsum and the gypsum had dissolved to form voids (Figure 7.60). This early blocky crystal phase predated calcite void fills. It is encased in zone 1 calcite and is now replaced by calcite. Its blocky rectilinear prism termination precludes either a gypsum or a baryte precursor. The process and the mechanism which could have created an anhydrite-saturated pore water in the voids after gypsum leaching, in what must have been a shallow unroofing setting, is not well understood. Lee and Harwood (op. cit.) argue that if it is a calcite pseudomorph of anhydrite it perhaps indicates a short-term increase in salinity of nearsurface pore waters brought on by widespread meteoric dissolution of large volumes of subjacent halite.

The succeeding calcite infill of the leached gypsum nodules occurred in two phreatic (isopachous) stages; Stage 1 crystals are circumvoid equant, while stage 2 crystals are coarser, circumvoid and columnar (Figure 7.60). Under cathodoluminescence the stage 2 columnar crystals are nonluminescent and alternate with internal sediment layers. Stage 1 crystals show three geochemically distinct cathodoluminescence zones probably

Figure 7.61. Microprobe traverse through a Stage 1 cement crystal growing inward from the nodule wall showing distinct geochemical differences between Zone 1 (bright orange), Zone 2 (dull orange) and zone 3 (nonluminescent). Shaded areas indicate values are below reliable detection limits (after Lee and Harwood, 1989).

related to increasing oxygenation of the crossflowing pore waters (Figure 7.61). The successive zonation reflects increasing groundwater flow in the phreatic zone as the exhumed rocks approach the landsurface. Stage 1 – zone 1 (bright orange) cement has high Mn and low Fe and Mg values. Stage 1 – zone 2 (dull orange-luminescent) has relatively high Fe and Mn and low Mg values. Stage 1 – zone 3 (nonluminescent) has negligible Mn and little Fe in the calcite. Stage 2 cements have much higher Mg levels than stage 1, while the orange luminescing cements (zones 1 and 2) contain much higher levels of Sr than zone 3 or stage 2 cements (Figure 7.61). This geochemical and cathodoluminescent zonation in calcitised nodule in the Raisby Formation is typical of increasing oxygenation in the pore fluids. It tracks the telogenetic passage of the uplifted strata into an increasingly oxygenated and active groundwater system. But what of the early blocky calcite that Lee and Harwood (op. cit.) interpreted as post-gypsification anhydrite?

The process of meteoric calcitisation of CaSO_4 nodules is complicated in some parts of the Zechstein subcrop in central Germany by the presence of neofomed aragonite growing in anhydrite/gypsum vugs (Peckmann et al., 1999). It may be this calcite replacement of aragonite prisms that gives the unusual blocky crystal outlines that were interpreted as an unusual post-gypsification anhydrite in the preceding discussion of the Raisby Formation. Similar misinterpretations of blocky elongate calcite prisms as pseudomorphs after gypsum not as aragonite cementstone replacements have complicated the evaporite history of the Proterozoic MacArthur Basin in northern Australia (Warren, 1999; Chapter 8). Low $\delta^{13}\text{C}$ values (-10‰ PDB) of

the aragonite inclusions growing in the Zechstein gypsum nodules indicate that some of its carbon is derived from organic matter that has been oxidized by bacterial sulphate reduction (see Figure 9.43a). The residual aragonite inclusions bear rhomb-shaped crystals of calcite that replace former dolomite. Elevated Mg/Ca ratios due to this dedolomitization may have promoted the precipitation of aragonite instead of calcite during gypsification. This aragonite has precipitated in the near-surface meteoric–vadose zone in recent times, it is a telogenetic precipitate. Aragonite crystals display a platy habit, while SEM analyses show that two types of micro-rods are associated with these plates (Peckmann et al., 1999). The mineralized micro-rods are

interpreted to be fossilized bacteria. Aragonite inclusions, most of which contain organic-rich aggregations, yield a distinctive biomarker pattern. High concentrations of specific unsaturated fatty acids are clearly indicative of newly produced organic matter and reflect the presence of a discrete microbial community being associated with the formation of the aragonite. At one locality the aragonite is accompanied by native sulphur and the formation of sulphur was mediated by H_2S -oxidizing bacteria. This is corroborated by the presence of densely packed curved aragonite rods representing permineralized bacterial cells on and within the sulphur.

So far, most of our discussion has emphasised the importance of bicarbonate-rich meteoric circulation in calcitising exhumed calcium sulphate beds. But is this always so? The work of Peckmann et al., (1999) shows that aragonite can be a local product of bacterial sulphate reduction acting on gypsum nodules during exhumation of diapir crests. Kendall (2001) argues that biogenic sulphate reduction can be a more widespread process in shallow burial and that bacterial metabolism can calcitise widespread evaporite beds beneath unconformities, independent of active meteoric circulation. He cites beds of anhydrite nodules that are locally replaced by calcite, pyrite and celestite beneath an unconformity atop Mississippian anhydrites of Saskatchewan (Figure 7.62a). Triassic clastics (Watrous Formation) immediately above the unconformity are green (reducing), rather than red (oxidising), and there is a regionally developed subunconformity alteration zone, where carbonates are dolomitized, and porosity is filled with anhydrite.

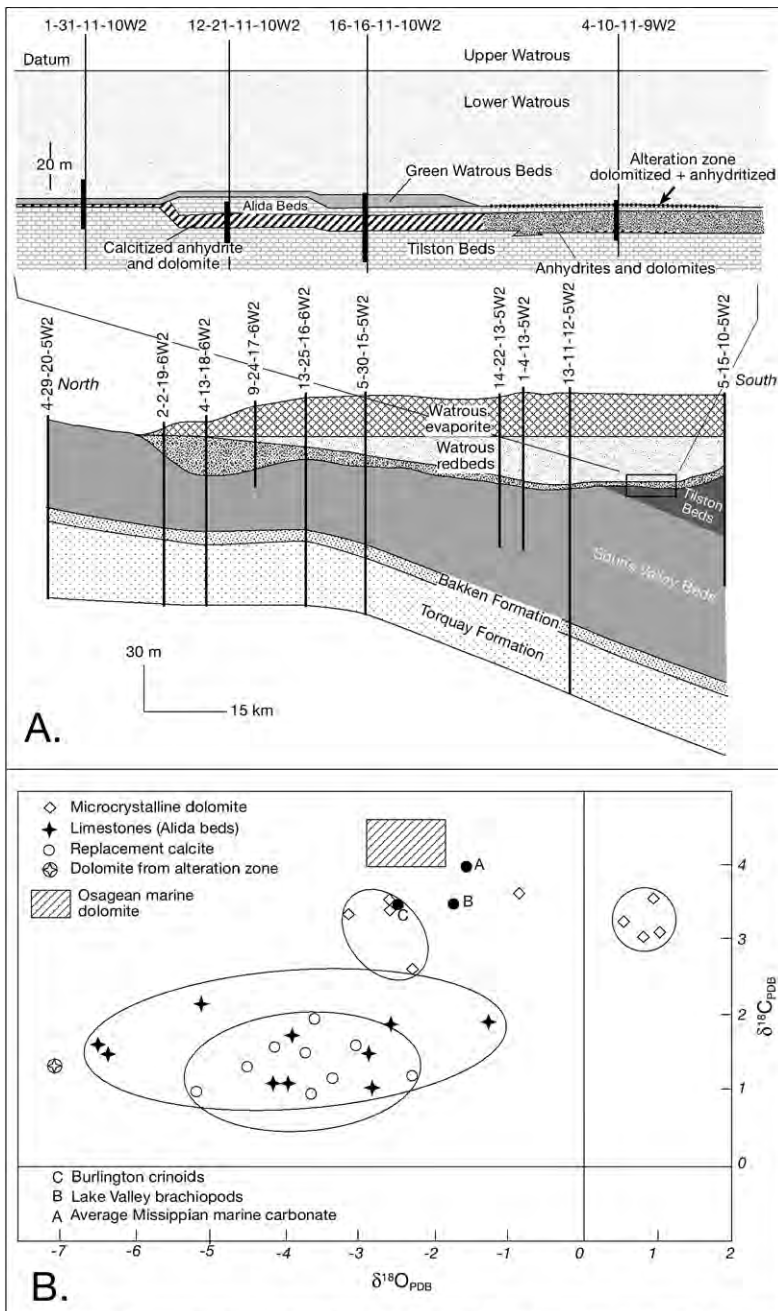

Figure 7.62. Bacterial calcitization, Saskatchewan (after Kendall, 2001). **A)** Diagrammatic section showing the regional unconformity, the northwards disappearance of older Triassic, Permian, Pennsylvanian and late Mississippian strata, and the northwards overstep of the Watrous by Jurassic deposits. Inset shows anhydrite (or calcitised anhydrite) and dolomite constitute the Tilston Evaporite. Most of Tilston Beds and overlying Alida Beds are limestones. Note the very thin calcitised anhydrite zone at the base of the Tilston Anhydrite (arrowed), and a dolomitised zone beneath the unconformity in the 4-10-11-9W2 well. **B)** Carbon-oxygen isotopic ratio cross-plot of calcites that have replaced anhydrite, host rock dolomites, and limestones of overlying Alida Beds. Note overlap of limestone and replacement calcites, and the distinct of dolomite values.

The unconformity lacks karstic features (unlike equivalent age surfaces in the USA), and probably formed in a hyperarid climate. Mississippian anhydrites near the unconformity are not preferentially dissolved, nor were they extensively hydrated. Anhydrite calcitisation probably involved sulphate-reducing bacteria and occurred only after the unconformity was shallowly buried by red beds. Hydrogen sulphide, generated by bacteria in saline brines reduced red bed pigments to form the green halo. Replacement calcite contains pseudomorphs and relicts of anhydrite, and pseudomorphs of secondary gypsum. These indicate calcitisation occurred only after original Mississippian gypsum was altered to anhydrite and this, in turn, was partially converted back to secondary gypsum beneath the unconformity.

Replacement occurred concurrently with the formation elsewhere of a dolomitised zone beneath the unconformity. Sulphur isotopic ratios of replacement pyrite are depleted relative to Mississippian sulphate values, consistent with the activities of sulphate-reducing bacteria. $\delta^{34}\text{S}$ values for Mississippian Tilston and overlying Frobisher Evaporite anhydrites cluster around +18 to +19 ‰, comparable with Mississippian sulphate evaporite values worldwide (Figure 2.23). Values from the much younger replacement anhydrite porphyroblasts, and one value from anhydrite in the dolomitised zone are similar. Sulphides, associated with replacement calcite from the Filmore area, have $\delta^{34}\text{S}$ values that are depleted (by up to 19 ‰) relative to the Mississippian sulphates. Whole-rock analyses of Mississippian (Alida and Tilston Beds) limestones exhibit a narrow range of $\delta^{13}\text{C}$ ratios of +1.5 to +2.2 ‰, averaging +1.8 ‰ but have a wider range in $\delta^{18}\text{O}$ -1.2 to -6.4 ‰, averaging -3.86 ‰ (Figure 7.62b). Carbon and oxygen are both depleted compared with estimated Mississippian marine carbonate values; almost certainly due to the addition of later diagenetic cements (Kendall, 2001).

Mississippian dolomites have heavier $\delta^{13}\text{C}$ values (+2.6 to +3.6 ‰) and appear to be less altered. Their $\delta^{18}\text{O}$ ratios, however, are more varied. Two populations are present: one has preserved Mississippian compositions or is slightly depleted (-2 to -3‰ $\delta^{18}\text{O}$), but most are heavier - clustering around values of +0.9‰ $\delta^{18}\text{O}$, possibly reflecting precipitation from evaporated Mississippian sea water (Figure 7.62b). A single analysis of dolomite from the dolomitized zone has a markedly different composition from the early diagenetic Mississippian dolomites. Replacement calcites have a narrower range of isotopic compositions, averaging -3.9 $\delta^{18}\text{O}$ and +1.5 $\delta^{13}\text{C}$. These averages are almost the same as those calculated for whole-rock analyses of the Mississippian limestones (-3.9 $\delta^{18}\text{O}$ and +1.8 $\delta^{13}\text{C}$). But the carbon isotopic ratios of replacive calcites, do not support this interpretation, rather they are identical to those of Mississippian limestones (Figure 7.62b).

Kendall (2001) argues simple replacement of sulphate by porewater bicarbonate (in equilibrium with host limestones) is unlikely because protons generated during the reaction should have created acidic conditions in which calcite would have dissolved. He notes a full explanation of the calcitisation remains elusive, but may involve replacement occurring in an active arid-zone groundwater system and/or bacterial sulphate reduction occurring upstream of the site of calcitisation.

Bustillo et al., (1999) describes some unusual mineralized and silicified carbonate-rich nodules hosted in Lower Triassic red mudstones in Central Spain (Figure 7.63). From their borders to their centres, the nodules (geodes) display a characteristic zonation of; a) a millimetric carbonate crust, b) a quartz rim, c) massive dolomite centres, d) gold-bearing iron-rich infills (haematite laths and goethite with up to 7000 ppm of gold) and e) uplift related calcite cements that sometimes seal the central hollow. Textural evidence indicates that the geodes were originally nodular anhydrite, subsequently replaced by quartz and dolomite. The resultant porosity from this replacement (“on the way down”), or porosity created by later dissolution, has been filled by epithermal gold-bearing iron-oxide hydroxides, romanechite and calcite.

$\delta^{13}\text{C}$ values indicate the participation of meteoric waters in an early burial environment, which was characterized by both a sub-desert climate and a temperate-tropical climate. Oxygen signatures reflect very variable temperatures for all minerals, with the exception of late stage calcite, which was precipitated at <38°C (“on the way up”). Iron-oxide temperature values in the gold rich cores can reach up to 85°C (epithermal stage). The mineralogical assemblages denote a multistage history to the nodules characterised by early silica, then dolomite infill of

a dissolving nodule (early diagenetic replacement “on the way down”) followed by the epithermal activity (“at the bottom”). This mineralization is linked to the Late Hercynian, calc-alkaline volcanism of Central Spain (the Hiendelaencina mining district). Once again, the evaporite replacement process is ongoing, not early versus late, but throughout the burial cycle.

Dedolomitisation of matrix

Dedolomitisation of the host matrix is frequently associated with calcitisation of entrained evaporite nodules. Dedolomitisation describes the conversion of a dolomite back to a limestone by the growth of calcite rhombs within the dolomite matrix.

This process can continue until the dolomite is converted to a limestone, or it may be arrested when the calcitisation of the matrix is no more than partial. Dedolomitisation has long been interpreted as a product of evaporite diagenesis and is typically ascribed to telogenetic calcium-rich groundwaters derived from a nearby dissolving gypsum/anhydrite or glauberite unit (Lucia, 1961; Warrak, 1974; Lee, 1994). An evaporite association is the emphasis of the dedolomitisation discussion in this section; but dedolomitisation can also occur under the influence of calcium-rich basinal waters (mesogenetic), where the elevated levels of calcium are independent of evaporite dissolution. For example, Land and Prezbindowski (1981) documented dedolomitisation from hot, calcium-rich brines moving up into a dolomite reservoir in the Cretaceous Edwards Group of the Gulf Coast. They attributed the high calcium content of these brines to the authigenic albitisation of plagioclase in downdip sandstones.

Evaporite-derived dedolomites are often associated with evaporite dissolution breccias, which indicate the now dissolved bed that supplied the excess calcium needed to dedolomitise (Lee, 1994). Dedolomite under this scenario forms via the reaction of calcium sulphate-rich solutions with a preexisting dolomite to produce calcite with magnesium sulphate as a possible byproduct. The latter is rarely preserved, as it is highly soluble, and either remains as dissolved ions in the escaping waters or is quickly redissolved and flushed by through-flowing groundwaters (Shearman et al., 1961). The CaSO_4 dissolution process is often driven by meteoric flushing of nearsurface oxidising waters and former ferroan dolomites are preferentially replaced. The resulting calcitised dolomites are outlined by intervals stained red with iron oxides and hydroxides.

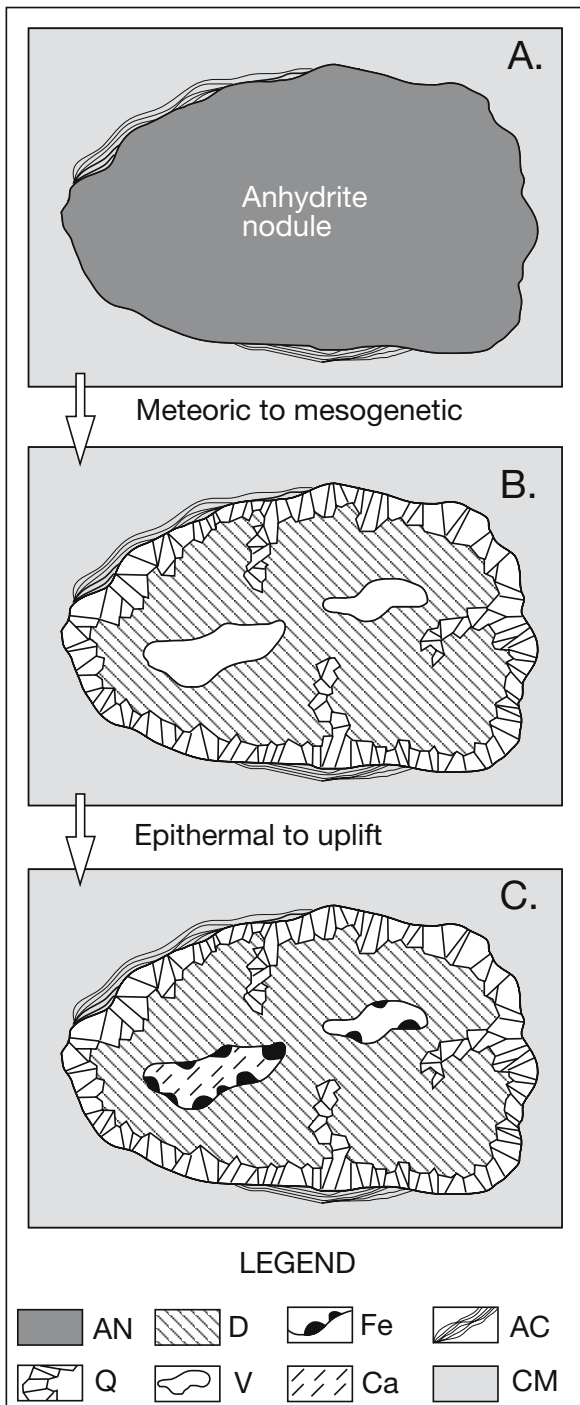

Figure 7.63. Model of the Tordelrabano geodes, Spain (after Bustillo et al., 1999). Abbreviations: AN, anhydrite; D, dolomite; Fe, oxides and hydroxides of iron; AC, carbonate crust; Q, quartz; V, voids; CA, calcite; CM, mudstones. A) Anhydrite nodules form in mudstones from early hypersaline fluids. Later, a crust (probably edaphic) forms around the anhydrite nodule. B) Replacement of the anhydrite by dolomite and quartz from continental groundwaters. Voids form by dissolution of anhydrite or dolomite. C) Filling of the voids by hydrothermal minerals (gold-bearing hematite-goethite). Subsequent precipitation of tectogenic calcite.

Dedolomites created by meteoric flushing of calcium-sulphate evaporite salts typically occur beneath exposure surfaces, dissolution breccias or unconformities. Well-exposed and studied examples of dedolomites, associated with karstification of a shallowly buried sulphate system, typify Miocene lacustrine sequences of the Madrid Basin in central Spain and the Calatayud Basin of NE Spain (Cañaveras et al., 1996; Arenas et al., 1999; Sanz-Rubio et al., 2001). A variety of calcite fabrics, initiated by dedolomitisation and calcitisation of magnesites, formed in association with well-defined solution collapse breccias (Figure 7.64). Dominant dedolomite textures are made up of sutured calcites and radial-fibrous calcites, the latter consisting of pseudospherulite mosaics and fibrous crusts. Other subordinate dedolomite fabrics consist of micro- to mesocrystalline mosaics of rhombic, occasionally zoned calcites, as well as reworked pseudospherulite crystals.

The diagenetic carbonate zone (DCZ) that hosts these textures in the Madrid basin overlies and grades laterally into lacustrine dolomite (lower dolomite unit - LDU) and evaporites (evaporitic unit - EU), and in turn is capped by a palaeokarst or exposure surface (Figures 7.36, 7.64a; Cañaveras et al., 1996). The boundary between the DCZ and the LDU is transitional and is defined by grading in the %MgCO₃ profile (Figure 7.64b). Mg values range from 0.1 to 1.2% in the dedolomites of the DCZ and micrites of upper limestone unit (ULU) and from 8 to 14% in the underlying dolomites of the LDU.

Geochemical evidence indicates dedolomitisation occurred in the shallow subsurface in early burial (< 40 m depth) via the throughflushing of oxidizing meteoric-derived ground waters (Cañaveras et al., 1996). $\delta^{18}\text{O}$ values of the dedolomites in the DCZ average -6.7‰ and range from -6.1 to -7‰ , while $\delta^{13}\text{C}$ averages -8.2‰ and ranges from -7.4 to -9.2‰ . The $\delta^{18}\text{O}$ values in the LDU average -0.3‰ while $\delta^{13}\text{C}$ averages -6.1‰ . Isotope values in the ULU range from -6.4 to -6.8‰ in $\delta^{18}\text{O}$ and from -8.2 to -8.9‰ in $\delta^{13}\text{C}$ (Figure 7.64c). The values of the dedolomites are consistent with precipitation from meteoric waters and give precipitation temperatures of 8 to 12°C. Vertical trends in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ can be used to define the average position of the water table in the DCZ at the time the dedolomites were forming (Figure 7.64d). This too supports a palaeokarst model characterized by an irregular shallow water table and a narrow vadose zone (Cañaveras et al., 1996). The

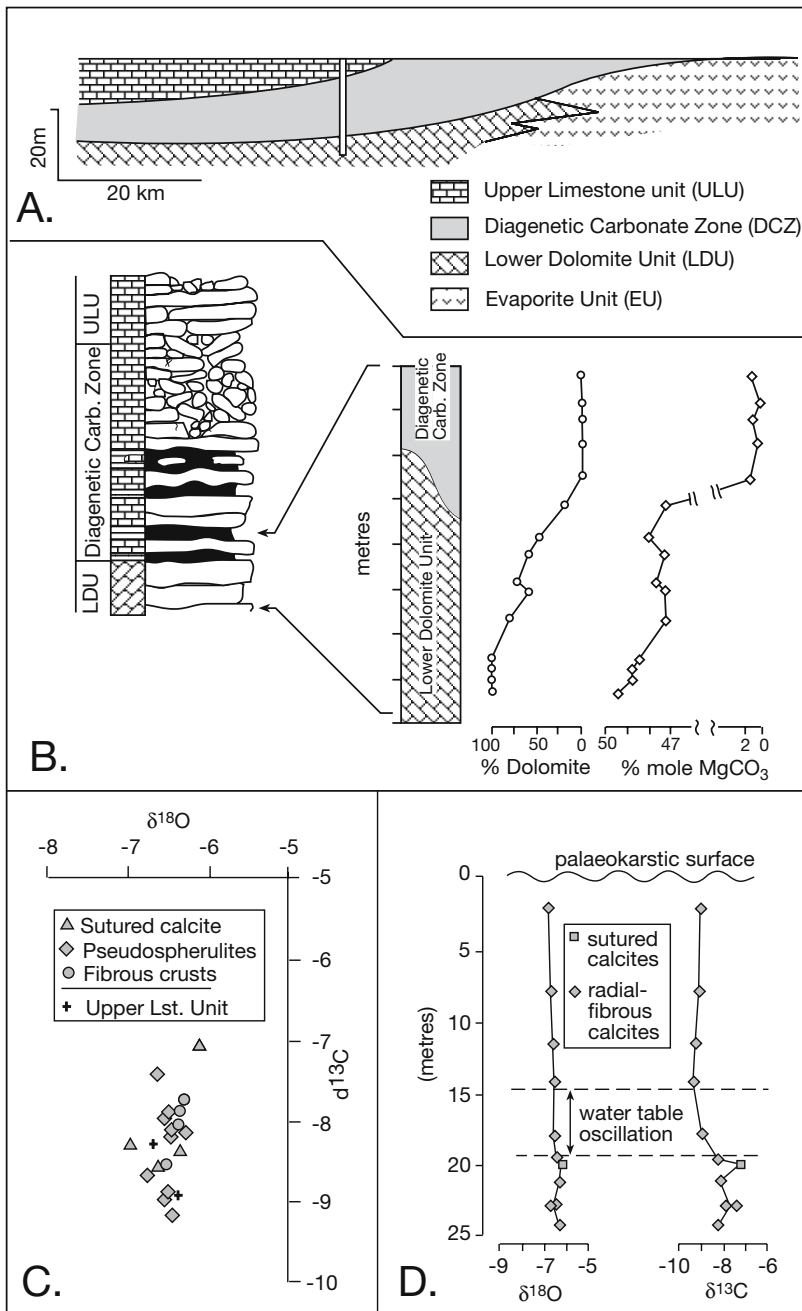

Figure 7.64 Dedolomite in the Madrid Basin, Spain. A) Distribution of the main subunits in Middle to Upper Miocene lacustrine units of the Madrid Basin, central Spain. B) Shows the position of the solution collapse breccia in controlling the dedolomites and the nature of the contact between the lower dolomite unit (LDU) and the dedolomites of the diagenetic carbonate zone. C) Oxygen-carbon crossplot of different types of calcite that make up the dedolomite. D) Vertical trends in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ in section of the Diagenetic Carbonate Zone (DCZ). The zone of carbon depletion between 15 and 20 metres below the palaeokarst surface corresponds to a trend of more constant $\delta^{18}\text{O}$ values above this interval and more variable values below. These observations are consistent with the preservation of a palaeo-water table within the DCZ (after Cañaveras et al., 1996).

diagenetic system behaved as an open system for nearly all trace elements analysed; but in the shallower zone (vadose zone) the system was partially closed with respect to strontium. The dedolomitisation was driven by two combined hydrographical patterns: authigenic recharge through limestone aquifers and allogenic recharge from adjacent mountains (Figure 8.10).

Dedolomites can also be formed via evaporite dissolution in the deeper subsurface mesogenetic realm where dissolution-derived basal brines are escaping into the basin margin. Budai et al. (1984) suggested a sub-surface setting for burial dedolomites of the Mississippian Madison Group of Wyoming and Utah. Two stages of fracture-related dedolomite are present, one that precedes and one that postdates regional dolomitisation. The early dedolomite occurred as active groundwaters flushed evaporitic sequences during shallow burial (on the way down in the burial cycle). The later post-styolitisation fracture-associated dedolomite records chemistries and isotopic signatures of deep burial and tectonic-vein mineralisation. Associated with this late dedolomite are calcitised anhydrite nodules and stylolite-bitumen-related dedolomites that also indicate burial-related episodes of dedolomitisation. This episode of dedolomitisation took place during hydrocarbon maturation as basal brines were moving through the Madison reservoir. Then hot Ca-enriched brines were able to dissolve anhydrite and dolomite, while at the same time precipitating calcite along stylolitisised seams and within anhydrite nodules.

Table 7.13. Worldwide occurrences of celestite and associated properties (in part after Scholle et al., 1990; Hanor, 2004).

Celestite as an indicator?

Celestite (SrSO_4) occurs as crystals, nodules and cements in many bedded carbonates, particularly karstified limestones, but also in dolomitic and marly hosts. Evaporite-associated celestite

may replace or pseudomorph individual evaporite crystals, or it may be isopachous and passively fill fissures, vugs and nodular cavities created by the dissolution of an evaporite precursor, or it may form interclast cements within dissolution breccias. Internal textures preserved within a celestite nodule replacing

an evaporite or an intergranular aggregate depend on the ratio of rock to fluid interaction and the timing of flushing.

Celestite, in association with baryte and strontianite can form massive intervals in diapir caprocks and haloes about the dissolving edges of salt allochthons. Caprock occurrences were discussed in the previous chapter and will not be discussed here. SrSO_4 in a bedded evaporitic carbonate host forms either as a primary precipitate from brines (Wood and Shaw, 1976) or, more usually, by the diagenetic interaction of gypsum or anhydrite with groundwater-borne Sr-rich waters (Table 7.13). In this case the dissolution of a calcium-sulphate-containing bed supplies the SO_4 , which then combines with Sr to precipitate as celestite, typically in zones of mixing between hypersaline and meteoric waters. West (1964, 1965, 1973, 1979) discusses the evaporite-celestite association in detail and the interested reader is referred to these benchmarks. Scholle et al. (1990) is recommended for a more general summary of celestite occurrence in sediments worldwide.

Strontium occupies calcium sites in the gypsum or anhydrite lattice, where it can be enriched ten times over the Sr content in enclosing dolostones (Carlson, 1983). Strontium levels are around 2,000 ppm in marine gypsum and 5,000 ppm in anhydrite of marine origin (Stewart, 1968). Leaching of such gypsum/anhydrite can create Sr-rich waters, as can the dissolution of aragonite. Documented sources of strontium-rich waters capable of precipitating celestite include:

- Marine-derived brines (Frazier, 1975; Baker and Bloomer, 1988)
- Waters formed during the conversion of aragonite to calcite (Nickless et al., 1975)
- Waters formed during the dolomitisation of limestones (Wood and Shaw, 1976)
- Waters formed during the conversion of gypsum to anhydrite (Kushnir, 1982; Orti et al., 1998)
- Waters formed during the dissolution of subaerially exposed gypsum (Taberner et al., 2002)
- Resurgent basinal waters that have leached Sr from feldspars and clays in arkosic redbeds (Scholle et al., 1990)
- Red bed successions prograding atop a carbonate evaporite system and carrying a progradational meteoric hydrology that leaches Sr from the redbeds (Taberner et al., 2002)
- Shallow subunconformity waters with elevated Sr from bacterially-mediated calcitisation of anhydrites (Kendall, 2001)

West (op. cit.) notes that sedimentary celestite has, in most cases, formed by direct replacement of gypsum or anhydrite; it tends to remain, even when exposed at the surface as it is much less soluble than either of those minerals. West's papers

on celestite occurrences and controls in the Jurassic Purbeck evaporites of the UK remain as highlights in competent scientific documentation of field relationships and observation-based interpretation of process. He concludes that celestite formed by the selective removal of strontium from groundwater by reacting with dissolving beds and nodules of calcium sulphate. Groundwaters containing a large proportion of calcium ions and a small proportion of strontium ions most commonly exist where limestones occur in proximity to the site of precipitation. Celestite is less common where sandstones are the aquifers adjacent to a gypsum bed. The groundwater may be ascending or descending as it reaches the CaSO_4 . Celestite beds of appreciable thickness are thus formed in Purbeck strata at the upper and lower boundaries of gypsum or anhydrite beds in contact with these groundwaters. Purbeck celestite replaced both nodular anhydrite and bird-beak gypsum roses (West, 1964). Ongoing flushing by bicarbonate-rich groundwaters locally converted celestite to calciostrontianite (Salter and West, 1966).

Carlson (1987) documented groundwater-driven replacement of calcium sulphate salts by celestite in Silurian carbonates of northwestern Ohio. Associated textures indicate evaporite dissolution and karstification. Celestites occur along the western margin of the Ohio (Cayugan) basin within the Greenfield Dolomite and undifferentiated Salina dolostones. The celestite replacements are more durable than the original evaporite salts, which have long since vanished from the outcropping carbonate. Replacement styles include: lenticular and prismatic crystals, replaced cauliflower nodules of anhydrite and laminar celestite beds replacing laminated evaporites. Remnants of the replaced material can be preserved as euhedral, deeply embayed outlines or within internally zoned growth bands that entrain inclusions of dolostone and anhydrite. Poikilotopically enclosed remnants of anhydrite in celestite prisms with lenticular outlines show simultaneous extinction in thin section, possibly indicating that at the time of celestite replacement the gypsum was a single crystal and not a felted anhydrite mat. Alternatively, these lenticular crystals may be after axe-head anhydrite, implying a possibly later origin for at least some of the CaSO_4 than argued by Carlson. Other nodular and laminar celestite pseudomorphs display relict chickenwire and enterolithic structures indicating a primary anhydrite parentage.

Early, almost syndepositional, replacement of CaSO_4 nodules by celestite occurred in both the vadose and the active phreatic zone of the evaporitic Silurian Steinsfjord Formation of the Oslo Region, Norway (Figure 7.65; Olausson, 1981). Marl and carbonate host sediments were deposited in supratidal, intertidal, and restricted subtidal environments. Celestite oc-

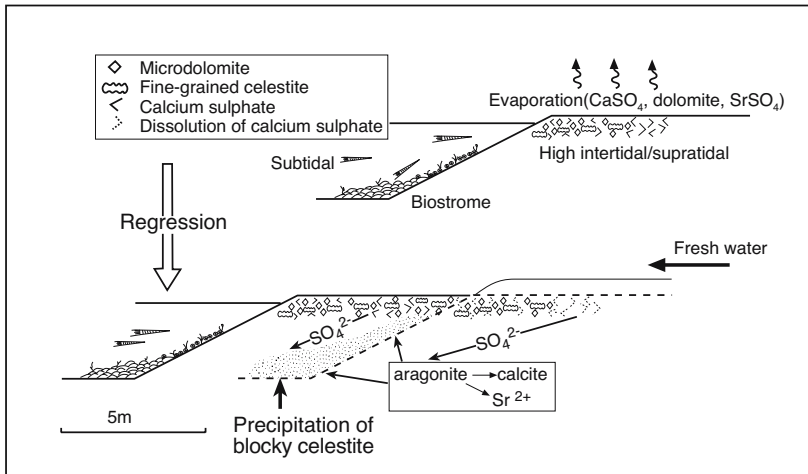

Figure 7.65. Formation of early celestite replacement in the Brattstad Member of the Steinsfjord Formation, Norway. Strontium is derived from freshwater leaching of anhydrite and aragonite (after Olausen, 1981).

curs in two distinct textural associations within these peritidal sediments: 1) as aggregates of tiny celestite crystals in nodular dolomicrites of the high intertidal facies, or 2) as anhedral or euhedral prismatic crystals infilling intrapores and interpores in the low intertidal to subtidal facies. Celestite is thought to have precipitated from SO_4 -enriched porewaters via the solution of calcium sulphate. Solution occurred early during evaporitic mudflat progradation as it was flushed by land derived meteoric waters (Figure 7.65). Released sulphate then reacted with strontium generated by an aragonite to dolomicrite transformation within the high intertidal and an aragonite to calcite transformation in the low intertidal-subtidal.

A similar progradational hydrology is documented in fracture-filling cements at La Tossa reef near Igualada, NE Spain, but in this case it was driven by a meteoric hydrology that continued to focus Sr flow well after the time of gypsum accumulation (Taberner et al., 2002). Fissure cements in other Eocene reefs along the same basin margin, such as Calders reef, tend to be dominated by baryte with only minor celestite. All reefs in the basin grew atop delta-lobe sandstones and prodelta marls, which at La Tossa, but not Calders reef, are overlain by Upper Eocene evaporites and hypersaline carbonates (Figure 7.66a). Stable isotopic analyses of all reef carbonates indicate meteoric recharge was responsible for aragonite stabilization and calcite cementation.

Celestite precipitation at La Tossa began as reef stabilization occurred in early burial. Strontium needed for celestite precipitation was partly derived in situ from dissolution of aragonite corals in the reef and more basinal counterparts. However,

$^{87}\text{Sr}/^{86}\text{Sr}$ data also suggest that Sr at La Tossa was also derived from dissolution of the overlying nearby evaporites (Figure 7.66b; Taberner et al., 2002). As the reef became lithified and stabilized, early burial fluid flow was increasingly focused in fractures and the cavities that linked them. The amount of residual strontium released from aragonite dissolution and recrystallization would have built up to supersaturated levels in the remaining interstitial fluids in the fractures.

^{18}O isotopic data suggest that local meteoric waters at La Tossa (a celestite-rich area) were enriched in Sr compared with those responsible for stabilization in other reefs in the area

where fracture-filling cements are richer in baryte, with lesser celestite (Figure 7.66b). At Calders, as in the La Tossa reef, meteoric cementation was completed before sulphate (baryte and minor celestite) cements precipitated in fractures and dissolution cavities. Calders reef is directly overlain by fluviodeltaic facies, related to the progradation of the St Llorenç del Munt fan-delta and so were susceptible to groundwater invasion immediately after deposition (Figure 7.66a). Baryte may have formed in preference to celestite as a result of more efficient flushing of Sr from Calders reef before sulphate authigenesis.

Relatively low $\delta^{34}\text{S}$ and $\delta^{34}\text{S}$ enrichment ratios show that celestite at La Tossa reef formed from residual sulphate in pore waters after bacterial sulphate reduction. Taken together they also imply that there was a prior episode of sulphate recycling at La Tossa. Meteoric water reaching the La Tossa reef and nearby basinal areas was most probably charged with SO_4 from the dissolution of nearby younger Upper Eocene marine evaporites. This sulphate-rich groundwater, combined with organic matter present in the sediments, fuelled bacterial sulphate reduction in the meteoric palaeoaquifer (Figure 7.66a). A progressive build-up of SO_4 and Sr concentrations occurred, it became relatively more important in time and drove ongoing celestite precipitation as more and more evaporites were dissolved.

In the other reefs (Calders Reef) a similar ongoing post stabilization source for Sr from dissolving gypsum was not present and so the volumes of celestite cement in their fractures are less. Furthermore, meteoric recharge at La Tossa post-dated the 34 Ma (Upper Eocene) time of evaporite deposition. Reef complexes in other parts of the same basin (e.g. Calders Reef)

were stabilized by direct contact with waters from the deltaic wedge well before the time of any evaporite formation.

One of the most impressive examples of celestite precipitated in an active phreatic hydrology at a gypsum-limestone boundary is the karst-associated celestite mineralization of Upper Permian successions in the Karstryggen Formation, central East Greenland (Scholle et al., 1990). With an area of 80 km² and a potential resource of 25-50 tonnes at a grade of 50-60% and local high grade zones of more than 90% celestite it constitutes one of the world's largest strontium deposits. It formed as a replacement of the margins of a pre-existing gypsum body that had precipitated in one of several small structurally-controlled evaporite basins along the edge of a larger marine embayment. Celestite replaces both carbonate and evaporite minerals, as well as forming a passive void infill in pre-existing karst. The

timing of celestite emplacement at the boundary of the gypsum is not well constrained. The sulphate came from the dissolution of calcium sulphate, while the isotopic values indicate the strontium-rich waters came from the deep meteoric or compactional flushing of underlying red beds.

Not all evaporite-hosted celestite requires flushing of the edge of a sulphate bed by meteoric hydrologies. Celestite precipitating waters can also come from mixing of waters sourced in the burial dewatering of hydrated salts. Paleokarst cavities in the Lower Werra Anhydrite (Zechstein) of northern Poland are usually filled by bluish semitransparent anhydrite and more rarely by celestite, polyhalite, halite, and carbonate (Hryniv and Peryt, 2003). In small karst cavities (a few centimetres across), rims of rod-like anhydrite crystals arranged in narrow bundles line the fissures, with the inner part of the cavity filled

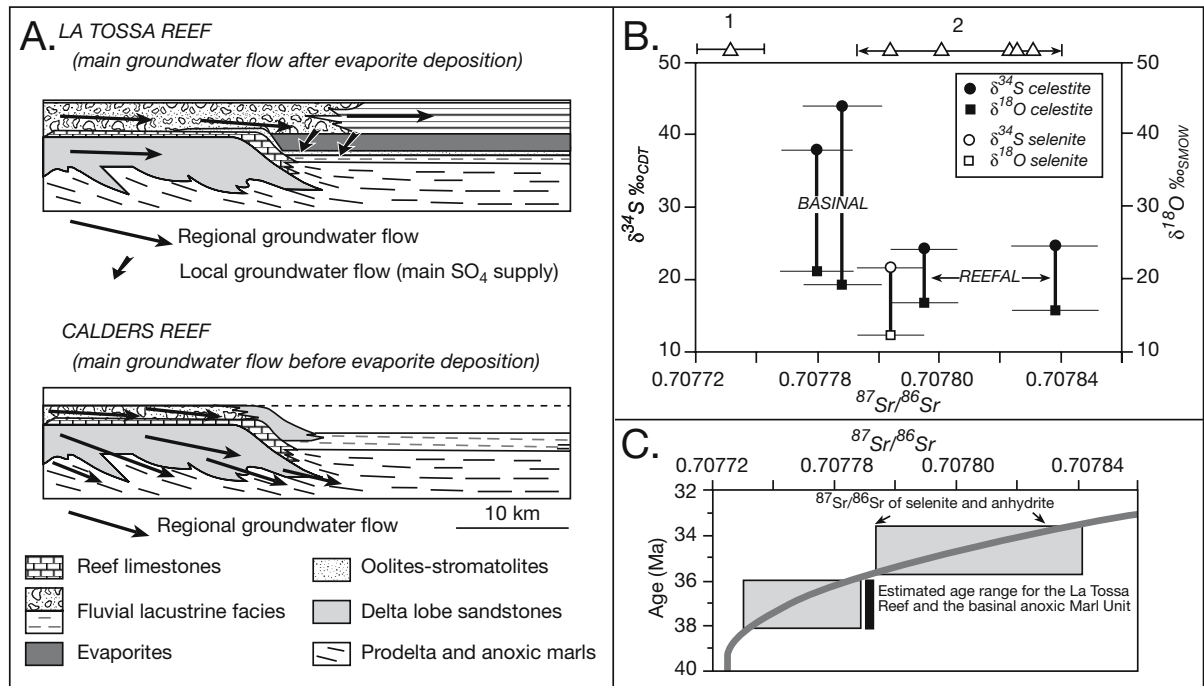

Figure 7.66. Celestite in the Eocene La Tossa and Calders reefs, Spain (after Taberner et al., 2002). A) Early diagenetic paleohydrology determined for the basin margin La Tossa reef at Igualada, compared with the interpreted flow system at Calders reef. Arrows indicate the direction of fluid flow. The reef at Calders was flushed by lateral groundwater flow before evaporite deposition, whereas the major meteoric influence at La Tossa, Igualada, occurred after evaporite deposition and featured a local ongoing meteoric flow system that leached SO₄ and Sr from basinal evaporites. B) Combined δ³⁴S and δ¹⁸O – ⁸⁷Sr/⁸⁶Sr cross-plot for celestite samples filling cavities in La Tossa reef and basinal sections. Isotopic ratios for the marginal selenitic gypsum are also plotted. The strontium isotopic composition are plotted as open triangles for stage 2 (meteoric-stabilisation) calcite cement from the reef (1) and the range of ⁸⁷Sr/⁸⁶Sr values for the Upper Eocene Lower Anhydrite Unit and selenitic gypsum (2). Celestite cements in reef fractures show δ³⁴S, δ¹⁸O and ⁸⁷Sr/⁸⁶Sr ranges that are closer to those of the Upper Eocene evaporites, whereas those celestites that depart from these values are from the basinal samples and later stage calcite cements in the reef. C) Temporal variation in marine ⁸⁷Sr/⁸⁶Sr values. Except for near the inflection point, the errors in age estimates are incorporated in the thickness of the line. The measured ⁸⁷Sr/⁸⁶Sr values from the evaporites give an age of 34 ± 0.9 Ma for their formation. The age of the reef is constrained by the stratigraphic relationships with the evaporites and by comparison with outcropping reefs from the eastern margin of the basin.

by a mosaic aggregate of short prismatic crystals of anhydrite and celestite, as well as coarse irregular anhydrite. Celestite crystals and fan-shaped aggregates, as well as spherulites of anhydrite, are rare in the smaller cavities and fissures. In bigger cavities (some ten centimetres across), multiple zones of fibrous anhydrite are arranged in different directions in the middle part of the cavity fill. The innermost parts of the larger karst cavities still remain as hollow in some cases, with the cavity walls encrusted by coarse, well-developed crystals of anhydrite and celestite.

Karst cavities in the Lower Werra Anhydrite developed in the subsurface by dissolution of CaSO_4 strata in halite-rich intervals flushed by gypsum dehydration waters. During gypsum dehydration, dissolution of halite increased the sodium chloride content of the solution and thus the solubility of calcium sulphate (Figure 2.11b). Dissolved calcium sulphate was leached by diffusion and/or downward flow in the interstitial spaces, and the minerals in karst cavities precipitated from the same solutions as solutions became oversaturated. The work of Hryniv and Peryt (2003) shows that karst in sulphate deposits can develop non-telogenetically during ongoing burial and dewatering in a system without uplift and/or near-surface meteoric flushing.

So far, we have considered celestite as tied to direct dissolution of former bedded and nodular calcium sulphates, typically with nodular and enterolithic textures that indicate the evaporite association. But there are also laterally extensive stratiform and layered celestine deposits that are sufficiently rich in strontium to be mineable and hosted in epeiric carbonates. De Brodtkorb et al. (1982) described such an economic celestite-baryte deposit in Early Cretaceous strata from the extra-Andean region of Neuquen, west central Argentina. The ores are located in the sub-Andean Mesozoic belt and show a conspicuous stratabound character with an aerial extent that closely relates to the presence of regionally extensive platform sulphates. Isotopic $^{87}\text{Sr}/^{86}\text{Sr}$ data confirm an evaporitic origin for this celestite (Table 7.13). Host sediments were deposited during the transition to an epicontinental marine shelf environment from an earlier saltern. The celestite is always hosted in saline and hypersaline facies as these beds were the source of the sulphate. Celestite forms as either syngenetic nodular beds with texture similar to those described earlier, or as more epigenetic stratabound ores composed of “in situ” celestite with texture showing stalactite growth and cavity infilling in its carbonate host, possibly as replacements of bedded saltern sulphates. There are also epigenetic vein-type ores. Open fill textures are interpreted as burial phreatic, precipitated by mesogenetic Ba-enriched solutions dripping into gas filled

dissolution cavities in a previously karstified (?bathypheatic) sulphate evaporite and carbonate host. Some have argued these enigmatic stratiform ores are primary seawater-derived precipitates, others see their origin as mesogenetic replacements of bedded calcium sulphate salterns.

Many stratiform celestites, including the Argentinian ores, have crystals encasing inclusions of solid hydrocarbons and textures showing they precipitated in association with saddle dolomite, burial anhydrite and metal sulphides. Hanor (2004) documents the worldwide association of such stratiform sediment-hosted celestite with epeiric carbonate platforms (Table 7.13). He notes their association with bedded platform sulphates and also points out that the largest known sedimentary celestine occurrences, each with several million metric tons of SrSO_4 , cannot be readily explained as primary precipitates or near-surface meteoric replacements of nodular sulphate evaporites. The largest deposits, as in South America and Greenland, tend to occur as epigenetic replacements in carbonate and evaporite hosts within epeiric platforms that range in age from Silurian to early Pliocene. There is variable evidence of associated hydrothermal activity in these deposits, and Sr isotopes typically have a more radiogenic signature than the prevailing seawater of the time (Table 7.13). Hanor argues the key to explaining the origin of these massive sediment-hosted celestites lies in determining why celestite is the replacement phase in these deposits and not baryte (BaSO_4), which is orders of magnitude less soluble.

Hanor (op. cit.) concludes that stratiform celestite hosted in epicontinental platforms did not form syndepositionally from Sr-enriched brines created by the evaporation of seawater. Sr is removed from concentrating marine brine during the halite stage of evaporation as a dispersed sulphate phase and not as precipitate bedded celestite. The association of large stratiform celestine deposits with marine platform carbonate–evaporite sequences most likely reflects, at least in part, the significant difference in the geochemical behaviour of Sr and Ba during mesogenetic diagenesis.

Concentrations of Sr in subsurface sedimentary fluids are buffered by silicate–carbonate mineral assemblages. Concentration of Sr in solution in modern subsurface waters increases significantly with increasing salinity (Figure 8.27). The concentration of Ba, in contrast, is controlled by equilibrium with the baryte solid phase and is inversely related to the concentration of dissolved sulphate in subsurface fluids (Figure 7.67a; Hanor, 2004). Basinal fluids having the highest Sr/Ba ratios are also the most saline and have moderately high levels of sulphate

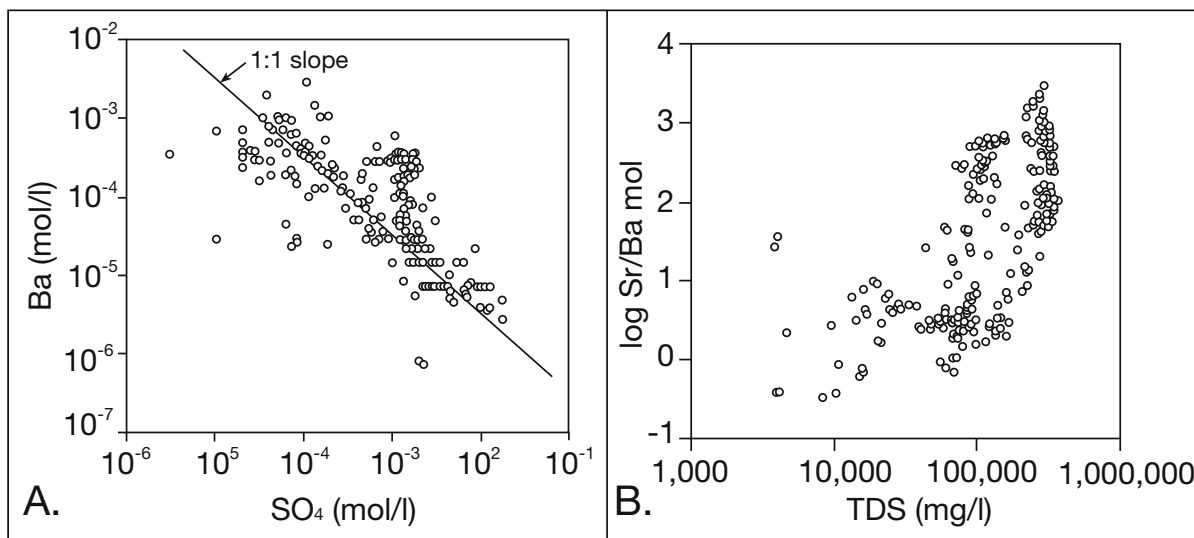

Figure 7.67. Ba in subsurface basinal brines (after Hanor, 2004). A) Variation in dissolved Ba versus dissolved sulphate in basinal brines. B) Variation in Sr/Ba ratio versus the salinity of basinal brines. See Figure 8.27 for Sr trend.

(Figure 7.67b). Thus hypersaline mesogenetic brines flushing through a carbonate platform will be more likely to be saturated with celestine rather than baryte. The precursors to such waters were produced in hypersaline pans and salterns by the evaporation of seawater. As these brines reflux into underlying or laterally adjacent sediments, they leach substantial amounts of Sr as they attempt to achieve chemical equilibrium with their host sediments. In contrast barium concentrations in subsurface reflux brines are kept relatively low by the presence of dissolved sulphate. Precipitation of widespread mesogenetic celestine occurs where these diagenetically altered reflux fluids come into contact with beds containing calcium sulphate minerals and/or sulphate-rich waters. Thus Hanor argues, the stratiform celestite ores of the world are not recrystallised primary precipitates or derived in meteoric mixing zones. They are the result of deeply circulating hypersaline brines moving through an anhydritic epeiric platform under a hydrological drive that is tied to platform restriction and creation of dense reflux brine. The elevated Sr does not come from the parent connate water, but from rock-fluid (brine) interactions with buried platform carbonates. Hydrocarbons are often mobile in the same sediments at the same time.

Not all celestite - calcium sulphate associations are hosted in sediments. An unusual late-stage celestite is intimately associated with hydrothermal $CaSO_4$ (now gypsum) in the Asaka gypsum mine (Koriyama City, Japan). Celestite occurs on the sides of fibrous (satinspar) gypsum in the mine area. The satinspar indicates telogenetic alteration. The celestite is interpreted by Matsubara et al. (1992) as a hydration product

of strontian anhydrite (SrO up to 0.94 wt %), which occurs in the same area. The hydration is very late, associated with uplift and meteorically-driven conversion of strontian anhydrite to gypsum, where the $SrSO_4$ molecule remains intact during the conversion and eventually crystallises as celestite. Warren (1999; Chapter 9) discusses the worldwide occurrence of hydrothermal anhydrites and their association with high-temperature sulphide mineralisation.

Fluorite as an indicator?

Fluorite (CaF_2) and baryte ($BaSO_4$) are not uncommon as hydrothermal phases in mineralised sedimentary carbonates. Compared to sediment-hosted celestite, the range of mesogenetic associations is more cosmopolitan and their appearance in a carbonate platform host typically reflects the carbonate's high susceptibility to replacement, especially when flushed by somewhat acidic, cooling hydrothermal and basinal fluids.

According to Richardson and Holland (1979), the solubility of fluorite in NaCl solutions increases with increasing temperature at all ionic strengths up to about $100^\circ C$ (Figure 7.68). At NaCl concentrations above 1.0 M, the solubility of fluorite increases continuously above $100^\circ C$, and it increases also with increasing $CaCl_2$ and $MgCl_2$ concentrations in the NaCl dominant solutions. According to Munoz et al., 1999, this means that most nonmagmatic fluorite-carrying basinal waters in a sedimentary basin are derived in part from interactions with dissolving evaporites. Evaporite-derived fluorine can even be involved in the formation of rubies (gem corundum) in meta-

Figure 7.68. Quantity of fluorite precipitated by cooling of $\text{NaCl} \pm \text{CaCl}_2 \pm \text{MgCl}_2 \pm \text{H}_2\text{O}$ solutions with Ca/Mg ratio of 9:1 and an ionic strength of 4 M from 260° to 25°C (after Richardson and Holland, 1979).

evaporites (Garnier et al., 2005). The interaction allows such hydrothermally circulated waters (high salinity and CaCl_2 -bearing) to attain the elevated levels of dissolved fluorine required to precipitate significant volumes of fluorite during subsequent brine cooling. Elevated salinities in the subsurface can come from evaporite dissolution or from brine reflux. Much of the nonmagmatic fluorite dissolved in these saline brines is sourced by subsurface flushing of organic-rich black shales.

For example, fluorite is a minor late stage mesogenetic cement in Devonian carbonates in the Keg River Formation, Canada (Aulstead and Spencer, 1985). The fluorite was carried to the site of precipitation by rising and cooling basinal brines that had flushed deeply buried bedded evaporites and organic laminites. Similar late-stage fluorite cements in voids and fractures have precipitated from structurally-focused basinal brine flows in the

Jurassic reefal carbonates in Zaghuan Province in north-eastern Tunisia, in the Smackover Formation of the Gulf of Mexico, in the Upper Permian Karstryggen Formation of Greenland and in many other buried and faulted carbonate platforms subject to metal sulphide and saddle dolomite emplacement (Souissi et al., 1997). All these fluorites precipitated from highly saline brines in deep halokinetic settings where mesogenetic salt dissolution dominates. Likewise, the isotopic signatures of authigenic fluorites in a number of European fluorspar deposits show the supplying hydrothermal waters were sourced in, or carried by, brines from dissolving or tectonically juxtaposed evaporites. Examples include vein fluorites (Pb-Zn-F) associated with the Permian Haselgebirge evaporites in the Austrian Alps (Göttinger and Grum, 1992) and massive fluorites in veins that crosscut Cambro-Ordovician clastics in the southwestern Massif of Albigeois, France (Munoz et al., 1999). There is also a halokinetic/hydrocarbon/thrust link to crosscutting fluorite veins in Jurassic carbonates of the Koh-i-Maran, Baluchistan in the North Kirthar Range, Pakistan (Guilhaumou et al., 2000). Clearly, the dissolution of deeply buried halite

(both bedded and diapiric) can supply the saline chloride brine needed to act as a fluoride and metal carrier in nonmagmatic sedimentary systems (Warren, 2000b).

Fluorite also forms a widespread, but volumetrically minor, early diagenetic and even syndepositional authigenic mineral phase in some evaporitic matrices where its precipitation may even be related to solar concentration of a surface brine. For example, fluorite has precipitated as ooids and pellets in a 40 cm thick tuff bed in the Gila Conglomerate of New Mexico (Sheppard and Mumpton, 1984). Fluorite also occurs as sparse isotropic euhedral cubes (50–200 μm diameter) within primary gypsum nodules at depths of 235–240 m below the present land surface in Eocene carbonate mudstones of Florida. Celestite also occurs in the same sediment. Cook et al. (1985) argued that the

Florida fluorite was syndeositional with the precipitation of gypsum in the capillary zone of an Eocene sabkha mudflat. If so, it was ultimately derived by the evaporative concentration of normal seawater. Additional fluoride in the parent pore waters may have been derived by fluvial transport of salts weathered from Appalachian volcanics.

Cook et al.'s conclusion is perhaps supported by the work of Kazakov and Sokolova (1950) who documented sedimentary fluorite in various marine carbonates/evaporites in Russia in hosts that range in age from Cambrian to Cretaceous. In related laboratory experiments they observed that fluorite can precipitate from seawater brines concentrated three to four times by volume, especially if an additional (fluvial or volcanic) source of dissolved fluoride was available in the depositional setting.

In a similar fashion, Sheppard and Mumpton (1984) explain the primary precipitation of early diagenetic fluorite using the analogy of high fluoride alkaline lakes in the East African Rift, such as Lake Magadi, Lake Natron and Lake Manyara (Table 4.3). Subsequent to Surdam and Eugster's (1976) documentation of fluorite as a common authigenic phase in Pleistocene sediments of the Magadi Basin, Icole et al. (1990) documented stromatolitic layers in lower Pleistocene lacustrine beds along the western edge of Lake Natron, Tanzania that are mainly composed of fluorite rather than calcium carbonate. Without doubt these are early rather than burial diagenetic precipitates. Moreover, Pleistocene fluorite is replaced by dolomite in the uppermost parts of some of these layers, but this replacement still preserves the original sedimentary texture. Fluorite is also reported in sediments of Lake Bogoria, Kenya, in an interval that also contains sodium silicate gels (magadiite; Renaut and Tiercelin, 1994). There is even a palaeobiological response to the high levels of fluorine in saline lake waters in the rift valley. Many fossil fish, preserved in the Plio-Pleistocene phosphoric lacustrine sediments of Lake Manyara, are hyperostitic (enlarged and fused bone structures), a biological response to elevated fluorine levels in the lake waters (Schlüter and Kohring, 2002).

Crocker (1979) proposed that granular blockspars (fluorite) ore in the Proterozoic Transvaal Supergroup of South Africa indicates primary syndeositional endogenic fluorite mineralisation and is a special precipitative stage tied to Precambrian dolomite evaporite facies. Rouchy et al. (1987) documented an association between fluorite, native sulphur and Visean (Carboniferous) evaporites. In an earlier paper, Amieux (1980) showed fluorite was a characteristic diagenetic stage in the black shale to evaporite transitional facies within the Ludian (Lower

Oligocene) sediments of the Mormoiron Basin, Vaucluse, southeastern France. There the major fluorite precipitation phase postdates major dolomitisation and gypsification but precedes celestite and silicification.

But, fluorite is not solely sourced or carried in evaporite brines, nor deposited only in a sedimentary host. That is just the focus of fluorite discussion in this chapter. Fluorite can be found in fissure veins and stockworks in granitic rocks, greisens, pegmatitic carbonatites, metamorphics, and igneous rocks that include volcanic sublimates (Hodge, 1986). These are not tied to an evaporite source. Nor are the vein and stratified (manto) fluorite deposits that are associated worldwide with areas of rifting and faulting where fluoride-rich hydrothermal fluids migrate up from the lower crust or mantle to replace carbonate hosts (Van Alstine, 1976).

Baryte as an indicator?

Baryte, like fluorite, is a widespread hydrothermal precipitate or replacement. In the sedimentary realm it occurs in a wide variety of settings ranging from lakes and soils to cold seeps and vents on the deep open ocean floor. Its occurrence is not specific to evaporitic sequences, but it is a commonplace replacement/cement in evaporitic hosts. This is especially true in those parts of a basin where evaporite-focused fluid flow brings together hot Ba-rich basinal brines (Cl-rich waters flushing and leaching arkoses (alkali feldspars and micas), redbeds, volcanics and volcanoclastics) and sulphate-rich waters from dissolving sulphate evaporites (anhydrite beds, halokinetic basal anhydrites, allochthon décollements, dissolution residues and diapir caprocks).

Economically, baryte's occurrence is mostly as gangue in various hydrothermal beds and veins entraining metalliferous ores (Warren, 2000b). Baryte also forms stratiform layers, veins, nodules and cavity fills in sulphate-rich sediments, especially in the early Archean, and is also a commonplace precipitate in black smokers and volcanic hosted massive sulphide (VHMS) deposits. In such cases much of the sulphate is nonevaporitic, it comes to the precipitation site either as sulphide in solution which is oxidised to sulphate at the site of deposition or as sulphate ions carried by hydrothermally circulated seawater. Baryte is also a widespread precipitate in deepwater cold seeps, mud volcanoes, springs and brine lakes on the supra-allochthon floor of the Gulf of Mexico (Fu et al., 1994) and their Neogene caprock counterparts (Saunders and Thomas, 1996). In the following section we will focus only on barytes with an obvious evaporite association.

Baryte can directly replace sedimentary gypsum or anhydrite throughout a rock layers diagenetic history. At 25°C and 1 bar, the value of the equilibrium constant, K , for the replacement reaction:

as calculated from Gibb's Free Energy values, and assuming pure solids is:

$$K = 10^{5.5} = a_{\text{Ca}^{2+}} / a_{\text{Ba}^{2+}}$$

Thus, it is thermodynamically feasible for baryte to replace calcium sulphate at earth surface temperatures whenever the activity ratio of ($a_{\text{Ca}^{2+}}/a_{\text{Ba}^{2+}}$) is less than $10^{5.5}$, a condition met in many subsurface waters (Mossman and Brown, 1986). At more elevated temperatures the limiting activity ratio is even less due to the retrograde solubility of anhydrite.

Loosely arranged platy crystals of baryte form pseudomorphs after lenticular gypsum in Quaternary soils from central Australia (Sullivan and Koppi, 1993). In older sedimentary deposits, evaporitic baryte typically replaces nodular forms with irregular and coalesced outlines reminiscent of anhydrite or gypsum, or forms stratiform layers. In several such cases, isotopic analysis indicates the sulphate in the nodules and layers was remobilised from a calcium sulphate precursor such as; caprock sulphate (von Gehlen et al., 1962), sedimentary gypsum (Kesler et al., 1988; Parafinuk, 1989), or anhydrite-rich evaporites (Mossman and Brown, 1986; Frimmel and Papesch, 1990).

Stratiform baryte is often found as a late stage precipitate in association with pervasive ferroan carbonate haloes in the alteration zones around growth faults and salt welds in halokinetic provinces. These haloes tend to define zones where escaping Ba-rich hypersaline basinal waters are flowing out of the basin via halokinetically-focused fault conduits, often feeding stromatolitic baryte seeps on the seafloor (Warren, 1999, 2000b). Sometimes these iron- and barium-rich ascending fluids interact with sulphate present in anhydrite or gypsum nodules, other times with sulphate beds or dissolution residues or with seawater sulphate. Modern examples of salt focused brine outflow in halokinetic provinces tend to occur in relatively deepwater muddy hosts. This is where the most active salt allochthon flow occurs, as on the continental slope and rise of the Gulf of Mexico or the tectonic high of the Mediterranean ridges. Because brine lakes are commonplace in such settings, it precipitates baryte in association with organic- and pyrite-rich laminites under the influence of sulphate reducing bacteria (Chapter 9).

Baryte in cores from the Magnet Cove baryte mine region, Nova Scotia, show a wide variety of massive stratiform to nodular textures. Isolated light coloured baryte nodules, typically hosted in a matrix of ferroan dolomite, show complete gradations from chickenwire to enterolithic and are interpreted as a direct replacement of precursor nodular anhydrite hosted in intertidal and supratidal platform carbonates (Mossman and Brown, 1986)). The mine itself exploited a lenticular to stratiform mass of baryte, not nodules (Figure 7.69a; Boyle, 1962). Unfortunately the Magnet Cove Baryte Mine ceased operations 20 years ago and the mine pit and shaft workings are now flooded. Boyle described the structure of the deposit as “exceedingly complex.” The region is marked by two major sets of faults oriented east-west and northwest-southeast. At the now abandoned Walton deposit the dominant feature is an east-west fault zone in the footwall of the baryte mass that joins a northwest fault that lies close to the hanging wall of the baryte mass.

Much of the baryte ore in the Magnet Cove deposit is associated with the Pembroke Formation (Figure 7.69a). Regionally the Pembroke Formation is a complex multi-origin breccia intimately associated with halokinesis and base metal mineralisation and regionally it is tied to former salt and thrust welds (Lavoie et al., 1998; Warren, 2000b). Faults in the Magnet Cove Mine are pre-ore and constitute brecciated intervals over several metres wide. Post-ore movement also brecciated the baryte and sulphides. The age of the faulting is probably post-Triassic. The ore-hosting sequence is the outcropping remnant of a halokinetic and allochthonous evaporite zone at the top of the Horton Group and it lies along the regional salt weld of the Ainslie Detachment. The likelihood of halokinetically focused extensional faults carrying Ba-rich basinal fluids into sulphate-rich horizons was not considered in the published literature on the Magnet Cove mine. But all the work on the mine geology, and its mineralogy, was published before notions of salt allochthons, rauhacke and burial anhydrite existed.

Similar halokinetic fault-focused salt welds define the position of the massive baryte deposit in the Neoproterozoic Oraparinna diapir and other baryte occurrences associated with halokinetic structures in the Flinders Ranges of South Australia (pers. obs.). The similarities between Magnet Cove and Oraparinna in both structural style and position atop a halokinetic breccia are obvious (Figure 7.69b). Unlike Magnet Cove, the baryte occurrence in the Oraparinna diapir was recognised as a halokinetic association (Dalgarno and Johnson, 1968). The ore at Oraparinna occurs in 1-2 metre wide extensional fracture fills. Like Magnet Cove, the detailed evolution of the Oraparinna diapir is yet to be fully documented in the light of modern ideas of salt

allochthons and salt-cored thrusts. Suprasalt minibasins can be seen to separate the various diapir outcrops throughout the Flinders Ranges and clearly illustrate the evolution of an active extensional diapiric province into a subsequent compressional regime. As in Magnet Cove, a geological map of the structure shows a distribution of facies that reflect the strong influence of diapiric and subsequent thrust breccia (rauhwacke) on the adjacent facies and faults (Figure 7.69b). Salt flow and passive diapirism controlled both the position of a collapse graben atop the Oraparinna diapir during its “falling diapir” stage and focused the subsequent compression of the same succession. What is yet to be studied in the Oraparinna Baryte Mine is the timing of baryte emplacement relative to salt dissolution and faulting in this succession.

A likely younger analog for baryte emplacement about salt structures is the fracture fills atop the Machar diapir in the North Sea (Figure 10.47). Many individual fractures host multiple generations of carbonate, baryte and fluorite growth (Doran et al., 2004). Fluid-inclusions in the fracture-fills show maximum salinities (22 wt% NaCl eq.), suggesting that fluids had dissolved salt from the diapir during their ascent. Maximum fluid-inclusion temperatures (150°C) from wells spanning the crest and flank of the Machar structure, are much hotter than expected for present depths of 1900 to 2800 metres. Carbon isotope signatures of the fracture-filling calcites range from +2 to +7 $^{13}\text{C}_{\text{PDB}} \text{‰}$ and exceed those of tightly constrained chalk matrix 0 to +3 $^{13}\text{C}_{\text{PDB}} \text{‰}$. Thus at least some of the carbon was derived externally to the chalk. Oxygen isotopes from fracture filling calcites (16 to 25 $^{18}\text{O}_{\text{SMOW}} \text{‰}$) are depleted relative to chalk matrix values (24 to 29 $^{18}\text{O}_{\text{SMOW}} \text{‰}$). The combined data sets indicate that fracture-filling material could not have formed from lo-

Figure 7.69. Massive and vein-fill baryte deposited via halokinetic focusing. A) Geology of the Carboniferous halokinetic section in the vicinity of the Magnet Cove Baryte Mine, Nova Scotia (after Boyle, 1962). B) Oraparinna Baryte Mine located in the compressed zone of an original falling diapir (Neoproterozoic Oraparinna Diapir) Flinders Ranges, South Australia (Redrafted from regional geological map of Dalgarno and Johnson, 1966; see Figure 7.23 for regional setting of the Oraparinna Diapir).

cal chalk matrix pore-fluids. The likely explanation is pulsed expulsion of hot saline and hydrocarbon-bearing fluids from geopressed sandstones in the adjacent rim syncline that are then cemented on cooling into fractures at shallow depths.

Figure 7.70. Highly schematic E-W cross section through the Galeana district showing localisation of baryte veins at the contact with the Huizachal red beds, directly beneath the Olvido gypsum (grey). Baryte formed as ascending Ba-rich waters ponded beneath the gypsiferous residues (caprocks to allochthonous salt) of the Olvido Fm. (modified from Kesler et al., 1988).

A similar set of hypogene chloride-rich waters flowing along faults probably controlled the formation of mined willemite (Zn-oxide ore) in Cambrian ooid grainstones and archeocyathid mounds in the vicinity of the Beltana diapir in the Flinders Ranges, situated some 80 km northwest of the Oraparinna diapir (Groves et al., 2003). There the ore was first emplaced during a series of Cambro-Ordovician compressional events that reactivated salt numerous diapirs and salt flows, which were first emplaced during Neoproterozoic extension and loading.

Yet another halokinetically focused baryte association is documented in the Galeana Baryte District of Mexico. Gypsum residues of the evaporitic Olvido Formation (Upper Jurassic) form an anticlinal trap, seal and sulphate source to barium carried by basinal waters which had flushed the underlying redbeds of the Huizachal Group. Baryte occurs mostly as monomineralic veins and lenses in a limestone matrix along this contact (Figure 7.70; Kesler et al., 1988; Conklin, 1974). Halites and anhydrites of the halokinetic Olvido Formation created the seal and the faulted structures that focused ore precipitates.

The Galeana district now lies at the western margin of the Sierra Madre Oriental in southern Nuevo Leon, Mexico, and it has been one of the leading BaSO_4 producers for the country. Ore-grade baryte fills reactivated steeply dipping ($50\text{--}88^\circ$ NW) fractures striking $\text{N}40\text{--}50^\circ\text{E}$ and, to a lesser extent, steeply dipping ($60\text{--}85^\circ$ SW) fractures striking $\text{N}60\text{--}80^\circ\text{W}$, all formed at the crest of the San Marcos anticline (Figure 7.70). Massive baryte veins also carry up to 10 wt% SrSO_4 . Baryte formed when ascending barium-rich basinal brines ponded beneath, and partially dissolved, the relatively impervious halites of the Olvido Formation to create the anhydrite precursors to the

gypsiferous residues that now define the outcrop of the Olvido Formation in the Galeana district. After baryte precipitated subsalt, the anticlinal crest was erosionally breached and so exposed mineable baryte at the surface.

Regionally, the Olvido Formation defines the salt-cored Sabinas fold belt, which is made up of a number of salt allochthon tiers and salt-cored detachments. This fold belt is now in compression and thrust welds are common, in part in response to the Laramide orogeny. But when Ba-rich fluids were migrating it may well have been in its earlier stage of halokinetic extension (as was likely the case in the Oraparinna diapir). The spectacular salt allochthons of the La Popa basin, detailed in Chapter 6, are part of the same Sabinas fold belt and were also created by the flowing salt of the Olvido Formation.

Baryte is also a widespread authigenic phase in bedded sandstones of the Salt Wash Member in the Late Jurassic Morrison Formation on the Colorado Plateau (Breit et al., 1990). There it forms as intergranular cements, poikilotopic cements, euhedral crystals and replacements of detrital grains. Areas that contain abundant baryte in the sandstone host coincide with the extent of evaporites in the underlying halokinetic Pennsylvanian Hermosa Formation. A genetic link between the baryte and the dissolving evaporite is reinforced by similar ranges in sulphur isotope data in both lithologies ($\delta^{34}\text{S}$ range from $+8\text{‰}$ to $+14\text{‰}$). Sulphate, derived from the dissolving evaporites, is thought to have risen along faults into the Morrison Formation; a process perhaps aided by halokinetic focusing. Evidence of a fault conduit for the Ba-rich waters is further supported by $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in the baryte cements, which tend to decrease with increasing distance from the supplying fault (from 0.7103

to 0.7084; Breit et al., 1990). This trend reflects the mixing of radiogenic strontium from waters ascending the faults ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7100$), with strontium in waters derived by dissolution of early diagenetic carbonate cements in the sands ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7080$). As the $^{87}\text{Sr}/^{86}\text{Sr}$ values along the faults exceed those in the underlying Hermosa anhydrite it is thought that radiogenic strontium was also added to the ascending waters by reactions between the rising brine and the arkosic horizons that intersect the fault conduit (Figure 10.60). These same arkosic sands are also a source of the copper in ores in similar structural settings in the nearby Lisbon Valley. A similar isotopic argument is used to show an evaporitic sulphate association for mesogenetic baryte mineralisation in the orefields of the northern Pennines (Crowley et al., 1997).

Local concretions of baryte precipitates in sandstones can create rosettes known as “sand rosettes” or “desert roses,” where the baryte acts as a poikilitic cement that encases sand grains. Such baryte is thought to have been precipitated by reactions between soluble sulphate (usually from nearby dissolved gypsum or anhydrite) and basinal waters carrying BaCl_2 . Baryte spar is a commonplace burial cement in reservoir sandstones where two basinal brines mix. The hydrodynamics of such deep mixing is often driven by tectonics, for example, the inversion tectonics

of the North Sea (later in this chapter). Oxidised pyrite can also act as a source of sulphate in subsurface waters, especially in the vicinity of dewatering organic-rich shales.

A more enigmatic but significant baryte-evaporite associations is found in early Archaean metasediments (Figure 2.31). Some of these beds constitute the oldest sediments in the world, namely the ≈ 3.46 Ga Warrawoona Formation at North Pole, Western Australia, with equivalents in South Africa. Both areas are characterised by baryte beds with obvious growth-aligned textures (Figure 7.71). Interpretations are that the baryte either pseudomorphs bottom nucleated subaqueous gypsum or that it represents a primary seafloor precipitate. The proponents of both interpretation are still involved in heated discussion (e.g. Shen and Buick, 2004 versus Runnegar et al., 2001).

Baryte can also be associated with meta-evaporite sequences. Stratabound baryte-hyalophane sulphidic orebodies, which were recently discovered at Rozna (in the Moldanubian zone of the Bohemian Massif, Czech Republic), are hosted within the high-grade metamorphosed complex (Kribek et al., 1996). The host entrains a meta-evaporitic succession and is composed of migmatitic biotite or sillimanite-biotite gneiss and amphibolite, with rare intercalations of marble, calcsilicate gneiss and lenses of coarsely crystalline anhydrite. Similar sequences were discussed in Warren (1999) in Chapter 6, which dealt with meta-evaporites.

Figure 7.71. Lower third of specimen is composed of growth aligned baryte (is it a possible replacement of bottom-nucleated gypsum or, is it a primary baryte precipitate, associated in some areas with silicified marine-derived nahcolite evaporites?). The sulphate layer is overlain by current-rippled and silicified volcanoclastic sands. Sample collected from the early Archaean 3.45 Ga Warrawoona Fm. near North Pole, Western Australia.

Authigenic anhydrite as a burial salt

As we have seen, some forms of silica, calcite, dolomite, celestite, fluorite and baryte are hydrothermal precipitates that mimic the outline of their evaporite precursor. They form syndepositionally, mesogenetically and telogenetic ally, wherever waters of appropriate chemistry can cool, heat, mix or change redox state. We shall now see that evaporite salts, especially anhydrite spar, can also precipitate mesogenetically. Precipitation occurs in relatively stable subsurface waters, so crystals tend to be coarse and poikilotopic, often co-associates to late-diagenetic calcite, saddle

Occurrence and age of host	Burial anhydrite fabric and subsurface temperature at time of precipitation	Reference
Yacoraitite Fm. (Upper Cretaceous), Argentina.	Sparry anhydrite cement, containing hydrocarbon inclusions and brine, fills intergranular, mouldic and vuggy porosity in a carbonate host. Indicates anhydrite precipitated at 121-137°C from 17% equiv. wt. NaCl brine (NaCl-MgCl ₂ -Na ₂ SO ₄ -NaHCO ₃ -NaCO ₃ basinal brine).	Cesaretti, 2000
Maha Sarakham Fm. (Upper Cretaceous), NE Thailand.	Coarsely crystalline saddle dolomite rhombs float within a matrix of coarse, recrystallized anhydrite spar in the Basal Anhydrite. Isotopes indicate dolomite precipitated at temperatures ≈ 72-123°C.	El Tabakh et al., 2003
Smackover Fm. sandstones, (Upper Jurassic), Gulf of Mexico.	Anhydrite both as poikilotopic spar masses in which detrital grains are replaced and as smaller patches that have replaced single detrital grains. Precipitation temperatures >100°C. Anhydrite is a relatively late cement and postdates all other volumetrically significant authigenic phases in the sandstones, including K-feldspar, dolomite, quartz, and most calcite cements.	Dworkin and Land, 1994
Smackover Fm. dolomites, (Upper Jurassic), Gulf of Mexico.	Anhydrite spar partially replaced allochems and prebitumen calcite cements in mesogenetic pores. Solid bitumen precipitated where hydrocarbons were present. Emplaced in temperature range 100-150°C.	Heydari, 1997, 2000
Khuff Fm. (Upper Permian-Lower Triassic), Abu Dhabi, UAE.	Burial stage poikilotopic crystals fill pore spaces between the detrital carbonate components. Crystals are typically 500 μm in length but locally may reach up to 3 mm.	Worden et al., 1995, 2000
Prider Fm. (Lower Permian) Kansas, USA.	Burial stage poikilotopic anhydrite cement replaces echinoderm fragments, parts of oncoides, some dolomite spar, and some stylolite seams. Precipitation occurred in the range 65-90°C, with a few samples possibly up to 150°C.	Luczaj and Goldstein, 2000
Rotliegende Fm. (Lower Permian), onshore and offshore NW Europe.	Poikilotopic sparry anhydrite enclosing sand grains. Distribution shows a strong fault/fracture control. Precipitation temperatures in the range 120-140°C.	Gauthier et al., 2000; Sullivan et al., 1994
Swan Hills Fm. (Middle to Upper Devonian), Canada.	Coarse bladed crystals of sparry anhydrite enclosing dolomite clasts and possibly related to faults. Fluid inclusions in the anhydrite show crystals formed from basinal fluids at temperatures in excess of 90°C.	Duggan et al., 2001
(Silurian) Gascoyne Basin, Australia.	Sparry anhydrite includes blocky poikilotopic cement filling interparticle and mouldic pore spaces in oolitic horizons, and as a bladed cement in larger, often vuggy pore spaces. Formed at elevated subsurface temperatures.	El Tabakh, et al., 2004
St Peter Sandstone (Ordovician) Michigan Basin, USA.	Late stage sparry anhydrite cements that precipitated in crosscutting fractures and postdates with late stage dolomite that had precipitated at higher temperatures.	Winter et al., 2000

Table 7.14. Selected examples of sparry burial anhydrite.

dolomite, hydrocarbons and metal sulphides. Conditions are typically anoxic and thermochemical sulphate reduction is likely (Table 7.14). Calcium and sulphate are carried by chlorine-rich saline basinal brines, generated by the dissolution of evaporites, and capable of precipitating their dissolved load at chemical interfaces. This may be in strata adjacent to the dissolving evaporite bed or some distance away and along fluid escape conduits such as faults and fractures (Table 7.14).

Morphologically near-identical coarse poikilotopic anhydrite cements can also form during early syndepositional brine reflux within brine-saturated pores beneath an accumulating evaporite (Purvis, 1989; Luczaj and Goldstein, 2000). These syndepositional reflux salts are true evaporites in that they formed in a hydrology driven by solar evaporation. In contrast, burial salts that form in brines generated by the subsurface

dissolution of salt beds are not true evaporites as they are not directly precipitated by processes driven by solar evaporation, nor do they replace the volume occupied by primary and secondary evaporite salts (Table 1.1). They are, in reality, evaporite transformation salts or burial salts. Distinguishing early reflux evaporite cements from later burial salts can require detailed petrographic and isotopic study, especially in the absence of saddle dolomite or metal sulphides.

Not all burial or sparry anhydrite is associated with evaporites. Anhydrite is a retrograde salt, so intergranular and replacive anhydrite cement precipitates when unmodified connate seawater is heated above 150°C (Blount and Johnson, 1969). This is a widespread process in hydrothermal circulation cells in midoceanic ridges and is probably also active in the deeper portions of many sedimentary basins (Figure 2.11a; War-

ren, 1999). Aqueous sulphides can be oxidised to sulphates, which then precipitate as an authigenic CaSO_4 phase, which often happens in surface regions of pyrite oxidation such as in mine wastes, especially when microbially facilitated. But this oxidative sulphate source is relatively uncommon in the deep subsurface where pore waters are typically anoxic and reducing.

Anhydrite is a late stage burial salt in quartzose Rotliegende reservoir sands in Leman Field, North Sea and throughout regions of deeply buried Rotliegende Formation (Figure 7.72a; Sullivan et al., 1994; Gauthier et al., 2000). Poikilotopic anhydrite spar in Leman field is best developed along coarser-grained sand laminae, suggesting their inherent higher permeabilities influenced sites of precipitation. The same sparry anhydrite cement also encloses late authigenic ankerite, ferroan dolomite and pressure-solved cemented grains, showing its deep burial origin. Anhydrite tends to be best developed in and near fractures forming cements zones up to 0.5cm wide and 0.5m

long in Leman core. Crystals in fractures are bladed, coarsely crystalline and tend to grow subparallel to the fracture walls. Cemented coarse-grained laminae and anhydrite-filled fractures frequently intersect suggesting both styles represent the same generation of anhydrite cement.

Timing is best resolved using Sr and O isotopic analysis of the anhydrite cements. Oxygen isotope compositions indicate precipitation temperatures between 120°C and 140°C in waters with a $\delta^{18}\text{O}$ composition similar to the present day formation waters ($\approx 0\text{‰}$ SMOW; standard mean ocean water). These are the maximum inferred burial temperatures for the Rotliegende sandstone in Leman Field. Such temperatures occurred during the Late Jurassic-Early Cretaceous, at the start of basin inversion with maximum burial depths of 3.5-4 km (Figure 7.72b). When corrected for their 150 Ma precipitation age, the Sr isotope ratios in the various anhydrite burial cements, and their Sr contents, are highly variable. ($^{87}\text{Sr}/^{86}\text{Sr}$) ratios range from 0.70797 to 0.71129 and Sr contents from 351 to 2952 ppm

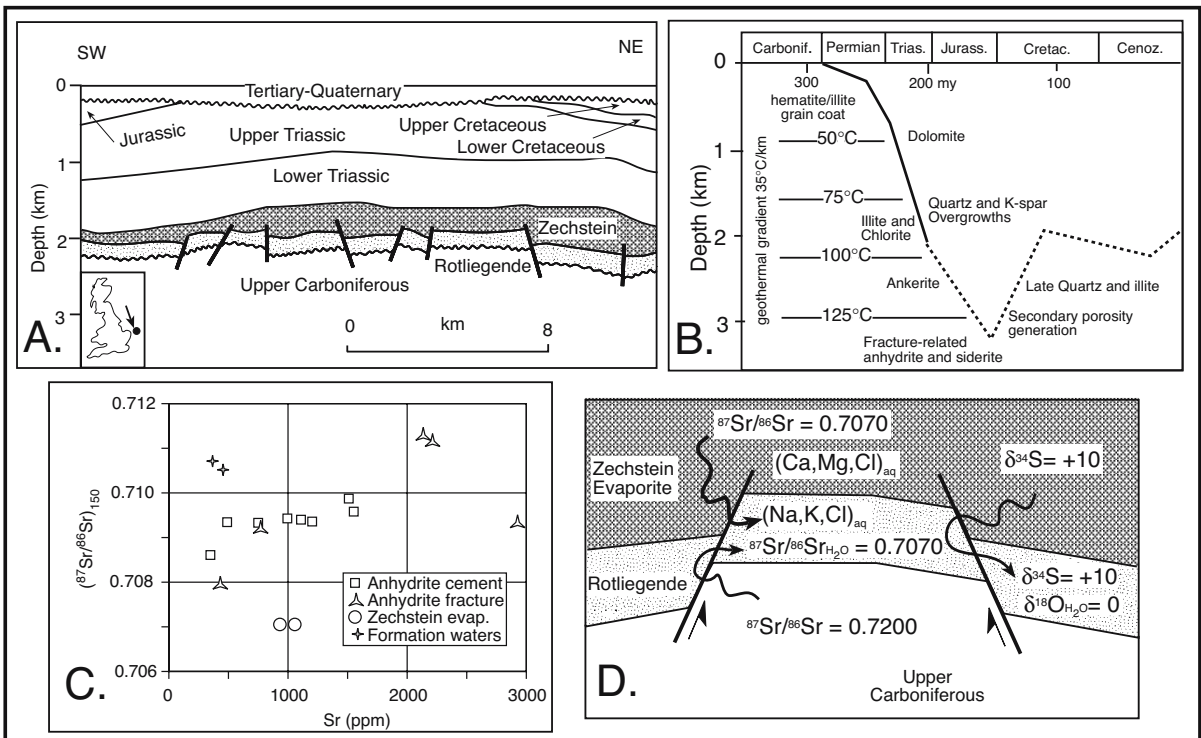

Figure 7.72. Late stage anhydrite in Leman Field, North Sea. A) Location of the Leman gas field and regional geological cross section. B) Subsidence history of Rotliegende reservoir sandstone showing time and temperature of anhydrite precipitation postdates other diagenetic events and precedes secondary porosity formation. C) Strontium isotopic ratios and composition of various anhydrite burial salts compared with formation waters and Zechstein salts. There is a general trend of increasing isotopic ratio with increasing Sr content. D) Schematic section showing major sources of sulphur, strontium and carbon along with their migration from above and below the Rotliegende and subsequent mixing that precipitated anhydrite cements and fracture fill (modified form Sullivan et al., 1994).

Figure 7.73. Plot of sulphur versus strontium isotopic ratios for coarse anhydrite cements from the German Rotliegende. It clearly shows the affinity of anhydrite cements in horst blocks for Zechstein sources rather than an early Rotliegende signature (after Gaupp et al., 1993).

(Figure 7.72c). Fracture-filling anhydrite spar also traverses this entire strontium range, implying an origin from the same fluid. There is also a general trend of increasing Sr ratio with increasing Sr content of the anhydrite burial salts.

According to Sullivan et al. (1994) the late stage anhydrite indicates an unusual, short-lived, catastrophic event that juxtaposed the Zechstein evaporites and sandstones. The resulting geometry facilitated cross-formational fluid flow via fractures that were tectonically induced by inversion. At that time pore fluids were squeezed from the overlying Zechstein evaporites and underlying Carboniferous mudstones into the lower pressures of the Rotliegende regional aquifer (Figure 7.72d). Mixing of the two waters precipitated dolomite and anhydrite cement, which in turn produced a Na-K-Cl formation water. This pore water was lower in Ca+Mg than the overlying Zechstein, which in turn supplied most of the sulphate and some of the Sr to the anhydrite cements. Like the isotopic evidence, the chemical evidence shows the burial anhydrite precipitated from extremely saline formation waters derived by deep subsurface mixing of Zechstein evaporite brines and deeply circulating meteoric waters. Even today, the Zechstein brines in the Leman Field are extremely saline (165,530–238,531 mg/l), with cation/chloride

ratios indicating ongoing mixing of Zechstein marine evaporite brines with fossil meteoric water.

Onshore in northern Germany the Rotliegende gas reservoirs also contain coarse authigenic poikilotopic anhydrite cements, particularly in the vicinity of faults. Cross-formational flow of Zechstein fluids and fault-related fluid flow was responsible for this anhydrite, especially during times of mixing tied to fault activity (Gaupp et al., 1993; Gauthier et al., 2000). This is clearly seen in the isotopically distinct values of burial anhydrite within horst blocks compared to samples with similar authigenic and nodular anhydrite styles, but from wells outside of the horsts (Figure 7.73). Anhydrite cements in sands atop horst blocks show affinities to Zechstein sulphates. In contrast, anhydrites in the other wells, where uplift has not juxtaposed Rotliegende sands to Zechstein fluids, retain an isotopic signature typical of early Rotliegende time. Once again, this observation underlines the importance of active faulting in facilitating brine mixing, which then precipitates authigenic minerals in the deep burial setting.

Late stage anhydrite and halite cements also characterise deeper burial cements in the aeolian and fluvial feldspathic sandstones of the Upper Jurassic Norphlet Formation and other Smackover sandstones of the Gulf Coast (McBride et al., 1987; Dworkin and Land, 1994). Coarsely crystalline anhydrite, along with quartz and ferroan dolomite, precipitated as intergranular cements. Anhydrite averages 3% by volume (maximum 21%) in Norphlet wells in Mississippi and 1.3% in Alabama. It occurs as scattered sparry crystals, in spherical and poikilotopic patches up to several centimetres across and can completely cement some sand laminae. All the anhydrite cements are patchily distributed in the Norphlet reservoirs and, as in the Rotliegende, tend to be better developed in the coarser sand laminae.

Oxygen isotopic values from the anhydrite averages 15.6 ‰ (SMOW). According to Dworkin and Land (1994) this burial anhydrite precipitated in near oxygen (and strontium) isotopic equilibrium with ambient burial fluids at temperatures of between 90°C and 100°C at depths ≈2.3 km (Figure 7.74a). Authigenic halite cements, along with late stage carbonates, followed at temperatures up to 120°C (<3km burial). Subsequent dissolution of the cements, along with some labile detrital grains, created secondary porosity that makes up at least half of the economic porosity in the Norphlet tight gas sand reservoirs in this region. Potassium-rich brines, generated by dissolution of nearby bitterns, tended to stabilise K feldspar in the Norphlet so that authigenic K-spar can even coat quartz grains, as well as its more commonplace occurrence as overgrowths on detrital K-spar grain substrata.

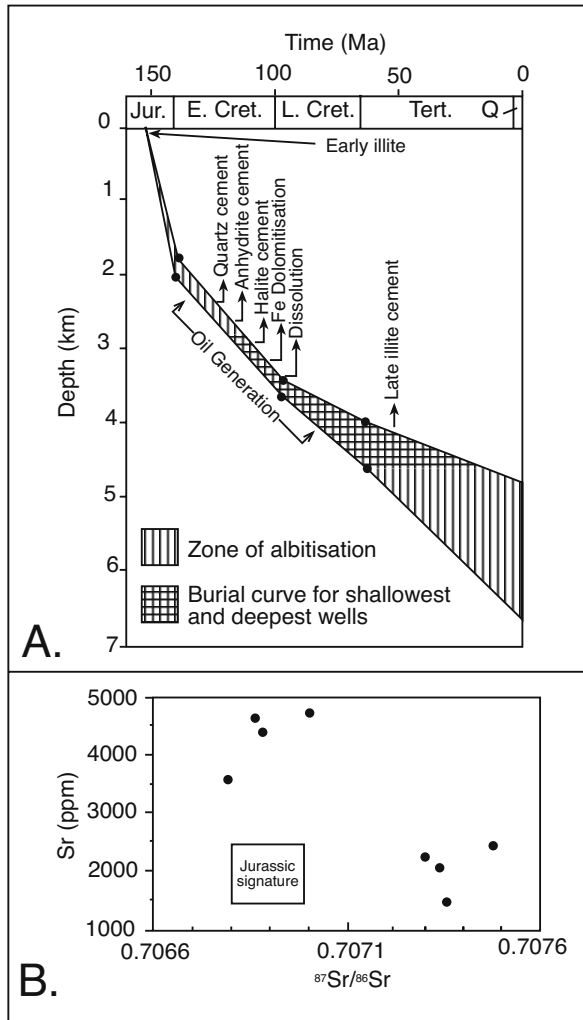

Figure 7.74 Norphlet Formation. (after Dworkin and Land, 1994) A) Burial evolution and diagenetic history. B) Sr isotope signatures.

Dworkin and Land (1994) argue that the expected isotopic composition and trace-element concentration of a marine brine-reflux-derived anhydrite cement in Smackover Formation quartzose sands should be: $\delta^{34}\text{S}_{\text{CDT}} = +16\text{‰}$, $\delta^{18}\text{O}_{\text{SMOW}} = +14\text{‰}$, $^{87}\text{Sr}/^{86}\text{Sr} = 0.7069$, $\text{Sr} = 1500\text{--}2500$ ppm, $\text{Ba} < 20$ ppm, and $\text{Mg} > 200$ ppm (the box in Figure 7.74b). When geochemical analyses of Smackover anhydrite cements are compared with the predicted composition, it is apparent that most of the coarsely crystalline anhydrite is not a marine reflux cement. Rather, two groupings or generations of anhydrite cement can be distinguished using a strontium isotope to strontium content crossplot (Figure 7.74b). An early cement, that may have been derived from slightly modified Late Jurassic sea water (possibly via reflux), is characterised by its Jurassic isotopic

signature and high strontium content ($>3,200$ ppm). A second group of cements, that represent the bulk of coarsely crystalline cements in the Smackover sandstones, has a depleted strontium content ($<3,000$ ppm) and an elevated isotopic ratio. It may have precipitated later in the burial history or may represent burial recrystallisation of the first cement. It probably formed at slightly higher temperatures, which would have maintained relatively low strontium concentrations, and in the presence of pore fluids that had radiogenic Sr isotopic compositions. Such radiogenic pore fluids were probably derived from waters that were involved in the burial dissolution of feldspars.

As well as in Smackover sandstones, dissolution-derived sulphate-rich basal brines also precipitate anhydrite burial salts in Smackover carbonates of the Gulf of Mexico (Figure 7.75; Heydari and Moore, 1989; Heydari, 1997). Precipitates are made up of orthorhombic laths and blades that form spars replacing both allochem grains and calcite cements. The anhydrite spar and the calcite spar formed prior to reaching the oil window and are post stylolitisation. The arrival of liquid hydrocarbons and the precipitation of solid bitumens temporarily retarded further precipitation of calcite, anhydrite and dolomite burial cements. Later, the anhydrite was dissolved and replaced by a more finely crystalline calcite spar and elemental sulphur via thermochemical sulphate reduction processes. This occurred

Figure 7.75. General paragenetic sequence for the Smackover Formation in the northern Gulf of Mexico showing approximate temperature range of various events (after Heydari and Moore, 1989; Heydari, 1997).

at the higher temperatures that typify the gas window (Figure 9.42c).

Dissolution-derived late burial anhydrite is also widespread in the Lower Cretaceous carbonates of the Pearsall and Lower Glen Rose Formations, South Texas (Woronick and Land, 1985). As in the Smackover, the anhydrite spar formed late, after the development of saddle dolomite cements. It crystallised mostly as bladed to fibrous anhydrite laths some 0.1 - 6.0 mm in length. Much of this anhydrite fills preexisting intergranular pore space in the carbonates, but it can also replace fossils, matrix material and earlier calcite cements. Once formed, it was subject to corrosion and replacement by calcite. $\delta^{18}\text{O}_{\text{SMOW}}$ values for the anhydrite range from 19.5-22.9‰, values that are much more enriched than the Cretaceous seawater sulphate (+15‰). Woronick and Land (1985) interpret these enriched values as proof that none of the subsurface anhydrite in the Pearsall and the Glen Rose (including some associated nodular anhydrite) was precipitated directly from Cretaceous seawater. They argue that even the nodular anhydrite (previously used as a sabkha indicator) was not primary but had recrystallised in the subsurface. This is supported by $\delta^{34}\text{S}_{\text{CDT}}$ values of the anhydrite and the modern Edwards Formation brines, which lie between 20 and 26‰. Directly precipitated Cretaceous marine evaporites should have $\delta^{34}\text{S}_{\text{CDT}}$ values of less than +16‰ (Figure 2.23).

They envision a basinward flowing deep meteoric aquifer, driven by hydrostatic flow, that was essentially saturated with respect to calcite, dolomite and CaSO_4 . Periodically the meteoric waters mixed with upwelling hotter basinal fluids that were derived from more deeply buried and dissolving Jurassic salts. These basinal fluids contained abundant carbon dioxide, calcium, strontium (radiogenic) and barium, together with small amounts of lead, zinc and hydrocarbons. Mixing of the two waters caused the precipitation of burial anhydrite, as well as other burial cements, including saddle dolomite and metal sulphides.

Other carbonate platform sequences that entrain burial anhydrite cements derived from evaporite dissolution and upflow of sulphate-enriched basinal waters include the Devonian Keg River and Swan Hill formations of Alberta (Aulstead and Spencer, 1985; Duggan et al., 2001) and carbonate reservoirs in the Middle Ordovician Trenton Group, SW Ontario (Middleton et al., 1993).

All these example of sparry burial anhydrite demonstrate the obvious association between advanced dolomitisation of

platform carbonates and the precipitation of later diagenetic poikiloprotic and replacive anhydrite spar. This process, also called anhydritization by Kendall and Walters (1978), is widely observed and significantly reduced porosity in potential reservoir dolomites in the Devonian of Canada, the Permian Khuff of the Saudi Arabia and the Emirates, the Zechstein of NW Europe, the Jurassic of the Gulf of Mexico and the Arab cycles of the Middle East (see Chapter 10). As yet, it has attracted the interest of relatively few researchers and documentation is sparse. As a process it should characterise burial diagenesis in most deeply buried sulphate evaporite systems.

Enigmatic outlines in pseudomorphs

This chapter discusses how evaporites can be replaced by various minerals at any time in their burial and uplift history. So far, I have focused on the more commonplace evaporites — namely, gypsum, anhydrite and halite morphologies — that are pseudomorphed by silica, calcite, dolomite, baryte and celestite. These three evaporite salts constitute more than 90-95% of modern and ancient precipitates, but there are also carbonate or silica pseudomorphs preserving the outlines of other evaporite salts, such as trona, gaylussite, pirssonite, glauberite, thenardite and other less common precipitates. Figure 7.76 illustrates some of the idealised and a few of the more typical shapes of these somewhat less common salts. If their euhedral forms are well preserved by their carbonate or siliceous replacements, they can be recognised still.

But all evaporites are soluble, so the preservation of a crystal form is often accompanied by enlargement or partial collapse of the void during the replacement process. This complicates the process of recognition and is, for example, the main reason why Archean baryte at North Pole is still variably interpreted.

Sodium carbonate salts are more likely to alter to calcite with burial as they already contain elevated levels of bicarbonate ions when they are deposited (Table 7.15; Southgate et al., 1989; Finkelstein et al., 1999). When preserved as isolated replacement crystals in a mudstone matrix, their calcitic pseudomorphs have easily confused or misinterpreted with gypsum, baryte of other lenticular forms.

Misidentifying a pseudomorphs can lead to significant differences in the interpretation of depositional setting. In the case of the Upper Oligocene Creede Formation, southwestern Colorado, the interpretation of lenticular calcite in lacustrine laminites, as either ikaite or gypsum, is one of the pivotal pieces of evidence in defining the lacustrine depositional setting as

Mineral	Formula	Crystal Habit	Brine Type
Gaylussite [#]	Na ₂ Ca(CO ₃) ₂ ·5H ₂ O	Often elongated; also flattened wedged-shaped.	Na—CO ₃ —Cl
Glauberite ^{#,**}	Na ₂ Ca(SO ₄) ₂	Tabular, prismatic, dipyramidal, and may be rounded or step-like.	(Mg) Na—SO ₄ —Cl
Gypsum ^{**}	CaSO ₄ ·2H ₂ O	Thin to thick tabular; elongate; step-wise depressions or rough; acicular; prismatic with nearly equant cross section. Lenticular crystals with rounded or irregular terminations. Warped or curved irregular surfaces, long prismatic crystals occur bent into irregular or hoop-shaped forms.	(Mg) Na—SO ₄ —Cl
Ikaite	CaCO ₃ ·6H ₂ O	Distinct asymmetry with a tendency toward a sigmoidal shape when viewed from the side and square-prismatic in overall shape that taper to the ends; strongly ribbed normal to the length.	Na—CO ₃ —SO ₄ —Cl
Mirabilite ^{**}	Na ₂ SO ₄ ·6H ₂ O	Short prismatic to acicular crystals.	Na—CO ₃ —SO ₄ —Cl and (Mg) Na—SO ₄ —Cl
Pirssonite [#]	Na ₂ Ca(CO ₃) ₂ ·2H ₂ O	Short prismatic; also tabular or pyramidal.	(Mg) Na—CO ₃ —Cl
Thenardite ^{**}	Na ₂ SO ₄	Dipyramid; tabular; rarely prismatic.	Na—CO ₃ —SO ₄ —Cl and (Mg) Na—SO ₄ —Cl

Table 7.15. Evaporite minerals susceptible to replacement by calcite and likely to show lozenge or discoidal outlines. (#) indicates likely diagenetic mineral; (***) indicates a depositional association (after Finkelstein et al., 1999).

deep, cold, fresh, and profundal versus shallower, periodically meromictic and hypersaline (Larsen and Crossey, 1996 vs Finkelstein et al., 1999).

Because ikaite is only stable at near freezing temperatures, it is typically converted to thinolitic calcite (syn. jarrowites, devil's horn calcites, glendonites). Internally, ikaite pseudomorphs may preserve a characteristic granular structure made up of sand-sized, rounded to rhombic, calcite grains set in a matrix of sparry and spherulitic cements (Shearman et al., 1989; Shearman and Smith, 1985). But the shape of a thinolitic calcite is easily confused with the outlines of other evaporite salts that have no implication of degassing in CO₂-saturated coldwater spring seeps (e.g. Figure 4.23).

Likewise, the recognition of ikaite in Neoproterozoic glacial sediments interlayered with pisolites and ooids can be used to imply that the high supersaturation of Precambrian seawater meant that coated grains were possible cold water precipitates. They were not exclusively tropical precipitates, unlike pisolites and ooids in today's oceans and inferred for similar coated grain textures throughout the Phanerozoic (James et al., 2005). Alternatively the interlayering of glendonites and coated grains can be used to support a "freeze or fry" climate model tied to "Snowball Earth."

For years, before ikaite was shown to be a cold water deposit, not an evaporite, many crystals described as ikaite were considered named in a way that could be used interchangeably with the mineral gaylussite, or ikaite was described as pseudo-gaylussite. In terms of depositional setting, ikaite and gaylussite are not

coprecipitates, but from older literature associations one could easily think they were.

Separating ikaite/gypsum/gaylussite is not the only difficult choice when attempting to identify the precursor to a fuzzy edged angular outline now filled by a later mineral phase. Other problem pseudomorph associations include baryte/siderite/gypsum; acicular aragonite/gypsum; pyrite/halite and even anhydrite/gypsum. The difficulty in deciding on the likely precursor of a possible pseudomorph, when the replacement process can destroy to varying degrees the original outline, emphasises the need to look at all sources of evidence when interpreting any ancient succession now leached of the original salts or the daughter products.

Summary

Evaporites are soluble in most subsurface situations. Even preserved evaporite beds show varying degrees of dissolution about their edges. The longer an evaporite bed remains in the subsurface the more likely it is to dissolve. Preservation or loss it is not a question of whether an evaporite will dissolve in the subsurface, but when. This is why there are few preserved beds of evaporite salts older than Neoproterozoic. As thick evaporite units dissolve they leave behind characteristic breccias and other textures and replacements that allow the recognition of former extensive salt beds. The breccias can be interstratal beds or trans-stratal chimneys, distinguishing the two forms differentiates between blanket or more focused inflows. Dissolution can be driven by basal fluids escaping from below or by fluids

infiltrating from above. Salt units may not dissolve until they have flowed into diapirs and welds (halokinetic breccias) or have acted as décollement surfaces in fold and thrust belts (rauhwacke). All evaporite salt units will ultimately dissolve, many disappear in the diagenetic realm while others may be preserved until they attain metamorphic grades or interact with a magmatic body.

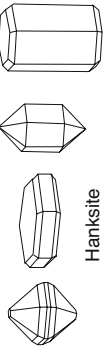

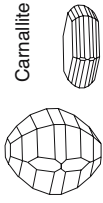

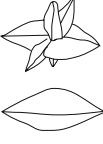

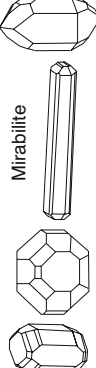

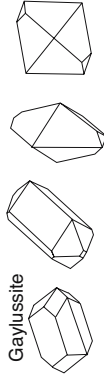

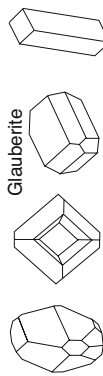

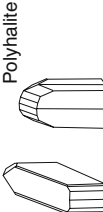

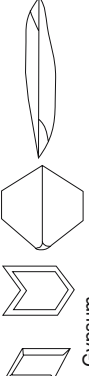

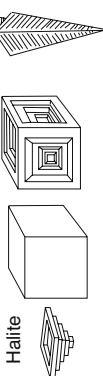

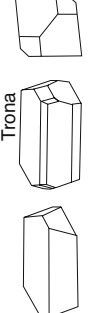

<p>Orthorhombic; Massive, granular, stumpy prisms, flat plates; Perfect (001) and good (010) cleavage; H=3.0-3.6; SG = 2.9-3.0; Tasteless.</p>  <p>Anhydrite</p>	<p>Hexagonal; Tabular or prismatic; good (0001) cleavage, uneven fracture; Weakly effervescent in dilute acid; H = 3.0 - 3.5; SG = 2.56; Deliquescent; Salty taste.</p>  <p>Hanksite</p>
<p>Orthorhombic; Massive, coarsely crystalline, bipyramids; Rare as euhedral crystals that tend to be barrel shaped; No cleavage, conchoidal fracture; H= 1.0-2.5; SG = 1.6; Very bitter taste, very hygroscopic or deliquescent.</p>  <p>Carnallite</p>	<p>Stable at temperatures $\approx 0^{\circ}\text{C}$ then converts to calcite (glendonite). Chapter 8: Burial hydrology and chemistry

Burial hydrology

In Chapter 2 we discussed the hydrology of evaporite deposition and early diagenesis, in this chapter we consider subsequent hydrological stages in a sedimentary system, that is burial, followed by uplift. Thick, buried and dissolving evaporites influence subsurface hydrology and formation water chemistries in a sedimentary basin, as do thermal and pressure regimes.

Flushing by basinal pore waters drives alteration, recrystallisation and dissolution of evaporites within four hydro-tectonic realms, namely (Figure 8.1; Table 8.1):

- 1) Passive-margin burial,
- 2) Pull-apart burial,
- 3) Collision margin burial, and
- 4) Post-orogenic burial.

The first three are often sequential, while the fourth can be part of, or adjacent to, the other three. Salt beds and allochthons act as foci for escaping basinal fluids within all these realms. Subsurface breaching of a stratiform salt aquitard, either by dissolution or halokinesis, typically focuses the outflow of basinal fluids. Fluids may rise or sink through a breach, depending on the local temperature and pressure regimes. Fluids flowing through the breach will mix with other basinal or meteoric fluids with differing chemistries and physical properties so that authigenic phases, including burial salts and metal sulphides, are common precipitates at or near the breach.

The passive margin burial realm is characterized by updip extensional tectonics, differential loading, growth faulting, relatively slow and steady subsidence and, in most salt-floored passive margins, by salt flow (Figure 8.1a). Compressional tectonics are commonplace in downdip positions. The Mesozoic and Tertiary evolution of the Gulf of Mexico and Atlantic-margin basins are typical examples of this salt-lubricated hydrologic

style. The shallower parts of this realm, down to $\approx 1-2$ km depth, are typified by active phreatic circulation. Below is the zone of compactional flow, which entrains both horizontal (average rates of 6 cm/year) and vertical flow regimes (average rates of

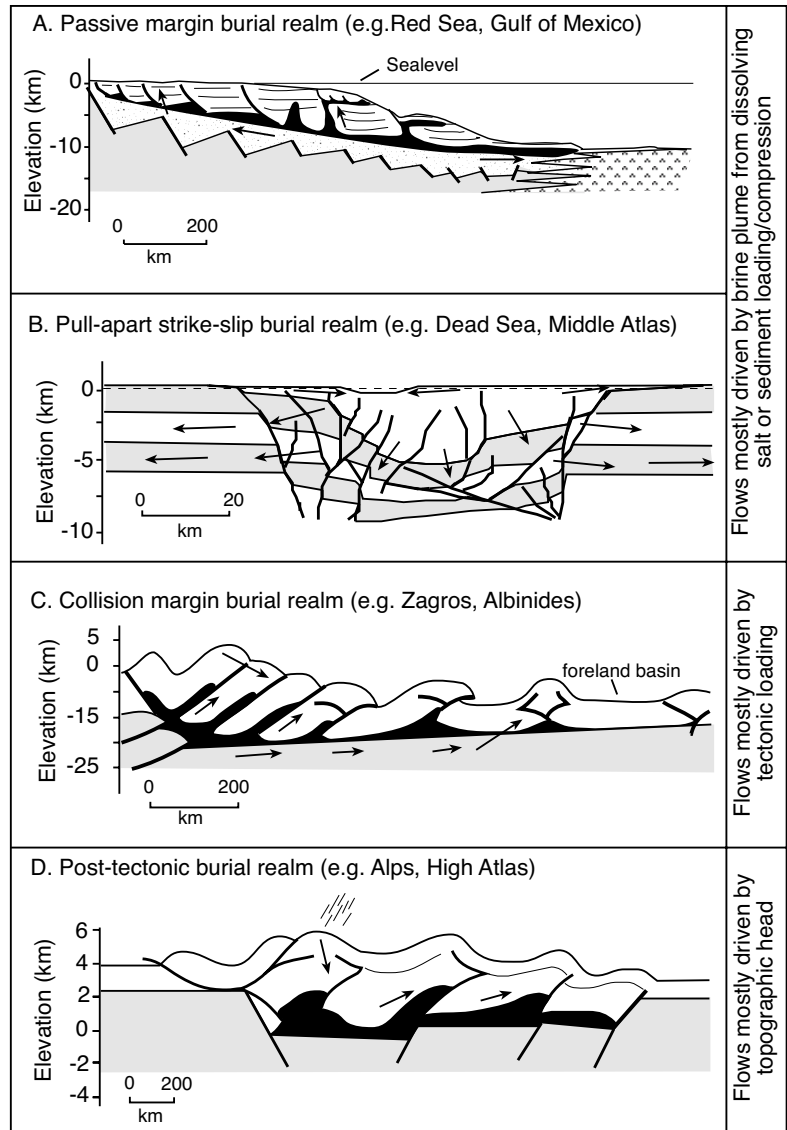

Figure 8.1. Hydrotectonic flow patterns. A) Passive margin circulation with water flow driven by sediment compaction and catabaric/thermohaline flow. Gravity drives nearsurface flow. B) Pull-apart circulation where dissolution-derived brine plumes from rapidly-buried thick evaporites drive deep lateral circulation into basement aquifers. C) Collision margin circulation where thrust sheet emplacement and loading drives burial water from sediments caught up in the orogenic belt into the craton interior. D) Post-tectonic circulation where deep burial flow in the basin sediments is driven by gravity head supplied by the adjacent weathering mountain belt. Note the varying vertical and horizontal scales.

	Location and age of brine source	Role of salt	Reference
Passive Margin burial	Gulf of Mexico, Jurassic	Fluid flow in Mio-Pliocene sediment near salt diapir crest is driven by brines derived from dissolution of salt mass. Suballochthon brine flow is focused by sheet geometry and evolutionary stage.	Cassidy and Ranganathan, 1992; Dworkin and Land, 1996
	Gulf of Lions, France, Miocene	Stratiform Late Miocene evaporite layer forms a widespread blanket that focuses fluid circulation and heat flow in units below salt.	Burrus and Audebert, 1990
	Canning Basin margin carbonates, Australia, Devonian	Chloride-rich metal carrying brines, created by dissolution of Silurian salt dissolving in basin centre, escaped along extensional faults into basin margin to form saddle dolomites and MVT deposits.	Warren and Kempton, 1997; Middleton and Wallace, 2003.
Pull-apart	Dead Sea, Middle East Miocene	Dissolution of Dead Sea halite acts as brine source in many deep water wells as far as 100 km away from the rift. Brine supplied for last 3-6 Ma with its layering and flow direction structurally controlled.	Gvirtzman and Stanislavsky, 2000 Stanislavsky and Gvirtzman, 1999
Collision margin burial	Timor Gap, Northwest Australia, Silurian	Mio-Pliocene inversion event reactivated fault-focused brine flow to surface breaches supplied from Mesozoic reservoirs with the brine originally derived from Silurian salt.	O'Brien et al., 1999; Lisk et al., 2000
	Pyrenees, Southern France and Northern Spain, Triassic	Evaporitic basinal fluids became syntectonic fluids in igneous basement. Brine direction was an evolving system with flow intensity and style of injection controlled by the structural stage of overthrust.	Bitzer et al., 1998; Travé et al., 2000; McCaig et al., 2000
	Slave Point Formation, Canada Devonian	Post Cambrian to pre-Cretaceous compression, associated with orogeny, squeezes basinal brine through carbonates of southern Rockies and drives formation of saddle dolomites of Presqu'île and MVT deposits.	Nesbitt and Muehlenbachs, 1994; Morrow et al., 2002
Post Orogenic burial	Ebro Basin, Spain, Triassic	Dissolution of buried evaporites caught up in the hydrology of compressional belt supplied much of the ionic content to active evaporite systems in the Miocene outflow zones in adjacent foreland depressions.	Sánchez et al., 1999; Salvany et al., 1994
	San Andres Formation, west Texas, Permian	Modern, deeply circulating Na-Cl brines in arkosic sandstone aquifers acquired their high salinity through the dissolution of halite and so displaced Permian age reflux brines.	Bein and Dutton, 1993; Stueber et al., 1998
	Alberta Basin Canada, Devonian	Two brine system; a 'heavy brine' that is a residual Middle Devonian evaporitic brine and a 'light brine' that probably originated from dilution of 'heavy brine' by deeply-circulating meteoric fluids in post-Laramide time.	Michael et al., 2003

Table 8.1. Selected example⁴ basinal fluid circulation.

0.15 cm/year). Deeper still, or in zones of thermal anomalies around growing salt structures and shale diapirs, is the zone of thermohaline flow.

Away from local thermal anomalies, temperatures increase steadily with depth according to regional geothermal gradients, which range from 15–30°C/km in most passive margins. Nonevaporitic sediments shallower than 2–3 km depth are typically hydrostatically pressured, while deeper strata, especially thick impervious shales in rapidly accumulating depocentres such as suprasalt minibasins, tend to be geopressed. A transition to overpressuring can occur at much shallower depths (\approx 1 km or less) where evaporites, not shales, are the predominant basin aquitard (e.g. Jowett et al., 1993). This reflects very rapid rates of basinwide evaporite sedimentation and a complete loss of intrasalt porosity at shallow depths within these basinwide units.

Pull-apart or transform burial is characterised by extensional tectonics and rapid subsidence, along with high sedimentation rates in the basin depocentre (Figure 8.1b). Pull-apart basins are an integral part of intraplate and interplate strike-slip fault zones in both rift and collision settings and tend to form at bends or sidesteps in the main strike-slip fault system (Figure 5.27). When located in arid zones, the fill in a rapidly subsiding basin can entrain thick salt beds, which subsequently become halokinetic. Such salt masses typify modern pull-aparts, such as the Dead Sea basin in the Middle East and Salar de Antofalla in NW Argentina (Stanislavsky and Gvirtzman, 1999; Kraemer et al., 1999). Rapid burial, so typical of this setting, quickly moves thick salt sequences into the subsurface, while contemporaneous salt solution can move large volumes of dense hypersaline brines into adjacent aquifers. High rates of subsidence and sediment fill, along with consequent overpressuring, means

porosity in associated nonevaporitic sediments can be maintained to much greater depths compared to similar lithologies in a typical passive margin deposit.

The collision margin burial realm is characterized by compressional tectonics, thrust faulting, extensive fracturing of strata and episodic movements of basal fluids often in response to tectonic loading (Figure 8.1c). Hot (100° to $>250^{\circ}\text{C}$), saline and highly pressured fluids are driven laterally out of the collision zone via porous and permeable horizons, typically toward the craton or continental interior and vertically along faults and fractures (Oliver, 1986). Such systems tend to characterise foreland basins, which in arid regions can become areas of interior drainage that quickly fill with various salts (Figure 5.27), as in seen in the widespread Miocene marine evaporites of the Zagros/Arabian Gulf region and the lacustrine trona deposits of the Eocene Green River Formation in the USA.

Buried evaporite beds caught up in a compressional suture are likely to be pressurized and remobilised, while crossflows of less saline basal fluids, as they are squeezed out of the collision zone, can drive evaporite dissolution further toward the basin edge. The resulting chloride-rich brines may in turn become metal carriers. Compression-driven hydrologies can precipitate widespread burial dolomites and Pb-Zn deposits, both within the orogenic belts and in the adjacent continental interior (see Warren, 1999, 2000b; for a discussion of various examples). The similarity between geochemistry of fluid inclusions in sphalerite in strata-bound sulphide deposits and that of oil field brines in the U. S. Gulf Coast sedimentary basin led Sverjensky (1986) to conclude that oil field brines can readily evolve into ore-forming solutions.

The post-orogenic burial setting is characterized by a lack of intense tectonic activity, the dominance of topographically driven flow, and by relatively high fluid flow rates, which in zones of deep artesian circulation range from 1 m/year to 30m/year (Figure 8.1d) Flow is driven by elevation gradients created during uplift in the preceding orogenic phase. Post-orogenic fluid flow takes over once the main phase of tectonic collision ends. This hydrologic style drives the dissolution of many buried salt units in continental interiors and encompasses the generation of Na-Cl brines, as is occurring today in the Permian and Michigan basins of the USA, the European Alps and the High Atlas.

Steep topographic gradients about basin edges of all three basin stages can create topographically-driven nearsurface fluid flow

rates as high as 20 m/year in aquifers in the high relief portions of the basin (rift rim, transform edge, and orogenic uplift zones). These are much higher rates compared to flow in low relief topographic settings such as passive margins and intracratonic sags, where nearsurface regional flow rates are typically ≈ 1 m/yr, with local thermal- and density-driven flow rates up to 10 m/year. Fracturing and karstification in any aquifer system creates higher local flow rates that can be orders of magnitude greater than that measured in the matrix.

Gradients within shallow aquifers beneath the more central parts of a basin's depocentre are less than in the steep-sided tectonically active margins, but can still be of the order of metres per year. Deeper aquifers in all basins have much slower flow rates (compared to near surface rates) and are typically measured in metres per year or less. Free convection cells driven by the buoyancy forces associated with temperature and salinity fields about salt allochthons have flow rates in typical temperature and density drive convection cells ≈ 1 m/yr, depending on thickness of the aquifer, fluid-density gradient, and regional permeability (Hanor 1987). Flow rates in deep aquifers within the cores of orogenic belts are typically \approx cm/year and dissipate quickly when stress is alleviated (Garven, 1995). Regional flow rates generated by compaction in a mud-rich sedimentary basin are typically much less than a cm/year, with locally or temporally higher rates during fault or microfracture venting of overpressured zones.

The presence of a subsurface evaporite unit as it flows and dissolves creates brine and density inhomogeneities that facilitate active and long term brine mixing interfaces and much higher local rates of subsurface fluid flow. For example, flow rates within descending brine plumes beneath thick buried and dissolving Miocene salt masses in the Dead Sea region are as high as 10 m/year (Stanislavsky and Gvirtzman, 1999). These rates approach those in aquifers in the margins of a high relief basin. Throughout all sedimentary basins containing flowing and dissolving salt the flow gradients tend to be highly variable.

Fluids in subsiding sedimentary basins

The zones of compactional and thermobaric flow lie beneath the zone of active phreatic circulation. They, rather than the active phreatic, dominate the greater part of the sediment pile accumulating in the extensional zone in a passive margin, in the subsiding foreland depression fill of a compressional regime and in the rapidly subsiding parts of pull-apart basins.

Compactional fluids

The compactional regime is characterised by the upward and outward expulsion of pore waters formerly trapped within the compacting sediment pile. If fluid cannot freely escape the compacting sediment may become overpressured. Compactional waters include connate waters, waters modified by brine-rock interactions, and meteoric waters originally buried within shale, sand or carbonate aquifers. Compactional or consolidation-related flow is a typical response to basin subsidence and ongoing sedimentary loading, which drives out interstitial fluids from compressible and hydraulically conductive buried strata. As it needs overburden loading to drive it, compactional fluid flow is characteristic of the mechanical dewatering stages of the basin's burial history and it dominates the early subsiding and filling stages of a sedimentary basin. Compactional loading of more mature sediment piles can be reactivated in regions of thrust sheet stacking, which can renew brine expulsion from the buried matrix (Garven, 1995). In this case it is the loading of the thrust sheets and the lateral compression of the basin that drives further fluid expulsion. It is a process that is quickly alleviated once thrust stacking ceases (Bitzer et al., 1998).

Compactional flow as an early-burial fluid migration mechanism is typical of young rapidly subsiding nonevaporitic basins, where it dominates mud-rich sections deeper than 1,000-2,000m (e.g. many Tertiary basins in SE Asia). Sediment ages in these basins typically range up to a few tens of millions of years. Differences in pressure heads between adjacent areas are the main driving force to fluid flow and the systems are often

compartmentalised by growth faults and mud diapirs. Most expelled fluid tends to move upward through still porous overlying strata during the earliest stages of compaction (Magara, 1986). Then, in the later stages of compaction, as interbedded clays become relatively impermeable, the principal direction of fluid migration becomes stratigraphic and is controlled by interbedded permeable beds of less compacted and variably cemented sandstones and carbonates.

In contrast, a subsiding basin succession entraining a widespread evaporite bed always contains a highly effective aquitard/aquiclude, almost as soon the salt is deposited. If water-saturated sediments are compacting beneath a thick rapidly accumulating unit of basinwide evaporites, its underside deflects the otherwise upward flow of escaping compactional waters (Figure 8.2a). Rising compactional water is initially undersaturated with respect to the evaporite salt but its underside quickly becomes a zone of salt dissolution and accreting insoluble residues (Chapter 7). Water flows obliquely along the underbelly of the dissolving evaporite bed until it reaches a breach in the salt or the edge of the bed. There fluid flow may once again become strongly vertical. As a general rule of thumb, thick evaporite units in a subsiding basin will focus and pond upward-escaping compactional waters and restrict regions of brine escape to areas atop fractures, growth faults, dissolution-induced breaches, or dissolution edges of the evaporite unit. Halokinesis, through its inherent thickening and thinning of bedded salt, may help focus fluid escape via welds into breached salt withdrawal basins, typically situated between growing salt anticlines, allochthon sheets and diapirs (Figure 8.2c).

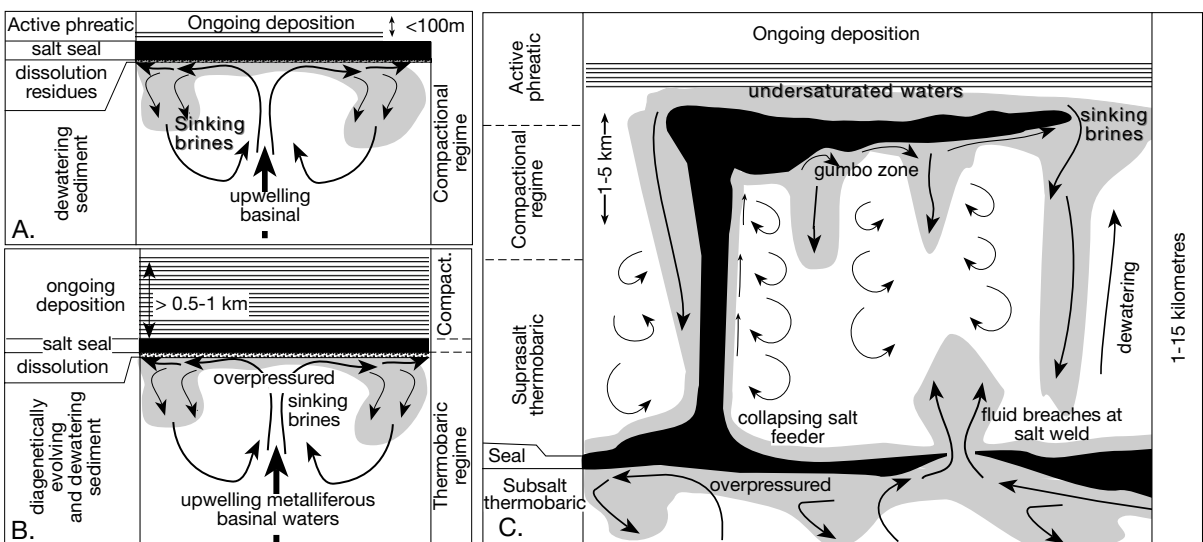

Figure 8.2. Brine flow regimes. A) Compactional regime. B) Thermobaric regime. C) Flow regimes in diapiric province, also shows potential region for escape of hydrocarbon bearing or possibly metalliferous fluids at breach zones in flowing salt bed (salt welds, growth faults, fault welds, etc.).

Figure 8.3. Mechanisms that release thermobaric waters into a basin with thick buried evaporites. Increasing burial releases fluids (brines, acids or gases) as indicated by the shaded portions of each row. The fluids would interact and when undersaturated with respect to the salt mass may have increased the rate of salt dissolution. (No vertical scale is implied).

Thermobaric fluids

Thermobaric fluid flow occurs in the deeper parts of a sedimentary basin where the temperatures and pressures are greater and is intimately related to compactional flow in its uppermost parts (Figure 8.2b, c). By definition, it is a zone of widespread diagenetic alteration where significant volumes of “new” thermobaric water are released by dehydration of clay minerals, catagenesis or the dehydration of hydrated evaporite minerals, such as gypsum or carnallite. Fluids in the thermobaric regime move in response to pressure gradients generated by the related phase changes, such as the generation of hydrocarbons, or the release of mineral-bound water, or ongoing lithostatic loading (Figure 8.3). Density contrasts created by salinity or temperature gradients beneath or adjacent to a dissolving salt bed can drive convective flow of thermobaric pore water. Chemical changes in the sediment matrix mean thermobaric waters frequently contain methane, carbon dioxide and hydrogen sulphide derived from the thermal alteration of organic matter, as well as metals leached from basinal shales and volcanoclastics.

Low permeabilities of deeply buried sediment between or below impervious evaporite beds mean typical rates of fluid flow in intra or subsalt beds are typically slow (mm-dm/year) except in zones of seismic pumping. As in compactional zone hydrologies, it is in the interval adjacent to a salt bed where overpressure tends to develop. Rates of fluid flow and the rate of creation of mixing zone interfaces can be enhanced by the formation of temperature anomalies in the buried sediment,

which are tied to the higher conductivity of salt.

Fluid density tends to increase in thermobaric waters in contact with the dissolving edges of salt units and the direction of brine flow is typically focused by the salt edge. These brines have locally anomalous chemistries and can drive diagenetic alteration when mixed with less dense brines derived from adjacent sediments. For example, the Slave Point, Sulphur Point and Keg River formations of Northeast British Columbia contain numerous gas fields, particularly along the

preferentially dolomitized reefal shelf edge margin (Morrow et al., 2002). The typical reservoir facies is a coarse-crystalline white dolomite known as the Presqu’ile Dolomite. It follows the shelf edge within the Slave Point Group, but coarse-crystalline dolomite is also regionally extensive within underlying strata. The dolomite is made up of two geochemically distinct but related phases, both precipitated from thermobaric waters (Figure 8.4a).

The organic-rich Klua Shale, the Otter Park Shale, and marlstones equivalent to the Sulphur Point and Slave Point formations are aquicludes that blocked the upward and lateral flow of warm dolomitising brines derived from dissolution of buried evaporites (Figure 8.4b). Presqu’ile dolomitization along the Slave Point shelf edge is interrupted in places where the Klua Shale extends shelfward underneath the Slave Point Formation. The Watt Mountain shale was also a regional aquiclude that prevented upward circulation of dolomitising fluids in areas behind the Slave Point shelf edge. The flow of dolomitising NaCl-CaCl₂-MgCl₂-H₂O brine solutions began early in the shallow subsurface perhaps even as their brine source (Slave Point evaporite) was still being deposited. This precipitated dolomite cements (type 1) at temperatures > 50°C, during northwestward-directed shallow subsurface brine reflux from the Elk Point evaporite basin. This was followed by later upward-directed subsurface convective flow of NaCl-CaCl₂-MgCl₂-H₂O and NaCl-MgCl₂-H₂O brines, generated by the

Figure 8.4. A) Chart of diagenetic events for the Keg River to Slave Point strata. Presqu'ile dolomitization (dolomite 1 and dolomite 2) precedes the thermal maturation of organic material and the emplacement of reservoir bitumen. Calcite cementation coincides approximately with the onset of gas generation followed by minor quartz and sulphide (sphalerite and galena) cementation. B) Schematic reconstruction of time of dominant Presqu'ile dolomitization around the Cordova embayment. Dense residual Elk Point brines flowed downdip and northwestward by gravity displacement of less dense subsurface fluids. This flow was confined beneath the Watt Mountain Formation shale. The absence of this confining layer allowed upward flow of brines into the overlying porous Slave Point Formation, where downdip brine flow may have been deflected upward against the low permeability basin fill of shaly units of the Cordova embayment. Initially, dolomitization occurred at temperatures below 50°C , but an increase in basal heat flow and ongoing burial caused dolomite precipitation to continue at 130°C (after Morrow et al., 2002).

ongoing burial dissolution of evaporites, mixing with less saline thermobaric waters escaping from nearby shale and so precipitating later dolomite cements (type 2). These type 2 dolomites are much less voluminous than type 1 and precipitated at temperatures $\approx 130^\circ\text{C}$ during the Late Devonian-Carboniferous. Later lower salinity brines that precipitated late calcite cements and some latest type 2 dolomite may have interacted with connate fluids of marine origin or, less likely, with meteoric fluids (Morrow et al., 2002).

The importance of a buried, slowly dissolving, salt mass in focusing thermobaric fluid flow throughout much of a basin's burial history was also illustrated by Wolfgramm and Mumm (2000). They used fluid inclusion analyses to reconstruct the spatial and temporal variation of fluid composition and thermal properties within sediments beneath the Zechstein salt in northeast Germany. Precipitates from early thermobaric fluids, migrating in the deeper parts of the basin, were characterised by complex salinities, with sulphur contents that increased toward the contact with the Zechstein. This suggests a partial exchange with the overlying evaporites. Inclusions of coexisting fluids dominated by NaCl, CaCl_2 and KCl are largely restricted to authigenic minerals in the Upper Carboniferous sediments and Rotliegende volcanics located in juxtaposition to the overlying evaporites. Younger, secondary fluid inclusions, sometimes containing gas phases, show increasing temperatures related to further burial. Thermal properties of all fluid inclusions indicate steep thermal gradients below the base of the Zechstein and Rotliegende sediments. This documents convective or advective heat and associated focused subsalt fluid flow in the deeper thermobaric parts of the basin. Throughout its burial history the Zechstein salt mass acts as the seal to a widespread convective system until its continuity is broken by salt withdrawal and thinning.

Deep flow in pull-apart basins

Another variation on this compaction/thermobaric theme is the evolving hydrology created by rapid subsidence and fluctuating tectonics that typify transtensional basins or pull-apart basins. The best-documented example of hydrological evolution associated with a salt mass in such a setting is the Dead Sea (Stanislavsky and Gvirtzman, 1999). Deep saline pores brine in the Dead Sea region are in part a residual product of intensively evaporated seawater that seeped into the depression back in the Miocene to accumulate as a widespread marine-fed basinwide halite. In places in the Dead Sea depression (e.g. Mt Sedom and surrounds), this halite is still near the surface, kept there by ongoing salt flow (Figure 8.5a). Dissolution of buried Miocene salt and the associated migration of a residual brine today drives zones of dolomitization within the adjacent

Cretaceous carbonate aquifers. This dissolutional brine occurs in deep wells located more than a 100 km from the Dead Sea depression. The feasibility of such longterm lateral migration of brine from Dead Sea evaporites over the past 3-6 m.y., was verified by palaeohydrologic modelling (Stanislavsky and Gvirtzman (1999).

Their results show that two basin-scale ground-water systems coexist in the present Dead Sea rift valley, one atop the other but with opposite flow directions (Figure 8.5b, c). The upper system is a topography-driven flow of meteoric water fed from the surrounding highlands, which flows eastward into the rift via shallow aquifers (<1 km deep). The second system is a density-driven migration of the Dead Sea brine moving in the opposite direction (westward) through deep Jurassic and Triassic aquifers (upto 4-5 km deep). This deep flow is

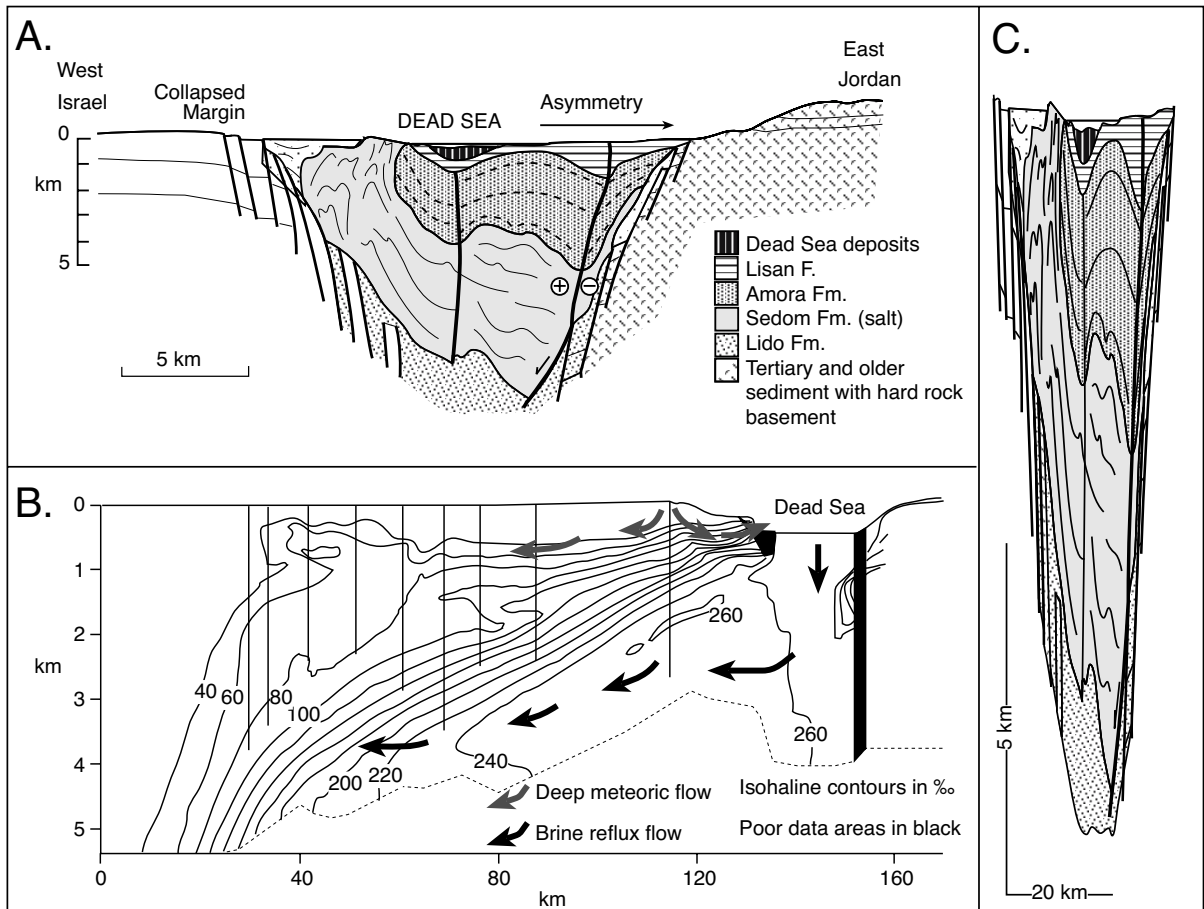

Figure 8.5. A) Dead Sea cross section showing asymmetric nature of fill. Shallow hard rock basement (aquiclude) occurs to the west of the basin fill (after Zak, 1980). B) Present deep westerly brine flow driven by dissolution of deeply buried Miocene salt (after Stanislavsky and Gvirtzman, 1999). C) Schematic geology based on 8.5a (which is a same scale section) stretched to match the same proportions as the vertically exaggerated scale of 8.5b so as to better demonstrate the importance of dissolving Miocene salt in driving deep brine flow.

maintained by ongoing dissolution of the thick halokinetic Miocene evaporites.

The longterm configuration of these flow systems has been modified by the hydrological evolution of the Dead Sea depression. There was an earlier (1.5 to 2.0 Ma) pervasive westward intrusion of brine into adjacent somewhat shallower (1-2 km) aquifers. The total mass of salt that entered the Cretaceous Judea and Kurnub aquifers at that time was 1.9×10^{11} and 3.9×10^{10} kg of salt per 1 metre width slice of cross section (Stanislavsky and Gvirtzman, 1999). Subsequent subsidence meant more than 80% of that earlier shallow outward-directed brine pulse seeped back into the Dead Sea depression. In contrast, for more than 2 million years, deep highly-saline dissolution-derived density-driven brines have been flowing westward toward the Mediterranean from the Dead Sea Basin. They have displaced older pore waters in deeply buried (2-4km) Jurassic and Triassic aquifers across a lateral distance of more than 150 km. Clearly, this is a region where ongoing brine flushing of adjacent deep aquifers is driven by salt dissolution.

Flow in and adjacent to Collision Belts

Compactional and thermobaric flow regimes are active as long as sediments are accumulating within areas of subsidence. With the cessation of sedimentation/subsidence, or with tectonic uplift, compaction driven flow decreases and ultimately ceases and most overpressure dissipates. When a mature basin, which is characterised by hydrological equilibrium in its sediment pile, then undergoes collision, overthrusting and basin inversion, a whole new set of disequilibrium processes are set up and can drive renewed deep-fluid migration (Figure 8.1c). Reverse faults and thrust welds in stacked thrust sheets in growing overthrust belts can focus fluid escape, while the thrust sheet loading acts as a huge press. Compression drives thermobaric waters out of the deeper parts of the compressing basin into the shallower basin margins, with periodic fault release sucking fluid into the fault ("squeegee" mode).

Some authors have explained MVT sulphides as forming in the basin margin zones of compressional terranes where these escaping chloride-rich metalliferous "squeegee" waters mix with topographically driven meteoric waters (Oliver, 1986). This process was thought capable of precipitating sulphides in passive margin carbonate platforms located hundreds of kilometres in front of the active thrust belt. Subsequent modelling of fluid flow and heat transport in compacting and dewatering thrust belt by Deming et al. (1990) showed flow velocities created by the "squeegee" effect are in the order of centimetres

per year and thermal anomalies of the order of 5°C, neither are sufficient to make significant contributions to mass and energy transfer. Likewise, Bethke and Marshak (1990) argued that rates of fluid expulsion in convergent margins are far too low to produce efficient advective heat transport. Most models assume systems that are tectonically and laterally homogenous with isotopic aquifers.

The inherent assumption in this modelling of chemical equilibrium between porewater and the enclosing rock in a sedimentary basin is probably justified by the inherently low flow rates associated with long term widely dispersed leakage (homogenous drainage) of compactional fluids in nonevaporitic mineralogically stable sediments. But assumptions of homogeneity of fluid flow are weaker in areas when episodic and focused dewatering (seismic pumping) is occurring in association with a mass of compressed impermeable salt. Flow velocities about the edges of any compressed but impervious salt mass can be locally high in relation to reaction rates. Drilling in compressional terranes in the Middle East and the Gulf of Mexico shows overpressure beneath sealing salt sheets periodically approach lithostatic. Vein textures and inclusion studies show hydrofracturing tends to occur preferentially and numerous times in zones of sediment adjacent to salt lubricated décollement. As fluid is sucked into these near-salt zones during fault release (typically along the base of the décollement) it doesn't come from the salt (it is impervious) but from the adjacent sediment. Then as compression takes over once more we have a system where the pore fluids drawn into the region of contact with the salt are renewed in an undersaturated state with respect to the salt mass and so are capable of dissolving salt as they are squeezed out ("squeegee" mode) along the underside of the salt mass. This gives a mechanism that drives the ongoing creation of chloride-rich waters capable of constant renewal and of carrying hydrocarbons and metals. The redox front across this interface and breach points in the salt are both capable of focusing base and precious metal precipitation (Warren 2000b).

Hence, inversion-related thrust faulting, which juxtaposes potential aquifers against pressured and dissolving evaporite beds, can mobilise focused thermobaric brine escape from deep aquifer systems. It can move hydrocarbons and metals, while at the same time precipitate late-stage authigenic evaporite cements. This is clearly seen in the authigenic sulphate cements in the Rotliegende Formation in Leman Field in the Southern Permian Basin of the North Sea (Figure 7.72; Gaupp et al., 1993; Sullivan et al., 1994).

Figure 8.6. Detailed cross-section through the Plan de Larri in the central-western Pyrenees centred on the Gavarnie Thrust (GT; after McCaig et al., 2000). D. phyll. is mostly low grade Devonian phyllite; D. Lst. is mostly low grade Devonian carbonate; the Triassic section is Upper Triassic shales, carbonates and evaporites; D. breccia is a Late Cretaceous breccia weld that in outcrop composed mostly of Devonian clasts; Cretaceous is mostly Upper Cretaceous carbonates.

Coarse-grained burial-stage poikilotopic anhydrite cements increase in abundance in the vicinity of faults cutting the Rotliegende sands. Isotopic data show this late stage anhydrite precipitated at maximum burial of 3.5–4 km during the Late Jurassic–Early Cretaceous, that is, at the start of basin inversion. The data indicate an unusual, short-lived catastrophic event of cross-formational fluid flow along fractures and reactivated faults induced by basin inversion. Late stage magnesite and dolomite cements may also be related to influx of the same subsurface brines.

Remobilisation of basinal brine during inversion typically occurs during a compressional event many millions of years after first burial (Wilson cycle) and may revitalise the formation and migration of hydrocarbons. For example, saline chloride-rich formation waters in Mesozoic hydrocarbon traps in the Timor Sea, Northern Australia are sourced in more deeply buried Palaeozoic evaporites (O'Brien et al., 1999; Lisk et al., 2000). Some 5.5 Ma there was a transient fluid flow event, driven by Mio-Pliocene inversion, and associated far-field fault reactivation, driven by the collision of the Australian plate with SE Asia. It had a major impact on the seal integrity of numerous fault dependant hydrocarbon traps in the Timor Sea and allowed hot (90–130°C), highly saline (>200,000 ppm) brines from deep Palaeozoic evaporite-derived brines to migrate up the reactivated faults to chemically and thermally overprint the reservoir and other shallower intervals. Apatite fission track data suggest that this regional episode of fluid migration was short and lasted for between 10,000 and 100,000 years. It resulted in the development of a prominent, localised Late Tertiary heating

'spike', that if ignored can significantly affect the accuracy of modelled thermal histories in the region.

High pressures associated with collision and thrusting can drive salt-derived fluids into lithologies where they would not otherwise be present, such as when evaporitic basinal fluids become syntectonic fluids in igneous basement. For example, deep basinal brines, derived from dissolving Triassic evaporites, were driven via fractures and shears into hard rock basement (phyllites and gneisses)

of the Pyrenees during the Hercynian orogeny (Figure 8.6; McCaig et al., 2000, discussed in detail later in this chapter). Worldwide, it is likely that dense salt-dissolution-derived brines, sourced deep in the basin by ongoing salt solution, are involved in a number of alteration and mineralisation events in the same general area of the basin. But they occur as short-lived diagenetic pulses or events ($\approx 10^5$ – 10^6 years) spread over hundreds of millions of years, even as the basin passes through all stages of the Wilson tectonic cycle (i.e. rift, collision and post-collision; Figure 5.27). Even after a salt bed has passed into the metamorphic realm it, and its dense brine halo, will continue to act as a source of Na and Cl. In this case the ions come not from halite (gone by 450°–500°C) but from compressed scapolite cages and other meta-evaporitic daughter phases, e.g., the Mt Isa–Cloncurry region of Australia (Warren, 1999; Chapter 6).

Flow in post-orogenic hydrologically-mature basins

After inversion or uplift, evaporite beds re-enter the zone of deep meteoric (artesian) circulation and active phreatic flow (telogenesis). Meteoric fluids enter via infiltrating rainfall and groundwater as strata are increasingly flushed by meteoric waters (Figure 8.1d). Gravitational sinking, driven by topographic gradients and recharge along the uplifted margin of the basin, is the most important mechanism driving fluid migration. This gravity-driven circulation is sometimes termed centripetal flow, as it encompasses flow into the basin centre

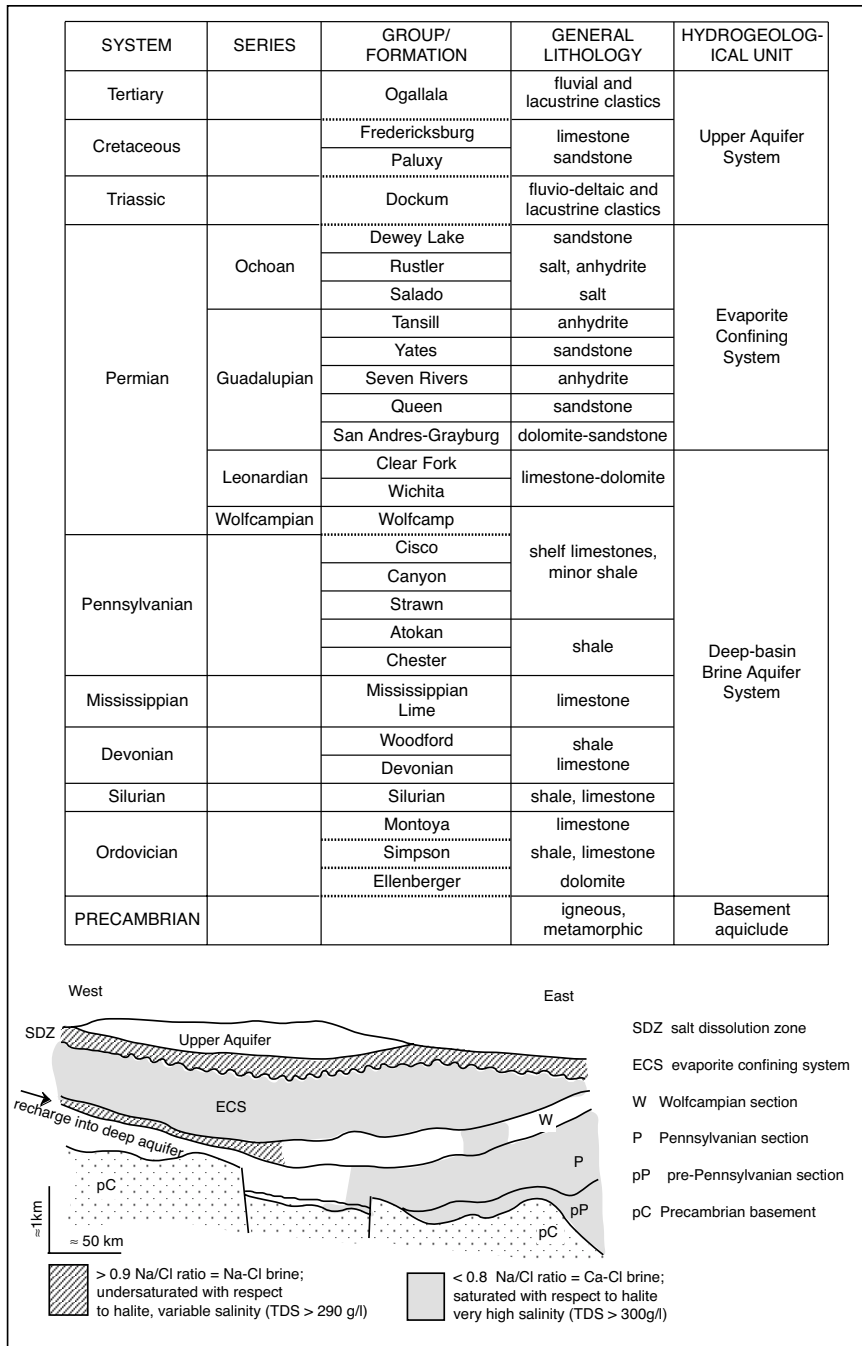

Figure 8.7. Na/Cl molal ratios define subsurface hydrology in Permian Basin, west Texas and Oklahoma. The relict Ca-Cl brines are held in place by the low permeabilities of the evaporite confining zone, while Na-Cl brines derived by halite dissolution are to be found in the salt dissolution zone (SDZ) and the Wolfcampian section (W) of the deep basin aquifer (after Bein and Dutton, 1993). The upper part of the figure shows the relevant stratigraphy of the region, centred on the Central Basin Platform and the occurrence of the major hydrogeologic units within this stratigraphic framework (after Stueber et al., 1998).

from the surrounding highland areas. It is opposite to centrifugal flow, which characterises the compactional, thermobaric and compressional regimes.

Three conditions must be met to allow topography driven flow: 1) the basin needs to be partially elevated above sealevel/brine level, 2) the flow system requires ongoing water replenishment via infiltrating rainfall and groundwater, and 3) aquifers must have sufficient permeability at depth to allow the entry of waters. An exception to the general requirement of a meteoric feed and suprasedalevel hydrologies is a subsealevel foreland basin or saline giant undergoing evaporative drawdown, such as the Mediterranean in the Late Miocene (Messinian), where seawater was the major groundwater feed (Figure 5.27).

Another exception to the general assumption that centripetal flow is driven by a potentiometric head that is always supplied by the uplift, may occur in glacial times. Today the Williston Basin in Manitoba has a hydrology controlled by recharge in the Rocky Mountains, but in the Pleistocene glacial periods this may have not been true. The thickness of the continental ice sheet over subglacial lakes may have provided sufficient hydrologic head to reverse the regional-scale flow system of evaporite-dissolution derived basinal brines in the Williston Basin (Grasby and Betcher, 2000).

Salt dissolution in the post-orogenic continental realm feeds brine into adjacent deeply-circulating confined aquifers beneath thick well preserved evaporite intervals. Over the last 5-10 million years, subsurface Na-Cl brines in various subsalt sandstone aquifers along the edges of the Anadarko, Midland and Palo Duro Basins have acquired their high salinity through the dissolution of halite by deep meteoric circulation of groundwaters. These basins make up the northern portion of the Permian Basin of west Texas and Oklahoma (Figure 8.7; Bein and Dutton, 1993).

Topographically driven, initially fresh, meteoric water moved into the western half of the deep-basin brine aquifer through nearsurface salt dissolution zones and then downward as Na-Cl brines seeped along the various deep aquifers to depths of thousands of metres (SDZ = salt dissolution zone in Figure 8.7). Above the deep aquifer are Ca-Cl basinal brines that are relict Permian mixtures of descending evaporitic brines and connate Permian and Pennsylvanian seawaters. Little or no Neogene meteoric Na-Cl brine has penetrated this Ca-Cl brine zone, which is hosted by the evaporite confining system (ECS). The lack of ingress reflects the extremely low permeability of deeply buried halite and intrasalt shale, anhydrite- or halite-cemented strata that dominate the ECS ("block of ice" analogue). Ages of the Ca-Cl brine in the ECS, based on ^4He and ^{40}Ar analyses of carbonates in the central part of the deep aquifer, range from 100 to 300 Ma (Zaikowski et al., 1987), making it a true "fossil" groundwater. This is the same salt where viable halobacteria have been cultured from brine inclusions preserved in its chevron halite (Vreeland et al., 2000).

To the south of the Palo Duro Basin, in the carbonate platform of the eastern Central Basin platform in west Texas, halite beds occur only in Upper Permian (upper Guadalupian and Ochoan) strata in the Permian Basin. As in the Palo Duro Basin, late stage uplift has influenced pore water composition of some of the original reflux brines in the more permeable subsalt beds. Extremely saline evaporated seawater apparently descended into adjacent Palaeozoic carbonates during halite deposition in the Late Permian, mixing with and displacing marine formation waters by buoyancy-driven convective flow (brine reflux; Stueber et al., 1998). These modified evaporitic brines were the dominant fluids in the Palaeozoic carbonates until the late Tertiary, when topographically-driven meteoric water began to flow into deeper Palaeozoic strata from outcrops and nearsurface aquifers in southeastern New Mexico in association with tectonic uplift that began at 5-10 Ma.

Meteoric water dissolved halite and anhydrite from Permian evaporites near the basin margin and seeped eastward along the regional hydraulic gradient, while mixing with and displacing modified evaporitic brine in the deeper parts. These meteoric waters, driven topographically, have now migrated large distances to displace saline waters deep and drive biodegradation in a basin characterised by numerous oil reservoirs with solution-gas drives.

The original dense brine that sank from Salado and Rustler evaporites into the underlying carbonates of the Central Basin Platform during the Late Permian may not have been of uniform composition, making it more difficult to separate it chemically from brines influenced by connate water or any subsequent deeply circulating meteoric waters. That is, initial brine composition was not solely of a composition that resulted from 23-fold concentration of seawater (Figure 8.8: Stueber et al., 1998). Multiple depositional cycles in Salado evaporites, as described by Lowenstein (1987a), represent periodic invasions of seawater into the Salado basin, followed by progressive drawdown and concentration of brine. Therefore, the degree of seawater concentration reached during each cycle probably varied, and the projection of the data trend plotted to a 23-fold concentration in the upper panel of Figure 8.8 is an oversimplification (Stueber et al., 1998).

The dense brines that began to sink into underlying carbonates during the Late Permian probably had a range of initial compositions along the seawater evaporation trajectory and lay somewhere to the right of the halite precipitation point (Figure 8.8a). The range of Br concentrations above 450 mg/l observed in formation waters from the 365 m (1200 ft) thick Pennsylvanian-Wolfcampian carbonate section in the Central Basin Platform below the Salado and Rustler evaporites is largely a relic of this inhomogeneity.

The present locations of the most saline formation-water compositions below the seawater evaporation trajectory in the Permian of west Texas probably indicate relict evaporitic brines mixed with seawater when they entered the carbonate strata, much like the mixing that has been documented for the Messinian drawdown (Figure 5.33) and is occurring today in the Dead Sea depression. As the brine mixed with phreatic seawater, each evaporitic brine composition along the seawater evaporation trajectory to the right of halite saturation would have been displaced along a line essentially parallel to the portion of the seawater evaporation trajectory prior to halite precipitation (Figure 8.8a, b). When the range of data points

Figure 8.8. Chemical character of 32 formation-water samples from carbonate reservoirs in the Southwest Andrews area (after Stueber et al., 1998). A) Log Cl versus log Br. Seawater evaporation trajectory is from Carpenter (1978). SW = seawater composition; Halite precipitation = 450 mg/l = 2.65 Log Br (mg/l). Dashed line marks the likely mixing trend among the brines. B) Cl/Br vs. Na/Br molar ratios in formation waters relative to the compositional trend formed by seawater evaporated past halite precipitation and seawater that has dissolved halite. Regression line drawn through data points has $r^2 = 0.99$. The range of theoretical compositions that result from dissolution and recrystallisation of halite in fresh water is also shown. C) Oxygen isotope composition plotted against Br concentration.

representing formation waters with present Br levels greater than 450 mg/l is projected along such lines back to the seawater evaporation trajectory to the right of halite saturation, a range of seawater evaporitic concentration between 11-fold and 16.5-fold is indicated for the more saline waters. The concentration dissolution trends are also clearly seen in the Cl/Br and Na/Br crossplot, while the $\delta^{18}\text{O}$ - Br crossplot clearly shows the effect of meteoric mixing (dilution) on both these values (Figure 8.8b and c, respectively).

Thus, modified evaporitic connate brines were the dominant precipitative fluids for cements and replacement in the Palaeozoic carbonates of the Central Basin Platform and the Palo Duro Basin until the late Tertiary, when meteoric water began to flow into deeper Palaeozoic strata from outcrops and nearsurface aquifers in southeastern New Mexico, in association with tectonic uplift that began at 5-10 Ma. Neogene meteoric water dissolved halite and anhydrite from Permian evaporites near the basin margin and sank eastward along the regional hydraulic gradient, mixing with and displacing the modified evaporitic brine in deeper hydrogeologic systems of the Devonian and San Andres aquifers. The mixing curve is indicated by the dashed line, lowered Br values and the negative $\delta^{18}\text{O}$ signatures (Figure 8.8 a and c). These late Cenozoic meteoric fluids probably are responsible for widespread biodegradation of oil in the San Andres/Grayburg interval in the Andrews oilfield area. More regionally such deep meteorically driven dissolution of gypsum/anhydrite beds supplied sulphate-ions for the bacterial production of reduced sulphur with the organics supplied by trapped and upwelling hydrocarbons. This reduced sulphur was then oxidised to form economic accumulations of natural sulphur in west Texas (Chapter 11; Hentz and Henry, 1989; Lee and Williams, 2000).

The Alberta Basin, Canada, is another area of post orogenic fluid circulation where evaporite-derived subsurface waters currently interact with less saline deeply circulated meteoric waters within artesian aquifers (Figure 8.9a; Michael et al., 2003). Regionally, the Devonian succession contains two brines types (a 'light brine' with TDS

< 200 g/l and a 'heavy brine' with TDS >200 g/l), and both brines are pressurized by the potentiometric head supplied by the Rocky Mountains to the west.

The interface between the two brine types is typically lobate and controlled by permeability variations in the host aquifer, as evidenced by concurrent, steep changes in hydraulic head, and salinities (Figure 8.9a). Hydraulic heads in the lower two aquifers (Elk Point and Woodbend-Beaverhill Lake), range from 625 to 750 m, whereas heads in the upper two aquifers (Winterburn and Wabamun) range from 500 to 800 m. This implies that the Ireton is an effective aquitard between the lower two and the upper two aquifers. According to Michael et al. (2003) the geological and hydrogeochemical data suggest the following processes determined the present composition of the 'light' and 'heavy' brines: original seawater, evaporation of brines beyond gypsum onset but below halite saturation, dolomitization, clay dehydration, gypsum dewatering, thermochemical sulphate reduction, and halite dissolution. As in the San Andres Fm., the two brines can be separated by Na/Cl proportions; lighter brines show values >0.9 indicative of derivation from halite dissolution, while heavy brines tend to show values <0.7 reflecting a more relict marine-derived signature (Figure 8.9b).

An influx of meteoric (from the south) and metamorphic (from the west) waters is recognized only in the 'light brine.' Albitisation (sodic replacement) is unequivocally identified only

in aquifers hosting the "heavy brine." The "heavy brine" is likely a residual Middle Devonian evaporitic brine from the Williston Basin of the Elk Point Basin, or it may have originated by partial dissolution of thick, laterally extensive Middle Devonian evaporite deposits to the east. The "light brine"

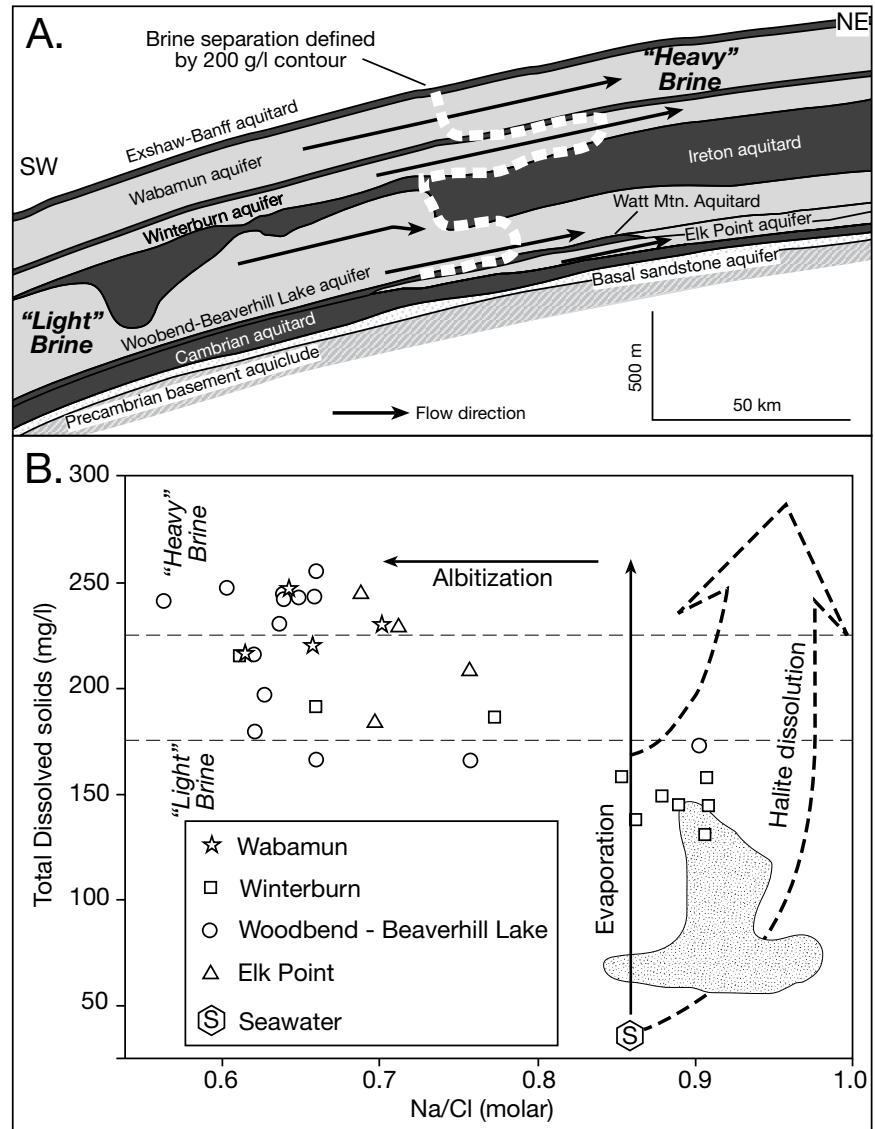

Figure 8.9. Basin fluids in Devonian of Alberta Basin (after Michael et al., 2003). A) Hydrogeological cross-section perpendicular to the deformation front to the west showing conceptually the differential advancement of the less saline formation water displacement front against a high-saline connate brine reservoir in the Cambrian-Devonian hydrostratigraphic group. B) Distribution of Na/Cl ratios versus salinity in Devonian formation waters showing some processes that may have influenced the brines. The stippled area shows the distribution of hydrochemical measurements for Mississippian strata where halite dissolution driven by deep meteoric circulation controls much of the hydrochemistry of the deep aquifer.

Figure 8.10. Palaeohydrologic pattern of the compressional (thrust) margin of the Miocene Ebro Basin, Spain (after Salvany et al., 1994). The Miocene lacustrine evaporites in the Ebro Basin are ultimately derived from the deep meteoric leaching of Triassic evaporites in the Iberian Range along the southern margin of the basin. Ongoing surface and nearsurface evaporative fractionation of shallow brines divided the Miocene chemical sediments into a series of bioturbated carbonate-rich gypsum lakes and a more central gypsum-halite-rich lake system.

probably originated from dilution of 'heavy brine' by deeply circulating meteoric fluids in post-Laramide times, similar to the dilution seen in the San Andres aquifer.

So far, we have discussed brine styles in the deeply buried portions of post-orogenic aquifers. But, when buried evaporites are caught up in the hydrology of compressional belts and subject to syn- and post-orogenic deep meteoric flow, their dissolution can supply much of the ionic content to actively accumulating evaporite systems in the outflow zones in an adjacent foreland depression. This was the case in the Miocene saline lakes of the Ebro Basin of NE Spain (Sánchez et al., 1999; Salvany et al., 1994). The current saline lakes in the same area (such as Lake Banyoles and Salada Mediana) are considered to be karstic relics of a more active saline hydrology that was set up during the Early and Middle Miocene, via intense compressional deformation and associated high relief in the basin margin.

Evaporite sedimentation at that time took place under a gravity-fed continental brine hydrology not connected to the sea (Sánchez et al., 1999). The sedimentation around the margins of the Ebro Basin was detrital, originating from alluvial systems that surrounded large saline and carbonate lakes in lacustrine systems that in their central depressions were dominated by playa depressions up to 100 km long and 30–50 km wide.

Three concentric hydrologically controlled and segregated subenvironments characterised the lacustrine depression: (1) central lake areas dominated by gypsum and halite pans; (2) intermediate lake areas with pervasive laminated gypsum and anhydrite as well as diagenetic glauberite, and (3) marginal lake areas with nodular diagenetic anhydrite, which gradually passed into distal alluvial plains (Figure 11.54). In some marginal lake areas that were isolated from the central lacustrine

systems there were small evaporitic lakes up to a few kilometres across. There local deposits of carbonate, gypsum and anhydrite precipitated from moderately concentrated brines, along with abundant diagenetic chert (Salvany et al., 1994).

Evaporitic successions in the central gypsum-halite lake area attain thicknesses of more than 200 m (Figure 7.44a) and almost all of it was derived from evaporation of deeply circulated meteoric waters that had dissolved Mesozoic evaporites and carbonates in folded basement in the adjacent Iberian Highlands (Figure 8.10). Most of the carbonate-rich marginal lakes corresponded to zones of the first diffuse emergence of this deep groundwater. Waters then fractionated as they moved toward the lowest parts of the lake depression. Since the Miocene the groundwater hydrology has evolved and matured to that of today where focused springs, rather than diffuse resurgence zones, define zones of initial groundwater outflow (Sánchez et al., 1999).

In summary, dissolving subsurface evaporites contribute to basinal pore salinities, chemistries and can drive fluid flow and mineral alteration at all stages of burial and uplift, and continue to do so as long salt and permeability live on in the sediment pile.

Alteration, pressure cells and salinity-driven convection

All water-bearing sediments compact and alter within the zones of compaction and thermobaric waters, as various connate or subsurface waters escape from the sediment pile. Pore waters issuing from compacting sands, shales and limestones are typically not halite-saturated, so salt masses tend to dissolve wherever fluids from dewatering sediment piles come into contact with salt beds or allochthons.

Evans and Nunn (1989) and Ranganathan and Hanor (1988) analysed salinity-driven convection in permeable sands near salt structures in the Gulf Coast. Sarkar et al. (1995) modelled salinity-driven free convection in less permeable shale-dominated media beneath a dissolving salt sheet or allochthon. Morton and Land (1987), Land (1991), and McKenna and Sharp (1997) noted salinity inversions in the south Texas portion of the Gulf of Mexico basin, where more saline pore waters (including brines > 100,000 ppm total dissolved solids) overlie less saline waters (\approx 20,000 ppm). Strong buoyancy gradients exist where such inversions occur, as the shallower pore waters are both cooler and more saline than deeper pore

waters. Most of these hydrologies are maintained by the rise of brine along fractures and faults from basal depths where deeply buried salt is actively flowing and dissolving. Convective return of brine occurs in areas away from the supplying structure (Sharp et al., 2001).

Haloed, convection and saltout

Over time, the ongoing dissolution of the edges of a salt bed, allochthon or salt wall sets up a dense subsurface brine halo. As it builds, the halo becomes so saline and dense that it starts to drive free convection. Saline pore waters slowly sink beneath the underbelly of the dissolving salt bed or allochthon, or spread laterally atop the upper side of a salt bed or edge of a diapir. Pore water from the salt underbelly sink to depths where it reheats, flows laterally and then rises to return once more to the underside of the evaporite bed to complete the convection cell (Figures 8.2a,b, 8.11). Such density-driven convective circulation is an important mechanism of depositing and remobilising pervasive secondary salts (burial salts) in subsalt beds that were originally nonevaporitic. It also creates basal “caprock” residues along the underside of the bed or allochthon.

Buried evaporite beds in contact with adjacent aquifers become sites of phreatic salt flushing as soon as the solar-driven active phreatic brine reflux hydrology starts to dissipate. Hence, burial dissolution of salt from its edges inward begins as soon as the bed enters the zone of compactional water flow (Chapter 7). This explains why the upper and lower contacts of many thick ancient evaporite beds are not depositional contacts. Rather they are zones characterised by dissolution residues, recrystallisation and pressure solution textures. For the same reason, well preserved primary and syndepositional textures in bedded evaporites are rarely found at the contacts with adjacent nonevaporite lithologies. Depositional fabrics are best preserved internally within an evaporite bed, away from the edges where basal fluids are eating into and altering the original evaporite textures. Diagenetic waters continue to dissolve or “melt” evaporite contacts until the evaporite dissolves or all effective permeability is lost in the adjacent beds.

The modelling of plumes beneath salt beds and subhorizontal allochthonous salt sheets, such as occur in the Gulf of Mexico, shows free convection has the potential to be a significant mechanism in both salt dissolution and mass transport, even if the sediments beneath the salt have permeabilities as low as 0.01 md (Figure 8.11; Sarkar et al., 1995). In such low permeability sediment it will take some 10 My for the sub-salt convection to develop to full strength. Once active, an average

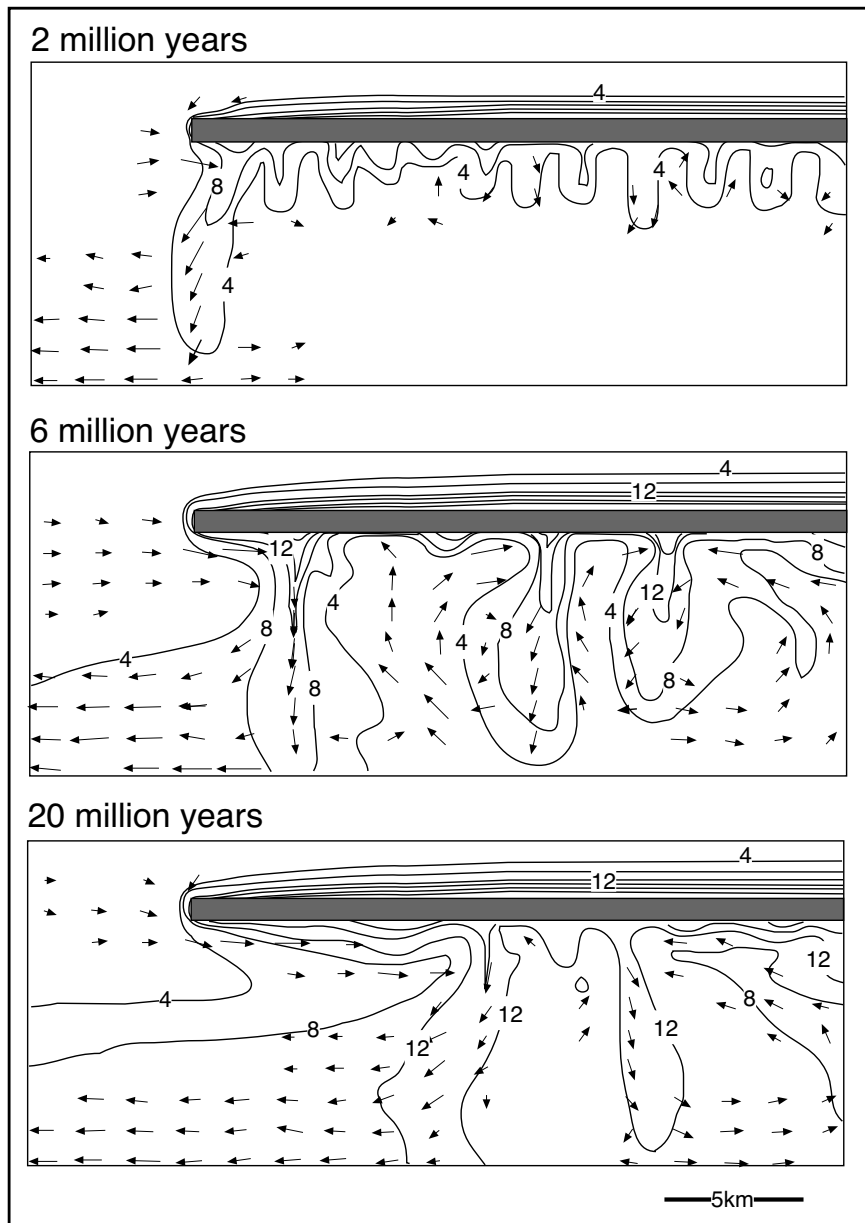

Figure 8.11. Modelled temporal evolution of brine plumes associated with ongoing dissolution of a salt sheet in a shale matrix at times of 2, 6 and 20 My. Salt sheet is grey (after Sarkar et al., 1995). Contours of plumes are given in terms of salinity difference: calculated as pore water salinity minus seawater salinity (3.5%). Numbers are in wt %. The leftmost plume is mostly fed by ongoing dissolution of the salt edge. Vertical exaggeration is 2x.

of 3-5-m of salt is dissolved off the underbelly every million years, with a maximum darcy flux of 3 mm yr^{-1} . Measured matrix permeabilities of overpressured shales immediately beneath allochthonous salt (the gumbo zone) are much higher than 0.01 md and so the actual flow and dissolution rates are much higher.

dissolution of the salt stem is quickly filled, either by salt from the stem, or, if dissolution is rapid enough, by the collapse of sedimentary beds against the stem to form “downthrown” slivers and blocks (Chapter 6). As dissolution of the salt

Chloride-rich density-derived convective flow cells are an inherent part of the hydrology beneath all dissolving evaporite seals. They continue to cycle subsalt pore water over and over through the underlying sediment column until subsalt permeability is shut down by compaction and thermobaric cementation. It can move volatile-entraining chloride-rich brines through base-metal and organic-containing shales and cupiferous redbed beneath buried salt beds and sheets. Wherever such waters break out from beneath the salt seal into suitably prepared ground, the associated cooling and brine mixing can precipitate metal sulphides or facilitate the focused escape of liquid and gaseous hydrocarbons (Warren, 2000b). Breaches typically occur via growth faults, salt welds or via seismic pumping along thrusts and thrust welds; all these features centrifugally drain basinal pore waters from beneath a salt bed or allochthon sheet. Simultaneously, the escape can drive other diagenetic reactions such as secondary porosity formation (via brine mixing and changes in $p\text{CO}_2$) or the precipitation of authigenic burial cements.

Where halite dissolution is occurring along the flank of a salt stock or diapir (shale sheath), the resulting dense pore fluids move into adjacent upturned permeable beds (Figure 8.2c). Any cavity created by local

stem proceeds, the resulting high salinity (high density) pore brines can spall off a sinking brine halo that is maintained by ongoing dissolution. Such high salinity pore waters tend to sink away from the stem down the more porous extensional portions of adjacent steeply dipping beds. Unlike the self-limiting rate of salt loss associated with the undersides of subhorizontal salt geometries, steeply dipping beds about a salt stem create a plumbing system with a tendency to self drain and so facilitate further dissolution of the stem and the set up of conditions suitable for the “salt-out” of rising hydrocarbons.

Hydrocarbons are less soluble in brines than in fresher waters. Price (1976, 1981) noted that at standard temperature and pressure (STP) the solubilities of n-pentane and methyl-cyclohexane decreased from 40 ppm in fresh water to 3 ppm in water with a salinity of 300,000 ppm. This means hydrocarbons dissolved in less saline basinal waters tend to “salt out,” or exsolve, in the vicinity of brine plumes adjacent to a salt stock or along the underside of a salt bed or allochthon. “Salting out” is a direct result of the increase in the salinity of the carrier fluid as the salt body is approached and the associated decrease in hydrocarbon solubility (Figure 8.12). The accumulation of oil and gas along the underside of a salt seal, or adjacent to a salt stock, drastically slows the rate of salt dissolution. Halite is near insoluble when in direct contact with exsolved hydrocarbons rather than pore waters. Such conditions help explain why hydrocarbon legs adjacent to a salt stem have a propensity to stack one atop the other with the hypersaline halo hydrology of the stem acting as a highly efficient seal. Of all the various evaporite traps, stacked salt-stem focused and sealed, steeply-inclined reservoir beds are among the most highly productive regions in the world in terms of barrels of oil equivalent (BOE) per unit area (Figure 10.45a; Halbouty, 1979).

Large-scale vertical migration of subsurface waters and crude oils via shears and fractures against salt structures was noted in the Louisiana Gulf Coast by Hanor and Sassen (1990). They concluded that the vertical upward flux of brine and hydrocarbons in this system followed fault and fracture permeability in sediments adjacent to the salt and did not otherwise move vertically through shales sandwiched between the various sand reservoirs. In the immediate region about the salt stem they found that higher salinities were localised in the same areas where hydrocarbon production occurred over and around the

Figure 8.12. Aqueous solubility of a C₄ - C₁₀ petroleum distillation fraction as a function of NaCl concentration at a near constant temperature ($\approx 195^\circ\text{C}$) and pressure (765 bars). Replotted from data in Table 4 of Price (1981).

salt domes. This implies dissolution of salt is driven by the same warm fluids rising from geopressured intervals and carrying with them the hydrocarbons to shallower depths. Thus, most of the vertical fluid transport out of the deeper levels in a halokinetic basin is focused into the zone of structural disturbance adjacent to diapir stems.

Put simply, salt stems, beds and allochthons create temperature, salinity and fracture discontinuities that induce fluid flow. As long as sediments adjacent to a subsiding/flowing stratiform salt bed or allochthon can maintain some degree of permeability, much of the more interesting subsurface hydrology occurs in and around brine haloes centred about intervals or masses of slowly dissolving salt. Ongoing dissolution, alteration and flow near the edge of the bed or stem and extending into adjacent beds creates chemical and pressure gradients that exert significant influence of the style and patterns of subsurface fluid flow. This in turn exerts a strong influence on the location and style of various hydrocarbon and metal accumulations (see Chapters 9 and 10).

Evaporites as pressure seals

Abnormal formation pressure is any pressure that exceeds or falls below the normal pressure to be expected at a given depth. A formation can only be abnormally pressured if the following conditions are met; 1) there must be porosity as the formation must have the means of storing a pressurized fluid, 2) there must be a horizontal and vertical seal. An

Fluid type	Density (gm/cc)	API (degrees)	Salinity (g/l)	Gradient (kPa/m)
Brine	1.250	-18	374	12.25
	1.20	-14	398	11.76
	1.115	-8	222	11.27
	1.125	-6	182	11.02
	1.100	-3	147	10.78
	1.075	0	108	10.54
	1.050	3	71	10.29
Seawater	1.025	7	35	9.99
Freshwater	1.000	10	0	9.80
Heavy oil	0.950	18		9.31
Light oil	0.850	35		8.33
Distillates	0.650	88		6.37
Deep gas	0.500			4.90
Shallow gas	0.300			2.94

Table 8.2. Pressure gradients of various fluid columns, including brines of different salinities.

abnormally pressured zone will be unable to retain its pressure differential if it is adjacent to a permeable boundary.

Normal or hydrostatic pressure is the pressure exerted by a column of fluid extending down to the depth of interest, for a typical porewater column it increases at a rate around 0.465 psi per foot of depth (≈ 10.5 kPa/m). Hence, the normal pressure expected at 10,000 feet is 4,650 psi; abnormal pressure at this depth would be higher or lower than 4,650 psi (32 MPa). In reality a hydrostatic pressure gradient will vary slightly depending on the salinity of the pore fluid (Table 8.2). For fresh water the gradient is 0.43 psi/ft (9.8 kPa/m) and for a salt-saturated solution it is 0.53 psi/ft (11.9 kPa/m).

Pressure gradients are classified as:

- Underpressured (subnormal): <0.465 psi/ft
- Normally pressured: 0.465-0.65 psi/ft
- Moderately overpressured: 0.65-0.8 psi/ft
- Highly overpressured: 0.8-0.9 psi/ft
- Extremely highly overpressured: >0.9 psi/ft

About 80% of the abnormally pressured basins of the world appear to be controlled by low permeability seals (Hunt, 1990). Most intervals of abnormal pressure can be related to: faults, thick shales, extensive salt seals, or various combinations. Overpressured cells are the most common type of abnormal pressure and are characterised by fluid-supported pressures (typically geopressed rather than hydropressed^{8.1}).

Underpressured cells are matrix-supported pressure seals and are not as common as overpressured cells. They may be the result of the depletion of a reservoir of all its fluids, or they can form by surface exposure of the permeable bed at a topographic depth greater than interval where the pressure is being measured or where it is penetrated by the drill bit, or they form by the uplift of a fully enclosed and compacted formation. Both underpressured and overpressured cells are sealed or isolated from their surrounds, otherwise pressures would quickly return to normal. Evaporites play important roles in this isolation due to their inherent low permeabilities. A salt unit does not generate overpressure as it lacks porosity, but due to its exceptional seal capacity can hold back substantially pressurized fluid columns.

Possible causes of abnormal pressuring in sediment pore waters held back by the evaporite seal are numerous and can overlap in the same sequence. They are:

1. *Epeirogenic Movements:*

- a) Compactional disequilibrium during subsidence associated with rapid deposition (geopressed). Porosity reduction beneath a rapidly accumulating mass of sediment is inhibited by the difficulty in expelling pore fluids from relatively impervious sediment. As water is not very compressible, most of the overlying sediment's weight is then borne by the pore water rather than the matrix so creating high fluid pressures in the undercompacted unit. Thus the creation of overpressures by compaction disequilibrium typically requires high sedimentation rates (or erosion rates for underpressure) and a permeability seal or aquitard.
- b) Uplift and topographic recharge (artesian) means that in areas of recharge (high elevation and descending flow) the fluid pressures are below hydrostatic. In areas of discharge (low elevation and ascending flow) the fluid pressures are above hydrostatic (hydropressed). If a seal is present adjacent to the artesian aquifer, then overpressure or underpressure can develop.

2. *Hydrocarbon Generation:*

Maturation of trapped organic matter generating fluids that

^{8.1} Geopressures are found in units of rock in which the free flow of fluids has been effectively prevented by either the in-situ formation of an impermeable barrier bed, or the appropriate placement of such a barrier through tectonic activities such as: folding, faulting, or diapiric action of shale or salt.

A hydro-pressured zone is a sequence where hydraulic communication to the surface is maintained and the excessive pressure is due to the weight of the overlying fluids (typically a topographic head - artesian waters).

1psi/ft=22.5 kPa/m=0.0225MPa/m=22.5 MPa/km

1MPa = 145.038 psi

cannot easily escape to the surface. Higher density kerogen is replaced by lower-density oil and gas, which requires more volume for the same mass.

3. *Clay conversion:*

Volume changes in reactions involving clay mineral transformation with the associated release of fluid. For example, under high pressure and temperature, structural water is expelled from smectite as it converts to illite.

4. *Aquathermal Pressuring:*

Water expands with temperature more than mineral grains do. Thus, as sediments are heated with burial, the expansion of water generates fluid pressure. This effect is much smaller than compaction disequilibrium and requires a near perfect pressure seal to be effective.

5. *Buoyancy Forces:*

Created by density differences between reservoir fluids.

6. *Tectonic Stresses:*

Compressive and dilational regional stresses create pressure cells.

7. *Osmotic Pressures:*

Created by membrane filtration by shales and clays with associated water flow to equalize brine concentrations.

Other than this list of possible causes our discussion will now consider only intervals of abnormal pressure where evaporites have played a role in the creation or retention of anomalous pressure, typically by acting as a highly effective permeability barrier. For a more general discussion on overpressuring, its causes and effects, the reader is referred to Hunt's excellent paper or more recent papers by Yu and Lerche, 1996 and Osborne and Swarbrick, 1997.

Unlike thick shales, evaporites better fit Hunt's (1990) definition of a true pressure seal, which he defined as an impermeable rock with zero transmissivity maintained over long periods of geologic time. Little subsalt fluid escapes through a salt mass, which until breached tends to hold back all the compactional and thermobaric waters, gases or liquid hydrocarbons coming from beds below. In contrast, shales leak all these fluids to varying degrees. Pore fluid pressures tend to rise rapidly in porous sediments beneath the rapidly aggrading salts of a basinwide evaporite seal or in fined-grained sediments accumulating atop active salt withdrawal basin (minibasin) and so both subsalt and suprasalt associations can quickly become overpressured (Figure 8.13; Burrus and Audebert, 1990; Yassir and Bell, 1994; Lerche and Petersen, 1995).

The early onset of subsalt overpressure, and consequent slowing of subsalt fluid escape means that brine-saturated shales and silts below the contact with the salt can remain unconsolidated or semiconsolidated (hence porous and overpressured) to much greater depths and ages than would compacting shales without an evaporite cover. This is the case in many Permian shale beds beneath Zechstein evaporite pressure seals in northern Germany. Drilling through sharp pressure boundaries into shales in order to reach underlying potential reservoir sands can be a problem, as can drilling through porous rafts of Permian anhydrite or overpressured dolomite suspended in halokinetic salt (Finnie et al., 2001). Despite their Permian age, subsalt Zechstein shales tend to retain fresh, highly porous and plastic physical proper-

Salt-maintained overpressure

Salts (especially halite) are second only to clathrates in ability to form effective seals to rising brines and hydrocarbons, including methane (Figure 10.4a). Sharp pressure boundaries tend to characterise the contacts with many salt seals and evaporites create the highest and sharpest depth-related pressure differentials known in sedimentary basins in both overpressured and underpressured settings (Fertl, 1976). Salt-sealed overpressured intervals can be as shallow as a few hundred metres below the surface or deeper than 6000 m.

Figure 8.13. Overpressure beneath Messinian evaporites in the Gulf of Lions in the Mediterranean, as indicated by mud densities in the offshore well drilled at kilometre 155 and by predictive modelling (after Burrus and Audebert, 1990).

ties, so that when intersected by the drill bit they are prone to severe heaving, especially below depths of 1-2 km (Thomeer and Bottema, 1961; Williamson et al., 1997).

Similar heaving shales beneath thick salt beds and allochthons are commonly encountered in the Gulf of Mexico, Russia, the Middle East, Asia and North Africa (Fertl, 1976). Overpressured rafts of porous Neoproterozoic platform carbonate and basinal silicilyte suspended in halokinetic halite are widespread in the South Oman Salt basin (Figure 10.54). In all cases the salt seal itself appears normally pressured, but its lack of permeability means it can hold back a substantial fluid column until the drill bit breaches its porous and overpressured underside. Wells through halokinetic salt are also subject to longterm creep and this too can create long term well stability problems (Chapter 12).

Some of the highest measured bottom-hole pressures (formation pressures) in the world, and some of the highest wellhead flow pressures (measured while wells are in production), are found in subsalt reservoirs. These high pore pressures can occur not just in compressed muds but in evaporite-sealed fractured and vuggy carbonates that are not particularly young. For example, highly overpressured intervals occur in deeply buried Jurassic Smackover Formation dolomite reservoirs in the gas and condensate fields of the Central Mississippi salt basin in the Gulf of Mexico region. Salt rollers in the Jurassic Louann Salt are associated with deeply buried growth faults that cut the overlying Smackover carbonate reservoirs. The faults sole above the Smackover and are cut off within the anhydrite seal (Haynesville and equivalents), and so fail to leak fluid from intervals below the anhydrite seal (North, 1985). Down to depths of 3,600 m the fluid pressure gradients approximate hydrostatic (0.465 psi/ft or 10.5 kPa m⁻¹). By 6,000 m a powerfully overpressured zone is entered and the gradient increases to 1.0 psi/ft or 20.35 kPa m⁻¹. This approximates the lithostatic (overburden) stress for that depth.

Another example of an overpressured basin in older strata lies beneath the Permian salt seal of the Tengiz oilfield in the Precaspian basin of western Kazakhstan. The structure traps some 25 x 10⁹ BBL of oil in an upper Palaeozoic carbonate platform (Figure 8.14a; Anissimov et al., 2000). It is part of the giant Palaeozoic carbonate platform of the Primorsky Bend on the northeast Caspian Coast. The reservoir is made up of Upper Devonian to middle Carboniferous carbonates that are variably overlain by a 150-200m thick shale and then sealed by thick Permian halite. This halite enables overpressuring

with pressure gradients beneath the seal of $\approx 20 \text{ kPa m}^{-1}$, values similar to those in the Smackover and once again approaching lithostatic. Gradients in the nearby water-filled Karaton structure are slightly less due to pressure loss through a breach in the evaporite seal (Figure 8.14b).

Likewise, the Permian salts of the Zechstein Group form seals to overpressured gas reservoirs in aeolian Rotliegende sands of the southern North Sea (Fertl, 1976). In the Groningen gas field in the Netherlands, one of the world's largest gas fields ($\approx 100 \text{ tcf}$), the gas reservoir is only slightly overpressured (0.5 psi/ft or 11.3 kPa m⁻¹). But formation pressures in Rotliegende sands below Zechstein salt in northern Germany are much higher ($\approx 0.9 \text{ psi/ft}$ or 20.5 kPa m⁻¹), and in some areas in the Main Zechstein dolomite (Hauptdolomit) once again approach lithostatic (1.0 psi/ft or 22.6 kPa m⁻¹).

One of the most impressive examples of the ability of an evaporite seal to generate and maintain an overpressured subsalt cell comes from the Alborz discovery in Central Iran (Gretener, 1982). The discovery well had drilled through some 400 metres of normally to slightly overpressured Tertiary salt (halokinetic) to penetrate some 5 cm into the fractured Qum Limestone (Oligo-Miocene). Then the entire drill string and mud column were blown back out the hole. At that time the mud pressure was 55 MPa (8,000 psi) at a reservoir depth of 2700 m (8,800 ft) a pressure depth ratio of 20.5 kPa/m or 0.91 psi/ft. In 82 days the well released 5 million barrels of oil and a large but unknown quantity of gas before it self-bridged and the flow died.

Some of the oldest documented occurrences of preserved overpressure, associated with producible hydrocarbons, come from blocks of Neoproterozoic silicilyte, encased within the halokinetic Ara Salt of Oman. Initial fluid pressures within fractured slivers of the Athel Silicilyte in the South Oman Salt Basin can be as high as 19.8 kPa m⁻¹ (Figure 10.54; Amthor et al., 1998).

All these older examples of salt-sealed overpressure clearly illustrate the ability of evaporites to maintain seal integrity over time frames of 250-500 Ma and atop pressure fields approaching those that induce hydrofracturing. In contrast, most compacting and subsiding shaly sediments, with permeabilities ranging from 10⁻⁴ to 10⁻⁸ darcies, are thought to be too permeable, by several orders of magnitude, to preserve overpressures for time frames longer than 200-250 million years (Lee and Williams, 2000).

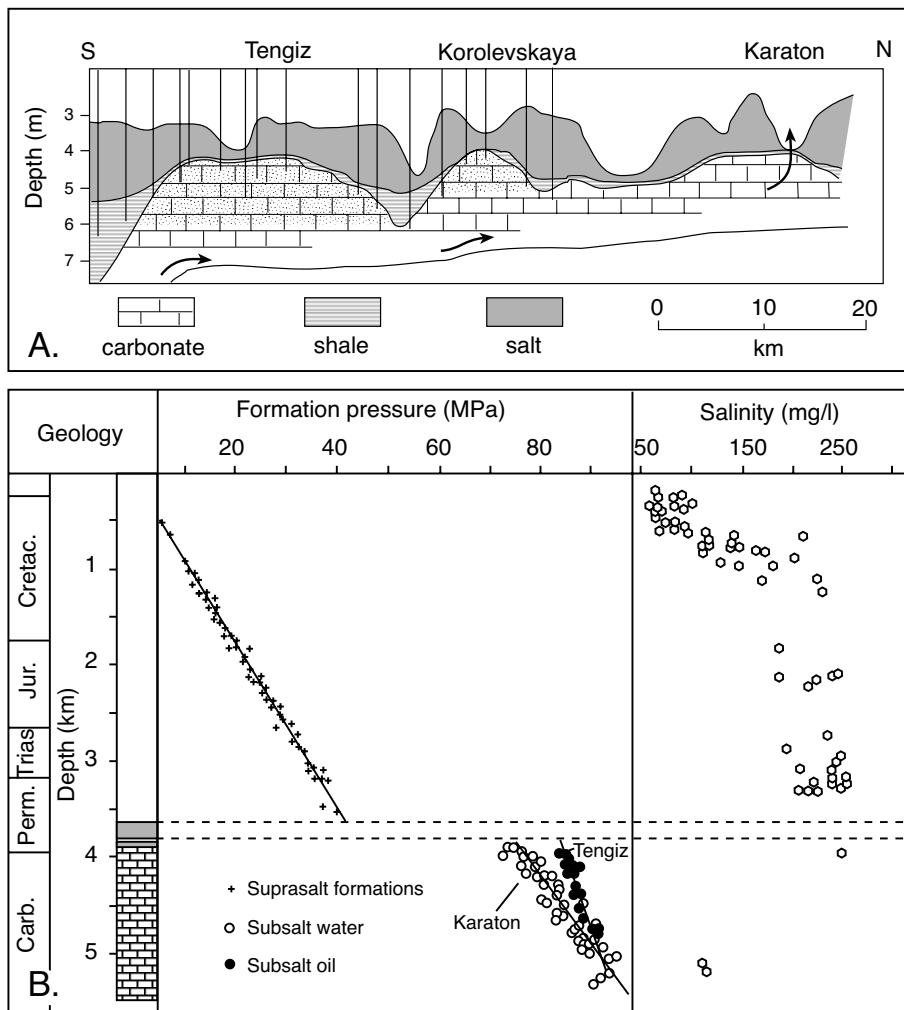

Figure 8.14. Tengiz oil field, Karzakistan. A) East west cross section showing how the evaporite seals the oil in a number of carbonate buildup traps. When the salt is breached at the Karaton structure the oil has escaped and the structure is water filled. B) Measured pressure plotted against depth, clearly shows the base of the evaporite (shaded grey) is the top of the overpressure (after Anissimov et al., 2000).

If hydrofracturing occurs with associated pressure release, growth-pulsed fibrous cements of halite, gypsum and carbonate may precipitate in new fracture nets immediately beneath the evaporite seal. But in systems where the evaporites are subsequently dissolved only carbonate vein fills and their fracture nets will remain as brittle sediment indicators beneath a layer of dissolution breccia or insoluble residues.

Salt's impervious nature and its ability to flow, while intrasalt beds fracture, leads to interesting pressure scenarios wherever rafts are caught up in masses of halokinetic salt. Fracturing of intrasalt beds and encasement in flowing salt is an

inherent mechanism in almost all autochthonous and allochthonous salt masses (Chapter 6). It explains unexpected pressure rises when drilling through thick sequences of salt on the way to testing subsalt hydrocarbon traps or creating purpose built salt storage cavities (Chapters 10 and 12 respectively). Porous blocks intersected in drilling halokinetic salt can be isolated or clustered (Figure 8.15). Common practice is to bleed them down, since they usually have limited extent within the salt mass. At the well site the observed rate of depletion should give some idea of how long the process may take. In the worst case scenario one raft will “blow-out” into another leaving the rig operator to wait until equilibrium is established. Generally, no pressure transitions are observed prior to drilling into a raft, reflecting their isolated nature within the salt.

In the Zechstein, for example, the Z3 bioclastic layer of dolomite, Plattendolomit, is deposited on top of the Z2 Stassfurt halite (Figure 5.48). A CaSO_4 layer was precipitated as gypsum, followed by the Z3 evaporites and the Leine halite (Finnie et al., 2001). Water from the gypsum was expelled as the sulphate dewatered and transformed into anhydrite. The overlying halite did not permit the upward movement of this water and so it forced into the adjacent porous platy dolomites. The Plattendolomite, already contained fluid and so excess fluid was accommodated in part by pressure-driven leaching.

When the Zechstein's most mobile salt layer, the Z2 Stassfurt halite, begins to move, it carries with it the overlying Platten/

Figure 8.15. Likely distribution style of isolated overpressured blocks of deformed and fractured intrasalt beds (shaded grey) in a diapir or salt wall (based in part on modeling of Koyi, 2001).

Hauptanhydrite, which begins to buckle and deform much more brittlely than the surrounding halite. Eventually these intrasalt beds fractured into discrete rafts and were carried along by the flowing Stassfurt salt as it pierced the base of the Z3 (Figure 8.15). Rafts floating in the salt becomes overpressured by either; i) being uplifted to shallower depths where they continue to hold their deeper pressures because of the surrounding impermeable salt, or ii) overpressures are generated in the raft by the folding and squeezing nature of almost all subsurface salt creep in the inverted structures of the North Sea (Chapter 6).

As well as these examples of overpressure associated with older evaporites, overpressure readily develops in salt-sculpted Tertiary basins, as occurs beneath some, but not all, shallow salt allochthons in Green and Mahogany canyon regions in the Gulf of Mexico (Figure 6.22a; Beckman, 1999). Where salt allochthons are climbing the stratigraphy, subsalt sealing and associated overpressure can occur beneath the salt mass at higher levels than is achieved in overpressured shale basins. Extreme overpressuring is commonplace in subsalt settings in the Gulf of Mexico at depths of 3000-4000 m. Gas being generated at greater depths in these regions can be trapped under the salt seal at pressures approaching lithostatic. It means drilling under the allochthonous salt on the Gulf Coast slope can intersect undercompacted sediments that are moderately to extremely overpressured (Hunt et al., 1998). This influence of Jurassic salt on pressure gradients in the Neogene stratigraphy of the Gulf of Mexico is seen in the increased mud weights typically required for safe drilling once an evaporite allochthon is breached by the drill (Table 8.3). Most wells intersecting salt allochthons in the deepwater realm of the Gulf of Mexico are overpressured at some depth below the base of salt with mud weights controlling pressures ranging from 14 to 17.5 ppg.

In the offshore Mahogany area, salts sheets are encountered below 2,300m (7,500 ft) seafloor with an average thickness of 1,150 m (3,800 ft; Walton and Urband, 1997). The interval of disturbed sediments (gumbo), first sealed below the salt as the allochthon sheet rolled into place across the seafloor, now extends 300-500 m (1,000-1,500 ft) below the salt base. Formation temperature at the salt base is around 75°C (170°F). Rotary sidewall cores in the salt show the salt is very dense and competent. Fracture gradient checks performed in and below the salt mass by pump-in leak-off tests, approach 0.988 psi/ft (19 ppg). The fracture pressure is only 0.5 ppg higher than the pore pressure in those wells. Yet in other subsalt wells the

underlying disturbed sediments cannot support a mud column of 16.9 ppg (0.879 psi/ft gradient). Pore pressure gradient decreases as drilling progresses below the salt, until the sediments became more competent and less affected by the influence of early sealing beneath the salt allochthon trap.

But subsalt pressures in allochthon basins are very unpredictable, as it is not the salt itself that generates abnormal pressure (it lacks porosity). The overpressure comes from the inability of basinal fluid to move through the salt mass or to drain freely from thick underlying shales. For adjacent sediment to be abnormally pressured, fluid must be generated by compactional or thermobaric processes in the sediments beneath the salt. The salt mass itself is only the barrier to this escaping fluid. So, where sediments immediately below a salt mass are not carrying overpressured fluids, the contact with the salt is not overpressured. In fact, lower than regional pressure gradients can be found below some salt allochthons, as well as the more typical higher pressures. For example, a few subsalt wells in the Mississippi Canyon have mud weights indicating much lower subsalt pressures (11 to 12.5 ppg mud weights). Such lowered pressures may indicate zones of rapid salt solution and creation pore space via dissolutional collapse. Nor can overpressure be correlated to the thickness of the overburden atop a salt allochthon. The only generalisation that can be made is that, if abnormal pressures are present immediately beneath or adjacent to a salt mass, the pressure boundary will typically be sharp and correspond to the contact with the salt mass.

Thick shale-rich suprasalt successions in the withdrawal sinks (minibasins) of some more deeply buried salt units are also overpressured (Figures 6.30, 6.31). Shale-sealed sands sometimes show evidence of permeability connections through shale gouge zones about salt masses. Shaker (2004) argues that at the scale of salt-rooted minibasins, higher pressure gradients tend to occur in areas where the salt was present, while lower gradients tend to occur in areas where the salt has been withdrawn into adjacent allochthons. But this is a dynamic situation in which seal rupture (often along growth faults in the edges of minibasins and atop a zone of thinned salt) is followed by a cycle of fluid movement, a pressure drop, resealing, and renewed pressure buildup from the continuous generation of thermogenic gas. It creates dynamic pressure regimes where overpressuring beneath salt allochthons can occur a number of times in the minibasin history (McBride et al., 1998a, b).

Such an active growth fault at the edge of a salt-cored minibasin creates a fluid conduit to the numerous shallower reservoirs in Eugene Island South Addition Block 330, offshore Louisiana.

The fault was intersected and sampled at a depth of 2460 m in the extended "Pathfinder" well (Figure 8.16; Anderson et al., 1994). Oil and gas in this region is being produced from Neogene reservoirs as young as 400,000 years old and the field is located beneath numerous active seafloor seeps. Eugene Island is the largest Pleistocene oil field in the world and is surrounded mostly by gas-dominated fields in the south additions of offshore Louisiana. More than 600 million BBL of oil equivalent has been produced from this field since its discovery in 1971 (Figure 8.16a, b). Sediments filling the minibasin consist of alternating sequences of sands and shales that are likely floored by deepwater turbidites from the ancestral Mississippi River delta. The studied fault sits atop a breached salt allochthon and defines the edge of a classic Gulf Coast minibasin (Figure 6.58).

In spite of the removal of what was once an underlying salt allochthon via earlier salt evacuation, deeper sediments are still geopressured. The pressure buildup reflects ongoing rapid deposition of thick deepwater shale above the evacuating salt allochthon. Rapid mud deposition produced permeabilities in the lower part of the minibasin fill that were too low for the compacting pore fluids to escape. Oil and gas today still seeps from silty shales adjacent to the fault zone, which are naturally fractured. Coring revealed that fracturing extends at least 100 m from the growth fault into the shales of the upthrown block. Hydrocarbons in the fault zone are geochemically identical to those sampled from producing reservoirs located within sands that abut shallower splays of the same fault zone system (Figure 8.16b, c). Hydrocarbons did not flow from the growth fault at economically viable rates during drillstem tests. Analysis of fluid pressures shows that the main 'A' fault is currently a profound lateral permeability barrier, with an 1800 psi water pressure differential across it. Even so, Anderson et al. (op cit.) noted that the larger the drawdown pressures applied across perforated intervals, the lower the permeabilities of the fault zone. Flowable hydrocarbons are present and must be partially supporting the matrix. The balance between tectonic stresses and pore pressures, within the relatively tight zone defined by the growth fault, was found to be such that with an increase in pressure of 500 psi or so, large volumes of fluid could be transmitted from depth, suggesting a method that may allow production from such deep zones in the future.

Pressure data in Block 330 supports the notion of periodic fluid flow in the fault being driven by "seismic pumping" within salt-floored extensional basins. The term seismic pumping comes from an analogy to a hand-driven water pump used to raise water from a water well. As the handle of the pump lifts the piston

Figure 8.16. Growth fault characteristics, Block 330 Eugene Island, Louisiana. A) Structure contour map of O1 sand, showing position of the Pathfinder well. B) Southwest-northeast cross section AA' showing Pathfinder (A20ST) and A6ST well trajectories, the 'A' fault, subsidiary structures and selected sand tops. it creates a low pressure region that draws in water across a one-way valve into the pump cavity. Then as the action of the handle is reversed it compresses the water beneath the piston forcing water out of the pump faucet. Likewise seismic pumping is related to cycles of dilatancy and fault release in the region of the fault. Extensional dilatancy in the fault and its vicinity draws in pore waters (and hydrocarbons) from its surrounds. This is followed by an episode of fault release, whereby overburden loading now compresses and drives water up along the fault into higher levels. Hence, with seismic pumping active in a normal fault or growth fault, the episode of fault release (earthquake) drives fluid up along the steeply dipping fault.

Seismic pumping of fluid is also possible in a reverse fault or thrust scenario. Once again the time of fault release is the time when fluid is sucked into the fault plane ("squeegee mode" mentioned earlier). But the low angle of the thrust means it does not easily drain up the fault to the surface but remains under subsequent compression to act as a fracture propagator, as evidenced in multistage fracture filling mineralisation associated with the thrust. This is especially so in sediment beneath salt-lubricated (and sealed) thrusts.

Based on their studies of the Eugene Island growth fault, Anderson et al. (1994) and Losh et al. (1999, 2002) concluded that hydrocarbon migration associated with the fault was episodic. It was driven by pressure increases deep within the

geopressed turbidites of the subsalt play, which rose until stresses reopened fractures in the various fault zones that connected with the upper reservoir chambers. At that time, large volumes of hydrocarbons were released rapidly as transient bursts towards the surface. With each pressure release, the faults closed back up. Losh et al. (1999) modelled coupled heat and mass flux in the A6ST well and concluded that the palaeothermal anomaly in the fault zone was short-lived, having a duration of less than 150 years. The anomaly could have been produced by a $2 \times 10^6 \text{ m}^3$ pulse of fluid ascending the fault at an actual velocity of over 1 km/yr (darcy flux of 330 m/yr) from 3 km deeper in the basin. Simple Darcy law computation indicates transient fault permeability on the order of 110 md during this flow. Pulsing of fluid up weld-floored growth faults is probably the norm. Put another way, with added pressure, fluid (including oil and gas) is expelled up the fault zone, but then the very act of releasing the fluids drops the pressure and the fault becomes tight once more. Over and over, the cycle repeats. A pulse of high-pressure fluid ascending the fault lowers effective stress in the fault zone sufficiently to produce a significant transient increase in fault permeability. If the fluid is in an area of the fault adjacent to downthrown, relatively low pressure reservoir sands, the fluid will discharge into them. Permeability in and adjacent to the fault then decreases, such that fluid cannot re-enter the fault zone and escape from the reservoir.

On the broader scale, salt's ability to deform with its accumulating overburden into growth fault-defined minibasins means pressure cells in suprasalt sediments not only show episodic changes in a high-gradient vertical pressure transition, they can also be subject to rapid lateral changes in pressure. Many lateral seals in this situation are subvertical and tend to follow fault trends with their geopressed tops sometimes defined by high temperature carbonate cements. Using a 3D model of fluid flow history in the Eugene Island area, Anderson et al. (1991) concluded that many convective heat flow anomalies at the surface indicated the upward movement of hot subsurface fluids along various salt-floored growth faults. Many of the larger fluid compartments in this laterally restricted system consist of a series of smaller compartments, each with a single top seal and several side seals, which are active growth faults (Gordon and Flemings, 1998). Similar episodic salt movement of various fault-defined pressure cells within the Jurassic Smackover Formation, atop the Louann Salt of the Mississippi Salt Basin, US Gulf Coast, has created a boxwork of large fluid compartments. Adjacent internal pressures ranging from normal (hydrostatic) in one compartment to 70 MPa (10,000 psi) above normal on the other side of the fault.

Pressure changes and drilling

When attempting to control bottom hole pressures during drilling, overpressures beneath evaporites are more of a problem to predict than when drilling thick variably pressured shales (e.g. Zilberman et al., 2001). Most current overpressure control methods, which use slightly overbalance methods of mudweight to minimise formation damage, were developed in shale sequences where there is typically a well-defined transition over tens to hundreds of metres into the zone of overpressure. Transitions are often identifiable by changes in resistivity, density and sonic signatures in MWD (measurement while drilling) logs. Close monitoring of bottom hole pressure and the recognition of this transition zone allows the drilling engineer to set casing, if needed, and to increase mud weight before entering the zone of overpressure. Evaporite seals can be much thinner (down to 3 m), with sharp pressure transitions at their lower boundaries. A sharp dissolutional contact along the underside of almost all thick evaporites and the inherent ability of a salt mass to support high fluid overpressure beneath intervals as little as 3-4 m thick means there can be little, if any, development of a pressure transition zone. Highly pressured sediments can be entered immediately below the base of the evaporite (e.g. Alborz discovery, Iran), whereas pressures appear normal as the evaporite is drilled.

If a basal anhydrite (upside-down caprock; see Chapter 7) has developed on the underside of a halite mass, there may be a slowing of the drill penetration rate immediately prior to entry into the overpressured interval. However floating anhydrite or dolomite rafts in diapiric halite also slow drill penetration rates. In one situation pressure tends to bleed off with time; in the other the well is susceptible to a major blowout.

Low strength casing set in a thick halokinetic salt mass, which tends to heave over time, will deform and can even shear during the active life of the well. Likewise, "drilling on" through heaving and often geopressed shales beneath a salt allochthon (gumbo) is a challenge for the drilling engineer, further compounded by the possibility of encountering heaving intrasalt "shales" or overpressured intrasalt anhydrite and dolomite rafts on the way to the lower contact (e.g. Seymour et al., 1993; Zilberman et al., 2001). Salt is also a good conductor of heat and impacts the local geothermal gradient (see later). It may be that heat is conducted to trapped formation fluids below the salt, so that overpressure of porous intrasalt rafts is further enhanced through restrained thermal expansion of these "shale" beds.

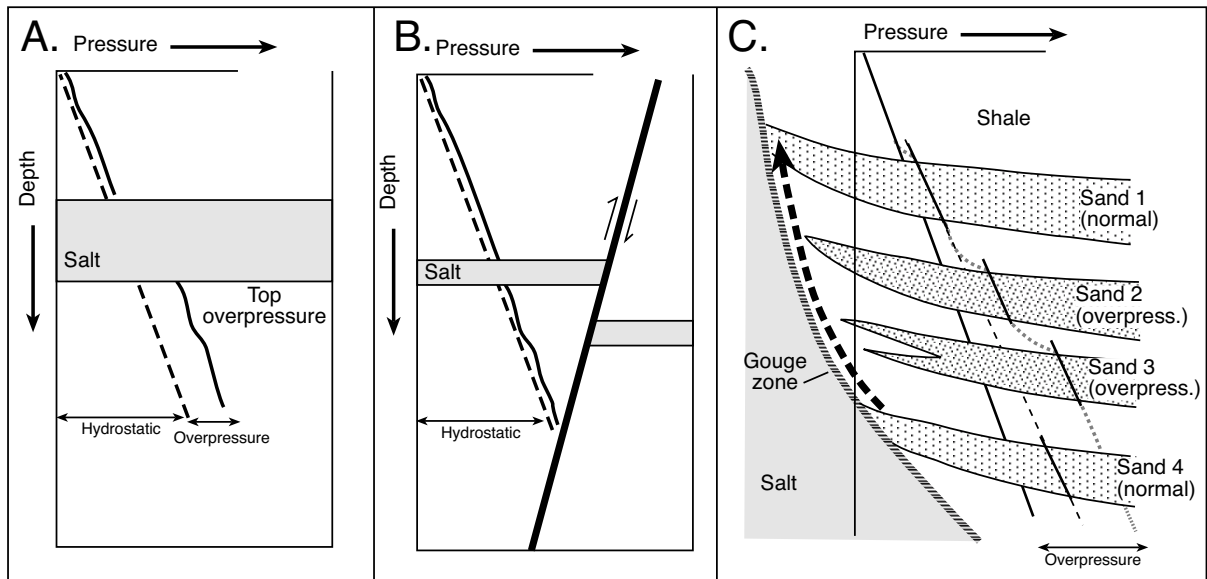

Figure 8.17. Pressure profiles of various evaporite profiles. A) Overpressure beneath a thick laterally extensive salt bed or allochthon. B) Normally pressured beneath a thin discontinuous (faulted) salt layer. C) Overpressure in suprasalt sands encased in shale. Sands which are in contact with the shale gouge tend to be in pressure connection, while those which are not are independently pressured (in part after Shaker, 2004).

Important factors controlling subsalt pressure distribution below both primary beds and allochthons are:

- Lateral extent and thickness of the salt body (Figure 8.17a; diameter of drainage collection)
- Presence of areas of halokinetically thinned, or faulted or discontinuous salt (Figure 8.17b; leakage)
- Depth of salt burial, salt buried at shallower depths (>1-2 km) may not have developed widespread overpressured intervals in the underlying sediments (with allochthons this is often due to a lack of lateral or updip seal)
- Rate of burial, slow burial may have allowed overpressure to dissipate in the subsalt beds
- Presence of a widespread sand-rich section underlying the salt may facilitate drainage and loss of pressure. More laterally restricted sand-rich sections under the salt can form both an excellent trap and reservoir for hydrocarbons (Figure 8.17c)
- Presence of a shale sheath or gouge about a salt structure. Suprasalt sands that connect to this gouge may be overpressured but tend to be in pressure connection. Intervening sands that are unconnected to the gouge can be independently overpressured (Figure 8.17c).

In summary, any actively subsiding and rapidly filling sedimentary basin containing widespread thick evaporite beds or allochthons is prone to subsalt overpressuring. The evaporite bed typically becomes the top of a shallow zone of geopressure and an evaporite in this situation can be thought of as a pres-

sure seal. An evaporite's ability to act as a pressure seal and so create overpressure in the underlying sediments can begin once the underlying sediment enters the zone of compactional dewatering and can continue well into the thermobaric regime. Salt's ability to act as a pressure seal is destroyed once it dissolves or its lateral continuity is breached, as occurs during salt allochthon evacuation. However the process of salt evacuation is often rapid and facilitates deposition of rapidly-emplaced thick deepwater muds within the lower parts of the minibasin fill. Growth faults, first instigated by the salt evacuation and soling into the salt weld, continue to act as escape foci for episodic pulses of upward-flowing hydrocarbon and metal-rich waters, even after the salt has moved on. Zones of salt breaching begin as foci for escaping pressured and metal-rich basinal fluids, they continue to act as episodic suppliers of volatiles, which typically move upward with the escaping basinal waters via the salt welds and growth faults that cut through the evaporite bed.

Salt-generated Underpressure

Most naturally underpressured cells are created by a combination of uplift and erosion or glacial rebound. Pressures in an underpressured interval are less than would be expected if a normal hydrostatic gradient was present. Reduction of lithostatic load in natural situations is most often related to erosion of a low permeability sediment pile, this typically creates an elastic

dilation of rock-pore volumes and so induces underpressuring. In regions of former ice sheets, fluid underpressuring is often tied to a rapid load reduction via melting of the glacier and associated isostatic rebound. Anthropogenically induced underpressure is often associated with hydrocarbon extraction.

One of the most striking examples of salt-associated underpressuring comes from the Keyes Field in the Oklahoma Panhandle. It has produced gas from a depth of 1460 metres (4790 ft) for more than 50 years and its pressure-depth gradient is shown in Figure 8.18 (Hunt, 1990; Powley, 1980). Keyes Field is located in an area of the Amarillo Uplift that rose by around 1500 m (4,920 ft) during the Laramide orogeny and later cooled. Fluid pressures above the Keyes gas sand and down to the Blaine Anhydrite show a normal gradient of 44.5 psi/100ft. Below the Blaine there are two anomalous pressure cells. The upper anomalous cell extends from the base of the Blaine Anhydrite to the top of the Wellington Salt seal (at a depth of 853 m or 2,800 ft). Fluid pressure at its top (≈ 1000 ft - 305m depth) starts at zero and increases down to the top of the Wellington Salt. The gradient in this upper cell is 44

psi/100ft. The lower cell extends from the base of the Wellington Salt to the top of the Precambrian basement. Beneath the Wellington Salt pressures once again start around zero, then increase along a gradient of 0.465 psi/ft (10.5 kPa/m). Overall the Keyes Field is underpressured for its current depth by some 9 Mpa (1,300 psi). Lithologies at the base of each of the pressure cells support the full weight of the overburden.

That both evaporite beds are acting as highly effective seals to their respective pressure regimes is indicated by the fact that fluid pressures start again at zero in the zone immediately beneath each evaporite. In terms of hydrocarbon components, underpressured compartments are important in that they indicate isolation of rocks in the underpressured cell, prior to extraction this isolation has prevented water washing and biodegradation of accumulated oils at depths where these processes would otherwise be important influences on oil quality.

Temperature anomalies and brine flow

Thermal anomalies associated with buried salt have been known since the 1930s (Hawtof, 1930) and can have significant influence on the maturation state of source rocks for hydrocarbons. Such anomalies are related to halite's higher thermal conductivity compared to most rock types (Figure 8.19a). Thermal differentials drive basin fluid circulation, especially in sediments adjacent to interval of halokinetic salt. At room temperature the thermal conductivity of salt is typically three times that of adjacent shales. At 150°C its thermal conductivity is about two thirds of its 25°C value and still more than twice that of an adjacent now compacted shale. Thus a salt bed or salt structure, with its much higher conductivity, exerts a strong influence on the thermal depth profile in an evaporite-en-training basin (Figure 8.19b).

When conductive salt remains as a bed, it raises the temperature gradient in sediments atop the salt bed, lowers the temperature gradient in the salt layer and makes beds below the salt layer cooler than they would be if the salt was not present (Mello et al., 1995). For example, with a 1 km-thick salt bed encased in shale, sediments below the salt are 20°C cooler than they would be if salt were not present (Figure 8.20a). According to Mello et al. (1995) the cooling effect is proportional to the thickness of the salt layer. All subsalt sediments are subject to non-transient cooling effects that last as long as the salt remains. Such temperature differences obviously affect organic maturation in sediments above and below the salt layer.

If the salt bed has flowed and a salt diapir is present, but with its crest buried well below the sediment surface, the conductive spine

Figure 8.18. Pressure-depth gradient for the Keyes gas field, Cimarron and Texas counties, Oklahoma. Underpressured intervals are due to uplift and the maintenance of isolated pressure cells across evaporite aquicludes (after Hunt, 1990, Powley, 1980).

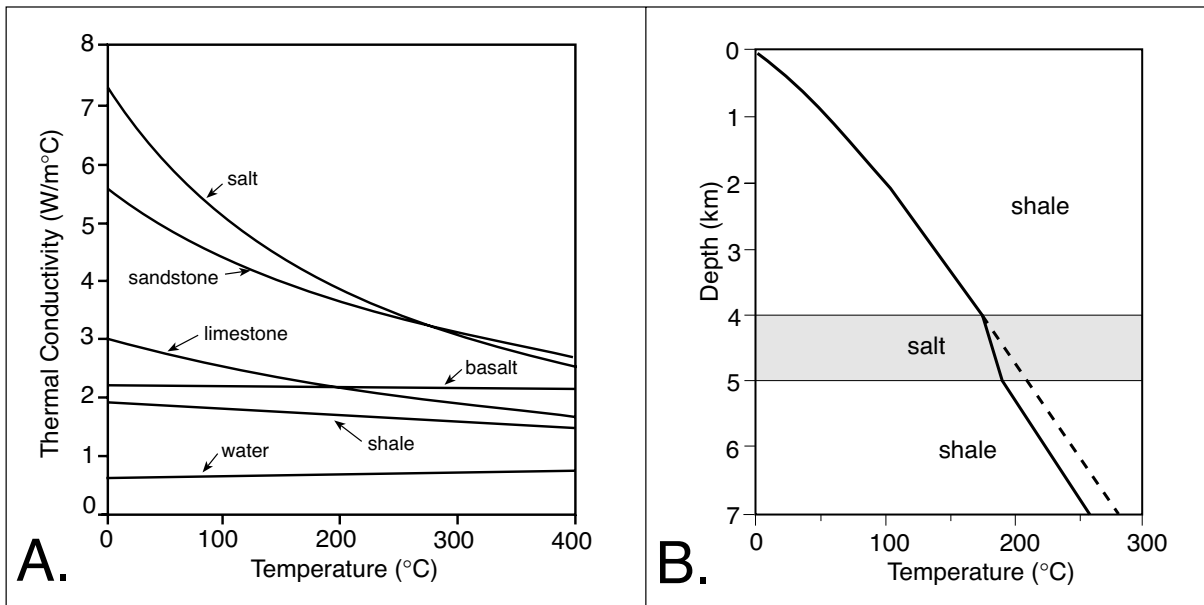

Figure 8.19. Thermal properties of salt. A) Thermal conductivity of various rock grain types (zero-porosity lithologies) and water as a function of temperature. B) Vertical steady-state temperature gradient for a shale section with salt (solid line) and without salt (dashed line). The temperature plot (A) was used to construct the steady state profiles of Figures 8.20 and 8.21 (after Mello et al., 1995).

of salt sets up a thermal dipole with a positive anomaly atop the spine and a negative anomaly at its base (Figure 8.20b). Sediments atop the spine are hotter than they would be without the salt, while sediments below the structure are cooler. Elevated vitrinite reflectance values above buried salt structures have been recognised in the oil industry for many years. However, the cooling effects on beds below a salt bed, diapir or sheet were largely ignored until the work of Mello et al. (1995).

If the diapir crest is at the sedimentation surface, as it is during the passive salt diapir stage, the structure acts as a thermal monopole. The salt spine acts as a sink that channels or drains heat to the surface (Figure 8.20c). In this situation temperatures around and beneath the salt spine and its source layer are less than would exist in a basin without salt. The amplitude of the negative anomaly locally reaches -85°C and its cooling effect extends out for more than three times the diameter of the salt spine (Mello et al., 1995).

The contrast in thermal regimes where a thermal dipole is created when the salt crest is deeply buried versus a monopole where the crest is at the surface raises the question, how close to the surface need a diapir crest be before it starts to act as a heat sink rather than a heat source? Modelling by Mello et al. (1995) suggests the following rule of thumb; the maximum negative anomaly amplitude is reduced $10\text{--}15^{\circ}\text{C}$ for every

250 m of increase in the depth to the top of the salt spine (assuming a shale-rich host). The amount of heat drained from a basin is thus sensitive to the depth to the top of a salt structure and the length of time for which the salt remains at or near the surface before the structure is buried. Basins characterised by syndepositional salt flow and the maintenance of salt spines near the surface will produce the coldest situation with respect to subsalt sediments. This mechanism may help explain why many oil-prolific salt basins still produce large amounts of hydrocarbons today, when some thermal calculations, which do not account for salt effects, suggest that most of the known source rocks in the basin should be overmature (Mello et al., 1995).

Of course, simple salt spines, as modelled in Figure 8.20b and c, are usually part of a much more voluminous allochthonous salt complex, where salt sheets form layers or tiered canopies at a number of different stratigraphic levels. Figure 8.21 presents a thermal model for such a system based on structures in the Gulf of Mexico. The salt sheet is modelled as a steady-state regime in a shale host; it lies within 500 m of the sediment-water interface and still connected with the mother salt bed. It should generate three negative thermal anomalies (Mello et al., 1995):

- a negative thermal anomaly beneath the salt source layer (mother bed);

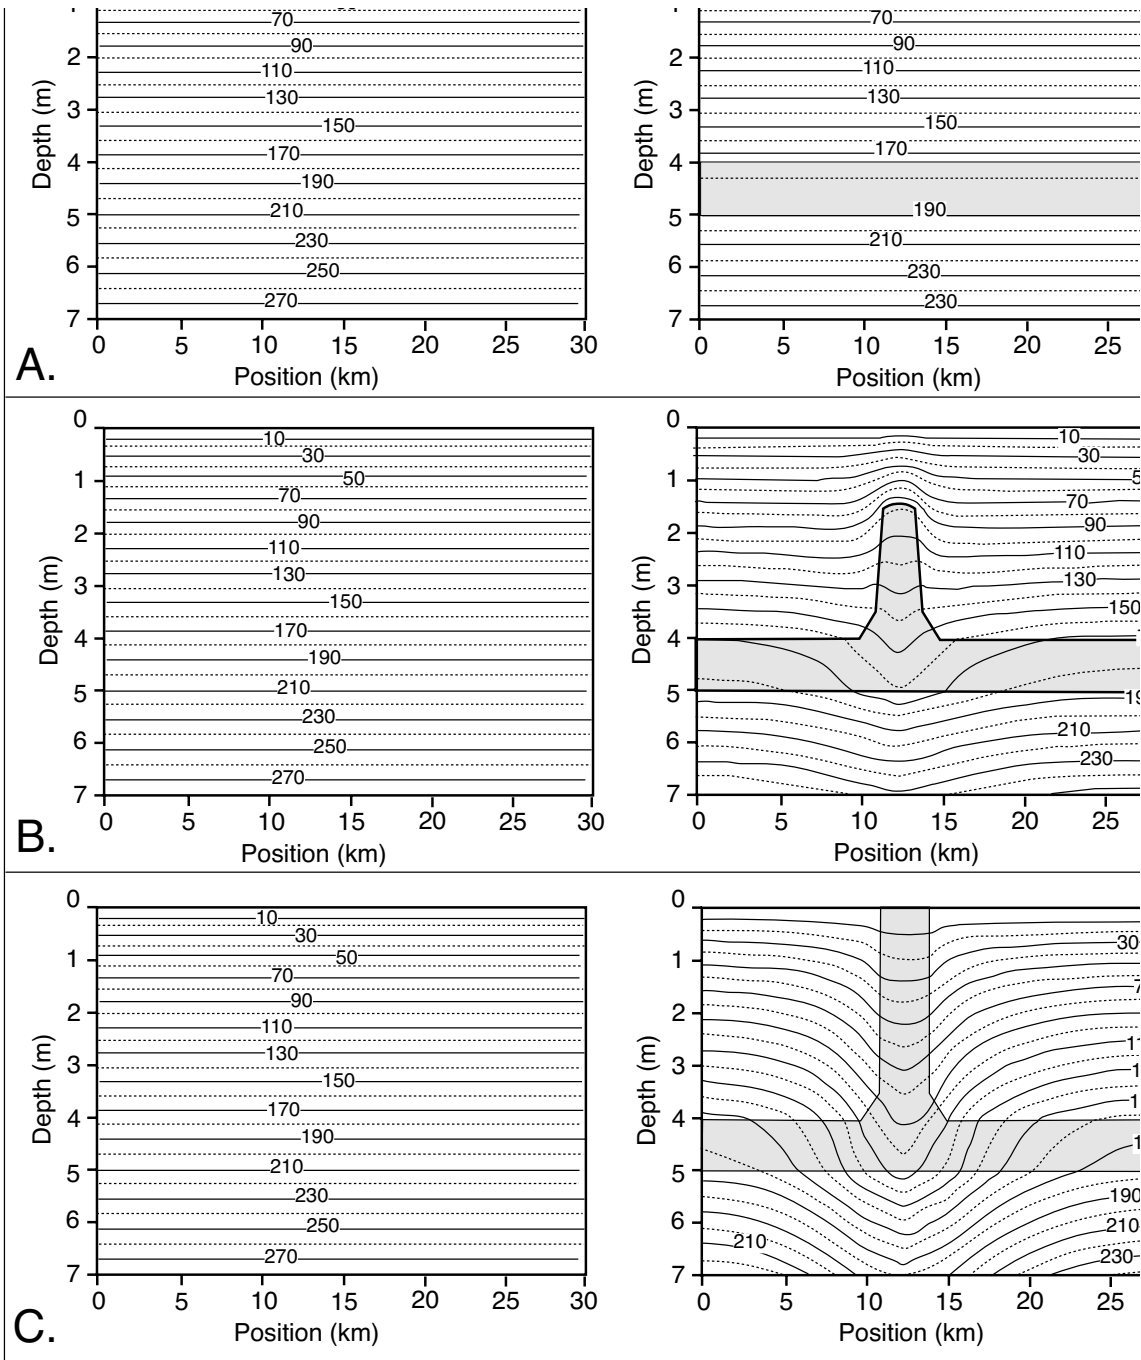

Figure 8.20. Model of steady-state temperature distribution for a shale section containing salt with varying geometries (shown on right hand side) versus the same shale section with no salt (left hand side). All calculations use shale and salt thermal properties and gradients given in Figure 8. A) Salt layer, note that sediments below the salt layer are 20°C cooler than in a shale section with no salt. B) Salt diapir that is connected to its source layer and is not in contact with the surface. Notice the elevated temperatures atop the salt spine and the reduced temperatures beneath the spine - a thermal dipole. C) Salt diapir that is connected to its source layer and is also at the sediment surface. The salt spine acts as a highly efficient heat drain that collects and channels heat from around and beneath the spine and delivers it to the surface. In this situation there is no heating associated with the spine, only cooling - a thermal monopole (after Mello et al., 1995).

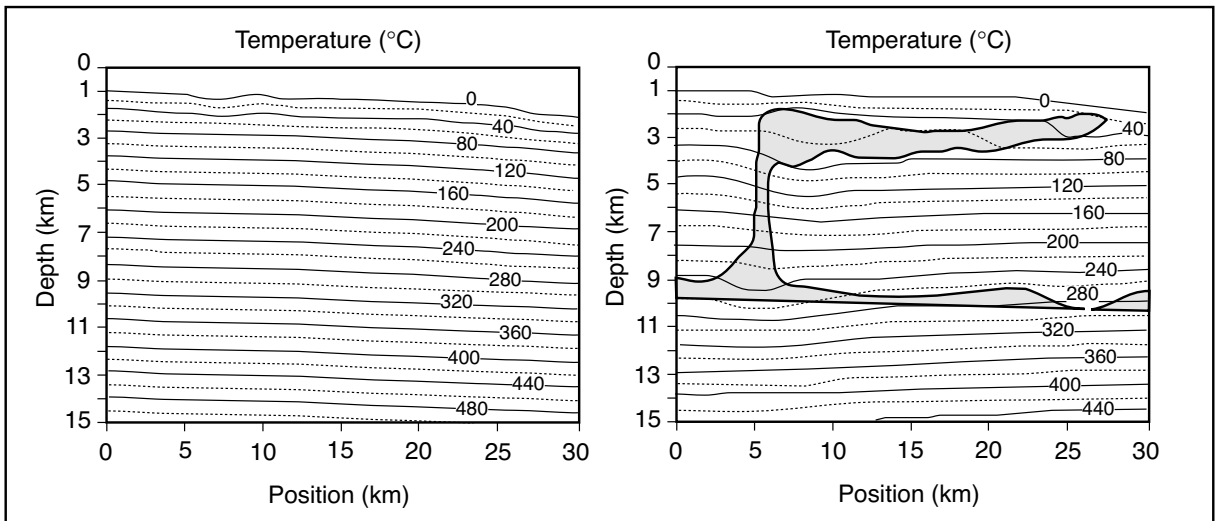

Figure 8.21. Model of steady state temperature distribution created by the emplacement of an allochthonous salt sheet (right hand side) versus profile in a shale section with no salt (left side) Three major negative anomalies are associated with this geometry: a zone of cooling beneath the sheet; a negative or cooling anomaly associated with the dome, which feeds the sheet; and a zone of cooling beneath the lower sheet (after Mello et al., 1995).

- a thermal anomaly associated with the salt stem that feeds the allochthonous salt sheet;
- a thermal anomaly below the salt tongue itself.

There are also some positive anomalies above the salt dome and its tongues, but these are small ($<15^{\circ}\text{C}$) compared with the magnitude of the negative thermal anomalies. The minimum anomaly with the greatest magnitude is $\approx 82^{\circ}\text{C}$ located directly beneath the salt dome (Figure 8.21; position 5 km, depth 10 km). The salt source layer or mother bed contributes only -10°C of the thermal anomaly in the deepest parts of the section. Constructive interference between the salt sheet and the feeding salt spine creates a local thermal anomaly of -55°C at the inside inflection point of the two structures (Figure 8.21; position 7.5 km and depth 4.5 km).

Fluid flow in halokinetic basins

Temperature models do not just indicate the maturation state of source rocks, but as most subsurface heat in a sedimentary basin is transported by fluid flow, also define fluid flow patterns in the subsurface. The thermal anomalies around salt structures by definition also drive brine flow and may be enhanced by density plumes created during salt dissolution (Figure 8.11).

Suprasalt fluid flow and alteration

Like dissolution from the underbelly of a salt layer, dissolution atop and adjacent to a salt spine can create free convecting density plumes in adjacent minibasin sediments (Figure 8.2c). In this case the thermal drive created by the thermal anomalies interacts with the density drive to speed up flow rates in fluids convecting adjacent to the salt spine. If the crest of a diapir has risen to where it lies once again in the active phreatic flow regime, intense dissolution-generated plumes can set up at even shallower depths. Both scenarios generate dense plumes of chloride-rich brine.

Using a dense network of well log data collected in the vicinity of the Bay St. Elaine salt dome in SE Louisiana, Cassidy and Ranganathan (1992) calculated salinity profiles in various strata surrounding the now buried dome crest (Figure 8.22). Salinities range from approximately 4 to 12 wt.%, with most isosalinity lines sloping away from the salt dome. On the southwestern side of the dome (cross sections OA and OC), salinities are 2-4 wt.% higher at a given depth than on opposite sides of the dome, possibly reflecting a greater rate of salt dissolution and enhanced fluid transfer of heat. Lowest salinities occur on the northeastern side (cross sections OA' and OC', Figure 8.22). On all sides of the dome, salinities increase with depth from the shallowest sands to a surface that roughly coincides with the top of overpressured sediments. Within the overpressured section, salinities decrease as depth increases, to levels on some flanks that are one-half the maximum value found in the

hydrostatically pressured zones. For example, the saltiest waters in cross section OC have a salinity of 12 wt.% and occur just above the shale sheath. Within the shale sheath, salinities of interstitial waters are as low as 6 wt.%. Similarly, in section OC', the saltiest waters have a salinity of more than 10 wt.% at a depth of 3 km. In hydrostatically pressured sections on the southwestern flank (cross sections OA and OC) and the northwestern flank (cross section OB), salinities are greatest near the dome and decrease away from the dome. In the overpressured section as well as in the shallower parts of sections OA' and OC', salinities are lowest adjacent to the dome, and increase away from the dome, perhaps reflecting a salt-stem-focused resupply of freshened waters from below. Salinity contours are deflected downward near the fault on the southeastern side of the dome (cross section OB'), but seem unaffected by the faults on the northeastern side (cross section OA').

In a hydrostatically pressured section, one would expect elevated salinities near the salt dome, assuming that the dome is the major source of dissolved salt (Hanor et al., 1986). However, the observed salinity distribution (Figure 8.22) in the vicinity of the Bay St. Elaine dome cannot be explained merely by radial diffusion^{8.2} of salt as it is dissolved from the dome into a static downwelling fluid column. With radial diffusion, the salt concentration should be highest near the dome and decrease away from the dome. A common observation in the subsurface waters of the Gulf Coast is that salinities of interstitial waters in the overpressured suprasalt section are actually lower than salinities of waters at the base of the hydrostatically pressured section (Figure 8.23; Hanor et al., 1986). However, the lobe of relatively fresh water (salinity of less than 6 wt.%) next to the dome in cross sections OA' and OC' (Figure 8.21) dips too steeply to be explained merely by the slope of the overpressured section near the dome.

Cassidy and Ranganathan, (1992) argue that the observed salinity pattern and Bay St. Elaine indicates fresher overpressured pore waters are now escaping upward in a halo around the diapir, especially on the northeastern flank of the dome (cross sections OA' and OC'), where the areas of highest salinity are separated from the dome by relatively fresh (salinity of less than 6 wt.%) pore waters. The low salinity of waters immediately adjacent to the northeastern flank of the dome also may

reflect a greater degree of insulation of the salt dome from dissolution on this flank. They note an alternate explanation is that the pore waters may be upwelling at a slight distance away from the salt-sediment contact, thereby retaining their low salinities as they ascend. The presence of faults on the northeastern side (cross section OA') does not appear to affect the salinity contours. There are not enough control points under the fault in section OB' to evaluate the sealing versus nonsealing nature of the fault.

The salinity field documented about the Bay St. Elaine dome is in striking contrast to the salinity fields mapped around the Bay Marchand and Welsh domes (Figure 8.23 a, b). There, much saltier waters occur next to the domes in sands feeding an adjacent brine plume. The plume extends as a brine layer sourced in regions near the dome tops down to the zone of freshened and geopressured waters at some depth below (Bennett and Hanor, 1987, Hanor 1994a, b). Bay Marchand dome is part of a deep-seated allochthonous salt ridge that also includes the Caillou Island and Timbalier salt domes (Figures 8.23a, 10.44). Something like 7.2×10^{11} kg of solid NaCl must have been dissolved to account for the elevated salinities around the Bay Marchand dome (Bruno and Hanor, 2003). This mass is equivalent to something 0.3 km^3 or a 300m reduction in the height of the current dome. This is a lower limit to the total volume of salt dissolved from the dome as it is based on dissolved ions creating the pore content only of the current system. Most likely, there were earlier pore volumes from dissolved salt that are now flushed from the system. In Welsh dome, the zone of highest salinities occurs atop the crest of the dome and not in a sinking plume off to the side of the dome (Figure 8.23b). Bennett and Hanor (1987) calculated that in this system the volume of brine in the current porosity corresponds to dissolution of at least 2 km of salt from the structure. A lack of a crestal collapse graben over this structure implies salt is still being replenished in the diapir stem. The salinity pattern above Welsh Dome cannot be explained by downwelling of salt dissolution-derived brines. Rather, the upward transport of dense high-salinity brines to levels well above the salt crest is perhaps indicative of episodic expulsion of saline fluids rising along the dome edge.

The salinity halo about St Gabriel dome is characterised by a crestal zone that is fresher than the more saline brine layers/plumes on either side of the dome crest (Figure 8.23c). It is yet another brine distribution pattern in this region of the Gulf Coast and may reflect a situation of fresher upwelling geopressured waters, which are locally displacing a more saline brine layer created by dome crest dissolution.

^{8.2}Diffusion is the movement of ions from areas of high concentration to low concentration and follows Fick's first and second laws. Diffusion is a slow process even in liquids and even slower in a porous medium because ions can migrate only through the pores and the rate depends on pore throat size.

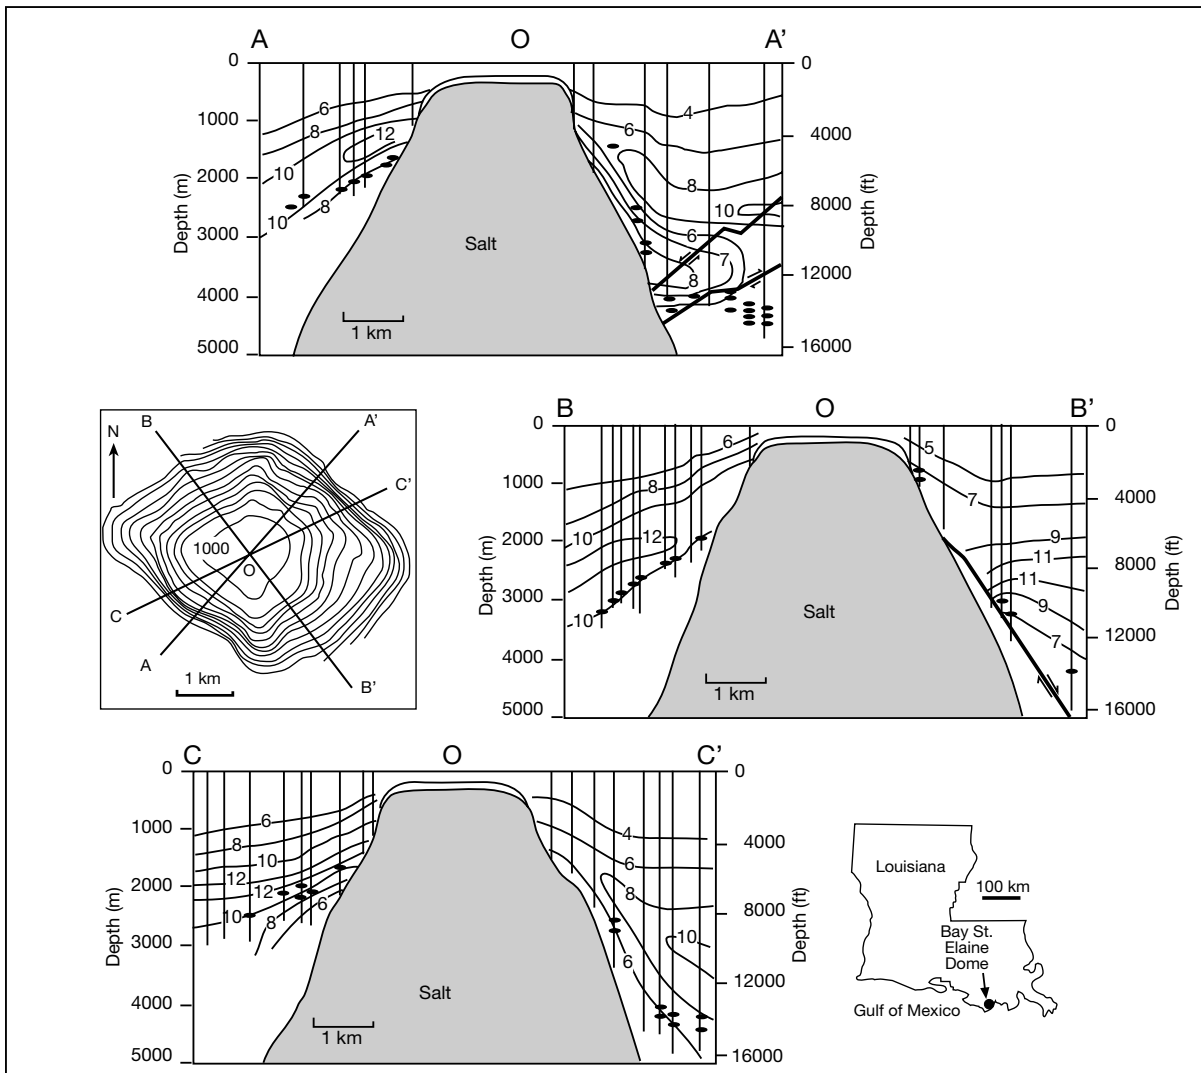

Figure 8.22. Cross sections of pore water salinity (wt%) about the Bay St. Elaine salt dome, Louisiana (depth contours on plan view are 1000 ft). Sections OA' and OC' show lobes or plumes of relatively fresh subsurface waters (<6 wt%) adjacent to the NE flank of the dome. Black ellipses on wells show intersected hydrocarbon zones (after Cassidy and Ranganathan, 1992).

Clearly, salt is still dissolving from the crests of shallowly buried salt structures in the Gulf Coast, this is especially so where there is a well-developed brine plume indicating solute transport directed away from the salt (Bay Marchand and Darrow domes). Clearly also, there are nearby domes in the same region where this brine is locally displaced by salt stem-focused upwellings of subsurface waters. These waters may be more saline (Welsh Dome) or less saline (Bay Marchand and St Gabriel). The interactions are complex and there is no simple single model to explain the variety of pore salinity fields. They vary according to differences in the rates of crestal salt dissolution versus rates of stem-focused upwelling and are

tied to the laterally varying mechanics of compaction flow and salt withdrawal, fluid buoyancy effects, and different suprasalt permeability fields (Cassidy and Ranganathan, 1992).

Density inversion created by the nearsurface dissolution of a diapir crest, in conjunction with a thermal drive and overpressured shales, is sufficient to drive large-scale suprasalt convective cells in the Gulf of Mexico with flow rates of metres per year (Hanor, 1994a). This is two to three orders of magnitude faster than the mm/yr rates that are typical of the thermobaric zone in nonevaporitic basins. Similar elevated flow rates typify the dissolving crests of many structures in the North Sea diapir fields (Williams and Ranganathan, 1994).

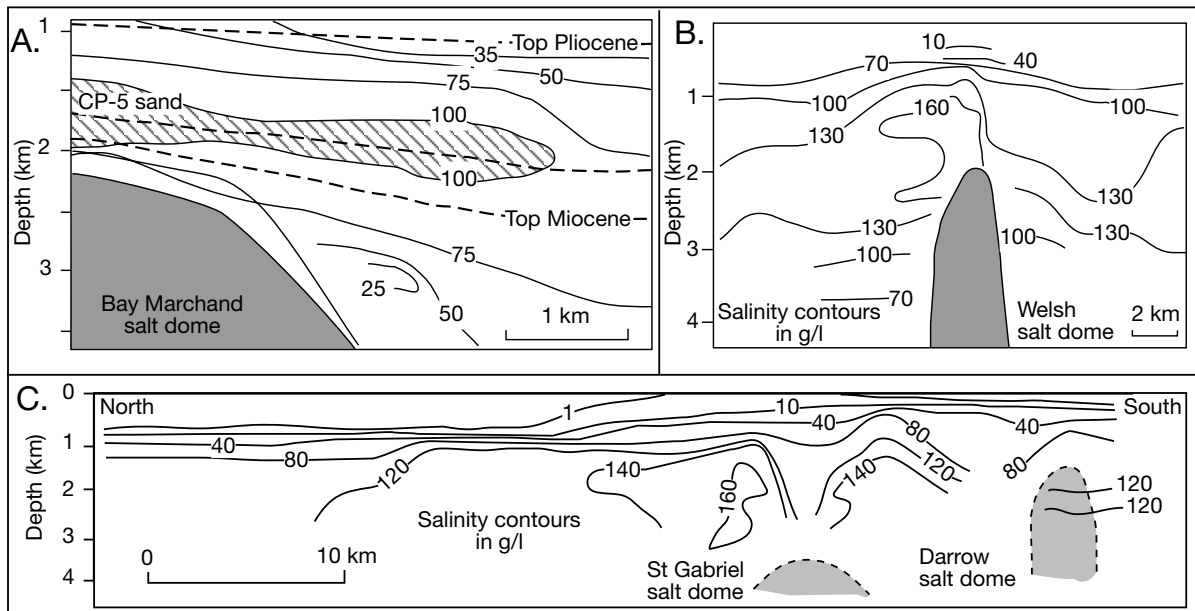

Figure 8.23. Cross section of salinities in the vicinity of several diapirs in the of the Louisiana Gulf Coast showing the various shallow salinity plumes (g/l) generated by subsurface brine dispersion away from the dissolving crests of the salt domes. A) East west section on the southwest flank of the Bay Marchand Dome. The cross hatched axis of the high salinity plume corresponds to the CP-5 Sand (after Bruno and Hanor, 2003). B) Welsh dome section where a regional high salinity layer (<130 g/l) sits atop a zone of overpressure, with higher salinity in the vicinity of the dissolving salt crest (after Bruno and Hanor, 2003). C) Salinity fields mapped around the St. Gabriel dome where saline waters occur near to, but not atop, the dome crest. Darrow dome data are limited but appear to follow the regional pattern of high salinity water near dome crest (after Bennett and Hanor, 1987).

Circumsalt fluid flow drives diagenetic alteration in sediments adjacent to a salt stem. This is demonstrated by zones of calcitic alteration on the west flank of the West Hackberry Dome, Louisiana Gulf Coast (Figure 8.24a; McManus and Hanor, 1993). Drilling has defined some 5×10^{10} kg of authigenic calcite-pyrite cement in Miocene sands adjacent to the salt spine at depths of 1.4 to 2.1 km, across a 1.5×1.5 km area. The Sr, C and S isotopic compositions of the cements show Ca and S were derived from dissolution of the salt-dome anhydrite cap and that carbonate was derived both by thermochemical oxidation of methane and by sulphate reduction, possibly at temperatures as low as 70°C. Constraints on the maximum aqueous concentrations of Ca, which can be released by dissolving diapiric salt, require that more than 5×10^9 m³ of aqueous fluid, equivalent to a fluid volume/pore volume ratio of >250:1, were involved in destroying salt, transporting Ca and SO₄, and precipitating these cements. Thus, the presence of such cements about a salt structure requires a dynamic subsurface mass-transport regime involving either large volumes of throughflushing fluid or fluids that are extensively recirculated.

An equivalent to this subsurface calcite/pyrite cement halo outcrops in a quarry in the Eocene Carrizo Sandstone adjacent to the Butler salt dome, east Texas (Figure 8.24b; Enos and Kyle, 2002). The Carrizo is a fine- to medium-grained quartzarenite to sublitharenite with up to 42-50% cement, principally poikilotopic calcite with local pyrite. Shallow drill holes in the surrounds of the quarry shows cemented zone is delimited by a steeply dipping normal fault, which is radial to the northeast part of dome crest. Cements extend southeast of the fault as a lenticular body some 750 m across and thickest near the fault where it is more than 25 m thick. Pyrite concretions are found on both northwest and southeast sides of the fault, as well as along the fault plane, whereas the calcite cement is present only to the southeast of the fault. $\delta^{13}\text{C}$ values for the calcite (-19 to -37‰) suggest bicarbonate was supplied mainly by bacterial oxidation of methane, whereas $\delta^{18}\text{O}$ data for calcite (-6 to -9‰) indicate meteoric water was involved in supplying diagenetic fluid. $^{87}\text{Sr}/^{86}\text{Sr}$ values for calcite (~0.7073) are within the range for Middle Jurassic seawater, suggesting that dissolution of anhydrite from the Louann Salt provided the Ca. Pyrite is more ³⁴S-rich ($\delta^{34}\text{S}$ range of 10 to 16‰) than typical sulphides in Gulf Coast salt dome cap rocks and is interpreted to represent H₂S supplied from deep sour gas reservoirs.

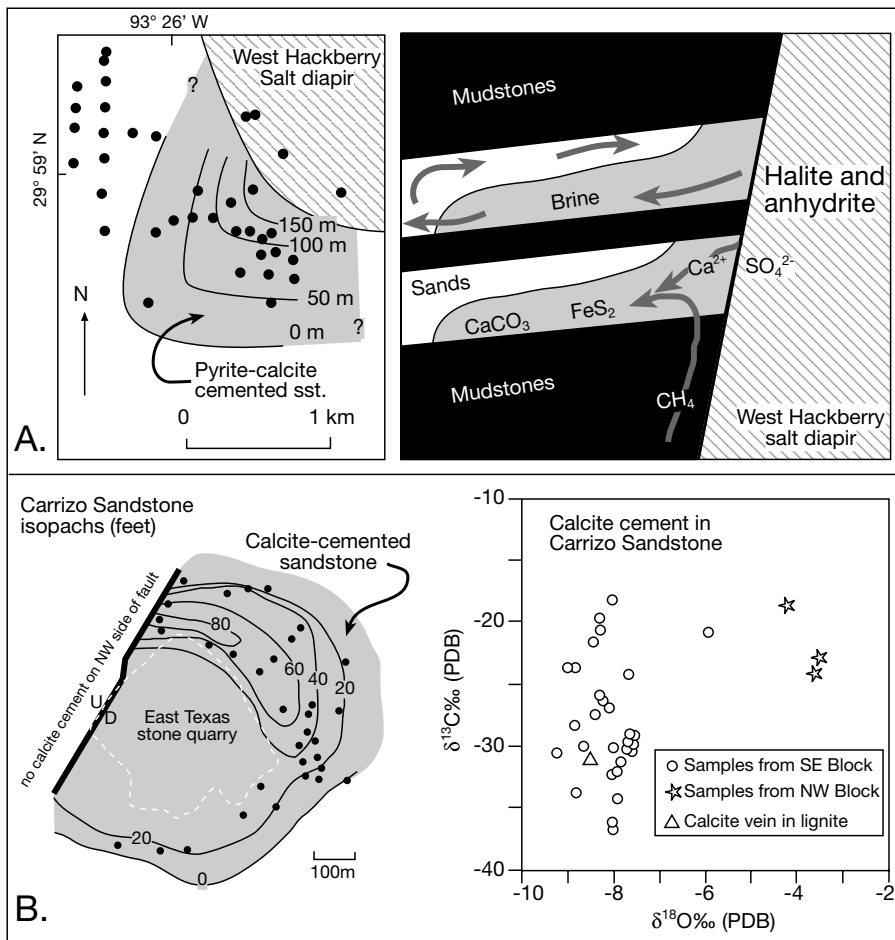

Figure 8.24. Pyrite and calcite cements in diapir edge sands. **A)** West Hackberry Dome, Louisiana showing cumulative thickness in metres of cemented sands, black dots show borehole control. Model schematic shows hydrological circulation at the time of cementation. Dense brines with Ca and SO_4 derived from dissolution of salt stock flow down basal parts of sand beds. Upward flow of less dense fluid above brine plume. Thermogenic methane migrates up side of dome. Thermal reduction of S and oxidation of C results in precipitation of calcite and iron sulphides (after McManus and Hanor, 1993). **B)** Isopach map of the cemented zone in the subcropping Carrizo Sandstone based on drill information (black dots). The NE-trending fault forms the northwestern boundary of the cemented zone. The detailed thickness of the cemented zone within the quarry is unknown but probably was 40 ± 20 ft. Also shown are the carbon and oxygen isotope compositions of calcite cements in the Carrizo Sandstone

Early H_2S supply from deep sour gas reservoirs was channelled upward along the flank of the nearby Butler Dome and outward along the radial fault, resulting in early pyrite precipitation along the fault zone and in adjacent sediments. Early pyrite cements along the fault may have formed a barrier to subsequent fluid circulation, blocking the northwestward movement of both Ca-rich waters from the dome and deep natural gas moving along the fault, thus confining calcite precipitation to the southeast of the fault. Bacterial oxidation of this thermogenic gas resulted

in calcite precipitation, although mixing with shallow ground water bicarbonate may account for the broader range in $\delta^{13}\text{C}$ values in the calcite cement. Enos and Kyle (2002) propose that this type of cementation occurs in similar settings associated with circumsalt hydrocarbon leakage to shallow levels and may represent a previously unrecognized self-sealing type of hydrocarbon trap.

Rapid upward advection^{8.3} of hot brines along the flanks salt domes in the Northern Gulf of Mexico Basin and in the Danish Central Trough seems to require an adjacent and deeper overpressured shale or mudstone succession to focus flow up the sides of the salt structure (Williams and Ranganathan, 1994). Their upward passage influences pore fluid chemistry interfaces, especially redox fronts, near the stem. This creates higher temperature gassy fluid haloes with interfaces that can precipitate metal sulphides and other diagenetic minerals. Inclusions in some of these diagenetic precipitates indicate temperatures were

^{8.3} Advection is a general term used to describe transport of fluids, solids and heat through porous media. It requires permeability to move pore fluids so that ion transport is related to the average linear velocity of water in the pores, which is equal to Darcy velocity divided by effective porosity. In the vicinity of a dissolving salt bed it is associated with dispersion, which describes movement within groundwater as ions or contaminants spread out by mechanical mixing and diffusion. For example, a slug of brine into fresh porewaters mixes with the fresh as it moves away from the dissolution front. The brine covers a larger area as its concentration declines.

some 40° to 80°C above the ambient temperature of the laterally adjacent sediment. Williams and Ranganathan (1994) conclude that thermal perturbations in excess of 60°C can be repeatedly produced near the margins and crests of salt domes via focused dewatering of thick strongly overpressured minibasin intervals around the dome.

Dewatering can be triggered and stopped by cyclically pulsing the permeability at the salt stem-sediment interface (analogous to seismic pumping - Figure 8.16). Modelling shows the upwelling thermal plumes about the dome crest will dissipate within 100,000 years from the cessation of dewatering (Williams and Ranganathan, 1994). Stratigraphically shallow and gravitationally unstable brine plumes from salt dissolution, once formed, will also dissipate once the salt has dissolved, but fade more slowly by sinking and mixing on a 1 m.y. time frame.

Burial dewatering of hydrated salts

So far we have focused on hydrologies in halite-rich shale-dominated basins undergoing various styles of salt flow and dissolution. Halite is the dominant mineral in most thick basinwide evaporite successions, but in some basins anhydrite, not halite, is the dominant salt. In such settings there can be interesting subsurface hydrological effects tied to dewatering of the gypsum precursor to the anhydrite. Conversion occurs whenever a thick gypsum bed is buried and passes into the thermobaric zone. As the burial temperature rises above 60°C, bedded gypsum alters and dewateres to nodular or laminar anhydrite, with an accompanying 39% decrease in rock volume. Potentially, at around a kilometre of burial, this can generate a pressure kick that is significantly in excess of hydrostatic. The conversion of gypsum to anhydrite also defines the depth below which calcium sulphate stylolites cannot form (Figure 1.37).

Conversion depth influences early organic maturation and rock strength (Jowett et al., 1993). Because gypsum dehydration occurs during shallow burial, it is unlikely to be responsible for overpressures that occur at greater depths, where the primary role of the evaporite in the pressure system is as a pressure seal to underlying compacting fine-grained sediments or as a facilitator, via its evacuation, to the rapid accumulation of thick piles of geopressed sediment.

Conversion to anhydrite is accompanied by a four- to six-fold increase in thermal conductivity (gypsum ≈ 0.8 W/m·K; anhydrite ≈ 5.6 W/m·K) and the consumption of heat. At 25°C the transformation of gypsum to anhydrite releases 4 kcal/mole.

In a hydrologically-open compacting sediment pile, gypsum conversion is typically complete by 800-1000 metres of burial, corresponding to a total pressure of ≈ 250 -300 atm (25-30 MPa). Transformation may occur at much shallower depths if the pore fluids are saline, or may not be complete until greater depths if the overlying unit is overpressured (Figure 8.25; Jowett et al., 1993; Testa and Lugli, 2000). When modelling organic maturation in an ancient calcium sulphate basin, via thermal modelling and backstripping techniques, it is important to know the depth at which the gypsum to anhydrite conversion occurred.

In a simple sensitivity test, using a basal heat flow of 2×10^{-6} cal/cm²/s or 2 HFU's, Jowett et al. (1993) calculated the thermal gradient through bedded anhydrite is 18°C/km, while through gypsum it is 63°C/km. With such large differences in thermal gradient, using the wrong lithology over a particular burial depth range can create large errors in organic maturation modelling. For example, assuming 500 m of anhydrite instead of 800 m of decomposing gypsum will produce a 42°C discrepancy at the base of the evaporite unit (Figure 8.25a versus 8.25b). Such an error significantly effects thermal maturation, so that a source beneath the anhydrite would not reach the oil window, while that beneath the gypsum would.

The temperature, and hence the depth at which the transformation occurs depends on the activity (salinity) of the pore waters where the transformation is taking place. Transformation to anhydrite occurs at progressively higher temperatures as the activity of water ($\alpha_{\text{H}_2\text{O}}$) increases. When pore fluids have an $\alpha_{\text{H}_2\text{O}}$ of 0.93 (equivalent to precipitation of gypsum from seawater) the transformation takes place at 52°C (Figure 8.25c; Hardie, 1967). When the water is at halite saturation with an $\alpha_{\text{H}_2\text{O}}$ of 0.75 the transformation occurs at 18°C. The $\alpha_{\text{H}_2\text{O}}$ in pore waters in ancient evaporites is indicated by the associated lithologies. If a thick anhydrite bed (deposited as gypsum) is associated with normal siliciclastics (shales and sandstones), the $\alpha_{\text{H}_2\text{O}}$ of the burial fluids at the time of transformation was ≈ 0.93 and occurred at a temperature $\approx 50^\circ\text{C}$. If the anhydrite retains evidence of coeval halite, or early diagenetic halite cement, then the temperature was around 20°C at the time of transformation and so occurred at much shallow depths, perhaps within metres of the surface (Hovorka, 1992).

When gypsum converts to anhydrite, the molar volume of the solid phase decreases by $\Delta V_s = -28.37$ cm³/mol of anhydrite formed, corresponding to a volume decrease of some 39% (Zen, 1965; Hanshaw and Bredehoeft, 1968). But the released fluid means there is a corresponding increase in molar volume of pore fluid of $\Delta V_f = 36$ cm³ for the 2 mol of water created by the

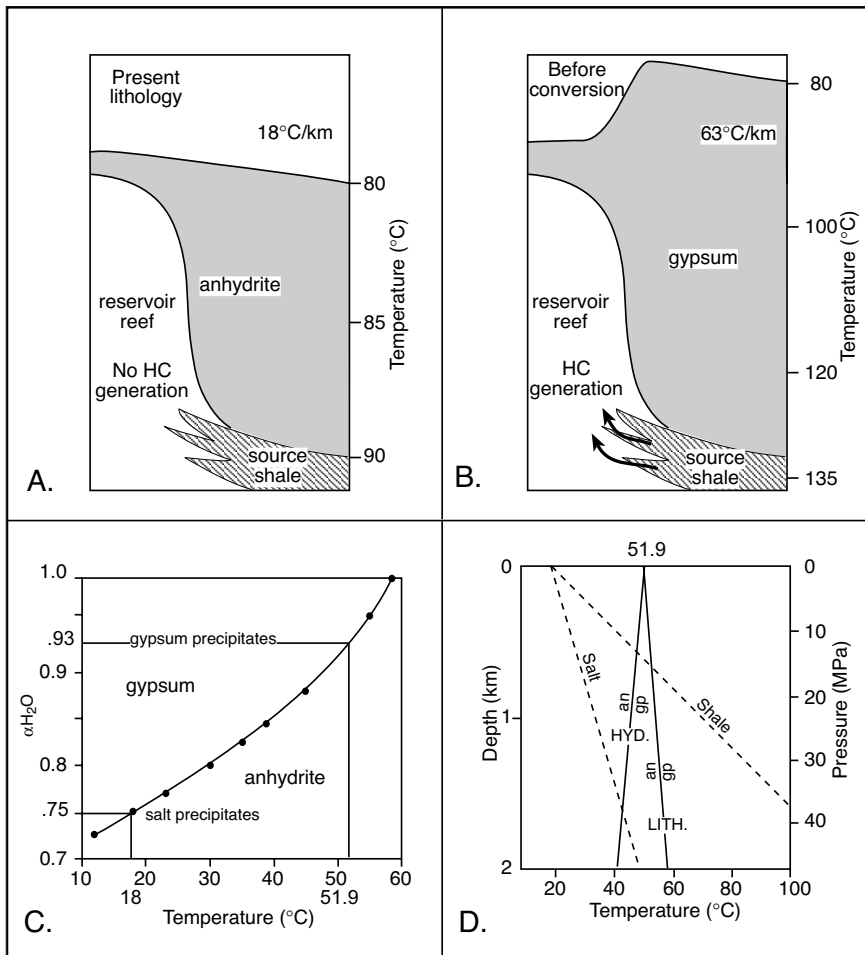

Figure 8.25. Gypsum to anhydrite conversion (after Jowett et al., 1993). A) In an evaporite basin containing 500 m of anhydrite, the calculated palaeothermal temperature implies the underlying source would not reach the “oil window.” B) If the conversion to anhydrite is later, so that the basin can be decompacted prior to gypsum converting to anhydrite, then the low thermal conductivity of the gypsum increases the geothermal gradient and the source rocks do reach the “oil window.” C) The laboratory relationship between the activity of water and the temperature of the gypsum to anhydrite conversion (after Hardie, 1967). D) Depth relationship for the temperature of the gypsum-anhydrite conversion below a shale insulator and a shale conductor. Conversion of gypsum to anhydrite occurs where the temperature line intersects the geothermal gradient in the overlying rock. Hence the conversion depth is much greater beneath halite (conductor) than beneath shale (insulator) (after MacDonald, 1953; Hardie, 1967, Hanshaw and Bredehoeft, 1968).

conversion. Because pressures on the fluid (P_f) and pressures on the solid (P_s) are different, the molar entropy change (S) and the molar volume change (ΔV) are related by the equation (Hanshaw and Bredehoeft, 1968):

$$dP_s/dT = S/(\Delta V_s + V_f dP_f/dP_s)$$

The measured entropy change is $\Delta S = -135.84 + 65.17 \log_{10} T - 0.043T$ (Hardie, 1967), where T is the temperature in degrees Kelvin.

In a hydrostatically pressure system with free drainage allowing escape of the conversion water (e.g. gypsum with intercalated sand beds or porous carbonates) the overburden pressure is taken up only in the solid phases, so favouring the denser solid phase (anhydrite). In this situation, $dP_f/dP_s = \rho_f/\rho_s \approx 0.4$, and the slope on a dP_s/dT on a P-T plot is negative. That is, the conversion temperature decreases with depth and gypsum converts at shallower depths (Figure 8.25d). If, on the other hand, the water from the conversion cannot freely escape from the decomposing gypsum, pore fluids may become geopressed (e.g. escaping pore fluids from a buried gypsum bed sealed beneath a thick widespread salt unit and intercalated with tight shales or lime mudstones). Overburden pressure is then taken up in both the solid and fluid phases. In this case P_f can approach P_s , dP_f/dP_s approaches unity, and the slope of dP/dT becomes positive (Hanshaw and Bredehoeft, 1968). Then the conversion temperature increases with depth and for a given geothermal gradient the conversion of gypsum to anhydrite occurs at progressively greater depths. Hanshaw and Bredehoeft (1968) calculated the lithostatic conditions created by the conversion can only be maintained for a “geologic instant,”

even when the confining beds have hydraulic conductivities as low as 10^{-10} cm/s ($\approx 10^{-3}$ md as in a tight shale).

Most natural systems lay somewhere between the hydrostatic and the lithostatic curves, the dominance of one over the other is difficult to quantify, it can only be estimated by looking at the nature and thickness of the overburden and the intercalated lithologies within the converting calcium sulphate bed. If the

water of hydration cannot drain freely from the dewatering gypsum, the bed converts to a quicksand-like consistency, typically indicated by thick nodular sequences of enterolithic folds with crestal fold vergences that may be oriented in the direction of minimum stress (Warren, 1991). Escaping conversion water ultimately seeps into adjacent strata and escapes the unit. This escaping water of crystallisation can help lubricate nearby growth faults and other relatively shallow slippage features, including nappes.

Based on the ubiquitous presence of flow-aligned anhydrite textures in décollement sutures in the European Alps and elsewhere (e.g. Jordan and Nuesch, 1989; Jordan et al., 1990) it seems that a common effect of sulphate dehydration is an initial decrease in the intrinsic strength of the CaSO_4 unit and an enhanced ability to act as a lubricant. Laboratory testing of mechanical strength during the dehydration of gypsum to bassanite ($\text{CaSO}_4 \cdot 1/2\text{H}_2\text{O}$) under closed drainage supports these observations (Figure 8.26). There is a large decrease in differential stress under undrained conditions at temperatures $\approx 110^\circ\text{C}$, indicating high pore pressures induced by gypsum dehydration (Heard and Rubey, 1966; Murrell and Ismail, 1976). Thus a non-draining dehydrating gypsum bed can act as a zone of weakness or décollement at the base of a thick salt or shale succession. However, in the low temperatures of the laboratory the reaction product is bassanite not anhydrite; a mineral that, like dolomite, is very difficult to manufacture under the kinetic restraints of the laboratory, but is abundant in the real world.

Building on earlier work, but now using varying degrees of pore fluid drainage, the experiments of Olgaard et al. (1995) and Ko et al. (1995) clearly show that under well drained conditions the weakening of the gypsum tends to occur only in the early stages of the dehydration reaction. Their experiments were run at varying temperatures ($23^\circ - 150^\circ\text{C}$), at confining pressures that mimic free to limited drainage (0.1-200 MPa), and at strain rates 0.7×10^{-7} to $6 \times 10^{-5} \text{ s}^{-1}$. As more porosity was created by ongoing dehydration there followed a rapid decrease in pore pressure. The experimental peak in pore pressure corresponded to an observed weakening and embrittlement in the gypsum. Under drained conditions this weakening occurred in the first 1% of the reaction. Ultimate strength was recovered within 3% of the reaction and ultimately exceed that of pure gypsum. They concluded that, unless the surrounding rocks had very low permeabilities, the pore pressures during real world dehydration could only equal or exceed lithostatic pressures during the earliest stage of the gypsum dehydration reaction.

Microstructural observations of Ko et al. (1995, 1997) showed that the initial stage of loss of water of crystallisation creates isolated areas of dehydrated gypsum surrounded by new fluid-filled porosity. Excess pore pressures develop as long as this porosity is not interconnected or fluid is produced faster than it can escape through any newly forming interconnected porosity. Under slow fluid leakage conditions an excess pore pressure first develops, which leads to weakening; but this is followed by strengthening (shown by time arrow in Figure 8.26). The timing of the development of minimum strength and maximum pore pressure is controlled by the drainage evolution of the various mosaics or networks of dehydrated gypsum within the converting gypsum unit. While the dewatered regions are isolated, a pore pressure can build up, which, as it becomes more pervasive, weakens the gypsum. But, as the locally dehydrated intervals start to fuse with each other, pore fluids can now flow from one area to another and ultimately escape into the adjacent non-calcium sulphate surrounds. This strengthening of the dewatering gypsum over time marks an internal transition from undrained to drained behaviour.

As well as acting as a lubricant, escaping water of crystallisation can act as a catalyst in dissolution-precipitation reactions within units subjacent to the dewatering evaporites. As buried

Figure 8.26. Plot showing differential strength of dehydrating gypsum decreases above 110°C in undrained conditions where the water of crystallisation cannot freely escape. Under drained conditions there is an initial decrease in differential strength followed by an increase. This is shown by samples at either end of time arrow (after Ko et al., 1995).

gypsum dewatering to anhydrite the escaping water is saturated with respect to CaSO_4 but undersaturated with respect to other evaporite minerals, including any nearby carbonates (Sass and Ben-Yaakov, 1977) as well as any halite and the bittern salts. As such water seeps through the surrounding rocks it can leach minerals to create secondary porosity or bring about mineralogical transformations. Throughflow of such waters has dissolved marine carbonate grains to form anhydrite-filled moulds during Permian brine reflux in the shallow subsurface of the Palo Duro Basin, Texas (Bein and Land, 1982). With complete dewatering, a gypsum bed that is 100 m thick will convert to a 62 m anhydrite bed (Borchert and Muir, 1964; p. 133). This releases a total of 48.6 m^3 of water per square metre of cross-sectional area. At 30°C this volume of CaSO_4 -saturated water can dissolve 8.1 m^3 of halite or 54 m^3 of carnallite or convert 81 m^3 of carnallite to sylvite:

Similar fluid rock interactions in the subsurface obviously influence many of the minerals and burial cements we now see in evaporites and adjacent beds. As well as basinal fluids derived from dissolving evaporites, fluids from dewatering evaporites (especially gypsum and the hydrated bittern salts, such as carnallite) may also exert a substantial influence on the diagenetic and metallogenic evolution of the sediment pile.

Brine-rock burial evolution

Approximately 20% by volume of most sedimentary basins is made up of pore water of varying salinity, temperature, pressure and ionic proportions. Pore waters in sedimentary basins are mostly calcium chloride waters with major cations present in the proportion $\text{Na} > \text{Ca} > \text{Mg}$ (Figure 5.27; Collins, 1975). More than 70% of oil field waters are either saline (10,000–50,000 mg/l) or brines (>50,000 mg/l). More than 50% of the world's basinal waters are more saline than seawater (>35,000 mg/l). All formation waters (aka subsurface or basinal waters) originate from meteoric, marine, or hydrothermal sources (Moldovanyi and Walter, 1992). Mechanisms proposed to account for elevated salinities of subsurface waters compared to most nonevaporitic surface waters include; membrane filtration or reverse chemical osmosis (reviewed by Graf, 1982), expulsion of evaporatively concentrated (connate) seawater (Rittenhouse, 1967; Carpenter, 1978; Stoessell and Moore, 1983), halite and potash salt dissolution (e.g., Land and Prezbindowski, 1981; Hanor, 1988), and meteoric water-rock interactions in sediments over thermal anomalies or in tectonically active areas (Hardie,

1990). Most of these alternatives can be rejected as significant factors in brine formation (Land 1987; Hanor, 1994a, b). It is now generally accepted that subsurface brines more saline than 100,000 to 120,000 mg/l are mostly related to evaporites via their depositional brine aprons or their subsequent dissolution haloes. Significant modifications to the connate fluid chemistry must occur during burial diagenesis in response to changing solution-mineral equilibria with increasing temperatures.

Several workers have suggested all basin water ionic compositions indicate mixtures in varying proportions of a) brines associated with evaporite residues, b) head-driven deeply circulating meteoric inflows and c) compaction waters (Kharaka et al., 1985; Egeberg and Aagaard, 1989; Moldovanyi and Walter, 1994; Land, 1995a, b). For much of the ensuing discussion we concentrate on subsurface brine chemistries associated with connate brines or evaporite dissolution.

Brine chemistry at depth

Hanor (1994a, b) studied the chemistry of basinal waters worldwide and divided them into three groups; a) Na-HCO_3 and Na-acetate waters, typically with $\text{TDS} < 10,000 \text{ mg/l}$, b) Cl -dominated halite undersaturated waters with salinities between 10,000 and 250,000–300,000 mg/l, these waters include Na-Cl waters and Na-Ca-Cl at higher salinities and, c) Cl -dominated halite-saturated waters, with salinities typically in excess of 300,000 mg/l. Major cation concentrations show a systematic trend with increasing concentration. Ca and K become increasingly dominant, while Na and pH decrease with increasing brine concentration, especially above 300,000 mg/l (Figure 8.27). In moderately saline waters, the monovalent cations Na and K have 1:1 slopes when plotted against TDS , while the divalent cations Mg , Ca and Sr show 2:1 slopes. The pH of moderately saline waters lie in the range 7–9, while high salinity brines are in the range 3–4. Most highly concentrated basinal brines are acidic; this has important implications for the leaching and transport of metals in the relatively low temperature range (<200°C) that typifies sedimentary basins (Warren, 2000b).

Well-defined ionic trends with increasing salinity seen in Figure 8.27 led Hanor (1988, 1994a, b) to suggest that the chemistry of most deep subsurface brine in salt-entraining basins is controlled by the subsurface dissolution of halite and the subsequent buffering of pore water compositions via interactions with multiphase silicate-carbonate mineral assemblages. Dissolution of halite produces a progressively more NaCl -dominated fluid without any systematic increase in K , Ca , Mg and Sr ions, which are supplied by fluid interactions

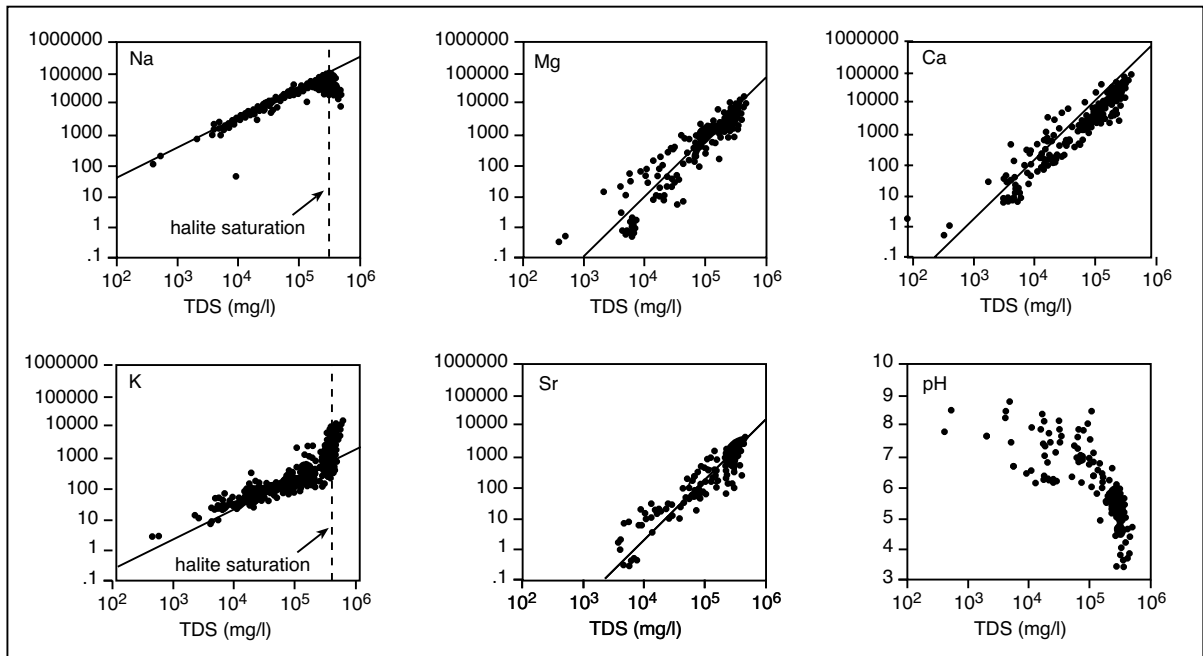

Figure 8.27. Scatter plots of the covariance of log Na, Mg, Ca, K, Sr and pH with log TDS (total dissolved solids) for typical saline basinal waters worldwide (after Hanor 1994a). Note the 1:1 slopes for Na and K and the 2:1 slopes for the divalent cations. All values, except for pH, are in mg/l.

with the adjacent silicate-carbonate assemblages. Such water-rock interactions explain the Na–Ca–Cl brines so common in subsurface brines. These proportions cannot be explained by a simple evaporitic concentration of seawater beyond gypsum saturation and the retention of connate reflux waters. Marine brines precipitating halite contain little or no Ca^{2+} as it has been depleted by CaCO_3 and gypsum/anhydrite precipitation (Figure 2.5). Volumetrically important subsurface reactions capable of modifying connate brines towards higher $\text{Ca}/(\text{Na}+\text{Ca})$ values include dissolution of anhydrite, albitisation of plagioclase feldspars, and dolomitization of limestones (Land 1987). Potassium (as well as Ba and perhaps Sr) can come from albitisation or illitisation of K-feldspar, especially in redbed and volcanoclastic sequences.

In terms of anions, the inherently high solubility of dissolving evaporites means they typically supply unbuffered components into pore waters, the most obvious being chlorine and bromine (Ranganathan, 1991). Other than halite cement, there is no source of chlorine in nonevaporitic lithologies (except minor hydroxyl-bearing minerals such as mica or apatite). Hence, average chlorine content in nonevaporitic basins worldwide is only 48,640 mg/l ($\text{Br} = 155 \text{ mg/l}$), while the average for basins entraining buried salt or their dissolution breccias is 118,392 mg/l ($\text{Br} = 1583 \text{ mg/l}$; Worden, 1996). Palaeozoic

basin brines also show higher average chlorine contents than Mesozoic basins, which are in turn higher than Tertiary basins (Worden, 1996). The difference probably reflects the longer time for more pervasive evaporite solution and circulation in the older basins. Worden (1996), like Hanor, concluded that in an evaporite-entraining basin the dissolution of halite is the major control on the chlorine content of subsurface waters.

If dissolution of thick buried salt explains the elevated salinity of deeply buried highly saline basinal brines, then any sediment undergoing burial will ultimately come into contact with these brines. It will experience water-rock diagenetic interactions tied to basinal fluids derived from this dissolving evaporite and these interactions will occur in the later deeper stages of the rock's burial history. The tie of basinal brine chemistry to buried dissolving salt is clearly seen in the pore water chemistry of the deeply buried Permian Gharif Formation in the Ghaba Salt Basin of Oman (see Figure 10.54a for basin location; Hartmann et al, 2000). The degree of diagenetic overprint varies, depending on burial history. Sandstone at shallow depth ($>2600 \text{ m}$) shows intense dissolution of aluminosilicate and carbonate minerals, combined with minor kaolinite precipitation and compaction, whereas deeply buried sandstone ($>2600 \text{ m}$) is highly compacted and tightly cemented by quartz, carbonate, and sulphate minerals.

The Lower Gharif in the Ghaba Basin consists of coastal-plain siliciclastic rocks passing upward into the marine bioclastic–oolitic Haushi limestone. The Middle Gharif is characterized by fluvial cross-bedded sandstone interbedded with red–brown, mottled siltstones and mudstones containing calcrite and root traces. The top part consists of alluvial-plain mudstone with less calcrite. None of the three formations entrain evaporites. The cementation history in these Gharif sands illustrates what is a typical depth-related set of burial cement stratigraphies for many sedimentary basins.

Eight carbonate cement phases were differentiated in the sands of the Gharif Fm. by Hartmann et al. (2000). In general, the sequence is: calcrite/dolocrete, calcite I/dolomite I and calcite II as consecutive eogenetic phases all predating early quartz I, this is followed by burial diagenetic dolomite II and calcite III/Fe-dolomite/ankerite. Calcrite and dolocrete are present in fluvial sandstone of the Middle and Upper Gharif. Trace amounts of calcite I and dolomite I overgrow reworked caliche nodules. Pore-occluding, poikilitic, brightly luminescent calcite II is present in shallow wells and in the Huqf–Haushi outcrops. Later-formed, patchy poikilitic, brightly luminescent calcite III is restricted to samples from depths of <2600 m. Dolomite II is present in some wells as small, red-luminescent rhombohedra.

Fe-dolomite/ankerite occurs in various amounts (0–27%) as intergranular rhombohedra that fill pores and corrode earlier quartz I and feldspar overgrowths.

Caliche carbonates have $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values from -0.3 to -0.7‰ and -1.8 to -2.2‰, respectively (Figure 8.28a). Pristine shell material and “whole-rock” shallow-marine Haushi limestone (Lower Gharif) show $\delta^{13}\text{C}$ values between 0.5 and 5‰ and $\delta^{18}\text{O}$ values ranging from -1.6 to -2.6‰. The stable-isotope composition of early calcite II ranges from -7 to -10‰ and from -19 to -23‰ for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$, respectively. Calcite III, which formed after calcite II, has $\delta^{18}\text{O}$ values of -4 to -9‰ and $\delta^{13}\text{C}$ values of -2 to -14‰ (Figure 8.28b). Fe-dolomite/ankerite has $\delta^{18}\text{O}$ values ranging from -4 to -9.5‰ and $\delta^{13}\text{C}$ values of -3 to -11‰ (Figure 8.28a). All these isotopic values of the various cements in these sandstones are consistent with ongoing burial diagenesis in an environment characterised by increasing temperature in the presence of hydrocarbons. The calcite II cements formed from meteoric waters that infiltrated the Gharif sands during the late Triassic Early Jurassic. This was followed by burial and the entry of high salinity pore water from dissolution of the Ara salt. During this time of deeper burial and more saline pore waters the Fe-dolomite and ankerite cements precipitated.

Figure 8.28. Hydrological signature of the Permian Gharif Formation, Oman. A) Stable isotope signatures of Gharif Formation minerals - see text for explanation of trends. B) Variation in dissolved cations and anions as a function of dissolved chloride in Gharif Formation pore waters. Open symbols represent low-salinity brines influenced by meteoric waters. Closed symbols are highly saline brines derived from subsurface dissolution of the Ara Fm. salt. Dashed lines represent the present trends between dissolved ions and chloride. Solid lines are the seawater evaporation dilution lines from Carpenter (1978). Crosses represent the seawater concentration for each dissolved ion (after Hartmann et al., 2000).

The current pore waters in the Gharif are Na–Cl brines with various amounts of Ca, Mg, SO_4 , and HCO_3 (Figure 8.28b; Hartmann et al., 2000). Dissolved Na increases with increasing Cl along the seawater evaporation–dilution curve (Carpenter 1978) confirming dissolving halite as the main ion source to the present saline brines. Values for Mg and Ca also increase, but values for Mg are depleted and those of Ca are enriched relative to the seawater evaporation–dilution curves, imply ongoing rock–fluid interactions. In addition, all brines are depleted in sulphate, but mostly enriched in bicarbonate compared to seawater, perhaps reflecting sulphate reduction processes (Figure 8.28b).

With time and burial the carbonate minerals precipitating from the evolving pore waters of the Gharif Fm. in the Ghaba Salt Basin evolved from depositional pore waters of low salinity (<50 g/l) with $\delta^{18}\text{O}_{\text{SMOW}}$ values of -0.5 to -1.5 ‰ in the more marine Lower Gharif to 2 ‰ in the arid fluvial Middle and Upper Gharif (Figure 8.28b). During subsequent shallow burial (Late Triassic to Early Jurassic), the pore water in the Gharif members changed to high-salinity brines (≈ 180 g/l) with $\delta^{18}\text{O}_{\text{SMOW}}$ values of -4 to -7 ‰. The current highly saline, deep-burial pore water with a heavy $\delta^{18}\text{O}$ signature (0.5–5 ‰) is the result of rock–water interactions in what is a rock-dominated system. Thus present porewater compositions in the deeper parts of the basin, as indicated by both isotopic and ionic compositions, mainly reflect interaction with pore fluids derived by deeper subsurface dissolution of underlying Neoproterozoic Ara Group evaporites. This process is coupled to the precipitation of late diagenetic carbonates and sulphates. Subsequent recharge of isotopically light surface water was driven by inversion along the uplifted southeastern basin margin and was driven by obduction of the Oman Mountains in the Late Cretaceous and the creation of the Huqf–Haushi Arch (Figures 10.5b, 10.54a).

Ceriani et al. (2002) documented a similar post-rift burial infiltration of saline brines in non-evaporitic sediments deposited in an evaporite-floored aborted rift. They studied the evolution of quartz overgrowths and burial dolomite cements in the Upper Sarir Sandstone (Lower Cretaceous) in Abu Atifel oilfield in the Sirt Basin, Libya. Fluid inclusions along the grain-overgrowth boundary of early quartz overgrowths yield homogenization temperatures from 130 to 141 °C and salinities between seawater and freshwater. Aqueous fluid inclusions in later quartz overgrowths have homogenization temperatures from 114° to 129°C and salinities between 18 and 21 wt. % NaCl equivalent. Fluid inclusions in adjacent dolomite burial cements have variable homogenization temperatures (120–141°C) and high salinities (20–22 wt. % NaCl equivalent).

This cooling trend in homogenization temperatures of fluid inclusions, tied to increasingly saline pore waters, is the result of quartz cements first forming in a bath of hot, low-salinity, connate fluids at a burial depth around 2.5 km. These hot fluids were flowing through the Sarir sands, driven by the increased heat flow related to regional rifting of the Sirt Basin. Later quartz overgrowths and burial dolomite cements precipitated during a time of regional cooling tied to the end of the rifting. Authigenesis occurred at a depth of around 3.8 km and was driven by the cooling of pore fluids concurrent with the invasion of dense saline fluids from subadjacent areas of salt deposition and brine reflux. The most likely brine source was a reflux plume from a thick section of Eocene evaporites, although dissolution of subadjacent Cretaceous salts cannot be entirely ruled out (Ceriani et al., 2002). A similar evaporite-associated reflux model was used to explain cool pore brines associated with U-rich dolomitization and subsequent anhydrite precipitation and replacement in the lower Krider Member of the Nolans Limestone in the Hugoton Embayment in Kansas (Luczag and Goldstein 2000).

Worldwide, the ionic proportions in a subsurface saline brine can reflect either the original make-up of the waters in the pores at the time of deposition (such as connate waters in inclusions in Guadalupian chevron halite in west Texas; Figure 8.7) or the effects on ongoing subsurface fluid flow and rock reactions changing the original depositional proportions (as in the salt-dissolution-derived Na–Cl waters of the Gharif Formation). Connate waters are subsurface waters with chemistries near-identical to those of waters which were present in the pores at the time of deposition (Hanor, 1994a). The term connate comes from the Latin (*connatus = born with*). Connate properties of subsurface brines include connate isotopic properties, connate Br/Cl ratios and other ionic proportions. Very few subsurface waters are truly connate because chemical alteration and diagenesis (water-rock interaction) influences the chemical make-up of most. Some authors use the term connate interchangeably with the more general term subsurface water, but to avoid confusion its use should be preserved for those waters and brines that are truly connate (Hanor 1994a). Most basinal brines are not connate, this is especially obvious in subsurface regions where thick evaporites are dissolving creating high salinity Na–Cl dominated brines.

With evaporite-associated subsurface waters there is still considerable debate about the role of residual evaporated seawater (=connate brine) in the chemistry of basinal brine versus dissolving buried evaporites (Moldovanyi and Walter, 1994). In part, the debate centres on the ability of thick evaporite sections

to store connate brine from the time of deposition due to the early creation of evaporite seals by early porosity loss. Most halite-dominated sequences are tight by 100-500 m burial. A “connate” versus “water-rock interaction” argument is made more difficult by requisite hydrology needed to precipitate and preserve a thick, near monomineralic, evaporite sequence. Significant volumes of salts can only accumulate where ongoing brine reflux drives the associated flux of considerable volumes of brine into the adjacent underlying sediments where it disperses into the regional flow system (as in the Sarir Sandstone).

This is the concept of brine disposal, brine leakage, brine reflux or the brine curtain as enumerated by Holser (1979), Sandford and Wood (1991), Rosen (1994) and Warren (1999), respectively. It is summarised in Chapters 2 and 5. The drawdown hydrology that typified the depositional hydrology of most ancient evaporite settings means that substantial volumes of relatively unmodified but dense pulses of concentrated seawater (=connate) or continental brines can be drawn into and stored in sediments about and beneath the evaporite bed and its brine curtain (Figure 2.52). This refluxed connate brine could be stored in subadjacent continental strata (e.g. fluvial or aeolian sediments) as well as in a marine host and can be released later during burial diagenesis and compactional flushing. The question becomes not whether connate pore waters were present beneath and within a thick evaporite bed, but when were these waters flushed from the system and how much water rock interaction took place during and after that flushing.

One reason for confusion between connate and dissolution derived subsurface waters is that some older studies did not distinguish between brine samples collected from porous beds encased within an evaporite sequence and those pore waters collected in adjacent more permeable sediments located above and below an evaporite bed. When this distinction is made, those brines collected within sediments with relict pore fluids encased by a bedded salt unit (with chevrons) are typically found to be connate brines, while those outside the evaporite succession are more likely to reflect chemistries related to salt dissolution and ongoing water rock interaction. For example brines within an evaporite aquitard and a nearby deep brine aquifer in the Palo Duro Basin of west Texas have $\delta^{37}\text{Cl}$ values of -0.4 to 0.0‰ (Figure 2.27b; Eastoe et al., 1999). They were not generated by dissolution of halite.

Another possible confusion in terms of a meteoric versus dissolution origin of diagenetic cements in carbonates in evaporite entraining basins lies in the possible misinterpretation of oxygen isotope signatures of some burial cements precipitated from

hypersaline pore waters. The work of Dickson et al (2001) on carbonates of the Central Basin Platform west Texas underlines this dilemma. Pennsylvanian to Lower Permian cyclic platform carbonates from the Southwest Andrews area of west Texas are now 3 km below the landsurface. Isolated samples of brachiopod shell, zones of calcite cement, and saddle dolomite from limestone cores of the Southwest Andrews oilfields were analysed isotopically in order to determine if: (1) diagenesis was dominated by early, meteoric processes, as suggested by earlier bulk rock isotope studies, (2) whether significant burial diagenesis occurred in hypersaline waters, and (3) whether most burial cements are allochthonous or internally derived.

Bulk isotopic analyses of the limestones show systematic variation in $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ that historically have been interpreted according to a geochemical model tied to length of subaerial exposure and stratigraphic position (Figure 8.29; Dickson et al., 2001). Chemically zoned calcite cements show four growth stages. Stage 1 and 2 cements have average $\delta^{13}\text{C}$ values of -4.6‰ and average $\delta^{18}\text{O}$ of -5.0‰, and most are thought to have precipitated early during subaerial exposure while bathed in meteoric waters. A few stage 1 cements with average $\delta^{13}\text{C}$ values of -4.7‰ and $\delta^{18}\text{O}$ of -1.4‰ apparently precipitated below the sediment surface from modified seawater in a sulphate reduction zone.

But stage 3 and 4 calcite cements precipitated later, thin sections show they are postcompaction and now compose up to 25% of the total rock volume. They have $\delta^{13}\text{C}$ values (-0.2 to -4.4‰) that vary according to stratigraphic position, and are similar to bulk rock samples of the host limestone. Their $\delta^{13}\text{C}$ values indicate these later cements are locally derived via dissolution of adjacent strata. $\delta^{18}\text{O}$ values of stage 3 and 4 cements (-5.5 to -3.5‰) are isotopically indistinguishable from the stage 1 and 2 cements precipitated from meteoric water (Figure 8.29a). The expected decrease in $\delta^{18}\text{O}$ expected from elevated temperatures during burial (the present formation temperature is $\approx 55^\circ\text{C}$) has been negated by their precipitation from late Permian hypersaline brine with $\delta^{18}\text{O}$ values of +5‰. These stage 3 and 4 cements are composed of sparry calcites and saddle dolomites with $^{87}\text{Sr}/^{86}\text{Sr}$ values that are lower than $^{87}\text{Sr}/^{86}\text{Sr}$ values for contemporaneous Permian marine carbonate (≈ 0.70830 ; (Figure 8.29b). This indicates incorporation of Sr with low $^{87}\text{Sr}/^{86}\text{Sr}$ values (0.70672 to 0.70682), which were derived from the same late Permian hypersaline brines. Entry into normal marine carbonates was driven by ongoing brine reflux during the deposition of the overlying Permian evaporites.

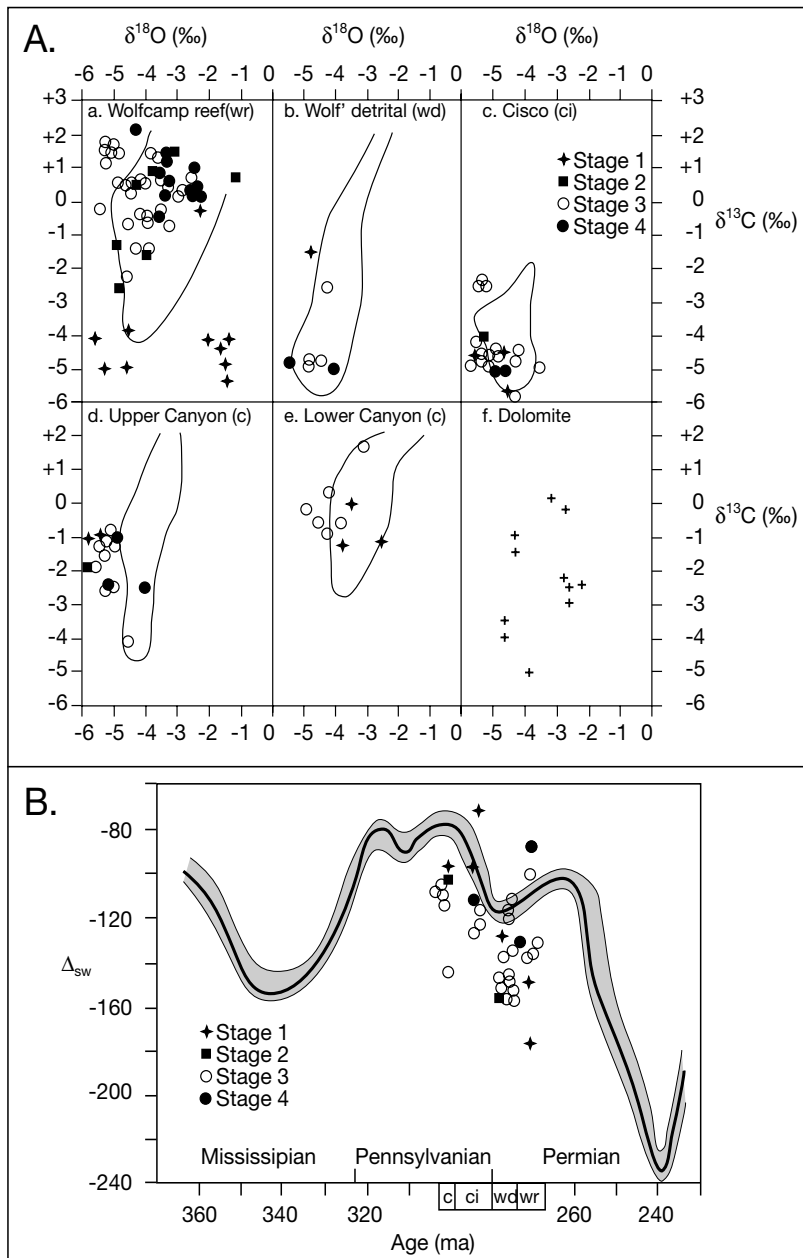

Figure 8.29. Isotopes from the Palaeozoic carbonate platform of the southwest Andrews area, west Texas (after Dickson et al., 2001). A) Carbon-oxygen isotope scatter-plots (A-E) of calcite cement crystals from Wells V7, X1, and Parker "B" 12. The cements are zoned and are grouped into four stages, stage 1 being the oldest and stage 4 being the youngest. Plots are listed by stratigraphic occurrence a) Wolfcampian reef, b) Wolfcampian detrital, c) Cisco, d) Upper Canyon, and e) Lower Canyon intervals, while f) is a carbon-oxygen isotope scatter plot of data from individual crystals of saddle dolomite in all stratigraphic intervals, except the Wolfcampian detrital. B) $^{87}\text{Sr}/^{86}\text{Sr}$ data from selected separated cement stages (1-4) of the same calcite crystals as in A) plotted on the late Palaeozoic seawater strontium isotope curve and its 76% confidence band (grey; curve from Denison et al., 1998). Δ_{sw} is defined as: $\Delta_{\text{sw}} = \left(\frac{^{87}\text{Sr}/^{86}\text{Sr}_{\text{unknown}}}{^{87}\text{Sr}/^{86}\text{Sr}_{\text{modern seawater}}} \right) \times 10^5$.

Dickson et al. (2001) went on to conclude that the buried platform carbonates of Southwest Andrews area have several diagenetic features, all driven by the creation of a reflux curtain, that are probably more common in ancient evaporite-associated limestones than previously recognized. They note: (1) Burial cements have $\delta^{18}\text{O}$ values similar to meteoric cements yet they were precipitated from later hypersaline pore waters with $\delta^{18}\text{O}$ values some 5 ‰ greater than contemporary seawater. (2) Deep-burial cements have $\delta^{13}\text{C}$ values similar to the bulk rock because carbon was derived from pressure dissolution of nearby carbonate. (3) Bulk-rock isotope values are characteristic of marine limestones subjected to meteoric diagenesis, yet they have suffered substantial deep burial diagenesis under the influence of hypersaline waters.

The chemical and isotopic compositions of highly saline water in evaporite-entraining basins complicate simple notions of meteoric versus normal-marine burial diagenesis, especially in intervals close to the dissolving evaporites. Most pore waters are not simply derived during the congruent dissolution of halite beds, nor are they only connate brines (Land, 1995a; Levet et al., 2002). Na and Cl dominate the ionic composition of most sedimentary brines, even in basins that lack preserved evaporites, with the next most abundant cation being Ca and the next most abundant anion Br. This is not the ionic hierarchy of seawater, where the next most abundant cation is Mg and the next most abundant anion is SO_4 , hence most subsurface waters in a sedimentary basin are no longer connate outside of sediments encased in salt.

Today, the three mostly commonly offered explanations for the formation of Na-Ca-Cl basinal brines are (Land,

1995b): 1) preservation of seawater-derived brines that have precipitated halite (raises the Br/Cl ratio) as well as participated in dolomitization and CaSO_4 precipitation (exchanges Mg for Ca and removes calcium sulphate from the brine), 2) subsurface halite dissolution accompanied by salt recrystallisation (partitions bromide into the brine) in association with the dissolution of detrital anorthite (component of detrital plagioclase) - this mechanism may include the deep circulation of meteoric water or escaping compactional waters from thick shale sequences, and 3) reverse osmosis (shale membrane filtration) driven by pressure resulting from compaction, whereby water molecules, uncharged species and small and univalent cations preferentially pass through the shale, so creating calcium, chloride and bromine rich residual brines. Some or all of the mechanisms may be acting concurrently in most sedimentary basins (Demir and Seyler, 1999).

Effects and indications of water-salt interactions

This chapter has shown that dense subsurface waters derived from dissolving evaporites, tend to move through permeable sediments or along permeable conduits such as faults and fractures. They drive various diagenetic processes and flow is typically maintained by density gradients (indicated by thermal or salinity changes). Ongoing diagenesis (or rock-fluid interaction) in nonevaporitic strata also means ionic concentrations of most basin waters are buffered and controlled by the solubility of minerals in the sediment. The low solubility of the common cement minerals such as calcite and quartz means large fluxes of pore waters through nonevaporite lithologies are required to move and precipitate significant volumes of such cements (Bjørlykke and Gran, 1994). In contrast, in the temperature range of sedimentary basins, little water flows through the interior of a salt bed or allochthon. But inherently high solubility means that when the edges of a dissolving evaporite unit are flushed by basinal water crossflows, the dissolving salt contributes large volumes of ions to adjacent more permeable sediments. Even so, most basin brines, even in intervals adjacent to the dissolving evaporite, have salinities well below halite saturation (350–400 g/l). A possible exception is the Michigan Basin where some of the higher salinity basinal brines are clearly halite-buffered (Wilson and Long, 1993).

Solution of buried evaporites explains why: a) salinities increase in a systematic almost linear fashion with depth in sedimentary basins with bedded evaporites near the base of the sequence (Dickey, 1979); b) salinity around active salt stems/domes indicates the advective flow of waters up along the

stem and then horizontally into overlying beds (Hanor, 1988; Bray and Hanor, 1990); c) pore waters in sediments adjacent to a dissolving halite-dominated section lack sulphate, while evaporite sections with a greater proportion of gypsum/anhydrite can generate sulphate waters (Pluta and Zuber, 1995); d) in halokinetic provinces such as the central graben of the North Sea the salinity of the pore waters correlates better with the inverse distance to the nearest evaporite mass than it does to burial depth (Gran et al., 1992); and e) why there is no significant increases in salinity with depth in the northern North Sea (59–62°N), which is an area with no known evaporites (Bjørlykke and Gran, 1994).

The total volume of salts in the world's oceans is about $2.2 \times 10^7 \text{ km}^3$ and there is about the same amount of Cl in the world's sedimentary basins (salts and porewaters) as there is Cl in the modern ocean (Borchert and Muir, 1964). This means that of all the major sediment types, evaporites have the shortest mass half ages estimated to be $\approx 2 \times 10^8$ years (Garrels and Mackenzie, 1981). Hence, there are no significant potash or thick halite deposits older than Neoproterozoic (Warren, 2000c). Evaporite dissolution throughout burial and metamorphism and the associated discharge of Na-Cl rich brines into the basin's subsurface waters, and ultimately to the ocean, explains much of the short mass residence time for chloride. For the same reasons, the residence time for Cl in the world's oceans is the longest of any element and is of the same order ($\approx 2.2 \times 10^8$ years) as halite's mass half-life (Land, 1995a).

Hence, the chlorinity of the Precambrian oceans could not be more than around 50% different from today's. It also means that when large ancient basinwide salt basins rapidly accumulated their salts via drawdown, they could have substantially altered oceanic salinity. For example, the Permian Zechstein evaporites of northwest Europe, with a volume of $2.4 \times 10^6 \text{ km}^3$, is equivalent to some 10% of the volume of the current oceanic reservoir.

High concentrations of the ions from dissolution of buried salts typically indicate effective diffusive or advective transport of the ions from the salt-sediment contact and concentrations usually decrease further away from salt beds or domes (Figure 8.23). Steep gradients or abrupt changes in subsurface salinity, rather than gradual changes, typically indicate limited advective mixing of pore water across a permeability barrier (Bjørlykke and Gran, 1994). Near a subsurface evaporite unit the chemical composition of the pore water concentrations are high and can approach equilibrium with the major evaporite minerals (typically halite or anhydrite). Burial cements can precipitate

Figure 8.30. Gamma-ray log, lithologic log, Br concentration and $^{87}\text{Sr}/^{86}\text{Sr}$ ratio in whole rock samples from the cored interval through the Louann Salt in the Champion-Klepac #1 well (after Land et al., 1995). The well was drilled to a total depth of 4,800 m. Based on the monotonous gamma log, pure halite, at least 1,050 m thick, underlies the cored interval.

in pores in this zone when saturation is reached. The precipitation of evaporitic burial cements is even more likely when subsurface waters of differing salinities and compositions are mixed (Chapter 2; Sullivan et al., 1994).

Subsurface halite-dominated sequences dissolve in two ways; by incongruent or congruent dissolution. Incongruent dissolution occurs typically at low water rock ratios, whereby the halite recrystallises as more soluble components are lost to adjacent pore fluids. For example, when halite recrystallises in the presence of waters with a bromine content less than that of the original salt-precipitating (connate) water, it will become bromine depleted. At the same time the pore waters become relatively enriched in bromine, supplied by the rupture and dispersion of bromine-enriched connate fluid inclusions during the recrystallisation process. Congruent dissolution is the total or bulk dissolution of salt via throughflushing basinal brines. It forms subsurface Na-Cl brines with high chlorine contents and higher Br/Cl ratios compared to nonevaporitic subsurface waters (Worden, 1996).

Congruent dissolution of potassium-rich bittern salts is an even more effective means of creating-Br enriched hypersaline wa-

ters as minerals like sylvite entrain order-of-magnitude higher levels of bromine compared to sedimentary halite. Congruent or incongruent dissolution of K-salts leads to waters that are bromine-enriched relative to evaporated seawater. Hanor (1994a) proposed that K-salt dissolution explained the bromine enrichment seen in many basinal brines in sedimentary basins with buried evaporites.

Incongruent dissolution is used to explain the bromine depletion of recrystallised Jurassic halite remaining in diapir crests in the Gulf of Mexico (Stoessel and Carpenter, 1986) and is thought to be an important process in regions of salt flow and deformation worldwide (Land et al., 1988; Land et al 1995). In the Champion-Klepac #1 well in the Gulf of Mexico, sylvite occurs atop a thick halokinetic halite succession at the top of the diapiric Jurassic Louann Salt (Figure 8.30; Land et al., 1995; Land, 1995a, b). The well recovered some 150 metres of salt, which is underlain by more than another kilometre of salt. The bittern sequence lacks MgSO_4 salts, giving a mineralogy that, according to Hardie (1990), is a prime candidate for a nonmarine, possibly hydrothermal, brine source, or perhaps indicates evaporation of a Jurassic seawater with ionic proportions different from today (Figure 2.30).

Alternatively, Land et al. (op. cit.) argue the sylvite is the result of incongruent halite solution. The present bittern zone, encased in recrystallised halite, is interpreted to be a diagenetically modified “fractionated residue” created during the dissolution of more soluble marine bittern phases that were once present along with the sylvite. Sylvite is less soluble in halite-saturated subsurface waters than other bittern salts, which were primary coprecipitates (kieserite, epsomite, carnallite, etc; see Figures 2.7, 2.8). Incongruent formation of recrystallised halite and the associated accumulation of the sylvite residue supplied Mg, Br and SO_4 to the escaping pore brines.

Bromine values from deformed halite lower in the Klepac core can be used to argue that incongruent halite dissolution and recrystallisation can supply bromine to escaping pore fluids. Br values in the primary halite chevron-dominated succession beneath the bittern succession is uniform and centred around 200 ppm (range 170–234 ppm). This fits into the range of typical marine values (Holser, 1979). Values in the deformed salt are much lower, averaging 110 ppm and decreasing to values of 29–60 ppm in the lower portions of the core. Did the bromine escape during incongruent recrystallisation of the flowing salt, or was the halite reworked and recrystallised at the time of deposition? Resolution hinges on an improved understanding of how flowing salt recrystallises (Figure 6.3). Over a time frame of millions of years can the outer portions of a thick flowing salt periodically pressurise and leak fluid, or is the flow mechanism purely one of localised halite recrystallisation, pressure solution and edge dissolution within a relatively closed hydrology? At the present time we simply do not have the answer.

Crustal cycling of brines?

Shield brines, which are ubiquitous hypersaline waters in open faults and fractures at depths > 1 km in Precambrian rocks around the world, are among the most enigmatic of all crustal fluids with respect to their age and origin (Bottomley et al., 2002). Not only do shield brines have very high salinities (upto 300 g/l), which are comparable to sedimentary formation brines in evaporite-floored basins, their chemical compositions are of the Ca-Cl type and their O and H isotopic compositions plot well above the global meteoric water line in $\delta^{18}\text{O}$ versus $\delta^2\text{H}$ space (i.e., they are depleted in ^{18}O or enriched in ^2H relative to meteoric water). Arguments for both in situ water-rock interactions (Frape et al., 1984), and ancient, concentrated marine sources have been presented to explain their compositions and widespread occurrences (Bottomley et al., 1994, 1999) and to model per descendum flow paths for some types of shield-hosted ore deposits (e.g. Mernagh et al., 1994).

Bromine elevation in a pore water in a sedimentary host is readily explained by the subsurface dissolution of the more saline evaporite salts, but saline Na-Ca-Cl type groundwaters and brines also occur in deep mines over extensive areas of the Canadian Precambrian Shield. These waters have elevated Br/Cl ratios which imply the chlorinity of these waters was derived from the deep infiltration of residual evaporitic brines, perhaps as remnants of the great marine/hypersaline apron that typify strata of the Palaeozoic era in this region (Bottomley et al., 1994, 1999). Boron concentrations in these waters are generally low (< ≈ 2 mg/l) relative to seawater or to Alberta Basin Devonian formation waters. However, the $^{11}\text{B}/^{10}\text{B}$ ratios of these waters are significantly greater than the average value for continental crustal rocks. Moreover, Bottomley et al. argue that the boron isotopic ratios generally trend to higher values with increasing chlorinity, which supports the conclusion from the Br-Cl relationship that most of the chloride in these shield brines is of marine origin, rather than a product of water/basement rock interactions. In a subsequent paper Bottomley (2002) used ^{129}I measurement to determine the minimum age of brines in basement fractures in the Con gold mine in Yellowknife (Northwest Territories), and found the brines are at least Cretaceous and probably Devonian. He concludes a Pleistocene age and cryogenic origin is impossible.

Yet seawater freezing has been proposed by Herut et al. (1990) and Starinsky and Katz (2003) as an alternative explanation for the saline chemistry of Canadian Shield brines (Figure 8.31). Based on minerals present in salt lakes in Antarctica such as Lake Bonney and Vanda Lake, we know that seawater freezing can form various sodium and magnesium salts and high salinity brines. Thick beds of mirabilite occur on the McMurdo Ice Shelf. From experiment, we know that when seawater freezes at -1.9°C , a small amount of calcium carbonate is the first salt to drop out, usually as aragonite. Next, sodium sulphate precipitates as mirabilite at -8.2°C , sodium chloride as hydrohalite ($\text{NaCl}\cdot 2\text{H}_2\text{O}$) at -22.9°C , and then sylvite + $\text{MgCl}_2\cdot 12\text{H}_2\text{O}$ at -36° (Nelson and Thompson, 1954). At -54°C this cryogenic sequence of salts ultimately produces a calcium chloride brine slurry that precipitates antarctite ($\text{CaCl}_2\cdot 6\text{H}_2\text{O}$). One of the few places in the world where this mineral occurs naturally is in a brine lake known as the Don Juan Pond in the Dry Valleys (Wright Valley) of Antarctica, where the TDS of the bottom brine can exceed 500 kg/m^3 (Torii and Ossaka, 1965).

Up to the point of halite precipitation, seawater freezing has the same effect on chlorine-bromine relationships in residual brines as solar-driven evaporation. So, seawater freezing beneath thick ice sheets may be an important process controlling

Figure 8.31. Isostatic and hydrological evolution of a marine-cryogenic basin: A) Continent-ocean boundary before the onset of a glacial cycle. B) An ice sheet develops on the continent, depressing the crust underneath and forming a forebulge along the coast. Seawater infiltrates into the marginal trough between the ice edge and the forebulge and sea ice crystallizes on its surface. The resultant brine sinks to the bottom and infiltrates the underlying sediments and rocks via cracks and shear zones and by non-equilibrium melting of the ice sheet base. Then, it migrates inland, along the inclined ice-rock contact, towards the center of the depression. Loss of brine from the trench is compensated by fresh seawater flow through the forebulge. C) During the glacial maximum the basement rocks below the ice sheet become saturated with brine. D) Increased melt water head developing during glacial decline, accompanied by postglacial lithospheric rebound, drive the brines outwards from the center of the glaciostatic depression to their present sites (after Starinsky and Katz, 2003).

the composition of formation waters seeping into fractures and cracks in sub-glacial hard rock sequences. However, recent work on the origin of the various salts in Antarctic salt lakes has shown that, while the mirabilite in Lake Bonney and Vanda Lake are derived by seawater freezing, the antarctite in Don Juan Pond may not be. Rather, it formed by freezing of a resurgent brine that was created by water-rock interactions in a deeply circulated groundwater moving through fractures within a granite host (Takamatsu et al., 1998).

At the other end of the temperature spectrum, the possible creation of hypersaline brines beneath the evaporite basin in a hard-rock basement host, via infiltration of connate waters, leads to an interesting quandary. Have hypersaline basinal brines entered and influenced the chemistry of the hard rock basement that lies

beneath most evaporite-floored sedimentary basins (such as the Gulf of Mexico), or are these waters juvenile residuals from magmatic or metamorphic fractionations (Markel and Bucher, 1998)? Land (1995b) argues for the former. Using quantified mass volume and element residence times he concludes that as the porosity of rocks is reduced during burial, discharge of saline formation waters contributes to crustal chloride cycling. During deep burial, corrosive saline formation waters dissolve metastable detrital minerals derived from crustal/basement rocks and transfer incompatible elements such as Li and B from the igneous crust to the sedimentary crust. Likewise, albitisation transfers Ca from the crustal silicate (igneous) mineral reservoir to the crustal carbonate and aqueous (sedimentary) reservoirs. Metamorphism, and then melting of albite-enriched rocks, accounts for the elevated sodium contents of igneous rocks relative to sedimentary rocks. In this way average sediments

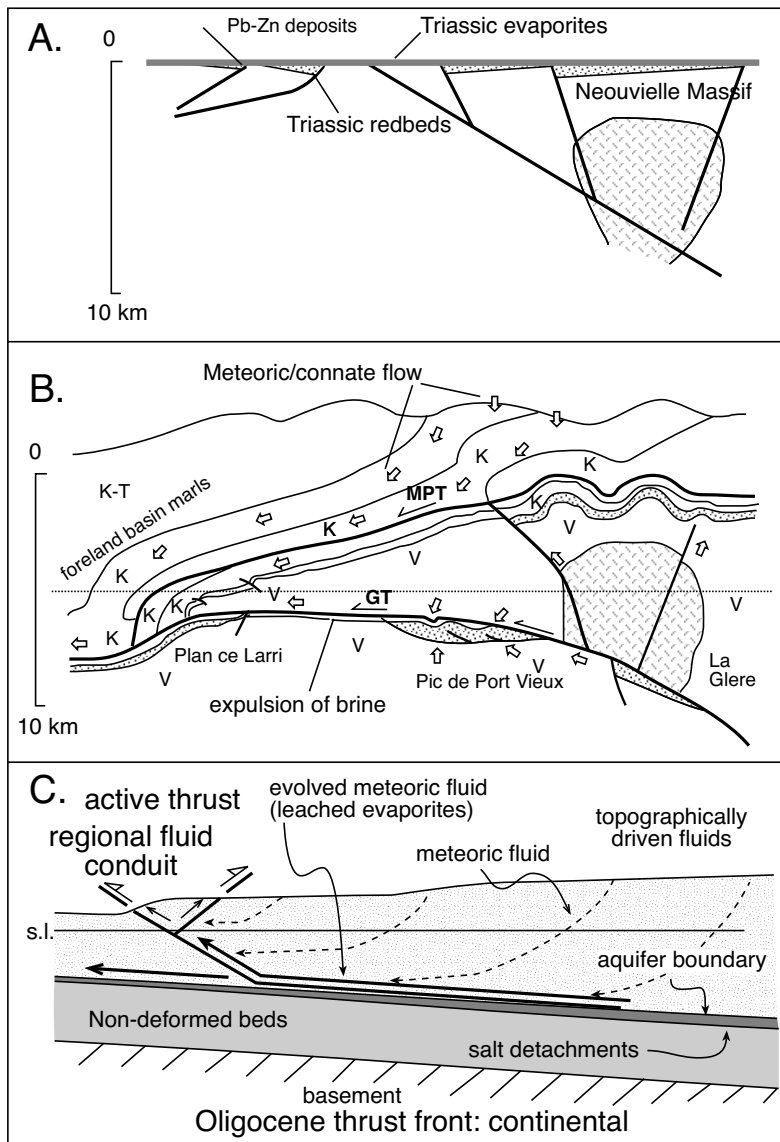

Figure 8.32. Model for fluid evolution and mixing in the Pyrenees. A) Situation at the end of the Triassic: Brines from marine-fed Triassic evaporites sink and displace older formation waters in the underlying redbeds and fractured basement rocks. Pb-Zn deposits formed along normal faults sometime between the Triassic and the middle Cretaceous, due to circulation of metalliferous basinal brines, probably due to density convection. B) Situation during Eocene thrusting. Section above the present exposure level is conjectural (above dashed line). Detail of part of section below thrust line is given in Figure 8.6. Arrows show inferred directions of fluid flow. Note local movement of fluid into the Pic de Port Vieux culmination driven by dilatancy. V = Variscan basement (Silurian and Devonian phyllites, Cambro-Ordovician schists and late granitoids). K = Cretaceous to Palaeocene carbonates. K-T = Tertiary marls and flysch of the foreland basin, locally interthrusted with Cretaceous carbonates. GT = Gavarnie Thrust. MPT = Mont Perdu Thrust. (A & B after McHaig et al., 2000; Horizontal and vertical scales are equal, but there is no precise correspondence between the two diagrams). C) Fluid flow in the El Guix anticline during the Oligocene when deeply circulating and evolved meteoric waters mixed with evaporitic waters from Triassic evaporites that also created the décollement for the thrust plane (after Trave et al., 2000).

have become enriched through time in Ca, Cl, Br, S, Li, and B, and depleted in Na relative to average igneous crust.

In support of the ability of evaporite brines to enter and so influence basement chemistry during metamorphism and overpressuring, McCaig et al. (2000) documented evaporite-derived Na-Cl brines in inclusions in the northern end of the Alpine shear zone, Europe (Figure 8.6; 8.32a,b). They occur where the shear cuts the Neouvielle granodiorite in the Hercynian Axial Zone and also to the south in several localities in the footwall and hangingwall of the Gavarnie Thrust on the southern margin of the Axial Zone. Inclusion fluids generally decrease in salinity from 27-35% at the northern end of the transect to 7-22% on the southern margin of the Axial Zone. The evaporitic origin is seen in the Cl-Br-Na systematics of the fluid inclusions, which show chemistries consistent with a change from halite to halite + sylvite precipitation with progressive evaporation. The fluids in the basement shear zones are interpreted to have essentially the same evaporitic origin as those still contained in nearby Triassic sediments. Brine inclusions in the sediments have Cl/Br ratios lower than seawater indicating relict signatures derived by marine evaporation and halite precipitation in the upper Triassic. It is possible that final concentration of brines in the Neouvielle Massif also involved retrograde hydration reactions via removal of water by precipitation of hydrous minerals.

The somewhat lower salinities seen at the southern margin of the Axial Zone are interpreted by McCaig et al. to reflect mixing of evaporite-derived brines with a higher level fluid (connate or meteoric water) circulating within the Mesozoic carbonates of the higher thrust sheets. At one locality where Triassic evaporites are still present, high Cl/Br ratios at relatively

low salinities are present in inclusions within the underlying Triassic redbeds, but low Cl/Br ratios at higher salinities are seen lower in the sequence. This is consistent with dissolution of halite by a dilute fluid, but with limited penetration downwards.

In a related paper, Trave et al. (2000) demonstrate the involvement of evaporite-related fluids in sediments atop the evaporite-lubricated thrust of the Al Guix anticline in the Pyrenees of NE Spain (Figure 8.32). The El Guix anticline is the southernmost structure of the south-Pyrenean fold-and-thrust belt. Compressional activity in the area represents the latest stages of Alpine compressional tectonics and overprints the Upper Eocene-Oligocene fluvio-lacustrine deposits that overlie halokinetic Triassic evaporites. Based on a detailed structure of the timing and chemistry of various microfracture cements, Trave et al. (2000) conclude that the Pyrenean fold-and-thrust belt and its deformed southern foreland basin were hydrologically compartmentalised, both in time and space. During the early Eocene, when the thrust front affected soft-sediment in the Ainsa basin, the thrust faults were dominated by medium-scale fluid flow cells. Fluids in the basin were largely formation fluids derived from Eocene marine waters with a minor meteoric influence. During the middle Eocene; coeval with the Gavarnie thrust emplacement, the thrust fault was dominated by medium scale fluid flow system and a fluid that was basically a hypersaline Sr-rich brine stored within Triassic redbeds. No evidence was found of any significant input of either surface or metamorphic fluids during this time. During the same period, the thrust faults in the crystalline basement of the central Pyrenees were dominated by a large scale fluid flow mainly derived from the underlying silicate rocks as a result of metamorphic devolatilisation reactions. During the Oligocene, the most external part of the fold-and-thrust belt developed on top of a salt detachment horizon (Figure 8.32c). Then the thrust front affected mostly cemented continental materials of late Eocene-Oligocene age and the thrusts were conduits for meteoric fluids and also for evolved meteoric fluids migrating a short distance upwards after being in contact with the underlying evaporitic beds focused by the décollement.

Thus, the fluid history in the Pyrenean collision zone evolved through a series of stages in time and space, linked also to economic accumulations of base metals: (1) Upper Triassic evaporite formation with sinking of brines into underlying redbeds and fractured basement rocks; (2) Circulation of brines with formation of Pb-Zn deposits along faults at some time between the Triassic and the Upper Cretaceous; (3) Renewed extension with erosion of Triassic rocks in many areas and further

draw down of Triassic brines into the basement; (4) Deposition of Upper Cretaceous and Palaeocene-Eocene carbonates containing connate waters of marine origin; (5) Formation of the Pyrenean thrust belt with overpressuring and expulsion of the brines along shear zones and faults; (6) Creation of topography with a high-level circulation system in the Mesozoic thrust sheets driven largely by topography (McCaig et al., 2000). At the southern margin of the Axial Zone there was limited mixing of the deeper, overpressured brines from evaporitic sediments with more dilute, hydrostatically pressured fluids (Trave et al., 2000). A similar interaction between hydrothermal ($\approx 200^\circ\text{C}$) fluid circulation, associated with the cooling of a granite mass, and hypersaline fluid circulation driven by sinking of dense hypersaline brines, derived in Triassic evaporitic rifts of the Western Approaches, is important in controlling the fracture-related low temperature base metal and uranium accumulations of South Cornwall (Gleeson et al., 2001).

Chapter 9: Halotolerant life in feast or famine (a source of hydrocarbons and a fixer of metals)

Introduction

A source rock for hydrocarbons is generally considered to be a fine-grained rock that, during its burial and heating, generates and releases enough fluids to form commercial accumulations of oil or gas (Figure 9.1a). Back in 1981, Kirkland and Evans made the observation that some 50% of the world's oil sequestered in carbonate reservoirs may be associated with mesohaline micritic source rocks. Heresy or not, the notion that much of the oil in carbonate reservoirs, sealed by evaporite

salts, may also have also been sourced in earlier less saline, but still related evaporitic (mesohaline) conditions, is worthy of consideration. The association between mesohaline waters, the accumulation of organic-rich sediments and the evolution of the resulting evaporitic carbonates into source rocks has been noted by many, including: Woolnough, 1937; Sloss, 1953; Moody, 1959; Dembicki et al., 1976; Oehler et al., 1979; Malek-Aslani, 1980; Kirkland and Evans, 1981; Jones, 1984; Hite et al., 1984; Eugster, 1985; Sonnenfeld, 1985; Ten Haven et al., 1985; Warren, 1986; Evans and Kirkland, 1988; Busson, 1991; Edgell, 1991; Beydoun, 1993; Benali et al., 1995; Billo, 1996; Aizenshtat et al., 1998; Carroll, 1998; Schreiber et al., 2001. As long ago as the middle of last century, Weeks (1958, 1961) emphasised the importance of evaporites as caprocks to major hydrocarbon accumulations. He also pointed out that many of the cycles of deposition that involve organic-rich carbonate marls or muds also end with evaporites. Many of these authors have noted the association of Type I-II hydrogen-prone kerogens in evaporitic source rocks and related their occurrence to the ability of halotolerant photosynthetic algae and cyanobacteria to flourish in saline settings. Such kerogens tend to be oil-prone rather than gas prone (Figure 9.1a).

Much of the organic matter preserved in evaporitic carbonates, and the resulting source rocks, originated as mesohaline planktonic blooms (a pelagic "rain from heaven") or from the benthic biomass (an "in situ" accumulation). It was typically laid down via a succession of pulses of organic matter (often pelleted) sinking to the bottom of a layered brine column. Each pulse indicates a short period when surface brines were diluted and halotolerant producers (mostly cyanobacteria and algae) flourished in the surface waters. That is to say, the laminated mesohaline mudstones that constitute evaporitic source rocks reflect biological responses to conditions of "feast or famine" in variably layered bodies of brine. Warren (1986) referred to the schizohaline salinity cycles of saline settings as repetitive episodes of "life or death."

Before it becomes a source rock the organic matter buried in organic-rich sediment undergoes numerous compositional changes, first dictated by microbial agencies and then by thermal stress (Horsfield and Rullkotter, 1994). This continuum of processes is called thermal maturation. Based on vitrinite reflectance (R_o) measurements of macerals in a maturing source rock, can be divided into three consecutive stages: ⁹¹diagenesis (eogenesis) ($R_o < 0.5\%$), catagenesis ($0.5\% < R_o < 2.0\%$), and

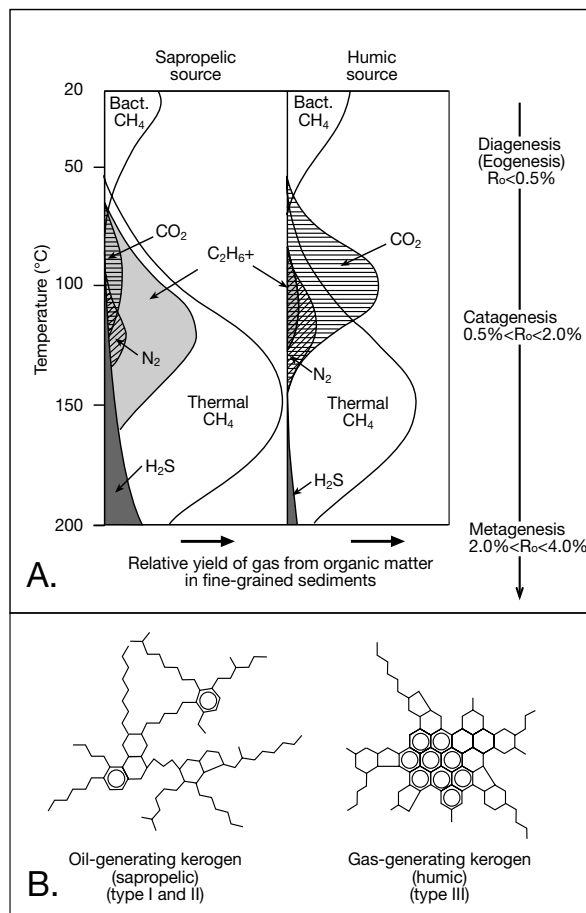

Figure 9.1. Organics and source rocks. A) Relative volumes of gases and liquids derived from a sapropelic and a humic source rock (after Hunt, 1996). Evaporitic source rocks tend to be sapropelic and contain less iron as a reductant so they are also likely to generate more H₂S. B) Molecular structure of typical oil-generating (sapropelic) and gas-generating (humic) organic matter showing the greater preponderance of long-chain hydrocarbons in the sapropelic material (after Hunt, 1996).

metagenesis ($2.0\% < R_o < 4.0\%$), with the oil generation window in the R_o range of 0.5-1.3% (≈ 65 -150°C). Reflectivity is measured by shining a beam of monochromatic light (with a wavelength of 546 nanometres) on to a polished surface of the vitrinite macerals and measuring the percentage of the light reflected with a photometer. Put simply, it measures the degree of darkening (roasting?) of the organics associated with heating of the rock during burial.

As originally defined, macerals are the microscopic organic components of coal and consist of an irregular mixture of different chemical compounds, which are analogous to minerals in inorganic rocks, but differ from minerals in that they have no fixed chemical composition and lack a definite crystalline structure. Macerals change progressively both chemically and physically during ongoing burial and heating, as the rank of macerals (coaly material) advances or the maturity of the organics increases. Macerals in any sediment can be classified into three major groups: vitrinite, inertinite, and exinite. Vitrinite is derived mostly from woody plant tissue and includes the macerals collinite and telinite, most coals have a high percentages of vitrinite macerals. The inertinite group comprises fusinite, micrinite, sclerotinite, and semi-fusinite, which are all rich in carbon but poor sources of volatiles. The exinite macerals, characterized by high hydrogen content (and hence excellent liquid hydrocarbon generating potential), include alginite, cutinite, resinite, and sporinite. Alginites are commonplace macerals in evaporitic settings, while vitrinites are rare, reflecting a lack of higher plants in most hypersaline settings. A lack of vitrinite and poor calibrations to alginite maturation indices can lead to poor correlations between actual source rock maturity and that indicated by vitrinite based estimates in evaporitic source rocks.

Transformation of organic matter to liquid and gaseous hydrocarbons is the result of thermal cracking of kerogen (the solid organic assemblage in a rock that is insoluble in organic solvents and encompasses numerous macerals). Kerogen is the major global precursor of petroleum and its formation, mostly via biologically-induced alteration of plant and animal detritus, is complete by the end of eogenesis. Around 90 percent of the

organic material in a source rock at the onset of catagenesis is dispersed kerogen, consisting of a range of residual materials with basic molecular structures that take the form of stacked sheets of aromatic hydrocarbon rings in which atoms of sulphur, oxygen, and nitrogen also occur. Attached to the ends of the rings are various hydrocarbon compounds, including normal paraffin chains (Figure 9.1b). Mild heating of kerogen over long periods of time results in the cracking of the kerogen molecules and the release of the attached paraffin chains.

Further heating, perhaps assisted by the catalytic effect of clay mineral transformation and evaporite dewatering in the source rock matrix, may then produce soluble bitumen compounds, followed by the various saturated and unsaturated hydrocarbons, asphaltenes, and others of the thousands of hydrocarbon compounds that make up crude oil mixtures. Thus kerogen cracking is induced by burial and heating and it releases micropetroleum (a mixture of liquid and gaseous hydrocarbon products that are soluble in organic solvents) into the pore system of the source rock. The maturity and evolution of the kerogen is paralleled and indicated by increasing maceral (vitrinite) maturity. Once released into the pores of the source rock, micropetroleum migrates toward the surface via secondary migration pathways and along the way a portion of this material can be trapped in a variety of reservoirs of varying quality.

The nature of the organic precursors to kerogen exerts a strong influence on kerogen structure and bulk composition, and hence on subsequent oil- and gas-generating characteristics. Source rock kerogens enriched in long chain hydrogens (aliphatics or paraffins) tend to be oil-prone type I sapropelic source rocks and associated with algal, bacterial and archaeal precursors (indicated by C_2H_6+ in Figure 9.1a), while kerogens that are strongly depleted in long-chain hydrogens are typically type III humic (vitrinitic) source rocks associated with organics from higher plants. They tend to generate gases consisting mostly of methane (dry gas), sometimes with associated hydrogen sulphide or nitrogen. Like hydrocarbons, hydrogen sulphide is generated both biochemically and thermochemically.

Obviously, not all source rocks are evaporitic. Organic matter accumulating in mesohaline sediment is derived from the activities of the ^{9.2}halotolerant and halophilic biomass, mostly algae, bacteria and archaea. Kerogen derived from burial of this organic

^{9.1}The term diagenesis, as used by petroleum geochemists, describes processes of organic modification or alteration in the presence of pore waters where circulation is driven by surface processes. This usage is much more restrictive than the sedimentological use of the term which encompasses all alteration or modification from the time of sediment deposition until the onset of metamorphism. In order to minimise any possible confusion, the term eogenesis is preferred by many workers.

^{9.2} *Halotolerant* organisms can tolerate high salt concentrations but grow better at somewhat lower salinities.

Halophilic organisms grow best at very high salt concentrations and can be killed by lower salinities.

Haloxene organisms cannot tolerate high concentrations of salts.

matter will be composed of their somewhat altered remains, as will the expelled hydrocarbons. Sapropelic organic matter is created by decomposition and polymerization of high-lipid organic materials (with aliphatic long-chain hydrocarbons), which are commonplace in algal and bacterial sediments deposited under anaerobic conditions. Hence, sapropelic organic matter tends to be associated with oil-prone Type I or Type II proto-kerogens (Figure 9.1b). Humic organic matter tends to contain less long chain hydrocarbons and so constitutes a large proportion of the more gas-prone source rocks found in coaly sediments and in dispersed terrestrial organics deposited in prodelta settings. It is mostly associated with Type III protokerogens.

Unoxidised evaporitic organic matter tend to be hydrogen-rich and oil-prone; its sapropelic kerogens (Type I or Type I-II) contain higher proportions of long chain hydrocarbons from cyanobacterial, archaeal and bacterial precursors. Higher plant material, which is the source of much of the humic component in nonevaporitic kerogen simply does not accumulate in large volumes in an evaporitic source rock; higher plants need fresh water and do not flourish in hypersaline waters.

This chapter summarises and classifies evaporitic source rocks, looks at controls on organic enrichment in saline environments, and at the styles of hydrocarbon generation and metal fixing associated with organic-prone mesohaline evaporites. The following chapter looks at how evaporites form the seals and traps to reservoirs that store the generated hydrocarbons.

Evaporitic Source rocks

Amass balance of oil in the global petroleum system indicates that 40% of the world's generated oil is lost to the surface, 58% is dispersed in the subsurface as oil, gas and pyrobitumens somewhere between source and reservoir, and 2% is to be found in pooled accumulations suitable for exploitation (Hunt,

1996). It also shows that the estimated reserves, plus ultimate undiscovered resources, for conventional oil and gas are about the same, each is about 2×10^{12} BOE (barrels of oil equivalent) or $3.2 \times 10^{11} \text{ m}^3$.

A plot of Phanerozoic source rocks shows that more than 90% of the world's discovered original reserves of oil and gas comes from six intervals of geological history, covering only 35% of Phanerozoic time (Figure 9.2; Klemme and Ulmishek, 1991). The six intervals are: 1) Silurian, which generated 9% of the world's recoverable reserves, 2) the Upper Devonian (Tournisian), 8%; 3) Pennsylvanian-Lower Permian 8%; 4) the Upper Jurassic, 25%; 5) the Middle Cretaceous, 29% ; and 6) the Oligo-Miocene, 12.5%. More than 78% of the world's oil and gas is sourced in sediments deposited in restricted or silled anoxic systems located in intrashelf basins on platforms, or in restricted areas formed by circular and linear sags. Four of the six stratigraphic intervals occurred in worldwide first-order sealevel highs (transgressions) associated with greenhouse climatic conditions and the deposition of mostly sapropelic

Figure 9.2. Time distribution of effective source rocks as a percentage of the world's original petroleum reserve generated by these rocks (after Klemme and Ulmishek, 1991).

organic matter. The other two, Pennsylvanian-Lower Permian and the Oligo-Miocene, which source 20.5% of the world's oil and gas, occurred during times of lowered sea level (regressions) and deposited mostly type III kerogens (Hunt, 1996). These were times of polar glaciation (icehouse climate mode). Something like two-thirds of the world's oil was generated in Tethyan basins in a system that covers less than a fifth of the world's land area and continental shelves. The efficiency of the Tethyan petroleum system, centred on the countries of the Middle East was facilitated by the deposition of widespread platform evaporite seals, such as the platform anhydrites of the Hith and Khuff formations and the basinwide halites of the Fars/Gachsaran (Chapter 10), as well as gentle structuration of the reservoirs beneath these platform seals via draping, often in association with the flow and dissolution of Infracambrian Hormuz salt, or in foreland fold belts driven by the Zagros collision.

A common theme to most source rocks, both evaporitic and non-evaporitic, is that they require anoxic conditions to accumulate and preserve their organics. This in turn requires some way of restricting the influx of oxygenated waters to the depositional site and is usually accomplished by thermal or density stratification of a water body, typically in a setting where plankton flourish periodically in the upper water mass. This is why so many subaqueous evaporitic settings are also settings where organics tend to accumulate. By definition, evaporites require restricted inflow conditions to accumulate, they are also typically areas of density-stratified waters with high salinities in the lower denser more saline water mass. Levels of dissolved gases are negligible to nonexistent in the lower brine body as it does not easily exchange with the atmosphere, so encouraging long-term bottom anoxia (Figure 2.37b).

This does not mean all of the world's source rocks were deposited in evaporitic settings, only that the restricted conditions that favour the accumulation of evaporites are similar to conditions that favour the accumulation of some types of organic-rich bottom sediments. In arid climates any minor changes in inflow conditions, such as hydrographic isolation from the ocean, can easily force a transition from one into the other. Hence the common association of source rocks with layered basin waters typical of the early mesohaline phase and the onset of evaporitic sedimentation in many lacustrine/epiiric settings (Table 9.1). In the marine realm, the same need for tectonic or eustatic restriction to create a basin suitable for source rock accumulation (intraself, circular or linear sag) also explains why, if further restriction and hydrographic isolation from the ocean ensues, the same region is easily covered by a sequence of salts (Figure 5.27).

Worldwide, studies of ancient evaporitic basins have shown that organic-rich mesohaline sediments can accumulate beneath ephemeral surface brines, in salterns, or in basin and slope settings in both marine and continental settings (Kirkland and Evans, 1981; Oehler, 1984; Warren, 1986; Evans and Kirkland, 1988; Rouchy 1988; Busson, 1992). The most prolific accumulations of organics in ancient evaporitic sediments tend to have been deposited as laminated micritic carbonates beneath density-stratified moderately-saline (mesohaline) anoxic water columns of varying brine depth.

There are three, possibly four, major mesohaline density-stratified settings where organic-rich laminites (source rocks) accumulate in saline settings that are also associated with, or evolve into, evaporite deposits (Figure 9.3; Table 9.1):

- 1) Basin-centre lows in marine-fed evaporitic drawdown basins (basinwides).
- 2) Mesohaline intraself lows atop epiiric evaporitic platforms.
- 3) Saline-bottomed lows in perennial underfilled saline lacustrine basins.
- 4) Closed seafloor depressions in halokinetic deepwater marine slope and rise terrains.

Basin Setting 1: There are two depositional styles for basin-centre or basinwide mesohaline source rocks; a) Basin-centre drawdown laminites intercalated and often sealed by basinwide salts, b) Basin centre laminites where the basin margin is a shallow, restricted, at times evaporitic, platform surrounding a slightly mesohaline deepwater starved-basin centre with bottom waters that were never drawdown or concentrated to where basinwide salts precipitated. Matrices in setting 1b basin-centre laminites range from fine-grained limestones through marls to siliciclastic muds.

In source setting 1a) the basin is largely isolated from a surface marine connection and high levels of organics accumulate as radiogenic "black shales" (typically carbonate laminites), which are intercalated with, and overlain by, thick basinwide evaporite salts (typically halite-dominated). These laminites accumulate on the bottom of mesohaline density-stratified stagnant brine pools in topographically closed parts of the basin floor during the early stages of hydrographic isolation and drawdown. Inactive, typically subaerial, shelf margin reefs and pinnacles typically lie updip or encircle the basin-centre lows (Chapter 5). Subsequent encasement of these platform buildups and other potential reservoirs by "fill and spill" evaporites means these basins easily become highly focused hydrocarbon flow systems. Hydrocarbons accumulate in the reefs or shelf margin

shoals beneath basinwide evaporite seals. Such systems typify the marine-fed Silurian reef/Salina Salt association in the Michigan Basin, USA (Gardner and Bray, 1984), the Devonian Rainbow Reef reservoirs of the Black Creek/Muskeg Basin of Alberta (Clark and Philp, 1989) and Messinian marls of the Lorca Basin, Spain (Russell et al., 1997).

Expulsion efficiencies suffer from encasement and widespread salt plugging of the potential source rocks in many evaporite-rich setting 1a basins. This tends to retain volatiles in the source beds

until the whole system becomes overmature. For example, in the Gibson Dome No. 1 well, in the Paradox Basin almost all of the black shales intercalated in the halite cycles in the Paradox Member are mature enough to have generated oil (Hite et al., 1984). But the hydrocarbons have been largely retained in this mature source rock, reflecting the highly efficient sealing effects of the intercalated evaporite beds and salt cements (mostly halite). Only where the black shales are intercalated or in contact with porous carbonates have the hydrocarbons escaped. The source potential of these shales is very high, the "Gothic shale" is capable of generating almost 5,000 barrels per acre. But that potential is never more than partially realised. Paradox "shales" are responsible for an accumulative production of a little more than 400 million barrels of oil and about 1 TCF of gas in the Paradox Basin in fields such as Ismay and Aneth (Peterson and Hite, 1969).

This problem of evaporite plugging plagues many basinal source rocks where the basin centre evolved to accumulate basinwide evaporites and is one of the main reasons for the dearth of large onshore oilfields beneath bedded salt or within intrasalt carbonates in the Zechstein basin of NW Europe. Organic-

rich source intervals such as the Stinkdolomit, Stink-kalk, and Stinkscheifer are widespread, but the associated oil accumulations are never more than localised and small scale. Setting 1a sediments can be characterised by very rich organic source beds but the intercalated seals prevent most of the volatiles from ever escaping into a reservoir. In later burial diagenesis, as dissolution of salt interbeds facilitates contact with basinal waters carrying Cu, Pb and Zn, they can play an important role as a reductant and metal fixer (Warren, 2000b).

Basin Setting 1b: Basin-centre mesohaline accumulations in this setting are much more efficient petroleum producers than style 1a as they lack intercalated beds of basinwide halite or

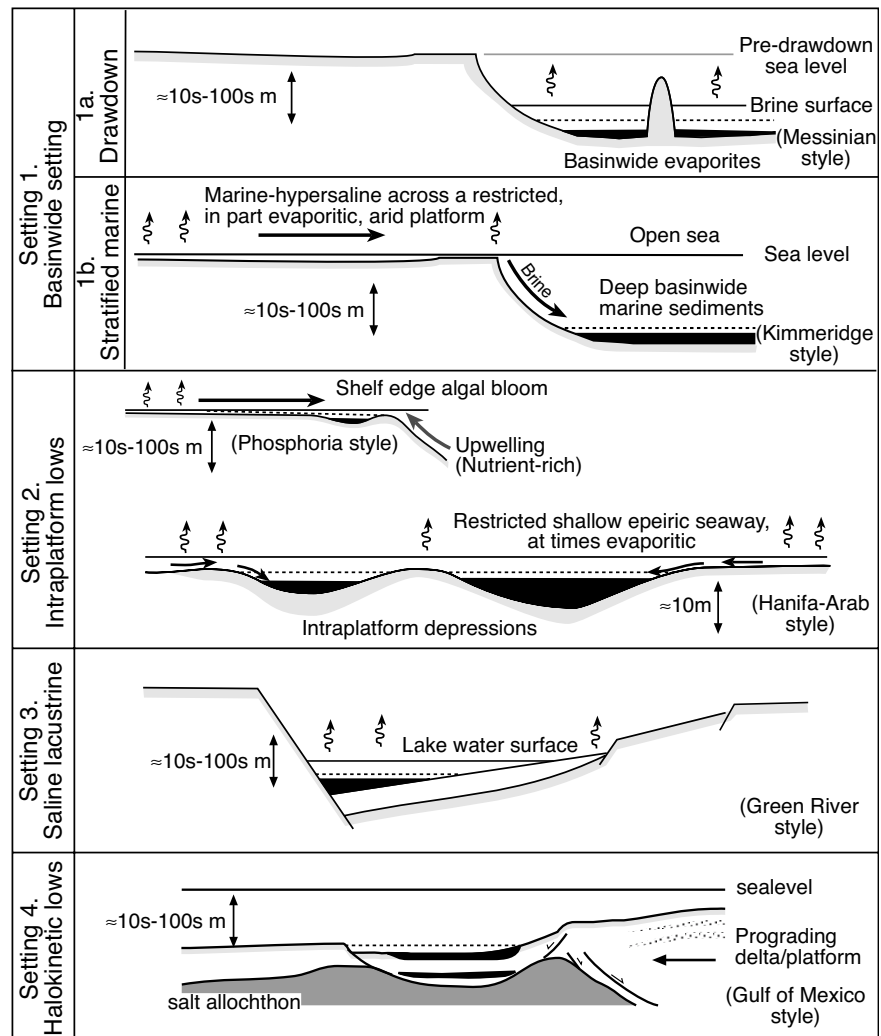

Figure 9.3. Dominant depositional styles for evaporitic source rocks (mesohaline laminites shaded black). All the water bodies show evidence of salinity-related density stratification (indicated by dashed line), also reflected in an associated heliothermic stratification.

Formation/Group locality and age	Basin Style	Characteristics and depositional setting	Reference
Messinian carbonates Lorca Basin, Spain Late Miocene	1a Basinwide evaporite marginal basin	Organic-rich laminated mudstones deposited in pre-evaporitic mesohaline marginal basins with density- and salinity-stratified brine columns. The basin underwent sporadic phases of circulatory restriction with marked production and preservation of organic matter, culminating in evaporitic sedimentation (latest Miocene). As the water in this basin evolved toward evaporitic conditions, a number of organic-rich depositional phases (>25 wt.% TOC) occurred. During the early parts of these phases, the upper water was nutrient rich and comparatively normal marine, and the bottom water was anoxic and more saline. This was followed by rising salinities in the surface waters, holomixis and short phases of evaporite formation.	Benali et al., 1995 Russell et al., 1997 Rouchy et al., 1998
Gessoso-Solffera Formation, Sicily Late Miocene (Messinian)	1a Basinwide evaporite marginal basin	Biomarker compositions from immature organic sulphur-rich marl samples from 10 of the 14 evaporite cycles in an Italian Messinian evaporitic basin (Vena del Gesso) indicate large variations in the composition of species in the water column (e.g. dinoflagellates, diatoms and other algae, cyanobacteria, methanogens, green sulphur bacteria and bacterivorous ciliates) and in contributions from the continent (i.e. land plants) within each marl bed and between marl beds. The marl beds were deposited within a stratified lagoon where anoxic conditions extended into the photic zone for much of the time.	Damste et al., 1995 Keely et al., 1995
Organic-rich marls, Gulf of Suez Middle to Late Miocene	3 Rift basin continental to transitional marine	Inclusion studies show evaporitic environment of deposition (reducing conditions and high salinities), favoured oil generating kerogen. Carbonate minerals and inclusions trapped in gypsum indicate possible mixing of marine water with a brine of restricted occurrence at the time source rocks were deposited.	Kholief and Barakat, 1986 Rouchy et al., 1995
Bresse and Valence salt basins, France Palaeogene	3 Rift basin continental to transitional marine	Organic matter is mostly immature and occurs in intercalated non-halite beds. Type III kerogen is tied to terrigenous deposition. Type I kerogen is abundant in mesohaline evaporitic laminites of Valence basin. Type II is more abundant in Bresse basin. Organics accumulated beneath a perennially stratified brine column of up to tens of metres. Syndepositional dissolution of halite may have aided the accumulation of significant amounts of oil-prone organic matter in non-soluble brecciated residues.	Curial et al., 1990
Salt IV Formation, Mulhouse Salt Basin, Europe Lower Oligocene	3 Rift basin continental to transitional marine	Biomarker assemblages are dominated by acyclic isoprenoids, especially phytane ($0.13 < Pr/Ph < 0.52$), n-alkanes with specific distribution patterns, and steranes. Large differences in distributions indicate changes in palaeoenvironment. The largest changes are in desmethyl- and methylsterane distributions and are probably linked to occasional reconnection of the stratified evaporite basin to the sea, leading to a dinoflagellate bloom in the upper waters of a density-stratified brine column.	Damste et al., 1993 Hofmann et al., 1993a, b Hollander et al., 1993 Keely et al., 1993
Eocene Qianjiang and Lower Eocene-Paleocene Xingouzhu Formation of Jiangling-Dangyang area, Jiangnan Basin of northwest China Eocene-Paleocene	3 Foreland flexure basins, mountain-front fault depressions	Anoxic evaporitic lacustrine source rocks generated most of the crude oils. High salinity and low Eh enhanced preservation of oil-prone organic matter and facilitated incorporation of sulphur. Anoxia and the unusual presence of abundant sulphate as gypsum resulted in microbial reduction of sulphate to sulphide and incorporation of this sulphur into the kerogen. Biomarkers show that source rock in the Sha 13 well (1322 m) was deposited under more saline, lower Eh conditions than the Ling 80 well (1808 m), although both are from the Qianjiang Formation. Sha 13 sample is more organic-rich (6.62 vs. 1.27 wt.% TOC), has a higher hydrogen index (794 vs. 501 mg HC/g TOC) and faster reaction kinetics. Kerogen from the Sha 13 sample is Type I because it has a high hydrogen index and an atomic S/C ratio (0.074).	Huang and Shao, 1993 Jiang and Fowler, 1986 Peters et al., 1996 Ritts et al., 1999 Hanson et al., 2001
Green River Formation, Wyoming and Utah Eocene	3 Foreland flexure basin from Laramide orogeny	Laminated organic mudstones and oil shales deposited in deeper anoxic bottom waters of a perennial saline and density-stratified alkaline lake. Gilsonite and tabbyite bitumens are associated with Parachute Creek Member, deposited during a major expansion and freshening of ancient Lake Uinta. Compound specific isotopic analyses of β -carotene and phytane ($\delta^{13}C = -32.6$ to -32.1 ‰) from these bitumens reflect input from primary photosynthetic producers such as cyanobacteria. Sterane $\delta^{13}C$ values (-34.5 to -29.2 ‰) reflect contributions from lacustrine algae, while extremely depleted $\delta^{13}C$ values for methylhopanes (-58.1 to -61.5 ‰) suggest input from methanotrophic bacteria. Variations in the $\delta^{13}C$ values of the α - β -hopanes (-51.4 to 37.7 ‰) imply additional input from other bacterial sources. The wurtzilite bitumen generated from the saline facies of the Green River Formation was deposited during a later regression of Lake Uinta. Compound specific isotopic analyses of phytane ($\delta^{13}C = -30.1$ ‰) and steranes ($\delta^{13}C = -29.6$ to -26.7 ‰) from this bitumen indicate continued input from primary producers and eukaryotes. The higher relative concentrations of gammacerane ($\delta^{13}C = -26.9$ ‰) indicate increasing input from aerobic species. Slight enrichment in $\delta^{13}C$ in the wurtzilite extract (and several biomarkers) suggests sulphate-reducing bacteria outcompeted methanogens, thereby, eliminating the influence of methanotrophs in this later saline stage of deposition.	Ruble et al., 1994 Katz, 1995
Shahejie Formation, Shengli Oil Province, East China Eocene	3 Continental half-graben Palaeogene rift with Neogene subsidence	Source rock is mainly the lower part of the Third Member (Es 3) of Eocene Shahejie Formation and is a lacustrine organic-rich dark mudstone/oil shale with good quality Type I-II kerogen at the oil-generative stage at $Ro = 0.4$ - 0.8 %. First Member (Es 1) of Oligocene portion of Shahejie Formation has excellent oil potential in the nearby Gunan Basin but is immature in the Fulin Basin. Oil and rock samples from both basins can be grouped into three major biomarker families. First family shows low Pr/Ph (<1), a high gammacerane index (>0.3) and notable beta-carotene, typical of carbonate-evaporite environments. It exists in Es 1 rocks and the related oils and is early mature [β $\beta/(\beta + \alpha)$] = 0.2 - 0.3, and S/(R + S) = 0.10 - 0.20]. Second family shows high Pr/Ph (>1), a low gammacerane index (<0.2) and abundant 4-methyl steranes, indicative of freshwater lacustrine conditions like those in Es 3. It shows higher maturation [β $\beta/(\beta + \alpha)$] = 0.30 - 0.50 and S/(R + S) = 0.35 - 0.55] and notable diasteranes. Third family is transitional, has source and maturity ratios between the above families, and occurs in the Es3 unit samples from the basin interior.	Chen et al., 1996

Table 9.1. Characteristics and settings of evaporitic source rocks; for basin setting, 1 = basin centre; 2 = intrashelf; 3 = lacustrine. See text and Figure 9.3 for further detail on the significance of basin setting.

Formation/Group locality and age	Basin Style	Characteristics and depositional setting	Reference
Bucomazi Formation, Cabinda, offshore Angola Cretaceous	3 Rift basin continental to transitional marine	The Lower Congo hydrocarbon habitat is dominated by the Pre-Salt Bucomazi petroleum system. These lacustrine, often super-rich, laminated evaporitic sediments reveal considerable organofacies variations between their early lacustrine basin fill and later sheet drape development with three major depositional regimes reflecting salinity and water depth control. ¹³ C depleted basal sediments, showing strong gammacerane/4-methyl sterane signatures, were segregated by a major isotopic excursion. This event represents the transition from an early saline playa lake to a deeper water salinity-stratified mesohaline lake supporting a high level of bottom anoxia. For the intermediate sediments, sterane and tricyclic diterpane abundances, plus sterane/hopane ratios, had marine connotations and can be interpreted as the result of intermittent marine incursions. Foreshadowing irreversible oceanic incursion, a resurgence of gammacerane abundance in the uppermost sediments typified littoral-shallow marine depositional conditions.	Burwood et al., 1992 Burwood et al., 1995 Burwood and Mycke, 1996
Lagoa Feia Formation, Campos Basin, Brazil Early Cretaceous	3 Rift basin continental to transitional marine	Rift-stage lacustrine sediments are the source rock of all petroleum so far discovered in the Campos Basin, the most prolific oil province in Brazil. These organic-rich shales were deposited in anoxic brackish to saline lakes. Petroleum migration pathways involve direct contact between source and reservoir rocks within the rift sequence. Later migration to the marine sequence reservoirs is related to windows in the halokinetic salt layer connected to growth faults and unconformities.	Trindade et al., 1995 Mello and Maxwell, 1991
Kimmeridgian Shale, North Sea Jurassic	1b Evap-carb platform surrounding sediment-starved deep marine basin centre generated by ongoing Permian-Mesozoic rifting	Seawater flowed southwards from Boreal Ocean into Tethyan Ocean but evaporation in the shallow waters of the archipelago of islands and shoals created waters of increased salinity and in some cases local strong brines and evaporites, which sank and flowed as saline bottom currents (from 34-42‰) into deeper water. Areas of ponded deeper mesohaline water were commonplace in the more rapidly subsiding grabens, separated by sills, denser waters accumulated until they were able to spill over the sills. In this way more saline waters migrated along the seafloor depressions, their paths being determined by local tectonic features, but mostly in a north to south direction. A stable water stratification ensued, the halocline being at about 50 m water depth and periods of widespread increased salinity are marked by "hot" shales.	Cooper et al., 1995 Miller, 1990
Shelf margin laminites, Arabian Gulf from NW Iraq through the Arabian Gulf to central Oman (e.g. Diyab, Tuwaiq and Hanifa Formations) Upper Jurassic	2 Density- stratified intrashef basins surrounded by evaporitic platform. Some lows are possibly tied to salt withdrawal	Organic-rich laminated mudstones and wackestones deposited in pre-salt intrashef, mesohaline basins on a gently downwarped epeiric platform. Intrashef basins that retain organics all have a density and salinity stratified water column with mesohaline bottom carbonates. These basins source more than 90% of the hydrocarbons in the Middle East. They are argillaceous dolomitic limestones that feed the most prolific petroleum system in the world and underlie the world's richest reservoir: the Arab D in the Arab Formation. One of the most prolific source units is the Hanifa Fm. in the Arabian Basin of Saudi Arabia. In the deeper parts of the intrashef Arabian Basin (waters ≈30m deep) the Hanifa is composed of laminite muds and marls, while in the surrounding shelf it is dominated by grainstones and packstones. Within the Hanifa laminites there are discrete but minor primary laminae of anhydrite (originally gypsum), as well as early diagenetic anhydrite nodules, both indicators of occasional hypersalinity. There are also laminae of fibrous calcite, which some authors have interpreted as another indicator of hypersalinity. The Hanifa is a widespread and prolific source, it can entrain more than 30 metres of laminites; total organic carbon exceeds 1%, with some sections having more than 5%. The kerogen is predominantly hydrogen rich, the generated oils have a high sulphur content, a Pr/Py <1, and a predominance of even-numbered normal alkanes.	Ayres et al., 1982 Palacas, 1984 Evans and Kirkland, 1988 Droste, 1990 Beydoun, 1993 Carrigan et al., 1995 Whittle and Alsharan, 1996
Smackover trend of Mississippi, Alabama and Florida, northeastern Gulf of Mexico Upper Jurassic	2 Shallow restricted-circulation salinity stratified intrashef basin on a broad carbonate platform	Oil and gas in this trend are generated from algal-rich light-brown to black laminated lime mudstones (argillaceous content <6%) of the Lower Smackover Formation. Deposition occurred in intraplatform depressions surrounded by a broad carbonate platform. Bottom waters were stratified with slightly saline waters supplied from the broad platform surrounds and the shoaling carbonate system was sealed by the sulphate evaporites of the Buckner Anhydrite.	Oehler, 1984
Todilto Formation Todilto Basin, USA Middle Jurassic	3 Foreland flexural basin (lacustrine?)	The Limestone Member of the Todilto Fm. is a widespread carbonate laminite up to 3m thick, overlain in the subsurface by up to 30 m of CaSO ₄ known as the Gypsum Member, although it is mostly anhydrite. The Limestone Member is the source rock for 6 known hydrocarbon accumulations in the sands of the underlying Entrada Fm, while it and the overlying CaSO ₄ are the seal. The quantity of TOC is low (≈1%) for such a thin source rock and it has some unusual characteristics compared to most evaporitic source rocks. Laminite couplets are 0.15 mm thick yet are laterally continuous for up to 3.7 km and form widespread cohesive "sheets", which invariably contain remnants of vascular plants. The Todilto is probably lacustrine with a marine seep hydrology, similar in hydrology to the coastal salinas of southern Australia. The organics reflect the growth of a healthy conifer cover in its surrounds and its waters were density-stratified lacustrine, probably fed via a marine seepage inflow and periodic seasonal runoff. This maintained a density-stratified brine column, first at carbonate saturation during deposition of the Limestone Member, then at gypsum saturation during the deposition of the Gypsum Member.	Vincelette and Chittum, 1981 Evans and Kirkland, 1988
Organic mudstones intercalated with evaporites, Mandawa Basin, Tanzania Triassic	3 Rift basin continental to transitional marine	Total organic carbon (TOC) values range from 1.23 to 7.41% (wt) of kerogen Type II/III. The evaporite (hypersaline) influence is indicated by the presence of C-24-tetracyclic terpanes, gammacerane and C-35-homohopanes. The relative abundance of tricyclic terpanes (C-19-C-28+) with respect to pentacyclic terpanes (C-27-C-35) seem to change with depth, whereby the tricyclic/hopanes ratio apparently increases with depth. The mixed organic input from marine and terrestrial precursors are indicated by mixed abundances of C-27-, C-28-, C-29- steranes.	Kagya, 1996

Sub salt-allochthon oil seeps, Windsor Group, Nova Scotia, Canada Carboniferous	3 Rift basin continental to transitional marine	The oil seeps are either associated with upper Horton Group (Ainslie Formation) or basal Windsor Group (Macumber Formation) sediments. The biomarker distributions of the samples are similar to Stoney Creek oils and their lacustrine carbonate source rock (Albert Shale) of the Moncton Sub-basin, New Brunswick, as are oils from seeps in the Pugwash Salt mine.	Fowler et al., 1993
Black shales in the Paradox Member of the Hermosa Formation, Paradox Basin, USA Carboniferous (Pennsylvanian)	1a Foreland flexural basin	Organic-rich black shales (informally known as the Cane Creek, Chimney Rock, Gothic shales) form a carbonate laminite basal sequence to a number of salting-upward evaporite cycles in the Paradox Member. Mineralogically the shales are between 30-50% calcite or dolomite with clays and quartz sand forming the remainder of the matrix. TOC values of 5% of hydrogen-prone organics in the black shales are usual, with values of 10% not uncommon and the highest values more than 20%. The organics are mixtures of halotolerant debris and marine-style organics formed when surface waters were at marine salinities, as well as occasional terrestrial organics washed into the basin from the surrounding hinterland.	Evans and Kirkland, 1988 Hite et al., 1984
Oil Shales, Junggar Basin, NW China Upper Permian	3 Controversial, with tectonic interpretations ranging from foreland flexure to regional transtensional basin	Junggar Basin is one of the largest oil-producing basins in China, its Upper Permian oil shales are among the thickest and richest lacustrine source rocks in the world. Together the Jingjingzigu, Lucaogou, and Hongyanchi Formations of the southern Junggar Basin comprise over 1000 m of organic-rich lacustrine facies. They record an evolution from relatively shallow, evaporative lakes to freshwater lakes with fluvial systems. Jingjingzigu Formation was deposited in a perennial saline lake characterized by low TOC and HI, and biomarker features (such as abundant β -carotane) consistent with a specialized saline or hypersaline biota. Biomarker distributions in Jingjingzigu Formation extracts most closely resemble oils from the giant Karamay oilfield. Overlying Lucaogou Formation represents one of the richest and thickest lacustrine source rock intervals in the world, yet it contradicts conventional lacustrine source rock models in at least two important aspects. First, deposition occurred at middle palaeolatitudes (39-43° N) rather than in the tropics. Second, limited nutrient supply in a drainage basin dominated by intermediate volcanic rocks appears to have caused low to moderate primary productivities. Stable salinity stratification and low inorganic sedimentation rates in a deep lake nonetheless resulted in deposits with up to 20% TOC and HI near 800. Overlying Hongyanchi Formation has 1-5% TOC but low HI, and was deposited in freshwater oxic to sub-oxic lakes.	Carroll, 1998 Carroll et al., 1992 Tang et al., 1997
Ravnefeld Formation, East Greenland Upper Permian	3 Rift basin continental to transitional marine	The Ravnefeld Formation is subdivided into five units that can be traced throughout the Upper Permian depositional basin. Two of the units are laminated and organic rich, and were deposited under anoxic conditions. They are considered good to excellent source rocks for liquid hydrocarbons with initial average TOC (total organic carbon) values between 4 and 5% and HI (hydrogen index) between 300 and 400. The cumulative source rock thickness is between 15 and 20 m. The source rocks are separated and enclosed by three units of bioturbated siltstone with a TOC of less than 0.5% and an HI of less than 100. These siltstones were deposited under relatively oxic conditions. The organic geochemistry of the source rocks is typical for marine source rocks with some features normally associated with carbonate/evaporite rift environments [low Pr/Ph (pristane/phytane), low CPI (carbon preference index), distribution of tricyclic and pentacyclic terpanes]. The establishment of anoxic conditions and subsequent source rock deposition was controlled by eustatic sea level changes.	Christiansen et al., 1993
Phosphoria Formation, Little Sheep Creek, Montana Permian	1b Foreland flexure basin	Correlations between biomarker indicators of anoxia and salinity suggest that anoxia was in part the result of a chemocline separating normal marine waters above from more saline bottom waters. Anoxia and salinity in the bottom waters increased with time making conditions in the basin progressively more hostile to benthic organisms.	Dahl et al., 1993
Kupferschiefer Formation, NW Europe Permian	1a Rift basin, restricted marine	Thin, widespread organic-rich laminated mudstone deposited in shallow mesohaline marginal sea-lakes with waters which were <100m deep and mostly 10-30 m deep. Surface exchange with Zechstein ocean was restricted by palaeohighs.	Bechtel and Puttmann, 1997
Anhydritic lacustrine beds, East Shetland Platform, North Sea Middle Devonian	3 Rift basin, restricted marine	The UKCS well 9/16-3 drilled on the western flank of the Beryl Embayment indicates local development of hypersaline environments equivalent to the Achanarras/Sandwick fish bed. Shows close affinity with contemporaneous Middle Devonian source rocks of the Inner Moray Firth and crude oil in Beatrice oil field.	Duncan and Buxton, 1995
Muskeg Formation and Lower Keg River Member, Alberta, Devonian Canada	1a Rift basin, restricted marine	Laminated organic-rich bituminous mudstones deposited in pre-evaporitic density stratified water columns. Vertical migration from the Muskeg formation to the Muskeg Reservoirs may have occurred through local fracturing of anhydrites driven by the dissolution of Black Creek halite.	Clark and Philp, 1989 Stasiuk, 1994
Laminated evaporitic A-1 mudstones, Michigan Basin Silurian	1a Rift basin, restricted marine	Biomarker characteristics indicate a carbonate/evaporite source rock deposited under hypersaline conditions in a strongly reducing environment. The source rocks occur in the basin centre in organic-rich laminites of the inter-reef A-1 Salina Formation, a mesohaline carbonate deposited beneath a density stratified brine column.	Gardner and Bray, 1984 Obermajer et al., 1998 Obermajer et al., 2000
Chandler Formation, Amadeus Basin, Australia Lower Cambrian	1a Foreland flexure	Thin bituminous pre-evaporitic carbonate mudstone deposited subaqueously in a restricted basin immediately prior to the deposition of the thick halites of the Chandler Formation.	Bradshaw, 1988
Hormuz Series, Arabian Gulf and counterparts in Oman, India and Pakistan Neoproterozoic to Early Cambrian	1 Rift basins, restricted marine	Almost all the Persian Gulf and large areas of southern Iran and northeastern Arabia are underlain by a thick sequence of sediments, known as the Hormuz Series, or the Huqf Group in Oman. It is made up of interbedded salt, anhydrite, dolomite, shale and sandstone. It is not only the cause of many salt-dome-related oil and gas fields but is also considered to have been a major source rock for hydrocarbons in Ordovician, Devonian, Carboniferous, Permian and perhaps younger reservoirs.	Amthor, 2000 Edgell, 1991 Grantham et al., 1988 Peters et al., 1995 Terken and Frewin, 2000

Table 9.1 cont'd. Characteristics and settings of evaporitic source rocks.

anhydrite, which otherwise plug and cement source intervals. Style 1b source rocks develop where dense mesohaline bottom waters pond in the deeper parts of deep density-stratified restricted-marine basins. Slightly elevated bottom brine salinities are maintained by a series of dense brine underflows, fed from nearby shoalwater evaporitic platforms (Figure 9.3). A deepwater “marine” centre typifies such basins, along with widespread evaporitic and shoal water carbonate sediments in the surrounding platforms and shelves. Setting 1b basins are best thought of as stunted or underdeveloped basinwide evaporite systems. Development of the basinwide evaporite hydrology was suspended prior to the basin centre drawdown reaching the state of complete hydrographic isolation, which is needed for widespread salt precipitation. Evaporitic conditions (mostly bedded anhydrites) dominated on isolated platform depressions about the basin margin. Typical examples of this style of association are Kimmeridge shales of the North Sea (Miller, 1990; Cooper et al., 1995), organic-rich laminites of the Cherry Canyon Formation in the Permian Delaware Basin of west Texas (Jones, 1984) and possibly some of the Devonian laminites of the Alberta Basin (Clark and Philp, 1989).

In this setting, waters in the deepwater basin centre remain starved of sediment and density-stratified, with the upper less saline part of the water column typified by normal marine water maintained through surface connections to the open ocean. The little sediment matrix that does accumulate in the basin centre settles into an anoxic thermally/density stratified bottom so that the sediment matrix of the source laminites is dominated by a planktonic or nektonic biota and a more or less constant elevated organic content. Carbonate banks or reefs in the surrounding platform grade landward through lagoonal and evaporitic platform facies in to terrestrial clastics. At times of slightly lowered sea level these epeiric platforms can go evaporitic and so deposit widespread platform salts (Chapter 5). Such basins show a centrifugal salinity gradient where the highest salinity areas are in the surrounding shallow evaporite platforms, which supply dense saline waters that trickle and seep basinward to pond in seafloor lows at the anoxic base of a density stratified water column.

With setting 1b, the formation of evaporites and saline waters about the basin edge is not typically followed by the deposition of basin-centre evaporites. At the time the deepwater organic laminites are accumulating, the deep basin centre waters lie at the bottom of the thick density-stratified water column in a semi-enclosed seaway. Bottom brines may be no more than 3-5‰ more saline than the normal marine waters. For example, at the time the Purbeck evaporites were accumulating on

the adjacent platform, the anoxic bottom waters in the marine basin centre, atop the accumulating Kimmeridge shales, had salinities around 42‰, temperatures $\approx 30^{\circ}\text{C}$ and densities ≈ 1.0270 . The overlying near normal marine waters had salinities of 34-39‰, surface temperatures of 26°C in the south and as low as 6°C further north in the region of the Boreal Ocean inflow and densities around 1.0267 (Miller, 1990).

Basin Setting 2: Upper Jurassic source rocks of the Middle East are well studied examples of the epeiric shelf or marine evaporitic platform settings and typify style 2 source rocks, which are deposited within local somewhat deeper, density-stratified mesohaline intrashelf lows (Figure 9.4; Table 9.1; Ayres et al., 1980; Evans and Kirkland, 1988; Droste, 1990; *pers obs.*). In the Tethyan of the Middle East this style of source rock feeds a petroleum system that is probably the most efficient in the world. It evolved from Upper Jurassic source rock accumulators (typically with TOC's $\approx 1\%$ and occasionally up to 6-10%) into evaporitic mudflats sealing the mostly bioclastic reservoirs of the carbonate platform of the Arab cycles, beneath the regional Hith Anhydrite seal, which was deposited on a saltern-covered platform (Figure 10.9). The laminite source rocks in the various intrashelf depressions were deposited at times of widespread epeiric carbonate deposition and stagnant oceanic circulation.

It was a time when much of the Arabian platform was covered by a warm shallow greenhouse sea precipitating varying combinations of carbonates and evaporites. Denser warmer waters, generated by evaporation of epeiric waters and water of the surrounding evaporitic mudflats, were concentrated to where they were somewhat more saline than normal seawater. Dense brines then trickled and seeped over the shallow seafloor into the lower parts of restricted intrashelf basins, to create density-stratified water bottoms that were not more than tens of metres deep and no more than 10-30‰ more saline than seawater (Ayres et al., 1982). Ongoing mixing and dilution of the bottom-hugging brines during their passage to the lows meant the basal water mass in the intrashelf lows, although saline, rarely attained gypsum saturation (mostly mesohaline anoxic brines). The overlying column was usually near normal marine salinity. Salt withdrawal and dissolution of salt diapirs and allochthons, sourced in the Precambrian Hormuz salt, perhaps helped create the intrashelf depressions and may also have played a role in generating a portion of the bottom brines. As the source rocks of the style 1b Kimmeridge Clays accumulated, halokinesis and salt solution of Zechstein mother salt probably also played a role in generating local briny anoxic bottoms (Clark et al., 1999).

One of the most prolific intrashelf source rocks in the Middle East is the Hanifa Formation deposited in the intrashelf Arabian Basin of Saudi Arabia (Figures 9.4, 10.10; Droste, 1990). It sources most of the hydrocarbons reservoirs in the Arab cycles of Saudi Arabia and is regionally sealed by the Hith Anhydrite. The organic-rich portion of the Hanifa, deposited in the “deeper” parts of the intrashelf basin (waters $\approx 30\text{m}$ deep), is composed of laminite muds and marls, while in the surrounding Arabian shelf it is dominated by grainstones and packstones. All Hanifa facies can be locally overprinted with later anhydritic burial and

reflux cements and later diagenetic dolomites. As the various depressions filled with laminites they shallowed to where the stratification was lost and the sediment became an open marine packstone-wackestone, equivalent to sediments deposited over the rest of the Arabian Platform.

Later episodes of hydrographic isolation of the platform, via buildup of a transgressive platform rim and a slight fall in sea level, then drove deposition of anhydritic saltern or mudflat caps of the various Arab cycles A-D and ultimately the deposition of

the regional Hith Anhydrite seal (Figure 10.10). Within parts of the Hanifa laminites there are discrete laminae and thin beds of primary anhydrite, as well as early diagenetic anhydrite nodules, both indicators of periodic hypersalinity. Likewise, the restricted evaporitic caps to some of the source cycles in basin margins to the Hanifa Formation in the Arabian Basin can locally preserve aligned gypsum ghosts, indicating a subaqueous gypsum precursor in the shallower parts of the epeiric seaway (Figure 9.9). Similar, but volumetrically less prolific, intrashelf source rocks characterise parts of the Lower Smackover Formation (Upper Jurassic) of the north-eastern Gulf of Mexico, as in the Mississippi Interior Salt Basin (Oehler, 1984), and parts of the Cretaceous Sunland Formation of Florida (Palacas et al., 1984).

A variation on this density-stratified mesohaline epeiric platform-depression style of source rock accumulation is the phosphate and organic-rich sediment of the Phosphoria Formation in the USA (Stephens and Carroll, 1998). This laminated unit

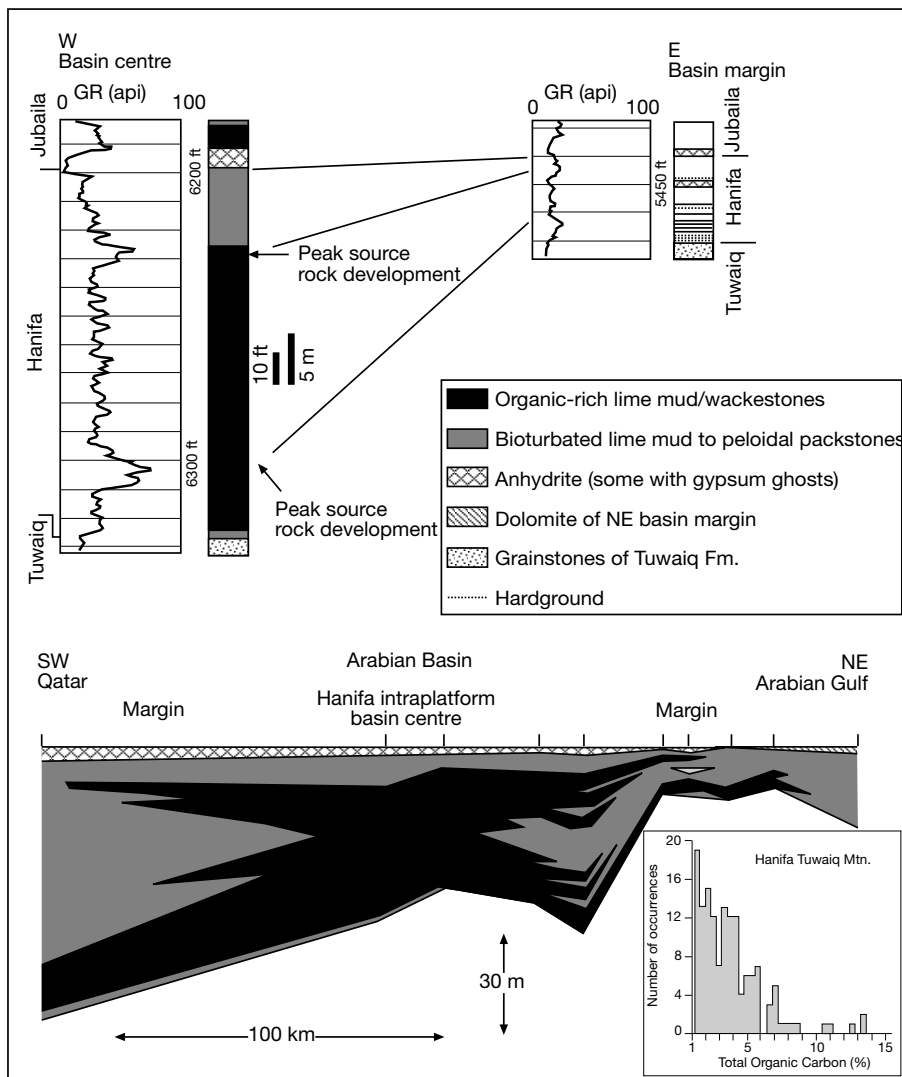

Figure 9.4. Characteristics of the Hanifa Formation, Saudi Arabia, a setting 2 intraplatform basin source rock that was deposited beneath relatively shallow and anoxic mesohaline bottom waters in a slight depression on the shelf and was surrounded by epeiric evaporitic sedimentation, as indicated by the presence of anhydrite in the Hanifa Fm. (after Droste, 1990). Peaks in the organic content of these carbonate mudstones are indicated by peaks in the gamma curve. TOC inset in lower right is redrafted from Carrigan et al., 1995.

sources much of the oil in Wyoming and was deposited in shelf edge depressions of the Phosphoria Sea adjacent to an area of marine upwelling. The nutrient-rich waters facilitated algal blooms near and atop the shelf edge, while bottom-hugging brines, seeping seaward from the evaporitic hinterland, ponded in stagnant shelf edge depressions. Overlap of the two systems created local anoxic shelf-edge mesohaline depressions with anoxic bottom waters that preserved a rain of organics detritus from the overlying algal blooms (Figure 9.3). This system requires an epeiric evaporitic hinterland to supply bottom-hugging brines and, like the saltern-sealed Jurassic intrashelf depressions of the Middle East, has no modern counterpart.

Basin setting 3: These source rocks accumulated in sediment-starved or underfilled saline lakes in arid climates. The laminites typically accumulated in the early continental stage of infill in an opening rift, prior to its opening into a marine-fed marginal evaporite basin, or in the restricted lacustrine stage of a foreland flexure in a collision belt (Figures 5.27, 9.3). Modern underfilled saline rift lakes have some of the highest rates of organic productivity known and can accumulate high levels of organics within carbonate laminites. Some of these lacustrine laminites accumulate beneath deep density-stratified water columns, while others accumulate as “moat facies” or microbial mudflats about lake margins (Figure 9.3; Table 9.1). The likelihood of numerous water level changes during the life of a saline lake especially effect laminites deposited in shoal water moats and margin mudflats and so can lower their preservation potential (Bohacs et al., 2000). Most oil-prone style 3 lacustrine source rocks were deposited at the bottom of perennial salinity-stratified hydrologies, with water column depths measured in metres to tens of metres, not as subaerially exposed algal mudflats. Examples include the Wilkins Peak Member of the Eocene Green River Formation, USA, the Lagoa Feia Formation of the Alagoas portion of the Campos Basin in Brazil, the Bucomazi Formation in offshore West Africa and the Jingjingzigou Formation in the Junggar Basin, China (Table 9.1).

The desiccation needed to form underfilled lacustrine succession typically means that saline lacustrine phases have lesser aerial extents compared to times of freshwater deposition.

Figure 9.5. Kerogen character of Laney Member and Luman Tongue of the Eocene Green River Formation, USA. A) Hydrogen and oxygen indices. B) Pyrolysis yields of hydrocarbon-equivalents (mg/g rock) plotted against organic carbon percentages. (after Horsfield et al., 1994).

But this does not necessarily mean the evaporitic lacustrine source rocks are less prolific than their freshwater counterparts. Within the Green River Formation there are two associations (fresh and saline) of lacustrine organic laminites exemplified by the Luman Tongue and the Laney Member (Figures 5.10, 9.5; Horsfield et al., 1994). The Luman Tongue consists of organic-rich mudstones deposited as profundal sediments at a time when lake waters were relatively fresh. Proximal organic-poor sediments, as well as coals and thin sandstones, were deposited in the lake plain. The highest levels of TOC in the Luman Tongue are found in lake margin deposits, which contain a mixture of alginite and vitrinite, but they have a low hydrogen index and a low petroleum generation potential. In fact, the petroleum generation potential of these freshwater deposits is no more than moderate.

In contrast, the organic percentages of the carbonate laminites of the Laney Shale are much higher (6-22%) and they are hydrogen prone. The most organic-rich samples were deposited in the

lowest parts of the lake and are composed mostly of alginite with relatively minor contributions from higher plants. The much higher petroleum potential of the Laney shale reflects the marked density stratification of Lake Gosiute waters at the time the Laney was accumulating. At that time bottom anoxia was stabilised by the perennial highly saline bottom waters (Fischer and Roberts, 1991). The vertical transition from saline lacustrine Jingjingzigou Formation to the highly prolific brackish oil shales of the lacustrine Lucaogou Formation in the Permian Junggar Basin of NW China may represent a similar dissolution induced transition in the lake water column and help explain the lakes unusual latitude (Table 9.1; Carroll, 1998).

Basin Setting 4: is an increasingly documented open-ocean evaporite-associated source rock setting where density-stratified saline bottom brines and organic-enriched laminites accumulate in brine-bottomed depressions atop and adjacent to shallow and dissolving salt allochthons (Figures 9.3, 9.33). With burial these laminites may act as source rocks, but unlike the restricted settings of the preceding three styles, deposition typically occurs beneath open marine water atop continental slope and rise sediments. The laminites accumulate on the floor of deep brine pools that form on or near the margins of actively flowing and dissolving shallow salt allochthons. This association is discussed in detail later in this chapter and it is also a significant setting for the formation of base metal-hosting laminites as in Tunisia and the Red Sea (Warren, 2000b). As yet it is not a widely documented environment for hydrocarbon source rocks, but it may in part explain the higher than expected source potential of many prodelta and slope muds in the passive margin fill of evaporite-floored halokinetic rifts.

Source rocks of settings 1a, 2 and 3 are typified by the accumulation of mm-scale layers of oil-prone organics typically in a matrix of fine carbonates. Setting 1b typically contains higher levels of siliciclastic fines and in many cases is a basinal marl or occasionally a laminated siliciclastic carbonate shale. The matrix of setting 4 laminites tends to be composed of whatever detrital sediment is accumulating atop the salt allochthon. In many situations, such as the Gulf of Mexico and the Mediterranean allochthon terranes, this matrix is a siliciclastic mud/clay laid down at the distal ends of prodelta wedges. In others, such as the Jurassic and Cretaceous of the Arabian Gulf and the Triassic of Tunisia, the matrix was carbonate mud.

The presence of mesohaline and marine carbonate muds, rather than aluminosilicate clays, in the matrix of many organic-rich evaporitic source rocks can change maturity and migration parameters. Mesohaline carbonate source rocks are susceptible to early generation of bitumens and volatiles compared with

terrigenous shales. The proportion of bitumens (extractables) in the organics of carbonate source rock is high compared to that of shales as most mesohaline carbonates are largely isolated from high levels of terrigenous influx and the associated load of “spent” or oxidised organic matter (Warren, 1986). For the same reason much of the early asphaltic product in a mesohaline carbonate laminite begins to migrate early in the burial history, whereas similar materials are held longer in the lattice of aluminosilicate clays (Warren, 1986; Cordell, 1992). Espitalie et al. (1980) showed that carbonate source rocks are likely to provide larger volumes of hydrocarbons for pooling than analogous terrigenous shales for the same levels of TOC. Geochemical analyses show that heavy oils from carbonate source rocks can form at marginally mature stages and at lower temperatures than required for oil generation from terrigenous shales, although much of the key data is ambiguous (Jones, 1984).

Evaporitic source rocks deposited from mesohaline waters are a reality (Table 9.1), let us now look to the modern and at relevant processes to see why this is so.

Halobiota: adaptations and biomarkers

As long ago as 1826 during his voyage on the *Beagle*, Charles Darwin described biological aspects of the production of solar salt from an inland lake some 23 km from El Carmen, Patagonia. Although unfamiliar with bacteria (after all, Louis Pasteur was only a 4 year-old child at the time), he recognised that there was a “putrefying life-form” in the mud; that algae caused a green colour on the lake; that flamingoes fed on the brine shrimp and worms; and that other “infusorial animalcula” were part of the salt producing system. Yet in 1957, in his classic book on evaporites, Lotze made the statement: “Nicht das Leben, sondern der Tod beherrscht die Salzbildungsstätten” (Not life, but death rules the locales of salt deposition). Likewise, the name of the Dead Sea in the Middle East comes from the time of the Roman occupation when it was given the Latin name *Mortuum Mare* for its perceived lifelessness.

For millennia, saline environments have been visualised as biotal deserts, largely devoid of biological activity and hence were sedimentary systems with little source rock potential. Like Sir Charles Darwin, we now know that this is not the case. Rather, almost all modern saline environments and water bodies are sites of periodic but intense organic activity, where numerous highly specialized algal, bacterial and archaeal species grow and die

Figure 9.6. Total organic carbon (TOC as dry wt. percent) in various modern saline settings (compiled from various sources listed in this chapter and Warren, 1986).

(cycles of feast or famine). Occasionally, they can leave behind substantial volumes of oil-prone organic residues in laminated bottom sediments, especially in mesohaline carbonates, which on burial can evolve into prolific source rocks. Even in modern saline settings, where evaporite depositional settings are not as diverse or widespread as those of much of the past, conditions are such that mesohaline carbonates can preserve high levels of total organic carbon (TOC; Figure 9.6).

Metabolic pathways in producers and consumers

Before we discuss how halotolerant and halophilic biomass accumulates in saline environments, we need to review some basic biology and biochemistry. Our understanding of the taxonomy and biogeochemistry of two groups, the cyanobacteria (bacteria) and the archaea that can dominate the biota of many hypersaline waters, has undergone quantum change in the last two decades. In the late 1970s, Professor Carl Woese proposed, on the basis of ribosomal RNA affiliations (gene mapping), that life be divided into three domains instead of two, namely: Eukaryota, Eubacteria, and Archaeobacteria (Woese and Fox, 1977; Woese 1993). He later decided that the term Archaeobacteria was a misnomer, and shortened it to Archaea and the term Eubacteria to Bacteria (Figure 9.7; Woese et al., 1990).

DNA base-pair studies show that Archaea are as different from Bacteria as from *Homo sapiens*, but Woese's notion of three domains of life did not take the biological world by storm. Before the advent of hybridization and genome mapping, the inferred evolutionary relationships among microbes were contradictory and very messy. Species or interspecies relationships were not easily established on the basis of intricacies of differences in cellular structure, which are minimal, or by staining, or by the fossil record, which is not species specific. For example, based on their morphology, the archaeal *Halobacteriaceae* can be grouped with the bacterial gram-negative rods (a gram positive or gram negative description indicates whether or not the microbial cell wall reacts with Gram's stain). The advent of gene-based classification threw classic morphological and stain-based groupings into disarray. All the dust from this confrontation between morphology and gene-mapped subdivisions of the biological realm has yet to settle.

The initial chagrin of those botanists and zoologists versed in classic ecological and cladistic techniques to Woese's laboratory-based tripartite classification is understandable; after all, in his nonanthropocentric regime the realms of botany and zoology are relegated to a few twigs on the outermost branches of the Eukaryan limb (Figure 9.7). Even today some books and articles today still refer to archaea as types of bacteria.

Figure 9.7. Tripartite classification of the domain of life based on genetic differences (as proposed by Woese et al., 1990).

Many microbiologists still feel Woese's system gives too much prominence to the microbial. In this Woese's detractors may be wrong. Estimates of the subsurface microbial biomass, known as the subsurface lithoautotrophic microbial ecosystem or SLiME, place it as high as 100 trillion tonnes (1×10^{14} to 1×10^{18} grams of carbon; Pedersen, 1993; Fredrickson and Onstott, 1996). As such, if it could be stacked above ground, this amount of "gray goo" would cover the earth with a biological layer some 15 metres thick. Since the surface biosphere mass is approximately 4.6×10^{17} grams of carbon, the biomass of the rock-bound subsurface microbial biosphere may well exceed that of the surface biosphere. Woese's tripartite conclusions are slowly moving into the general biological literature.

Cyanobacteria, formerly known a blue-green algae, are now placed in the bacterial kingdom as cells lack a membrane-bound nucleus, like all prokaryotes, but they are not totally at home there. Unlike any other bacteria, they photosynthesise aerobically. Instead of the bacteriochlorophyll pigments found in purple and green bacteria, blue-greens contain chlorophyll-a, as do all eukaryotic^{9,3} phototrophs, and produce free oxygen as a photosynthetic byproduct. Yet they lack the organized chloroplasts of eukaryotes and have their photosynthetic apparatus distributed peripherally in thylakoids within the cellular cytoplasm. Cyanobacteria are often a significant component of modern laminated microbial mats in saline settings that are often called "algal mats" or "cryptogalaminites" in ancient strata. A more correct description for these ancient counterparts is microbial mat or microbialite (Chapter 1).

All three domains of life are represented in saline environments, although most higher plants and animals only survive at the lower end of the mesohaline range. Photosynthesising^{9,3} autotrophic cyanobacteria (prokaryote) and algae (eukaryotes) are the dominant primary producers in modern mesohaline waters, along with lower and varying inputs from the higher

plants and photosynthesising bacteria. When nutrients are available, halotolerant alga and cyanobacteria constitute the bulk of the planktonic biomass in the upper layer of a stratified brine column and construct the upper parts of microbial mats in oxygenated settings wherever light penetrates to the sediment surface. Although the cyanobacteria are prokaryotic, like eukaryotic algae and higher plants, they are photoautotrophic and require oxygen to photosynthesise. The typical aerobic photosynthetic reaction is:

That is, carbon dioxide and water react in the presence of chlorophyll and sunlight to form carbohydrate plus water plus oxygen.

All aerobic photosynthesising organisms that split water molecules and generate oxygen, contain varying proportions of the pigments chlorophyll-a, phycobilin and β -carotenes. Chlorophyll-a is a green pigment that absorbs red and blue-violet light, hence the green colour of photosynthesising cyanobacteria and plants. It is made up of molecules that contain a porphyrin 'head' and a phytol 'tail' (Figure 9.19a). The polar (water-soluble) head is made up of a tetrapyrrole ring and a magnesium ion complexed to the nitrogen atoms of the ring, its phytol tail typically extends into the lipid layer of the thylakoid membrane.

^{9,3}*Autotrophs* (literally "self feeders") are organisms capable of producing organic compounds from simple inorganic compounds.

Heterotrophs (literally "feeders on others") use organic molecules synthesized outside their body as a source of energy and carbon.

Chemoautotrophs use endogenous light-independent reactions to obtain energy, these reactions involve inorganic molecules and an electron donor other than water and do not release oxygen.

Lithoautotrophs depend upon inorganic compounds as electron donors for energy production.

Photoautotrophs use light as a source of energy and CO_2 as a source of carbon (oxygenic photosynthesis).

Chlorophyll-b is a closely related molecule and occurs only in green algae and plants, while chlorophyll-c is found only in the photosynthetic members of the Chromista kingdom (includes diatoms, kelp and coccoliths), as well as in dinoflagellates (which are alveolates along with the foraminifera).

Phycobilisome pigments are water-soluble proteins that occur only in the cyanobacteria and red alga (rhodophytes). They absorb light in the blue-green, yellow, and orange regions of the spectrum compared to chlorophylls, which absorb light in the blue and red regions. Its presence allows communities to photosynthesize into deeper waters and sediment depths where only the longer wavelengths penetrate (blue-green spectrum). Phycobilin molecules are linear tetrapyrroles and are structurally related to chlorophyll-a, but lack the phytol side chain and the magnesium ion (see biomarker discussion later in this chapter). They must pass their absorbed photic energy to chlorophyll and so occur in chlorophyll-rich oxygen-evolving photic reaction centres called chloroplasts. Cyanobacterial chloroplasts make up an extensive, intracellular system of flattened, membranous sacs, called thylakoids, the outer surfaces of which are studded with regular arrays of phycobilisome granules.

Carotenes are accessory water-insoluble pigments in most oxygenic photosynthesizers and are directly attached to cellular membranes. They are orange-red or yellow in colour and absorb the blue-violet and blue-green wavelengths missed by chlorophyll. Structurally they are isoprenoids (terpenes) and are what give autumn leaves their colour when deciduous plants re-absorb chlorophyll in preparation for winter. In the hypersaline realm, carotene pigments from algae like *Dunaliella* sp. and some Archaea are what give the characteristic red or pink^{9,4} colours to brines where they are blooming.

In contrast to the cyanobacteria, all other photosynthetic bacteria in saline waters are^{9,3} chemoautotrophs. The green and purple sulphur bacteria take their hydrogen atoms from biologically or volcanogenically produced H₂S and generate sulphur as a waste product (hence their names; Table 9.2). They utilize a single type of photosynthetic reaction centre with a different photosynthetic pigment (bacteriochlorophyll) to the cyanobacteria and higher plants. It absorbs light of longer, less energy-rich wavelengths compared to chlorophyll and phycobilin. Green sulphur bacteria (Chlorobiaceae) and purple sulphur bacteria (Chromatiaceae) typically oxidise this H₂S via anoxygenic photosynthesis and produce native sulphur or sulphate, but some species can use inorganic elemental sulphur, sulphide, or thiosulphate as the electron donor. In contrast the purple and green nonsulphur bacteria use electrons from organic substrates or hydrogen gas (Table 9.2).

The following simplified equation typifies photosynthesis in purple or green sulphur bacteria:

That is; carbon dioxide and hydrogen sulphide react in the presence of bacteriochlorophyll and sunlight to form a carbohydrate (such as glucose) as well as water and sulphur. Light-absorbing pigments of the purple and green sulphur bacteria consist of various bacterial chlorophylls (a-d) and carotenoids. Phycobilins and chlorophylls, characteristic of the cyanobacteria, are not found in these chemoautotrophs.

^{9,4}The pink to purple colours that typify many hypersaline water bodies comes from concentrations of mostly carotenoid pigments present in the cytoplasm of various halophilic microorganisms. Most haloarchaea are red due to a high content of C-50 carotenoids of the bacterioruberin series in the cell membrane. Photosynthetic cyanobacteria and eukaryotes (e.g., unicellular green algae of the genus *Dunaliella*) contribute to the pigmentation of the hypersaline waters thanks to the presence of chlorophylls and C-40 carotenoids (mostly all-*trans*- and 9-*cis*-β-carotene). Chloroplasts in *D. salina* and *D. parva* accumulate large quantities of this β-carotene at their peripheries in the form of droplets (plastoglobuli) and so blooms appear brown-red, not green like most other algae and cyanobacteria. The carotene seems to act as photo-protective ‘sun-screen’ to protect chlorophyll integrity and shield cellular DNA from the high levels of irradiance that characterizes the normal habitat of halophilic *Dunaliella*. It may also act as a ‘carbon sink’ to store excess carbon produced during photosynthesis under conditions where growth is nutrient-limited but photosynthetic carbon fixation must continue.

Chlorophylls absorb red and blue wavelengths much more strongly than they absorb green wavelengths, so chlorophyll-bearing cyanobacteria and most photosynthesizing plants appear green. In contrast, the carotenoids and phycobiliproteins strongly absorb green wavelength, so microbes and algae with large amounts of carotenoid pigments appear yellow to brown, those with large amounts of phycocyanin appear blue, and those with large amounts of phycoerythrin appear red.

Pigment levels can indicate the stratification of the microbial community in any photoresponsive biomass in a brine column. Red wavelengths (long wavelengths) in white light are absorbed in the first few metres of a brine column or the uppermost millimetre or two of a microbial mat (chlorophyll utilizers flourish). The blue and green wavelengths (shorter) reach deeper into the brine column.

Halophilic archaea were first investigated microbiologically as a common cause for spoilage of salted fish, with their carotene imparting a characteristic red colour. None of the halophilic Archaea have proved to cause disease, so their effects on salted foodstuffs are largely aesthetic. Haloarchaeal spoilage explains the red colour and the foul smell in “red herring.” The phrase “throw in a red herring” means to mislead. Spoiled salted fish were once used by poachers to distract hunting hounds. Poachers would interpose themselves between the prey and the hunting party and drag a sack of red herring across the trail to mislead the dogs, who would follow the scent trail left by the red herring and not the prey. This would give the poachers the opportunity to bag the prey.

Many purple and green sulphur bacteria store elemental sulphur as a reserve material that can be further oxidized to SO_4 by using it as a photosynthetic electron donor. Some of the green sulphur bacteria are probably the most energetically efficient of all phototrophic organisms, they are capable of living photosynthetically in environments where light intensities that are less than 0.01% of typical daylight.

All the groups we have discussed to date are primary producers that are light-dependant and along with halotolerant photosynthetic eukaryotes made up the base of the food chain in most modern hypersaline ecosystems. But there and another class of microbes, the 9,3 lithotrophs and chemotrophs than can metabolise independent of a light source. Modern purple and green chemoautotroph sulphur oxidising communities inhabit the narrow oxygenated interface at the edge of anoxic H_2S -rich chemistries where hydrogen sulphide is bubbling up from below. In saline microbial communities they generally inhabit an unlit layer beneath the lit-community of aerobic cyanobacteria and purple bacteria above (photosynthesizers) and the community of sulphate reducers and fermenters below. This is true in both mats and stratified brine columns (Figure 9.8). Lithotrophic microbes are also a common halocline component in deep seafloor seep communities and in caverns formed by the action of sulphuric acid (Figure 7.45).

Lithotrophic sulphur-oxidisers do not require light to metabolise (chemoautotrophs not photoautotrophs) include both bacteria (e.g. *Thiobacillus sp.*) and archaea (e.g. *Sulpholobus sp.*). Other lithotrophic bacteria use substances such as nitrate and reduce it to nitrite (e.g. strains of *Nitrobacter sp.*). *Sulpholobus* is an archaeal hot spring dweller and transforms H_2S to elemental sulphur, it flourishes at temperatures in excess of 90°C and can live in environments where pH hovers around 1, such as the gypsum wall coats and snottites in sulphuric acid caves (Figure 7.49). *Thiobacillus sp.* are widespread in marine and hypersaline settings, where they oxidize thiosulphate and elemental sulphur to sulphate. For example a unicellular halophilic, chemoautotrophic sulphur-oxidizing bacterium, *Thiobacillus halophilus*, was described in a hypersaline salt lake in western Australia where it grows in waters with salinities of up to 240‰ (Wood and Kelly, 1991). In the last few years, many of the sulphur-oxidizing bacteria originally classified under the genera *Thiobacillus* have been reclassified into the α , β , and γ subclasses of the Proteobacteria. It probably means there is a broader range of sulphur-oxidising forms in hypersaline environments than current species listings suggest and that the informal separation of sulphur oxidisers into the purple and green bacterial groups is still confused.

Archaea, life's third domain, are mostly extremophiles that thrive in highly stressed conditions, including the extremely saline (Kates et al., 1993). Archaea are further subdivided into two kingdoms: 1) the Crenarchaeota; of which all members presently isolated are either thermophiles that metabolise sulphur (via sulphur oxidation, respiration and reduction) or are psychrophiles (cold-dwelling), and 2) the Euryarchaeota; a diverse group, which includes the halophilic *Halobacteriaceae*, some thermophiles and all methanogens (Table 9.2). Some sulphur-oxidizing Archaea are also acidophiles that can grow at a pH approaching zero, others are hyperthermophiles growing at temperatures of up to 115°C on the deep seafloor.

Archaea and Bacteria that require extreme salinities to metabolise are called halophiles, those that can tolerate salinities in excess of 25‰ are termed hyperhalophiles, most modern hyperhalophiles are Archaea. Many aerobic halophilic Archaea (order Halobacteriales) are moderate thermophiles with growth optima at temperatures between 35° and 50°C and sometimes even higher. This may be an adaptation to high temperatures that typify stratified waters in heliothermic salt lakes worldwide. One of the most impressive extremophiles is *Halobacterium lacusprofundi*, it is both a halophile and a psychrophile and thrives in microbial mats in the supersaline (≈ 350 ‰) cold bottom waters ($< 0^\circ$ to 11.7°C) of meromictic Deep Lake in Antarctica (Franzmann et al., 1988). The lake lies in an isolated depression in the Vestfold Hills with a brine surface that is some 50 metres below sea level. Its waters are thermally and chemically stratified and the bottom water mass is too saline to freeze.

Halophilic Archaea in hypersaline depositional settings typically function as 9,3 heterotrophs (decomposers) with the ability to facultatively photosynthesize whenever conditions are suitable. Other Archaea are anaerobic chemo-autotrophs that are sulphur dependant and can flourish in the dark (Table 9.2). They thrive in the vicinity of hydrothermal/volcanogenic vents in saline lacustrine rifts or in marine hydrothermal brine springs atop salt allochthons or in the basal waters of density-stratified brine lakes and seaways. They also inhabit subsurface hypersaline brines that characterize bathypneatic hydrologies atop dissolving sulphate caps of salt allochthons. Sulphur-dependant Archaea resemble ancestral prokaryotes, as do modern methanogenic Archaea, and in the early Archean were the dominant life forms (Figure 9.7). All methanogens are obligate anaerobes and today thrive in three habitats; a) bodies of anaerobic mesohaline to fresh water (e.g. the warm anoxic bottom brines of Solar Lake, b) haloes about anoxic brine springs and, c) the anaerobic digestive tracts of ruminants and some molluscs. Today all

Phylum or family		Informal Group	Dominant metabolic pathways and lifestyles	
Prokaryotes	Halo-adapted Bacteria	Cyanobacteria	Cyanobacteria (T, L) Aerobic oxygenic photolithotrophs with chlorophyll-a plus phycobiliproteins for light gathering; they use hydrogen by splitting water as electron source and generate oxygen; use the Calvin cycle to generate carbohydrates; some heterocystous cyanobacteria (<i>Anabena</i> , <i>Nostoc</i>) form heterocysts, which facilitate nitrogen-fixation.	
		Proteobacteria	Purple sulphur bacteria (T, L)	Anaerobic obligate photoautotroph (use H ₂ S or S ₂ , not water) and may form sulphur granules. Contain bacteriochlorophyll a or b. Group includes many sulphur and sulphate-reducers (e.g. <i>Desulfovibrio</i>).
			Purple non-sulphur bacteria (T, L)	Oxygen-tolerant anaerobic facultative photoautotroph (use hydrogen from simple organic compounds, but not from water, as the electron donor). Contain bacteriochlorophyll a or b.
		Chlorobiaceae	Green sulphur bacteria (T, L)	Anaerobic obligate photoautotroph (use H ₂ S or sulphur as electron donor, not water). Sulphur deposited extracellularly. Contain chlorophyll a and bacteriochlorophyll c or d.
		Flexibacteria	Green non-sulphur bacteria (L)	Anaerobic thermophilic photoheterotroph in sulphide-rich zones, but are capable of autotrophy. Remove hydrogen in simple organic molecules (such as ethanol, lactic acid or pyruvic acid) or hydrogen gas substrate. Can grow lithotrophically or organotrophically under appropriate conditions, or as thermophilic aerobic organotrophs.
		Spirochaetes	Spirochaetes (L)	Free-living obligate anaerobe in waters like Mono Lake, also symbiotic, parasitic. Aerobic, microaerophilic, facultatively aerobic, or anaerobic organotrophs; catabolize carbohydrates, amino acids or lipids.
		Bacteriacea	Flavobacteria (L)	Anaerobic organotrophs, e.g. halocline dwellers in Urania Basin; <i>Bacteroides</i> ferments sugars to acetate and succinate, whereas <i>Flavobacteria</i> ferments glucose (almost exclusively). Chemoautotroph, parasite.
	Archaea	Euryarchaeota	Halophile (L)	Aerobic photoautotroph, chemoautotroph that require very high salinities (1.5-5.5 M, prefer 3-4 M) and complex nutrients for growth. CO ₂ fixed via Calvin cycle. Anaerobic respiration used by some <i>Halobacterium</i> species with nitrate, sulphur, thiosulphate as terminal electron acceptors.
			Methanogen (T)	Strictly anaerobic chemoautotrophs; <i>Methanopyrus</i> is an extreme thermophile; some can fix nitrogen. Lithotrophs generate methane using hydrogen and carbon dioxide (<i>Methanobacterium</i> , <i>Methanothermus</i> , <i>Methanococcus</i> , <i>Methanogenium</i> , <i>Methanoplanus</i>). Organotrophs - generate methane from methyl groups of formate, methanol (<i>Methanosphaera</i> , <i>Methanosarcina</i> , <i>Methanococcoides</i>) or acetate.
		Crenarchaeota (sulphoarchaea)	Thermophile (T)	Obligate anaerobic chemotrophs that require temperatures above 50°C for growth (sometimes higher than 70°C) and use sulphur as electron acceptor (except <i>Sulpholobus</i> , which uses oxygen or ferric iron). Organotrophs oxidize organic compounds for energy (oxygen or sulphur serves as final electron acceptor). Lithotrophs - can also grow organotrophically using sulphur as an electron acceptor.
			Acidophile (T)	Acidophilic thermophilic aerobic chemoautotroph, organotroph.
		Nanoarchaeota	Symbiont on <i>Ignococcus</i> (T)	Hosted on hot vent Archaea in Iceland. Its cell is only 400 nm long.
		Korarchaeota	New group of extreme thermophile (T)	Only described from RNA samples (if it is a real phylum then it is the closest to life's universal ancestor of the earliest Archaeon ~3.7 Ga).

Table 9.2. Summary of metabolic styles of prokaryotes focusing on Archaea and halophilic Bacteria (T = thermophilic; L = can construct laminated microbial communities).

biogenic methane passed into the atmosphere from the guts of animals as well as from decomposing organics in salterns, swamps, marshes, paddy fields, dumps and sewage works is the work of a few dozen species of methanogenic Archaea. It is a little modified group with a clear ancestral line extending back to the early Archean (Margulis and Dolan, 2002).

Halophilic Bacteria as a group is more biochemically divergent than the halophilic Archaea and capable of using a range of aerobic and anaerobic metabolic styles (Table 9.2). Some halophilic purple and green sulphur bacteria are chemo-autotrophic halophiles that can function independent of a light source, while other halotolerant and halophilic bacteria (including cyanobacteria) are oxygenic photoautotrophs (oxidisers). Within the anaerobic halophilic bacteria of the order Haloanaerobiales there are several moderately thermophilic representatives. *Haloferoxanthus orenii*, the first truly thermophilic halophile discovered, was isolated from Chott El Guettar, a warm saline lake in Tunisia. It grows optimally at 60°C and up to 68°C at salt concentrations as high as 200‰ (Cayol et al., 1994). The halophilic *Acetohalobium arabaticum* strain Z-7492 has a temperature optimum of 55 °C (Kevbrin et al., 1997). Under suitably stressed conditions many halophilic bacteria become heterotrophic, utilising either anaerobic or aerobic respiration pathways.

By evolving the ability to symbiogenetically split water as a hydrogen source some 2.5 billion years ago, and so excrete oxygen, the prokaryotic cyanobacteria ultimately enabled the eukaryotic lineages to flourish and displace anaerobic Bacteria and Archaea as the world's primary producers (Margulis and Dolan, 2002). By the Mesoproterozoic this had allowed eukaryotic photosynthesis to develop and ultimately led to the evolution of the higher plants. As oxygen became more plentiful in the ocean and the atmosphere, it was increasingly difficult for anaerobes to flourish in most surface waters. Some retreated to the inhospitable and typically anaerobic environments where they still flourish today, others acquired aerobic bacteria as endosymbionts and today thrive in the aerobic/dysaerobic conditions that typify the hypersaline bottom waters of many density-stratified brine bodies.

Many halotolerant and halophilic Bacteria and Archaea living in hypersaline surface waters are heterotrophs and usually feed on the remains of other organisms. Heterotrophic metabolism shows variation in the terminal electron acceptor. In aerobic respiration it is oxygen and the breakdown product is CO₂, in anaerobic respiration it may be sulphate or nitrate and the breakdown product is H₂S or nitrite (Table 9.2). In all life

forms, including ^{9,3}heterotrophs, energy is obtained from high energy electrons using cyclic or non-cyclic electron transport schemes during which the energy is transferred into and stored as adenosine triphosphate (ATP), while low energy electrons are released by the end reaction. Adenosine triphosphate (ATP) is the basis of all life as it is the energy-carrying molecule found in the cells of all living things. ATP captures chemical energy obtained from the breakdown of food molecules and releases it to fuel other cellular processes.

Exceptions to this general metabolic scheme are the fermenters, like the methanogens, where energy is stored in the form of proton-motive force (PMF), as well as in ATP. Fermentation may be the only metabolic mechanism in halotolerant and halophilic species that inhabit the lowermost living parts of a microbial mat or flourish in the vicinity of the halocline in layered brine column communities, while it may be an emergency system in others (Table 9.2; Figure 9.8). Fermentation always occurs under anaerobic conditions when there is no electron acceptor. It breaks down an organic compound, such as a sugar or amino acid, into smaller organic molecules that then accept the electrons released during the breakdown of the energy source. As glucose is broken down to lactic acid, each molecule of glucose yields only two molecules of ATP, and considerable quantities of glucose must be degraded to provide sufficient energy for microbial growth. Only a relatively small output of energy is obtained per glucose molecule consumed, as the organic molecule is only partially oxidized. Hence, the presence of fermentative halotolerant Bacteria and Archaea and their less efficient metabolisms, rather than oxic decomposers, facilitates preservation of larger quantities of organic end products (proto-kerogens).

Methanogenesis and sulphate reduction are two terminal anaerobic biomineralization pathways in hypersaline systems that convert low molecular-weight products of other bacterial processes (degradation of polymers, fermentation) into CO₂ and methane (Teske et al., 2003). Sulphate-reducing bacteria are physiologically and phylogenetically highly diverse compared to the methanogens and range across a number of bacterial groups. They are capable of oxidizing a wide variety of low-molecular weight compounds (short-chain fatty acids, alcohols, alkanes, aromatic compounds, acetate) to CO₂. When biochemical conditions are suitable for growth the range of sulphate-reducing bacteria is limited only by sulphate availability. When sulphate is depleted, methanogenic archaea become the dominant anaerobic microbial population. Autotrophic methanogens (all Archaea) utilize hydrogen as an energy source for the reduction of CO₂ to methane; specialized genera of metha-

nogens are also capable of inter- and intramolecular disproportionation of C_1 and C_2 carbon compounds (methanol, methylamines, acetate) to methane and CO_2 .

Where methane and sulphate coexist in any anoxic environment (for example, at the interface of sulphate-reducing and methanogenic sediment layers, or at methane seeps and vents beneath marine or hypersaline waters), sulphate-dependent anaerobic methane oxidation takes place whereby methane of biogenic origin is oxidized to CO_2 with sulphate as the terminal electron acceptor (Teske et al., 2003).

The varying metabolic pathways of the microbial communities inhabiting a layered brine column create an interdependent layered microbial ecosystem that reflects the varying degrees of light penetration, oxygenation and anoxia within a variably layered brine body (Figure 9.8). A similar layered pore fluid community (greater anoxia with depth) also characterises microbial mats (Figure 9.17). Oxygenic photosynthesizers (mostly alga and cyanobacteria) characterize the upper well-lit oxic portions of the brine column. Below this community of producers, the remainder of the euphotic zone is characterised by downward decreasing light levels and the increasing dominance of oxygenic decomposers (bacteria, zooplankton and metazoans) over producers, with secondary production occurring in the microbial community (green and purple sulphur bacteria) that floats atop the halocline. If light penetrates to anoxic waters below the halocline, anoxic photosynthesizers flourish there (sulphur-oxidising phototrophic bacteria and archaea). As light levels fall away in the anoxic waters below, the biota is increasingly dominated by the anaerobic decomposers (sulphate-reducers, methanogens and fermenters). If light does not reach the halocline, specialised forms of chemosynthetic green and purple sulphur oxidisers (not photoautotrophs - e.g. some flavobacteria) occupy the narrow interface at the halocline created by the contact between oxic and anoxic waters. In schizohaline settings subject to periodic freshening of the surface waters, the associated bloom of halotolerant produc-

Figure 9.8. A layered brine lake (not to scale) with anoxic waters below the halocline and oxic waters above controls the distribution of the microbial communities via their metabolic requirements and pathways.

ers (alga and cyanobacteria) in the upper water column can swamp the ability of the various decomposers to degrade all the organic matter before it reaches the bottom and so laminated organic-rich and hydrogen-prone mesohaline carbonates can then accumulate on the bottom.

Salinity tolerance in the halobiota

Progressive brine concentration leads to sequential blooms of diverse macro and microbial species adapted to different ranges of salinity (Figures 9.9, 9.10). As modern surface brine is concentrated from 60‰ to around 200‰, dense eukaryotic algal and cyanobacterial populations appear, grazed by ostracods, brine shrimp and brine fly larvae (Figure 9.9a, b). Halotolerant protists are also found feeding in this salinity range, along with yeasts and other fungi. Halotolerant microbial mats cover the bottom of many hypersaline ponds and shallow lakes at this stage. In anoxic waters in this salinity range there are a variety of sulphur-oxidizing, sulphate-reducing, homoacetogenic, methanogenic and heterotrophic bacteria and archaea flourishing at the base of stratified brine columns or in the lower parts of mesohaline microbial mats. Increasing osmotic stress and loss of appropriate habitat as a water body shrinks with ongoing desiccation means much of the macroscopic stenohaline benthic fauna dies off or dies back to refugia about springs and seeps (Figure 9.9c). From about 240‰ to more than 320‰, halophilic archaea and bacteria come to dominate. As ever more elevated salinities are attained,

most other biological activity first slows and then ceases. At the elevated salinities where halophiles and hyperhalophiles flourish, a few eukaryotes, such as brine shrimp, and a handful of algae, including various *Dunaliella sp.* (a naked unicellular biflagellate green alga), are the only other living forms that the halophilic microbes encounter (Figure 9.9a, b).

Primary producers

A variety of obligate and facultative halophytic higher plants (angiosperms) can survive in moderate-to-high salinity conditions that surround saline pans and lakes. Many such terrestrial halophytes must survive long periods of drought and live where vadose soils completely desiccate, such plants are called xero-halophytes. Xero-halophyte adaptations include, deep and extensive roots, high levels of water storage (cacti), highly reduced leaf areas sometimes reduced to spines and scales, fine hairs on the leaf surface, sunken stoma and stoma that only open at night and permanently rolled leaves or leaves with a propensity to roll in drought and so reduce their surface area. They have leaves with salt bladders that can excrete salt with the evaporation water (e.g. saltbush genera such as *Atriplex*, *Halimione*, *Rhagodia* and *Chenopodium*), so that over time the leaf can be covered by extruded salt crystals. Most xero-halophytes cannot survive in water-logged saline conditions where roots are subject to long term low oxygen conditions. There the halophytic succulents tend to dominate and constitute a group generally known as the samphires, they include genera such as *Salicornia*, *Arthrocnemum*, *Halocnemum* and *Halosarcia*). These succulents are capable of surviving on the landward edges of saline mudflats and pans where they can be continually immersed in saline waters for weeks to months.

Then there are the hydro-halophytes that grow in settings subject year round to partial or completely submersed by brine. Modern hydro-halophytes are most common along the lower salinity edges of mesohaline waters (e.g. mangroves on the landward side of Khor al Bazam in Abu Dhabi) but cannot flourish in environments where longterm salinity is more than 5-10‰ above seawater. For example, mangrove seedlings cannot survive immersion for more than 48 hours in concentrated seawater with a salinity of 60‰. Salt in adult mangroves is preferentially stored in the bark and in old leaves so that it is dispersed back into the environment when the leaves or bark are shed.

Continually submersed halophytic angiosperms are largely restricted saline-tolerant varieties of seagrass. All marine seagrasses die back once bottom salinities exceed 60-70‰. For example, four species of *Halophila sp.* collected in Redfish

Bay, Texas, were able to grow in tanks with salinities of up to 74‰, without chlorophyll levels being affected, but only for a relatively short period of time (McMillan and Moseley, 1967). In more continental settings the subaqueous angiosperm with the highest salinity tolerance is *Ruppia sp.* (aka duckweed or widgeon-grass), with an occurrence range of 0.6-390 g/l TDS (seawater salinity \approx 31-34 g/l TDS = total dissolved solids). It thrives in normal marine waters, but also in the schizohaline coastal lakes of the Coorong region of southern Australia. There perennial *Ruppia sp.* communities occupy deeper (up to metres deep), well lit permanent water bottoms with salinities of 12-50 g/l. Annual or seasonal communities inhabit shallow lake bottoms, characterised by less permanent waters with seasonal surface water salinities up to 230 g/l prior to complete lake desiccation (Brock, 1982a, b). In ephemeral lakes in Western Australia, Geddes et al. (1981) found healthy *Ruppia sp.* growing in waters of 4-78 g/l TDS, but at 82-142 g/l, only drupelets (fruits) were present. *Ruppia* taxa are opportunist plants that die back to root mats when salinities rise or the saline lake dries out. They quickly return once surface waters return to salinities suitable for growth.

Preservation potential of organics from xero-halophytes is low as the organic matter is typically oxidised and degraded in the desert soils. Halophytes growing in submersed or brine saturated soils are more likely to be preserved. Kenig et al. (1990) found that, along with intertidal microbial mats, the other major contributors to organic matter preserved in the modern supratidal sediments of the Abu Dhabi sabkha were derived from mangroves (especially cuticle from *Avicennia sp.*) and lagoonal seagrasses (especially *Halodule sp.*).

Charophytes are another group of opportunistic submersed halotolerant plants that flourish in lower salinity regions of a saline lake or lakewide at times of brine freshening (Figure 9.9a). They are thought to show strong affinities to green alga, although some taxonomists link them more closely to bryophytes (Burne et al. 1980). Parts of their structure may become calcified, typically the oogonia or female reproductive organs. These are readily preserved as fossils and can be a major contributor to the numerous calcispheres found in ancient saline mudstones and lunettes. *Lamprothamnium papulosum* is the most common charophyte in the saline lakes of Australia. Studies of this species in saline lakes in the Coorong region Australia, show it can be part of a healthy bottom community at 70‰, although it does not generally successfully germinate or grow above 53‰ (Burne et al. 1980). This is two to three times the typical salinity association documented for charophyte occurrences in brackish lakes in the northern Hemisphere.

Charophytes can regenerate in ephemeral saline lakes after considerable periods of desiccation, although for germination and growth to take place this does require a transient period of suitably freshened water cover. It means charophytes in saline lakes are opportunist species that dieback or retreat to “seep” refugia in harsh times. Widespread oogonia horizons in evaporitic sediments indicate episodes of freshening as in the carbonate lakes of the Coorong and the coastal gypsum salinas in the “Chain of Lakes” at the southern end of Yorke Peninsula, South Australia (Figure 4.7a). Likewise, sediment layers with the remains of *Lamprothamnium papulosum* in Fuente de Piedra, southern Spain, indicate times of freshening in a saline lake with a flora typically dominated by *Dunaliella sp.* (Garcia and Niell, 1997).

Rather than higher plants, halotolerant green algae and cyanobacteria, are the dominant primary organic producers in moderately hypersaline (mesohaline to penesaline; 60-200‰) settings. With elevated salinities restricting the grazers, green algal densities in a surface brine layer can be more than 10^5 ml^{-1} . Mesohaline algae are mostly obligately aerobic, photosynthetic, unicellular microorganisms. Green algae of the genus *Dunaliella*, e.g. *Dunaliella salina*, *D. parva*, and *D. viridis*, are ubiquitous in modern brine lakes, such as Great Salt Lake, Hutt Lagoon and the Dead Sea, where they constitute the base of the food

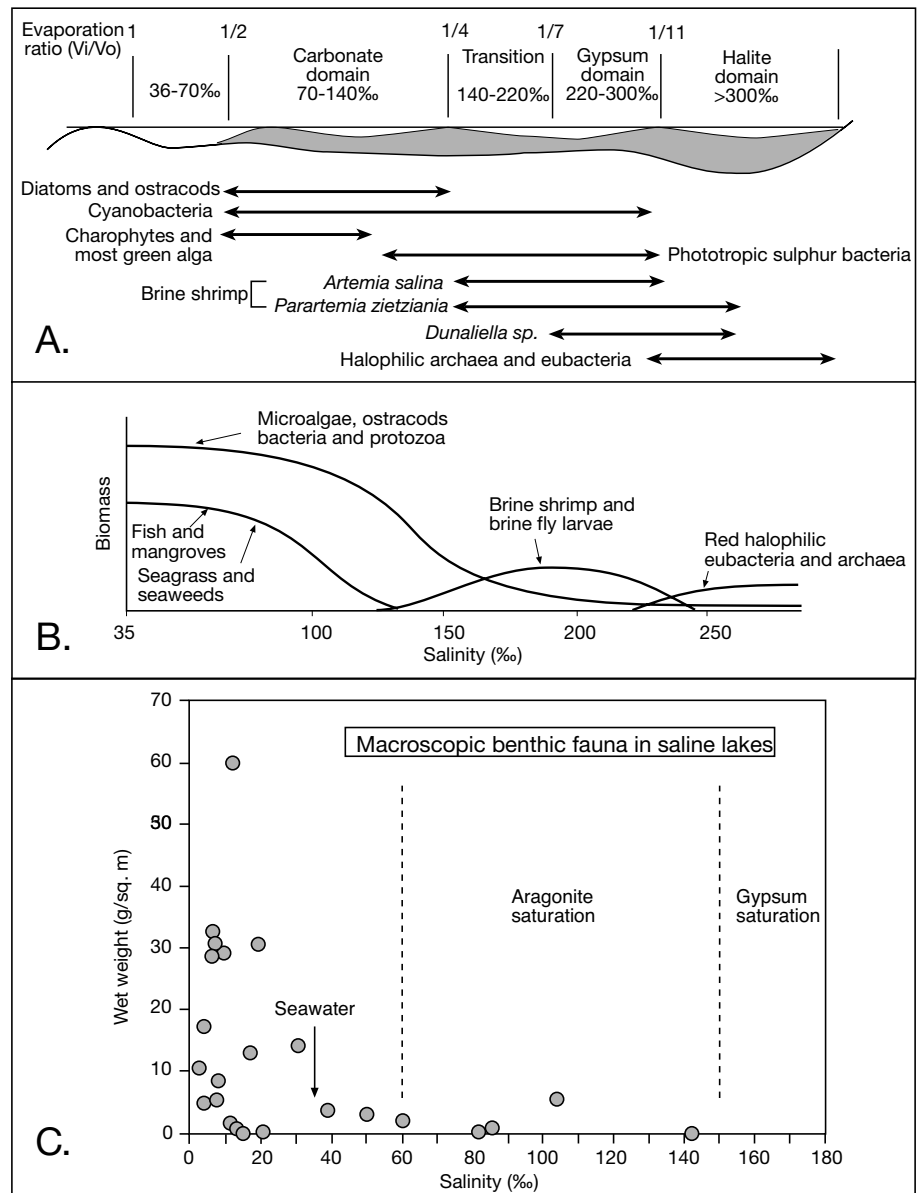

Figure 9.9. Salinity tolerances. A) Typical salinity ranges of the halotolerant biota where V_i is the volume of inflow to the basin and V_o is the volume of outflow (includes evaporation and reflux; after Barbé et al., 1990). B) Typical salinity ranges and biomass proportions of the biota in modern marine saltwork ponds. C) Standing crop (g/m^2) of the macroscopic benthic fauna in selected athalassic (nonmarine) saline lakes of the world (after Hammer, 1986).

chain for the halotolerant fauna (Figure 9.10a; DasSarma and Arora, 2001). Planktonic blooms of photosynthetic microbes can colour saline waters pink or red, especially at the higher end of this salinity range. Most species of green algae are moderate halophiles, with only a few extreme halophiles, e.g. *Dunaliella salina*, *Dunaliella viridis* and *Asteromonas gracilis*.

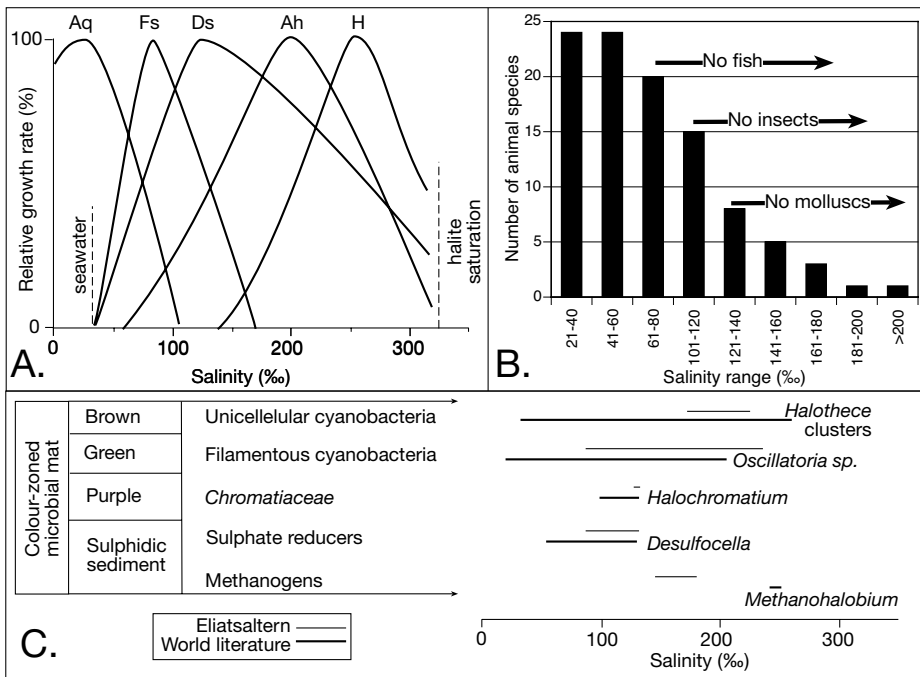

Figure 9.10. Salinity tolerances. **A)** Optimal ranges of selected halotolerant and halophilic micro-organisms. *Agmenellum quadraplicatum* (Aq) is a slightly halotolerant cyanobacterium, *Fabrea salina* (Fs) is a moderately halophilic protist, *Dunaliella salina* (Ds) is a halophilic green alga, *Aphanothece halophytica* (Ah) is an extremely halophilic filamentous cyanobacterium, and *Halobacterium sp.* (H) is an extremely halophilic archaea (after Das Sarma and Arora, 2001). **B)** Decrease in variety of animal species in saline lakes of southeastern Australia (after Bayly and Williams, 1973). **C)** Range of observed optimum salinities for phototrophs in various microbial layers and for the sulphate-reducing bacteria and methanogenic bacteria in microbial crusts. It plots the ranges for a mat from a gypsum saltern in Eliat, Israel and compares values to those in the worldwide literature (plotted from data listed in Table 2 in Sørensen et al., 2004).

The halophilic *Dunaliella parva* is the sole primary producer in Dead Sea brines, with several species of haloarchaea dependent on its periodic blooms (Figure 9.26). *Dunaliella sp.* can survive in marginward refugia, even when the upper and low water layers in the Dead Sea are NaCl-saturated. *Dunaliella salina* is one of the most environmentally tolerant eukaryotic organisms known and can cope with a salinity range from seawater to NaCl saturation, and a temperature range from $<0^{\circ}\text{C}$ to $>38^{\circ}\text{C}$.

Halophilic *Dunaliella sp.* can contain high levels of β -carotene and pigment levels tend to increase with increasing salinity. It means that blooms in hypersaline pans can be harvested and processed to manufacture β -carotene. *Dunaliella salina* contains more than 10 times the levels of β -carotene compared to other halophilic *Dunaliella* species and at higher salinities cells can contain as much as 10-14% β -carotene dry weight, so it is the preferred commercial species (Moulton and Burford, 1990). Two of the largest β -carotene producers in the world are Western Bio-

technology Ltd. (Perth, Western Australia) and Betatene Ltd. (now Cognis Nutrition and Health, Melbourne, Victoria), both began operations in 1986 in Australia. Both operators grow the algae in large and shallow (approx. 20 cm deep) wind-stirred ponds constructed either on the bed of the hypersaline coastal salina known as Hutt Lagoon, or formed by artificially expanding and isolating a lagoon flat. Each of the artificial production ponds atop the surface of Hutt Lagoon is 5 ha in area and was constructed using earthen berms. The Hutt Lagoon production plant has a total current pond area of 50 ha and there are also smaller ponds for research purposes. Ponds used by Betatene Ltd. at Whyalla in coastal South Australia are even larger. High salinity is maintained in the shallow pond waters using a combination of wind-driven mixing, solar evaporation and seawater pumped into the ponds. Uncontrolled episodes of freshening (rainfall) can lower pond salinities. This can favour the growth of the less carotenogenic species (*D. viridis*, *D. minuta* and *D. parva*) as well as allowing grazing protozoa such as the ciliate *Fabrea salina* and the amoeba *Heteroamoeba sp.* to invade the pond. Such invasions can rapidly decimate algal production.

Along with *Dunaliella sp.*, numerous species of cyanobacteria flourish at the elevated salinities where the activities of metazoan grazers are severely limited. Typically they construct laminated microbial mats and stromatolites in water-covered mesohaline areas and peripheral strandzone mudflats (Figure 1.3). Various cyanobacterial species constitute the upper parts of these microbial "high rises" with species dominance in the layer changing according to their tolerances to salinity and light (Figures 9.10c, 9.17). *Microcoleus chthonoplastes* is a

cosmopolitan mat former and is the dominant filamentous blue-green in flat laminated mats in Guerrero Negro in Baja California Sur, Mexico, in Solar Lake in the Sinai and in Deep Lake in South Australia. In Guerrero Negro it grows best in brine-covered pans with a salinity range of 60-95‰. *M. chthonoplastes* tends not to do as well beneath pan waters with longterm salinities above 100‰. In Solar Lake it flourishes beneath waters with an annual salinity range of 45-180‰ and it still manages to photosynthesise, although not all that well, at salinities approaching 300‰. *Spirulina subsalsa*, another filamentous form, flourishes in mats worldwide at salinities of up to 150-180‰. At higher salinities and higher light intensities the nonfilamentous unicellular and coccoid cyanobacterial species come to dominate. The unicellular *Aphanothece halophyta* dominates mat surfaces in Guerrero Negro in pans with surface salinities up to 200‰. In Sabkha Gavish in the Sinai it occurs across an even broader salinity range of 250-330‰. Why the same cyanobacterial species seems to have different salinity ranges in different parts of the world is not clear. It may reflect a response to differing temperature regimes or to different rates of change in salinity of the waters atop the growing mats.

Diatoms (halotolerant bacillariophytal algae with siliceous tests) are another commonplace primary producer in mesohaline and lower penesaline environments (Figure 9.9a). They flourish at times of freshened lake waters or in perennial seepage and dissolution ponds (posas) about the edges of some salars, where they become a major detrital component in some lacustrine stromatolites (Figure 1.3c). Some varieties of diatoms can live in lake brines with longterm salinities around 120‰, while the upper limit for diatom growth is around 180‰ (Clavero et al., 2000). The most halotolerant diatom taxa in the saltern ponds of Guerrero Negro are *Amphora subacutiuscula*, *Nitzschia fusiformis* (both *Amphora* taxa), and *Entomoneis* sp.; all grow well in salinities ranging from 5 to 150‰. Three strains of the diatom *Pleurosigma strigosum* were unable to grow in salinities of less than 50‰ and so are true halophilic alga.

Anoxygenic halotolerant to halophilic sulphur-oxidising photobacteria are another group of primary producers and can create dense biolaminae in a variety of a sulphide-rich environments. Sulphur-oxidising bacteria are further divisible into purple and green sulphur bacteria according to their respective bacteriochlorophylls and carotenoids (Table 9.2). Modern halophilic phototrophic sulphur-oxidising bacteria are filamentous CO₂-fixers (both green and purple sulphur bacteria) utilising sulphide as an electron donor for their photosynthesis (Figure 9.11a). In modern saline environments they grow in niches where light reaches into anoxic, sulphide-containing

bottom water layers or pore waters a few millimetres below the surface of a microbial mat. Different species thrive in different salinities ranging from seawater to halite precipitating (Figure 9.11b). Most of the H₂S they metabolise is biogenic from nearby sulphate reducers, except perhaps around well-lit brine springs and hydrothermal vents where it can be thermogenic.

In contrast to the cyanobacteria and alga that use oxygen, these bacterial phototrophs are anaerobes that use H₂S as an electron donor to produce various oxidised sulphur metabolites, the final product being sulphate or sulphur (Figure 9.11a). Commonplace sulphur-oxidising primary producers in mesohaline waters and microbial mats include; *Chromatium salexigens*, *Thiocapsa halophila*, and *Rhodospirillum salinarum*, with optimal growth in these species between 60 and 110‰ (Figure 9.11b; Caumette, 1993; Ollivier et al., 1994). Phylogenetic studies in the last two decades have removed fully halophilic species, once classified as *Ectothiorhodospira* sp., into a new genera the *Halorhodospira*; that is *Ectothiorhodospira* is the basonym for the halophilic grouping *Halorhodospira*. Shallow brines of the small soda lakes in the Wadi Natrun may be coloured an intense purple-red, due to the development of *Halorhodospira halophila*. *Halorhodospira abdelmalekii*, and *Halorhodospira halochloris* show green pigmentation in pure cultures while *Halorhodospira halophila* is red. Small puddles in hypersaline locations may show separate development of green- and red-coloured species of *Halorhodospira*, while top layers of the sediments of Wadi Natrun lakes (Egypt) show separate layers of the green-coloured and the red-coloured *Halorhodospira* sp. (Imhoff et al., 1979).

Halorhodospira abdelmalekii, *Halorhodospira halochloris*, and in particular *Halorhodospira halophila* are among the most halophilic phototrophic bacteria known (Imhoff, 1988). Isolates of *Halorhodospira halophila* from soda lakes in the Wadi Natrun have salt optima of 250‰ total salts and can survive in halite-saturated solutions (Figure 9.11b). The moderate halophile *Ectothiorhodospira marismortui* is a strict anaerobe found in the hypersaline growths about sulphur springs in the Dead Sea, where spring waters at the time of collection had a pH around 5.2, a salinity ≈ 170‰ and a temperature of 40°C. Isolates of this species grew poorly at a pH of 5.5 but thrived in the neutral pH range between 7 and 8 (Oren et al., 1989).

The ingesters, grazers and pelletizers

Large numbers of a relatively few species of halotolerant invertebrates can survive, graze and produce pellets in low to moderately mesohaline environments (Figure 9.10b). As in the

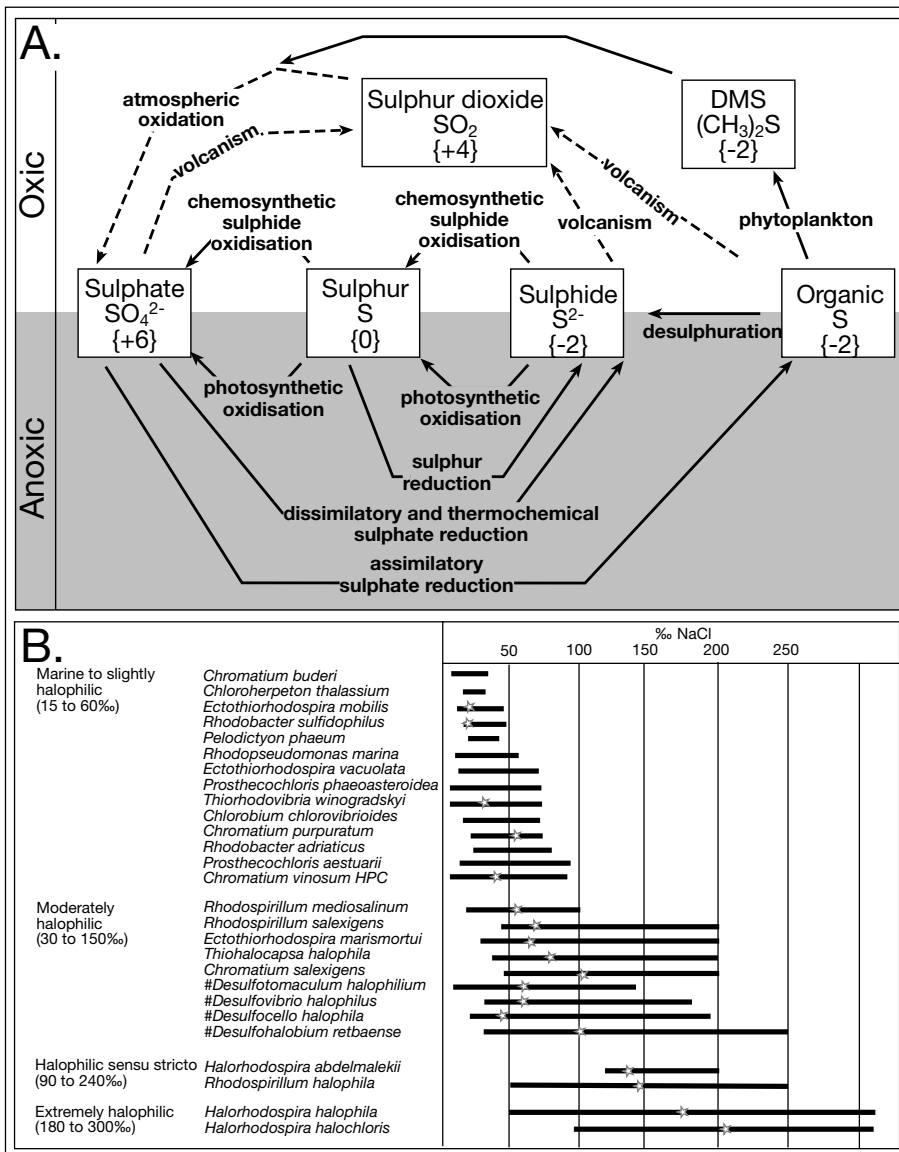

Figure 9.11. Sulphur cycle and salinity tolerance. A) Summary of the sulphur cycle showing the two types of microbially-mediated sulphur oxidation photosynthetic versus chemosynthetic (oxidation states of sulphur are shown in parentheses). Microbial pathways shown by solid lines; broken lines show geological processes involving sedimentary organic-sulphur, calcium sulphate (gypsum/anhydrite) and Fe-sulphide (pyrite). B) Salinity tolerances in phototrophic halophilic bacteria including sulphate-reducers(#). Star on bar indicates the salinity for optimal growth (in part after Caumette, 1993; Ollivier et al., 1994).

oceans, faecal pellets of the zooplankton are very important in rapidly moving organic matter to the water bottom in brine lakes and salterns. It is a mechanism that quickly moves suspended planktonic algal and bacterial debris from an oxygenated freshened water layer into a sediment layer beneath hypersaline anoxic bottom brine. There the anaerobic decomposers are

far less efficient destroyers of long chain hydrocarbons than their aerobic counterparts. Examples of pellet producers that feed on alga and bacteria during times of freshening and feast include; copepods, brine shrimp, ostracods and molluscs such as *Fragum erugatum*.

Fragum erugatum thrives beneath the mesohaline bottom waters of Shark Bay, Australia where it can survive salinities in Hamelin Pool of up to 70‰, but flourishes at salinities around 50-55‰. In the well-lit low nutrient mesohaline bottoms where it filter feeds, its metabolic efficiency is greatly enhanced by the rich xooanthellate flora that symbiotically populate its mantle (Berry and Playford, 2002). During intense storms (hurricanes or cyclones) the remains of this almost monospecific community have been washed into beach ridges that now define the edge of Hamelin Pool.

A more unusual marine association of symbiosis in molluscs living in hypersaline waters occurs on the deepsea bottom of the Gulf of Mexico. There, even though they cannot tolerate elevated salinities, biostromes of chemosynthetic molluscs rim the halocline-defined edge of methane-saturated brine lakes, situated atop salt allochthons. Biostromes are dominated by *Calyptogena* clams, along with serpulid worms, sea anemones, galatheid crabs (stone crabs like *Paralomis* sp.), swimming holothurians and amphipods (Macdonald et al., 1990). The worms and molluscs are chemotrophs with symbiotic

chemosynthetic microbes inhabiting their flesh and thriving on the H₂S and methane escaping across the halocline.

On land, insects flourishing about the edges of hypersaline lakes include halotolerant brine flies, such as *Ephydra hians* and *E. gracillis*. They hatch their eggs in microbial mats and organic scum about the strandlines of modern saline lakes, where their larvae feed and pupate before emerging as adults (Figure 9.9b). Both the larvae and the adult flies are scraper-gatherers feeding on the cyanobacteria and diatoms in benthic mats. The term *mono*, used in the name Mono Lake, California, is a Yokut Indian word for naturally salted brine-fly pupae, a local delicacy before European settlement. Brine-fly larva are well adapted to saline conditions and adults often form thick flying and feeding carpets around the edges of salt lakes. *Ephydrella marshalli* larvae collected from subaqueous benthic mats about the edges of commercial salt works/lagoons on Port Phillip Bay, Victoria, have survived several days immersed in hypersaline sodium chloride media at ≈200‰ (upto 5850 mOsm/l; Marshall et al., 1995). Likewise larvae of dolichopodid brine fly *Hydrophorus plumbeus* collected in Mono Lake survived immersion for a week in NaCl brine with a salinity as high as ≈190‰ (5600 mOsm/l; Herbst and Bradley, 1988). Adult flies have extra long body hairs that enable them to encase themselves in an air bubble and so walk about on the underside of the water surface of a brine lake. They do this to gain access to richer food sources and to lay eggs.

But, in terms of preservation potential in evaporitic settings the remains of most flies and insects, and their carapaces, rank low unless encased in saline concretions (Park and Downing, 2001). Then the three-dimensional preservation of soft tissues is possible via replacement by silica-based minerals as well as calcite, celestite, apatite, and gypsum. But the more usual evidence of arthropods and other invertebrates living in saline settings is via mineralisation of the organics and matrix in faecal pellets.

Halotolerant pellet-producing planktonic crustaceans include; ostracods such as *Cypridis torosa*, *Paracyprideinae sp.*, *Diacypris compacta*, and *Reticypris herbsti*, copepods such as *Nitocra lacustris* and *Rob-*

ertsonia salsa, and brine shrimp such as *Artemia salina*, *Parartemia zietzianis* and other related species. Halotolerant ostracod remains are a common component of mesohaline sediments and flourish at times of freshened surface water layers (Figure 9.12). For example, *Platycypris baueri* has the broadest salinity range of any ostracod found in Australia, it is able to survive at salinities ranging from 5‰ to 195‰, but is much more abundant in the middle of this salinity range and does best in waters with salinities above 70‰ (De Deckker 1981). Yet, it was not present in this upper range during the 1989 flood of Lake Torrens, Australia, when it occurred only at much lower salinities (Figure 9.12; Williams et al., 1998). The species diversity plot in Lake Torrens shows a typical saline pan biotal response to strandline retreat. This allows the halotolerant terrestrial insect population to follow the retreating strandline to scavenge and feed on the decomposing victims of the increasing salinity in the retreating brine sheet. Thus they are found scurrying about the edges of highly saline water sheets but do not actually inhabit the water.

Brine shrimp (*Artemia sp.*), another pellet producer, survive across a wide range of salinities from 25 to 340 ‰, with their optimal range around 60–100‰ (Post and Youssef, 1977). They are well adapted to the fluctuating oxygen and salinity levels that characterize mesohaline ecosystems. Encysted *Artemia* eggs, with their natural cyst coat of glycerol and trehalose hatched after 4 years of anoxic storage in a laboratory, something that the eggs of most arthropod species cannot achieve (Wharton, 2002). Geddes (1975a-c) argued increased osmotic stress is the dominant limit on the upper salinity tolerance of adult Australian brine shrimp (*Parartemia zietzianis*) and this is probably also true for most, if not all, *Artemia sp.* in hypersaline waters

Figure 9.12. Salinity related occurrences of major macrofauna during the 1989 flooding of Lake Torrens, Australia (after Williams et al., 1998).

(Geddes, 1981). Halotolerant ostracods and brine shrimp feed on plankton living in the upper water mass of density-stratified brine columns but can also ingest benthic mats wherever a less saline water mass intersects the lake margin or when bottom waters salinities are suitably lowered (De Deckker, 1981; De Deckker and Geddes, 1980).

Historically, based on studies in the Northern Hemisphere such as in Great Salt Lake, brine shrimp have long been considered to be obligate planktonic filter feeders. Any grazing of benthic mats was assumed to take place by accident when the organisms' constant random swimming knocked pieces from the mats into the brine column where it was ingested. But observation of the feeding habits of brine shrimp feeding on microbial scum in the subaqueous gypsum domes of Lake Inneston, South Australia (pers obs.) and on the benthic mats of Lake Haywood in Western Australia (Savage and Knott, 1998) show that brine shrimp are capable bottom feeders that choose to feed on benthic mats in shallow hypersaline lakes. They will alter their normal planktonic feeding pattern to do so. The animals roll over so their ventral surface faces the benthic mat and their phyllopods continue to beat although all forward motion has ceased. The phyllopods brush the mat, releasing diatoms and cyanobacterial cells, along with crystallites, which are then ingested by the shrimp (Savage and Knott, 1998). Both ostracods and brine shrimp produce large amounts of pelleted carbonate detritus, which is a common component of many ancient evaporitic laminites and source rocks.

Halotolerant gastropods, another pellet producer, follow a lifestyle that allows them to graze on halotolerant algae and plants. Modern examples, such as *Coxiellada* sp., flourish during short periods of freshening in saline environments and are quite common in saline lakes in central Australia and the schizohaline lakes of the Coorong region and the maar lakes in Victoria, Australia. These coxiellids withstand lake desiccation and high salinities (up to 124‰) by sealing its aperture with mucous along the edge of its operculum (De Deckker 1982). Nevertheless, it cannot survive in lakes that remain dry for several years and requires a relatively high frequency of flooding to survive. Low beach ridges, composed almost exclusively of dead coxiellid tests, define the strandzones of many Australian salt lakes. Isolated tests of immature coxiellid gastropods can be found in penesaline sediments well away from the freshened lake margin (e.g. in the somewhat deeper water lacustrine clays of Lake Eyre and some Coorong Lakes). They may have been deposited there as a result of juveniles of the species traveling and grazing upside down along the underside of water-air interface, held there by surface tension forces. As the feeding

gastropods grow they become too heavy and lose contact with the air-brine interface. They sink through the salinity-layered water column, only to osmotically desiccate and die in the anoxic hypersaline bottom waters. Complete shells are incorporated in the bottom laminites to give some characteristic biometrics in a biocoenosis of these lacustrine sediments (mostly diminutive adults and very few juveniles).

Some marine foraminifera are commonplace epibionts on marine seagrasses and where seagrasses can live and survive, so can some species of foram. This is evidenced by the rich foraminiferal biota living on seagrass banks in Shark Bay, Western Australia where seawater salinities ranging from 40-56‰ (Davies 1970), and occasionally up to 70‰, yet even at this level of salinity stress a few porcellanous taxa still grow and survive. One of the most impressive halotolerant forams is *Peneroplis planatus*. In Khor al Bazam, Abu Dhabi, it is epiphytic on seagrass in lagoon waters with a salinity of 42‰ and on seaweed growing in the same lagoon in salinities ranging up to 70‰ (Murray, 1970).

The ability of some marine foram species to survive in a range of salinities has led to some interesting death assemblages in continental lacustrine sediments. Viable marine foraminifera living in continental saline lakes was documented in Australian salt lakes by Cann and De Deckker (1981). Some species can encyst and survive fluctuating salinities and periods of desiccation in both coastal and inland salt lakes, whereas others can only be found in permanent waters. Forams in continental settings generally prefer salinities and/or chemistries of lakes that approach that of sea water, optimum growth and the appearance of new generations typically occur at these values.

Two species that flourish during short periods of flooding in the inland salt lakes in Australia (such as Lake Eyre) are *Ammonia beccarii* and *Elphidium crispum*. *A. beccarii* requires water chemistries and salinities similar to sea water, i.e. with sodium and chloride as dominant ions. Although this species can survive a broad range of salinities (from 7‰ to 67‰), it grows and reproduces most successfully at salinities between 20‰ and 40‰ (Cann and De Deckker 1981; De Deckker 1982). Encysted forms of *A. beccarii* cannot survive summer droughts in modern coastal salinas and it requires permanent surface water to survive in these lakes. *E. crispum* is a marine foram species that thrives in ephemeral saline lakes of the Coorong without needing avian replenishment after a drought. It can survive summer evaporative episodes by encysting in numbers necessary for widespread re-establishment in the following winter freshening. The salinity range of this species is

as yet unknown, although it is thought to survive at relatively high salinities (De Deckker 1982). Encysted forms of both species are carried hundreds of kilometres inland on the feet and bodies of coastal sea birds, which flock every few years to newly flooded inland salt lakes, such as Lake Eyre, to nest and feed (a time of “feast”). If surface water salinities are suitable the forams bloom. Later as salinities in these inland lakes increase once more, the foram population dies back and tests are deposited in a lacustrine sediment matrix (Ludbrook, 1965). Ancient counterparts preserving evidence of this opportunistic lifestyle could create a palaeontological dilemma.

Halotolerant protists, like the forams just discussed, lack a cell wall, can be planktonic or benthic and typically ingest algae and bacteria. Protists are unicellular eukaryotes that were once classified as single-celled animals under the general term protozoa, but as some are not animals this term is now obsolete. Protists are phylogenetically grouped in the Eukaryota at the same level as animals, plants and fungi. Protists encompass groups such as the rotifers, forams, radiolaria. Identified protist species living in hypersaline waters include the moderate halophile *Fabrea salina* from Hutt Lagoon in Australia, where it feeds on populations of *Dunaliella salina*, and the extreme halophile *Porodon utahensis* from the Great Salt Lake, Utah (DasSarma and Arora, 2001). Salt-tolerant rotifers (aka wheel animalcules) include species such as *Brachionus angularis* and *Keratella quadrata*.

Fungi, mostly yeasts (unicellular fungi), are another significant component of a saline salt lake biomass, some are black halophiles that occur in their highest numbers in waters at the onset of halite saturation (Gunde-Cimerman et al., 2000). They are ^{9,3}chemoheterotrophic eukaryotes that grow best in aerobic conditions on carbohydrate substrates at moderate temperatures and in acidic to neutral pH brines. *Debaromyces hansenii* is a halotolerant yeast that when isolated from seawater can grow aerobically in salinities up to 250‰ and is capable of assimilating hydrocarbons. A saprophytic hyphomycete (a minute fungi), *Cladosporium glycolicum*, was found in the Great Salt Lake Utah, growing on submerged wood panels at a salinity exceeding 260‰.

The vertebrates

The highest brine salinity at which viable vertebrates have been observed living in a permanent brine is around 60‰. For example, the white-lipped or alkaline tilapid fish (*Oreochromis alcalica*) lives in such mesohaline waters in African rift lakes and even flourishes at 36–40°C and pH ≈ 10.5 in thermal spring

and moat brines about the edges of Lake Natron and Lake Magadi. Desert pupfish in the Sonoran Desert can survive for short periods in waters of drying pans that are as saline as 100–140‰ (Helfman et al., 1997, p.313). But tilapids are one of the few higher organisms that can tolerate perennial hypersalinity (DasSarma and Arora, 2001). Some birds feed on the periodic planktonic blooms that occur at times of freshening in nutrient-rich hypersaline environments. One of the most spectacular examples of avian exploitation of the halotolerant plankton is the pink flamingo population of African rift lakes. Stilts, gulls and pelicans are other opportunist avians that feed on halobiotal blooms that occur in periodically freshened saline lakes.

Throughout the Neogene, hippopotami (*Hippopotamus amphibius*) are probably the largest vertebrates capable of leaving traces of its presence in semi-arid to arid lake-margin sediments. This is especially so in regions of muddy organic-rich sediments near brackish lake margin springs, as in the saline-alkaline mudflats rimming the crater lake of the Ngorongoro Crater, Tanzania (Deocampo, 2002). In such an environment the organic content of muds that infill hippopotami trackways or furrows leading to the spring is as high as 17% TOC versus organic contents around 6–7% in mudflat sediments adjacent to the trackways.

Bacterial decomposers and chemosynthesisers

The habitat range of the halobiota described so far largely exists in, or near, an environment where light penetrates to the sediment surface. But there is also a range of halotolerant and halophilic organisms that can flourish in environments where light may no longer penetrate. These are the decomposers, fermenters and chemosynthesisers and it is their biochemical signature that is frequently found as biomarkers in many ancient source rocks.

Bacterial sulphate reducers

Dissimilatory sulphate reduction can occur up to quite high salt concentrations and black, foetid sulphide-containing sediments form the bottom to modern coastal salinas and salt works, well into the penesaline salinity range (Oren, 2001). Amongst the bacteria, the most salt-tolerant sulphate reducer is the halophilic *Desulphohalobium retbaense*. Isolated from Lake Retba in Senegal, it is capable of growing at NaCl concentrations of up to 250‰ (Ollivier et al., 1994). Two other sulphate-reducing halophilic isolates are *Desulfovibrio halophilus* and *Desulfovibrio oxyclinae*, which can tolerate NaCl concentrations of up to 180–225‰ (Figure 9.11b; Caumette, 1993; Krekeler et al., 1998). Another isolate, similar to *Des-*

ulfovibrio halophilus has been collected in brine pool samples from the allochthon-associated deep-water brine lakes on the floor of the Red Sea. There it grows at salinities up to 240‰, but only slowly. No viable bacterial sulphate-reducing communities have been collected at the more extreme salinities where halite precipitates. Some sulphate reducers may also be alkalophiles; for example, *Desulfonatronovibrio hydrogenovorans* is a H₂-utilising sulphate-reducing bacterium isolated from the trona beds of Lake Magadi that functions optimally at pH 9.5 and 3% w/v NaCl.

Most halophilic and halotolerant sulphate reducing bacteria are incomplete oxidisers that grow on lactate and produce acetate. Dissimilatory sulphate reduction provides relatively little energy, and therefore the need for sulphate reducers to spend a substantial part of their available energy budget for the production of organic osmotic solutes may set the upper limit to the salt concentration at which these bacteria can grow (Oren, 2001 and later discussion). The oxidation of lactate to acetate and CO₂ yields much more energy. Recently, the first halophilic acetate-oxidizing sulphate-reducing bacterium was isolated: *Desulphobacter halotolerans*. It was collected from the hypersaline bottom sediments of Great Salt Lake, Utah, and found to have a rather restricted salinity range, being unable to grow above 13% NaCl (Brandt and Ingvorsen, 1997). Even so, it possesses the highest NaCl-tolerance reported for any member of the genus *Desulphobacter*.

Bacterial chemosynthesisers (sulphur oxidizers)

Because oxygen and sulphide flux in hypersaline environments occur in opposing gradients, the growth of halotolerant and halophilic sulphur-oxidising bacterial chemosynthesisers is confined to narrow oxic zones of chemical overlap (Figures 9.8, 9.11a). This narrow niche occurs at the interface between the oxygenated layer created by the primary producers and the underlying anoxic layer created by the sulphate reducers. In stratified brine columns, it defines a narrow aerobic zone immediately atop the halocline where chemical gradients are stabilized by density and temperature differences between the cooler less saline surface waters and the warmer more saline bottom layers (Figure 9.8). Ongoing bacterial growth via sulphur chemosynthesis (not the photosynthetic purple and green sulphur bacteria discussed earlier) occurs at many subphotic haloclines where the chemical gradient of rising sulphide is stabilized by the salinity contrast that prevents pervasive vertical mixing (e.g. Figure 2.48). In layered microbial mats it is defined by a layer of purple and green sulphur-oxidising bacteria which flourish below the depth of light penetration. This interesting

group of secondary producers, which often inhabit haloclines, is discussed later in this chapter in the context of secondary organic production in saline brine columns.

Extremophiles (mostly Archaea)

As surface water salinities rise above 200-240‰, rates of oxygenic photosynthesis in algae and cyanobacteria slow and ultimately cease. Halophilic bacteria and archaea come to dominate, mostly as decomposers and fermenters (Figure 9.9). Of the halophilic bacteria, two groups are well represented in elevated salinity ranges; the fermentative bacteria belonging to the family Haloanaerobiaceae and the halophilic members of the autotrophic sulphur-oxidizing bacteria of the family Ectothiorodospiraceae (Figures 9.11b, 9.13). Both families were discussed earlier in this chapter. As the name suggests, the group loosely called halobacteria^{9.5} flourish in supersaline waters, most halobacteria are not bacteria but archaea, belonging to the family Halobacteriaceae.

One species of halophilic bacteria is worthy of special mention is *Salinibacter ruber* as, unlike most other Bacteria, it can flourish in the range of extreme salinities that until recently were considered to be the exclusive province of Archaea. It is a new genus and species (Oren, 2002). *Salinibacter* is a motile rod, pigmented red (probably by a carotenoid) with an absorption maximum at 482 nm and a shoulder at 506-510 nm. Because of the red pigmentation, colonies of this bacteria in superhaline waters have probably been overlooked in the past. Historically, red colonies growing at salinities in excess of 250 g/l have been widely considered to be archaeal. But this bacteria organism is no less halophilic than the archaeal halophiles: no growth was obtained below 100 g/l NaCl, and for optimal growth concentrations between 150 and 230 g/l are required. The physiological properties of *Salinibacter* are unusual for most bacteria: the organism apparently uses KCl to provide osmotic balance, while lacking high concentrations of organic osmotic solutes. Thus, its physiology resembles that of the halophilic Archaea more than that of other aerobes within the domain Bacteria.

We shall now concentrate on salinity ranges of halophilic archaea (haloarchaea). All known extremely halophilic archaea stain gram negative, do not form resting stages or spores and reproduce

^{9.5}The term halobacteria (as opposed to the family Halobacteriaceae that encompasses the halophilic Archaea) is a terminological carry over from the old two-part morphology-based classification of life (see earlier discussion of Woese and his influence on microbial nomenclature).

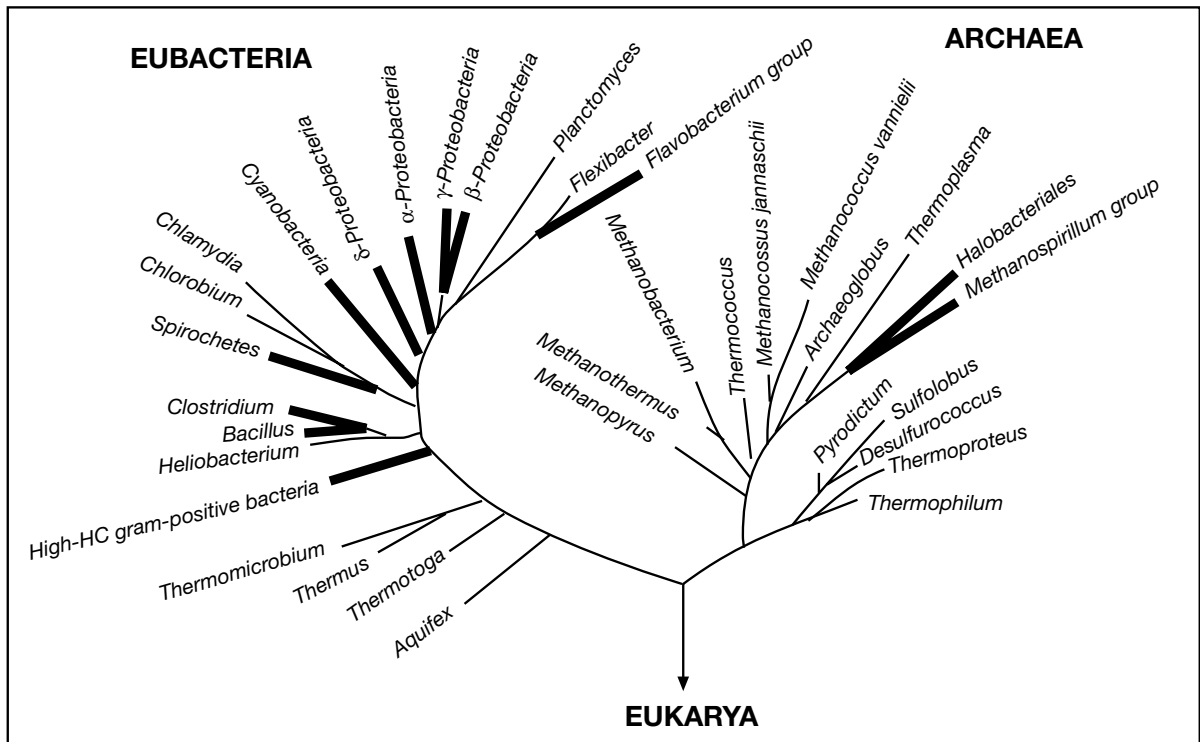

Figure 9.13. Phylogenetic tree of the Bacteria and the Archaea, based on 16S rRNA sequencing comparisons, Bold lines indicate branches containing representatives able to grow at or near optimal rates at NaCl concentrations exceeding 15% (after Ventosa et al., 1998).

by binary fission or budding (Table 9.3). They are morphologically diverse and cell shapes include spheres, spiral, rods, lobed, plate-shaped, irregular-shaped or pleomorphic. They may exist as single cells, as aggregates or form filaments. Cell diameter range from 0.1 to 15 μm and the length of a filament can be up to 200 μm . Currently, in the family Halobacteriaceae there are around 15 genera with 40 species of extreme halophiles (Oren, 2002), Some genera are monotypic: *Halobacterium*; *Halobaculum*; *Natrosobacterium*; *Natrialba*; *Natrosomonas*. The other genera are: *Natrarococcus* (2 species); *Haloarcula* (2 species); *Halococcus* (2 species); *Haloferax* (4 species); *Halorubrum* (5 species), and an eleventh genus, *Haloterrigena*, has recently been proposed (DasSarma and Arora, 2001).

Cosmopolitan haloarchaea genera are *Halobacterium*, *Haloferax*, *Haloarcula* and *Halococcus* (Table 9.3). Haloarchaeans prefer near somewhat acidic to near neutral pH brines and so are commonplace in marine-fed brines, seeps, sea-bottom brine lakes and continental salt lakes. Some Archaea flourish in caprock brines, along with the sulphate-reducing bacteria and are also resident in sulphuric acid caves. *Halococcus sp.* are strict aerobes, their name reflects their coccoid cell shapes; they form pairs, tetrads, sarcinae or irregular clusters. Cells

produce several orange or red carotenoid and retinal pigments needed to better cope with high levels of ultraviolet light that characterise supersaline brine sheets. *Haloferax* prefers high Mg waters and is a major constituent in the halophilic biota of the Dead Sea. The pleomorphic *Haloarcula* typically grows with square and triangular shapes, with straight edges, sharp corners, and is very flat. It is very similar in appearance to the interstices in a mass of halite crystallites. These highly angular shapes are unusual for a lifeform and only possible because internal salt concentrations are as high as they are outside the cell (see cellular adaptations). It means there is little or no net osmotic pressure on the cell wall, allowing it to adapt such high surface-area shapes. Similar shapes are not possible for organisms with 'normal' ionic strengths in the cell interior. Their cell shapes show surfaces and outlines that are indicative of "minimization of surface energy," whereby curved edges and spheroid outlines dominate.

Of the recognized genera of haloarchaea, two have representatives that live only in high pH soda lakes such as Wadi Natrun and Lake Magadi, they are *Natronobacterium* and *Natronococcus*. They grow in highly alkaline brines (pH 9-11) with very low levels of Mg (<0.024 g/l). This group or Archaea is not found in marine-fed salterns or less alkaline continental systems,

Feature	Halobacterium	Halococcus	Haloarcula	Haloferax
NaCl (g/l) required	>120	>120	>90	>90
optimal	204-263	204-263	117-175	117-175
Oxygen requirements	aerobe/facultative anaerobe	strict aerobe	aerobe/facultative anaerobe	strict aerobe
pH optimum	5.5-8.5	5.5-8.5	5.5-8.5	5.5-8.5
Temperature optimum (°C)	20-40	30-37	30-55	35
Pigment	Bacteriorhodopsin Halorhodopsin	Carotenoids Retinian type pigments	Bacterioruberin Retinian type pigments	Bacterioruberin Retinian type pigments
Mg (g/l) required	>0.12	>0.1	>0.12	>0.49
optimal	0.12-1.22		0.12-1.22	0.49-1.215
Size (µm)	0.5-1: 2 x 1.6	0.8-1.5	n/a	1.3 x 2.3
Shapes	irregular rods	cocci	pleomorphic	irregular rods, disks
Gram (+ or -)	+	- (+)	-	-

Table 9.3. Characteristics of the main halophilic archaea (after Perthuisot and Castanier, 2000).

(Grant et al., 1999). How *Natronobacterium* and *Natronococcus* survives in soda lakes is a problem for them (or at least for us, trying to understand how they get can away with it). At such elevated pH levels any protons (H^+) pumped to the outside of a cell by electron transport or rhodopsin membranes, are sucked up by the hydroxyl ions and gone forever. Even though the resulting electric potential is still there, it can't be harvested by an ATPase-based metabolism unless it can recycle protons from outside the cell (see next section). How they get around this problem is not known, and it is probably the issue that limits the upper pH range of life.

Methanogenic archaea, as the name implies, produce methane as a byproduct of their autotrophic metabolism. Methanogens are all Archaea and constitute the strictest anaerobic grouping known. In saline settings, most methanogens do best in anoxic waters with salinities less than 150‰. No other group of living things breathe methane and so their metabolic enzymes are unique (as are the related biomarkers). Several, mostly moderate halophilic, methanogens have been identified in saline ecosystems and include *Methanohalophilus halophilus* from a microbial mat in Shark Bay, *M. mahii* from the Great Salt Lake, and *M. portucalensis* from a coastal saltworks in Portugal (DasSarma and Arora, 2001). The slight halophile *Methanosalsus zhilinae* is also an alkaliphile and a slight thermophile. The extremely halophilic methanogen, *Methanohalobium evestigatum* comes from a salt lake in the Crimea; it has a NaCl optimum of 260‰ and is also a thermophile with a temperature optimum of 50°C. Worldwide these and other methanogens form the base level in chemosynthetic foodchains in salt lakes and are common contributors to the chemosynthetic biota of deep-sea brine pools atop salt allochthons in the Gulf of Mexico (Figure 9.40).

Methanogenesis oxidizes hydrogen using metabolic mechanisms that are not sufficiently efficient to rip out all the hydrogen from the carbon chains. As a biochemical process it occupies a terminal position in the degradation of carbohydrates in the reaction cycle of hypersaline ecosystems. Methanogenic Archaea in hypersaline environments utilise noncompetitive organic substrates such as methanol, methylated amines, and dimethyl sulphide, which originated largely from the breakdown of osmoregulator amines (osmolytes). Methanogens do not utilise carbon dioxide, acetate and hydrogen, which are the substrate for the sulphate-reducing bacteria living nearby. The reason for this metabolic restraint is the greater effectiveness of sulphate-reducing bacteria, which are out-competing methanogens for hydrogen and acetate (i.e. methanogens eat the leftovers).

Cellular adaptations to hypersalinity.

Halotolerant and halophilic species have developed special biochemical mechanisms to cope with the tendency to desiccate in the high osmotic pressures of mesohaline and hypersaline waters namely; slime, osmolytes, halo-adapted membranes and specialized proteins. Halotolerant cyanobacteria constitute a significant component of the upper layers in microbial (algal) mats in modern sabkhas and shallow brine lakes where they are subject to both periodic desiccation and hypersalinity. Such microbial mats show a worldwide recurrence of a few well-adapted cosmopolitan cyanobacterial species in the upper stories of a microbial mat; *Microcoleus chthonoplastes*, *Lyngbya sp.*, *Entophysalis sp.*, and *Synecococcus sp.* All are slimy; they are embedded in matrices of extracellular polymeric mucous that

stores large amounts of water. It protects the cell from osmotic stress and acts as a buffer against extreme temperatures and ultraviolet rays (Gerdes et al., 2000a).

Other halotolerants and all halophiles adapt to osmotic stress at the intracellular level. *Dunaliella parva*, a halotolerant unicellular green alga that flourishes in mesohaline waters (optimum = 120‰, survival 20–340‰), distributes glycerol throughout its cytoplasm to increase the total solute concentration in the cell and so better cope with the high osmotic pressure induced by its high salinity surrounds. Glycerol is an osmotically active substance (osmolyte) that takes up space in the cellular fluids. It lowers the relative water content of the cell and so raises the internal osmotic pressure. Cytoplasmic concentration of glycerol in *Dunaliella parva* can reach 7 mol/l and can constitute over 50% of the dry weight of cells growing in salinities ≈280‰. Glycerol is used as an osmolyte in other halotolerant and halophilic algae, as well as by yeasts, fungi and brine shrimp. Halotolerant and halophilic prokaryotes also use a variety of other sugars, sugar alcohols, amino acids and compounds derived from them (such as glycine betaine and ectoine) as osmolytes, leading to characteristic biomarker assemblages in ancient saline sediments.

Halophilic archaea have two main intracellular defence mechanisms to cope with the extreme osmotic gradients induced by hypersaline to supersaline conditions. One is a modification of the plasma (cell) membrane; the other is an adaptation of the protein structure itself. Unlike most life, the plasma membrane of halophilic archaea is dominated by rhodopsins and the cell membrane does not actively exclude salts, so the overall internal salt concentration in haloarchaeal cytoplasm is high. But the cell membrane is selective, it tends to exclude sodium, while actively pumping potassium into the cell against a thousand-fold concentration gradient. The total ionic strength remains the same on both sides of the plasma membrane, but the ratios of specific ions differ inside and outside the cell wall. Potassium is the dominant cation within the cell. Many cell functions require potassium, but would be disrupted by high levels of sodium. Cells of halophilic archaea can contain up to 4 moles/litre of potassium chloride, which is eight times its concentration in seawater. Anaerobic fermentative halophilic bacteria of the order Haloanaerobiales use a similar “high potassium in the cell” strategy.

Rhodopsins (bacteriorhodopsins) constitute much of the protein in the purple patches in the cell membranes of photo-active haloarchaea. Patches contain 25% lipids and 75% protein, all of which is bacteriorhodopsin (Figure 9.14a). Bacteriorho-

dopsin structure is arranged in groups of 3 protein molecules surrounded by a lipid with a few more lipids in the centre of the molecular cluster. These light-sensitive purple pigments convert light energy into chemical energy (proton pump) and so power the cell's ion pump (Figure 9.14b). Thus, the purple membrane is a site of photosynthesis, but not the chlorophyll-based photosynthesis of cyanobacteria and eukaryotes. Purple membranes obtain energy from light but, unlike chlorophyll, do not use light to generate reducing power and cannot fix CO₂. Haloarchaea with purple membranes are still mostly heterotrophic but can function as facultative autotrophs in low oxygen conditions where they supplement their metabolic power with photosynthesis via the purple membrane patches. Almost all of this extra energy is used to pump potassium across the cell membrane and so maintain the cellular ionic balance (Figure 9.14b).

As an example of the adaptive chemistry of this halophilic lifestyle, consider the archaea *Halobacterium halobium*. Its cell carries a combination of orange-red carotenoids: mostly β-carotene (C-40) and bacterioruberins (C-50). It is an aerobic-facultative anaerobe. When oxygen levels fall, as often happens in hypersaline water bodies, but light still penetrates the brine, anaerobic photophosphorylation takes place in the cell membrane in the absence of chlorophylls and redox carriers. Waters and sediments where *H. halobium* flourishes then take on a blue or purple tint, as in the Dead Sea. In the past, prior to gene sequencing studies, bacteriorhodopsin's characteristic purple colour led to many haloarchaea in their photoactive stage being described as a separate species of purple bacteria. In the same brines but with higher oxygen levels the main cellular metabolism of *H. halobium* is heterotrophic, not photoautotrophic. Cells in the heterotrophic mode are mostly coloured by carotenoids and now waters where it is thriving appear red, not blue-purple. This is its more normal respiratory metabolic mode in hypersaline waters, where it depends on b and c cytochromes as well as cytochrome oxidase to create ATP via the breakdown of glycerol and the other cellular contents from the now dead algae and cyanobacteria. This cytochrome mediated pathway is not a particularly effective metabolic pathway for decomposers living at lower salinities. But in hypersaline waters these more efficient metabolisers cannot function. So, these highly salt-adapted halophilic cells can respire and produce ATP using their red membranes (carotenoids), under little or no stress from any other competing life forms, even if brines maintain relatively high levels of oxygen. The adaptive chemistry of *H. halobium* means it acts as a decomposer in oxygenated water, and as an anaerobic phototroph in dysaerobic to anoxic, but lit, hypersaline waters.

Figure 9.14. Bacteriorhodopsin proton pump (MW = approximately 25,000), A) Molecular structure emphasising retinal. Overall, bacteriorhodopsin is a protein that has 7 alpha-helical segments each spanning the halobacterial cell membrane. It contains one molecule of retinal per protein molecule which is bound via a Schiff base to the side chain $-NH_2$ group of a lysine residue. The Schiff base lysine is located 40 amino acids from the N-terminus and is near the outside of the membrane in the second helical segment. Interaction of retinal with the protein causes a large red shift, and hence light absorption is at 560-570 nm. The pigment looks purple when bound to the protein. Also shown is the structure of bacterioruberin. B) Photon pumping; light rapidly changes the "straight" all-trans form of retinal in bacteriorhodopsin into the "bent" 13-cis form of retinal, with a concomitant release of a proton outside the cell membrane. The 13-cis form spontaneously returns to the all-trans form in a light-independent reaction, with the concomitant uptake of a proton from within the cell.

There it can survive, although at lower metabolic rates, by using its purple membrane patches (bacteriorhodopsin) to pump protons across the cell membrane (Oesterhelt and Marwan, 1993; Kates et al., 1993). Interestingly, the same species can colour the waters it inhabits either red or purple in response to changing oxygen levels.

Bacteriorhodopsin in the purple membrane of haloarchaea is best described as a two-dimensional oriented crystal containing the pigment molecule retinal. When bacteriorhodopsin captures a photon with its retinal "antenna" this induces isomerization of the retinal, which then becomes detached from the protein, triggering conformational changes in the protein itself (Figure 9.14b). This eventually leads to a bleaching and the pumping of a photon across the cell membrane. Bacteriorhodopsin has an orderly orientation or "sidedness" in the plasma membrane, such that when it releases hydrogen/ Na^+ ions in an illumination and bleaching cycle, the hydrogen ions are expelled only at the outer side of the membrane (ion pump). Conversely when bacteriorhodopsin regains its colour the necessary hydrogen can only approach from the inside of the membrane. Thus a cycle of bleaching and recovery sets up a hydrogen ion pump, which in turns sets up an energy gradient that drives ATP synthesis.

What is so impressive about bacteriorhodopsin is its extreme durability and stability. It survives intact at temperatures up to $140^\circ C$ and can reliably run through a photocycle more than 10 million times. There are a large number of intermediates in the bacteriorhodopsin reaction cycle, each of which can be addressed by light of a specific wavelength. This has led many to proclaim its potential in the development of biomolecular computers and biological solar cells. Synthetic bacteriorhodopsin is a working bistable optical switch, it can be fabricated in a monolayer by self-assembly and reliably store data with 10,000 molecules per bit. In the early 1970s it was extensively studied in the former Soviet Union as a way to counteract the West's dominance in semiconductors, some of this research is still classified as a state secret in Russia today.

Some halophilic archaeal strains, including *Halobacterium salinarum*, contain another rhodopsin pigment in their purple membrane called halorhodopsin. It acts as a Cl^- pump, once again generating energy in highly saline conditions. It is usually present in the cell membrane in much smaller amounts than bacteriorhodopsin, but contains the same retinal pigment. It too absorbs light, which it converts to an ion gradient. However instead of pumping protons out, like bacteriorhodopsin, it pumps chloride ions inwards, which helps maintain osmotic

balance in highly saline conditions. Since chloride ions have a negative charge, moving chloride inwards is equivalent in terms of energy to moving a proton outwards. Thus halorhodopsin generates a chloride ion gradient, which also supplies energy to the cell.

All this membrane adaptation merely shifts the osmotic balance problem from the cellular to the molecular level. Ions within the cell's cytoplasm still compete with proteins and other biomolecules for that universal solvent, water. In order to cope with high osmotic stress at the molecular level, halophilic archaeal proteins have evolved to maintain a high negative charge on the protein surface. This attracts water molecules and envelops the protein in a protective shroud of bound water.

For example, in the Dead Sea halophilic archaea (*Haloarcu-
marismortui*) the proteins of its metabolic enzyme (malate de-
hydrogenase) and its electron transfer protein (ferredoxin) are
both wrapped in coats of acidic amino acid sidechains, both of
which carry a negative charge in neutral media. This predomi-
nance of charged amino acids on the surface of enzymes and
ribosomes stabilizes the hydration shell of various cytoplasm
molecules in high salinity intracellular surroundings, even when
the extracellular brines are well into the halite saturation field.
High-density surface charge binds water molecules to the pro-
tein surface much more ef-
fectively than any mesophile
protein. Hence, *Haloarcu-
la* proteins do not dehydrate or
unfold (denature) even when
exposed to extremely high
salinities. But, high levels
of shielding cations (mostly
potassium) are lost via
osmosis in low salinity en-
vironments and an excess of
negatively charged ions then
destabilizes the molecular
structure by ionic repulsion
and the proteins lyse or dis-
integrate. Any species using
a “salt in cytoplasm” strategy
has an innate restriction to
highly saline environments
(obligate halophiles). Ironi-
cally, the intracellular acids
that unfold normal proteins
counteract this tendency in
the halophiles.

In summary, bioadaptations at the cellular level to highly saline conditions can be divided into two groups of responses (Oren, 2001):

a) **The “high-salt-in” option.** Accumulation of salts in the cytoplasm at concentrations equal to or higher than those of the outside medium. Generally KCl is used as the main intracellular salt. Aerobic halophilic archaea (family *Halobacteriaceae*) utilise this strategy, as do fermenting bacteria, bacterial acetogenic anaerobes (*Haloanaerobium*, *Halobacteroides*, *Sporohalobacter*, *Acetohalobium*), and some sulphate reducers. This strategy is energetically relatively inexpensive, but requires far-reaching adaptations by the intracellular enzymatic machinery to the presence of high salt concentrations. Cells utilising this strategy show limited adaptability to changing salt concentrations (obligate halophiles) and have achieved success only after a long and complex evolutionary history.

b) **The “low-salt-in” option.** Exclusion of salts from the cytoplasm and the accumulation of organic osmotic ‘compatible’ solutes (osmolytes) to provide osmotic balance. This strategy is used by halophilic and halotolerant eukaryal microorganisms, by most salt-requiring and salt tolerant bacteria, and also by halophilic methanogenic archaea. This strategy is energetically expensive; the energetic cost depends on the type of organic

Figure 9.15. Approximate upper salinity limits of selected microbial metabolic pathways (after Oren, 2001 and references therein). Values presented are based on laboratory studies of pure cultures (black bars) and on activity measurements of natural communities in hypersaline environments (white bars).

solute synthesized. No major modification of the intracellular machinery is needed in comparison to non-halophiles, and in most cases cells can rapidly adapt to changes in salinity, as exemplified by *Dunaliella salina*.

As Oren (2001) clearly illustrates, organisms living in increasingly high salinity environments have to devote increasing large proportions of their bioenergetic budgets to osmoregulation, either to synthesize organic solutes or to activate and maintain ionic pumps. This creates a natural salinity-related control over various metabolic pathways, their energy efficiencies and hence their biomarker distributions in the resulting sediments. The following metabolic styles function best at high salinities (Figure 9.15):

1. Those processes that use light as an energy source (and are generally not energy-limited).
2. Heterotrophs (bacteria as well as archaea) that perform aerobic respiration, denitrification, and other dissimilatory processes that yield large amounts of ATP.
3. All types of metabolism performed by organisms that use the 'high-salt-in' strategy, even if the efficiency and amount of ATP obtained in their dissimilatory metabolism is low.

Growth of phototrophic microorganisms in hypersaline surface waters is generally limited by the availability of inorganic nutrients and not by lack of light energy (Oren, 2001). Accordingly, both oxygenic (*Dunaliella sp.*, cyanobacteria) and anoxygenic phototrophs (*Halorhodospira*, *Thiohalocapsa*, *Halochromatium*), all produce organic solutes for osmotic stabilization. They may be found up to very high salt concentrations and in several cases can survive well into the halite saturation field. However, in the case of chemolithotrophs and anaerobic heterotrophs the amount of energy generated in the course of their dissimilatory metabolism is often insufficient to supply the demands of cell growth, osmotic adaptation, and life maintenance. Longterm growth and survival in hypersaline environments is not possible in such species. The 'high-salt-in' strategy is preferable for strongly energy-limited organisms (haloarchaea and fermentative halophilic bacteria) as it is energetically much less costly than the production of organic osmotic solutes. Clearly, salinity controls the various metabolic styles at the cellular level (Figure 9.15; Oren, 2001). Biomarker distributions indicative of the various metabolic pathways will likewise become salinity-related indicators in the rock record.

Life in a layered microbial mat?

The laminated sediments (biolaminites) that typify many evaporitic carbonates and described by sedimentologists using the general, and perhaps somewhat dated, terms algal mats and cryptogalaminites are in effect microbial "high rises," as are many living stromatolites (Chapter 1). They, and their entrained biomarkers, indicate the activities of an ecologically layered microbial community. As a mat surface accretes, its organic constituents are buried. The biochemical make-up of the initial halobiota, which flourished in the hypersaline conditions at or above the mat surface, is altered by the metabolic activities of various decomposers flourishing below.

In order to investigate early or syndepositional changes in the dominant organic constituents and the main diagenetic processes, Grimalt et al. (1992) studied organic profiles in cross sections through two different cyanobacterial mats in a modern marine-fed salina in southern Europe. Changes in lipid composition were compared to the vertical distributions of the various microbial populations. Vertical distributions in the lipid patterns were defined using enrichment cultures from typical species of cyanobacteria, diatoms, purple bacteria, sulphate-reducers and methanogens obtained from the layered mats.

Cyanobacteria *Phormidium valderianum* and *Microcoleus chthonoplastes* were the dominant primary producers in the sampled mats, they occurred almost as monocultures in the upper 6 mm of the mats (Figure 9.16). Worldwide, these and other cosmopolitan filamentous cyanobacterial photosynthesizers are the most obvious organisms in most mesohaline algal mats. Their chlorophyll creates a green layer a few mm thick beneath a sticky or slimy mucosic surface. As layers of these mucilaginous-sheathed cyanobacteria aggrade via periodic growth spurts, it creates biolamination (Chapter 1).

Figure 9.16. Typical microbial community in an evaporitic laminite in a modern coastal salina with salinity in the range 130 to 200 ‰ (after Caumette, 1993).

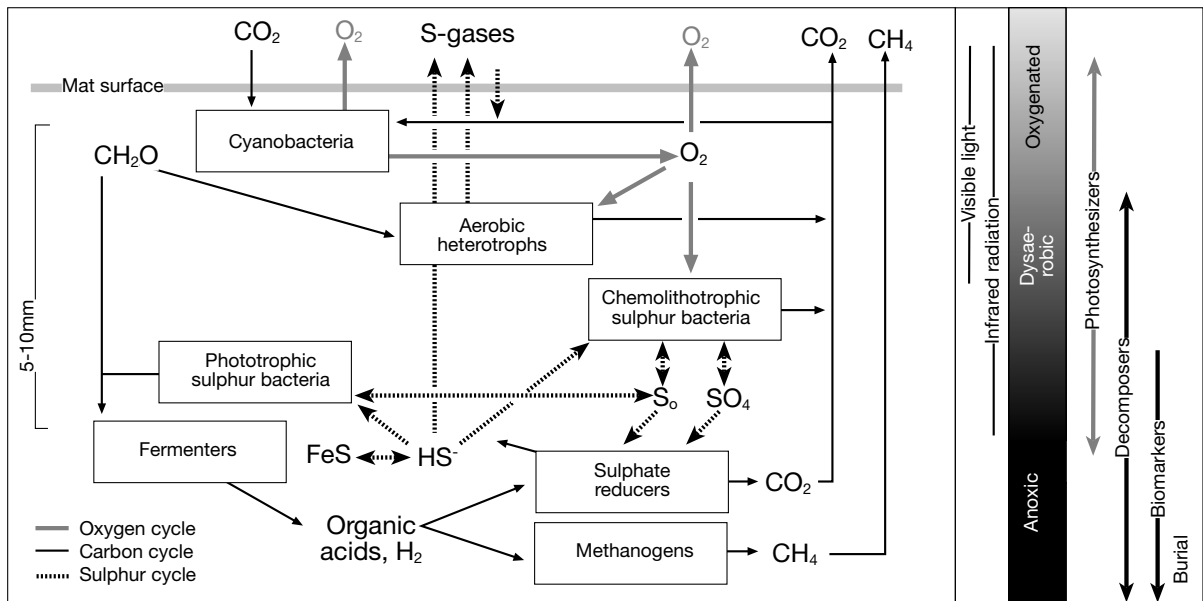

Figure 9.17. Inter-relationships between microbes and the oxygen, carbon and sulphur cycles in the uppermost 5-10 mm of a microbial mat. The oxic-anoxic transition shifts lower in the mat in the daytime and higher in the mat at night (photosynthesis has stopped).

Below the cyanobacteria is a layer of aerobic to dysaerobic heterotrophs (bacteria and archaea), which in the presence of oxygen break down the organic materials produced by the living cyanobacteria (mostly abandoned algal sheaths and slime; Figure 9.17). But because oxygen is only produced by photosynthesis, these organisms can only perform this process during daylight. The next layer below is dominated by chemolithotrophic sulphur bacteria, these are lifeforms that use the redox energy contained in the biochemical gradient between reduced sulphur compounds produced by sulphate reducers (below) and oxygen produced by the cyanobacteria (above). Utilising this redox gradient these purple sulphur bacteria synthesize organic matter and create the characteristic purple-orange layer seen below the green layer in an aggrading microbial mat. Because they can only metabolise in a suitable redox gradient, they need to locate themselves exactly within this gradient, so they are typically the most motile forms in a microbial mat. The redox gradient lies deeper in the mat community during the day due to oxygen production by the cyanobacteria, but it rises and can even reach the mat surface in the dark of night (Figure 9.18). Below the chemolithotrophs are the phototrophic sulphur bacteria. They are anaerobic photosynthesizers that fix sugars by utilising the infrared portion of the light spectrum as they convert sulphide to sulphate. Infrared radiation penetrates deeper into microbial sediment than the visible light used by the cyanobacteria.

Below them are the sulphate reducers, fermenters, and methanogens (Figure 9.17). Fermenters are relatively inefficient decomposers and do not completely break down the organics but break them into alcohols, lactates and other compounds exploited by other decomposers. During the day the sulphate reducers metabolise organics deep in the microbial mat via anaerobic respiration utilising a variety of chemicals including manganese, nitrate, sulphate and even CO_2 . At night they rise somewhat with redox gradient and at times of prolonged bottom brine anoxia and brine column turbidity can even reach the mat surface or enter the lower parts of a density-stratified brine column (Figure 9.18; Des Marais, 2003). They are very important decomposers in most mesohaline microbial mats and give the lower parts of a mat its characteristic "rotten egg" smell. They generally consume up to a third of the organic carbon present in a typical mesohaline microbial mat.

Deeper in the mat are the methanogens. All are anaerobes and utilise simple compounds created by the fermenters (CO_2 and hydrogen, along with organic components such as methanol, acetic acid, formic acid and methylamines) to produce methane. This metabolic pathway produces little biochemical energy and is usually the "last resort" community and makes up the lowermost living layer in the microbial high-rise.

Grimalt et al. (1992) found that the uppermost layers, dominated by cyanobacteria, typically leave no more than minor traces in

Figure 9.18. Schematic of vertical gradients of O_2 and H_2S during the day and at night. The vertical bars at upper left represent the relative depths of penetration of blue (B), green (G), yellow (Y), orange (O), and red (R) light. Profile is for a filamentous micritic mat. Profiles in filamentous and unicellular mats are qualitatively similar, although the depth scale (mm) of such profiles tends to be greater for unicellular mats. It will also be deeper in mats growing in an around clear crystals such as gypsum or halite, which act as light tubes (after Des Marais, 2003).

sediment at the base of benthic mat communities or within the brine column at the halocline of a density stratified brine body. Defining where halotolerant and halophilic decomposers lived in ancient microbialites is not possible from their organic signatures alone; it requires a sedimentological interpretation of the sediment matrix, which is usually a laminite. But, as discussed in Chapter 1, evaporitic laminites and biolaminites are subaqueous sediments with near identical textures beneath stratified and unstratified brines across water depths ranging from less than a metre deep to hundreds of metres.

the solvent-extractable lipids (biomarkers) in buried mat sediments. Rather, the predominant fatty acid distributions in the lower parts of a mesohaline mat sediment parallel the compositions observed in the enrichment cultures of purple bacteria and appear to be mixed with acids characteristic of heterotrophic bacteria, including purple bacteria and sulphate-reducers. In other words, the organic signatures, even as the mats were accumulating a few millimetres above, were those of the decomposers not the primary producers. This implies that many biomarkers used to typify organic production in hypersaline settings typically do not come from organics of the primary producers but from the products of the decomposer community.

Anaerobic decomposers flourish within the

Biomarkers and microbial responses to changing salinities

Salinity-controlled transitions between a halotolerant and halophilic biota can be seen, indirectly in their organic residues and subsequent biomarkers. Biomarkers can be thought of as molecular or chemical fossils with a basic carbon skeleton derived from once-living organisms. Biomarkers are found in all modern sediments, as well as in petroleum and rock extracts and can provide information about species diversity, depositional environment, thermal maturity, migration pathways and hydrocarbon alteration (Table 9.4; Brocks and Summons, 2003; Peters et al., 2005).

Commonly accepted environmental generalisations based on biomarker distributions include the notion that variation in the ratio between the 96 isoprenoids pristane and phytane indicates oxidising versus reducing conditions (this assumes pristane and phytane are both breakdown products of chlorophyll). In an oxidising environment the cleavage of the phytol side chain of chlorophyll is followed by decarboxylation to produce phytane (Figure 9.19a). In a reducing environment the sidechain cleavage of chlorophyll is followed by its reduction to ultimately produce pristane. Low pristane/phytane ratios are thought to indicate reducing conditions, while higher values (>1) indicate oxidising conditions (Table 9.4). But Philp and Lewis (1987) have shown that the chemistry of chlorophyll breakdown is much more complicated in many natural systems and that variations in the ratio may also indicate varying inputs from the archaea, which contain much higher levels of phytane chains than bacteria. Values of pristane/phytane less than 0.5

⁹⁶Isoprenoids are a major class of nonsaponifiable lipids that occur in plants, animals, and bacteria and are characterized by chains of modular groups of five carbon atoms in which the typical pattern has four of the carbon atoms in a linear chain and a single carbon attached at the carbon one position removed from the end of the chain. The term isoprenoid is derived from the name of the five-carbon, doubly unsaturated branched hydrocarbon isoprene, which could in principle be the simplest monomeric chemical precursor for this class of compounds.

Isoprenoids are also known as terpenes. Terpenes are usually grouped according to the number of isoprene (C_5H_8) units in the molecule: monoterpenes ($C_{10}H_{16}$) contain two such units; sesquiterpenes ($C_{15}H_{24}$), three; diterpenes ($C_{20}H_{32}$), four; triterpenes ($C_{30}H_{48}$), six; and tetraterpenes ($C_{40}H_{64}$), eight. The carotenoid pigments are the best known tetraterpenes in the geological realm.

Indication	Biomarker	Detail
Hypersaline	Gammacerane	High relative to C ₃₁ hopanes in oils derived from sources deposited under hypersaline depositional conditions. High values indicate stratified water column during source deposition (Sinninghe Damste et al., 1995).
	Pristane/phytane	Very low values (< 0.5) in oils derived from source rocks deposited under hypersaline conditions, indicates substantial contribution of phytane from halophilic archaea (ten Haven et al., 1987; 1988).
	C ₂₁ to C ₂₅ isoprenoids enriched in δ ¹³ C	C ₂₁ to C ₂₅ isoprenoids enriched in δ ¹³ C relative to biomarkers of phytoplanktonic origin consistent with halophilic archaea (<i>Halobacteria</i>) as the dominant source (Grice et al., 1998).
	2-methylhopanoids and the MTTC ratio	Specific polar side-chain groups and sometimes an additional methyl substituent at position 2 of the hopane skeleton as being largely of cyanobacterial origin (Summons et al., 1999). Cyanobacteria are commonplace in mesohaline waters and the MTTC ratio can be used to characterise cyanobacterial versus archaeal inputs. MTTC ratio is defined as 5,7,8-trimethylchroman/total MTTCs. (Peters et al., 2005).
Anoxic	C ₃₅ homohopanes	High relative to total hopanes in oils derived from source rocks deposited under anoxic conditions (Peters and Moldowan, 1993). Abundance of C ₃₅ homohopanes in oils (relative to C ₃₁ -C ₃₄ homohopanes) is correlated with source rock hydrogen index (Dahl et al., 1994).
	Pristane/phytane	>1.0 can indicate anoxic conditions, but the ratio is affected by many other factors (see text).
	Isorenieratane and derivatives	Presence in oil indicates anoxic photic zone during source rock deposition, these compounds are biomarkers for green sulphur bacteria (Summons and Powell, 1987).
	V/(V+Ni) Porphyrins	High = reducing conditions (Lewan, 1984).
	28,30-bisnorhopane	High in certain reducing environments (Schoell et al., 1992; Moldowan et al., 1994).
Lacustrine	Botryococcane	Presence = lacustrine source. Absence = meaningless (e.g., Moldowan et al., 1985).
	β-Carotane	Presence = lacustrine source. Absence = meaningless (Jiang and Fowler, 1986).
	Sterane/Hopanes	Low in oils derived from lacustrine source rocks. (Moldowan et al., 1985).
	C ₂₆ /C ₂₅ tricyclic terpanes	> 1 in many lacustrine-shale-sourced oils (Zumberge, 1987).
	Tetracyclic polyprenoids	High in oils from freshwater lacustrine sources (Holba et al., 2000).

Table 9.4. Depositional significance of selected biomarkers.

may indicate hypersaline conditions where archaea dominated (Grice et al., 1998).

Differences in the distribution of n-alkanes are also thought to indicate depositional differences in the organic contributors. Waxes in higher plants have significant concentrations of the long chain C₂₂₋₃₆ alkanes^{9.7} with a pronounced odd/even distribution, such organics tend to be relatively rare in evaporitic source rocks, unless surface waters were freshened by periodic runoff from the land. Much of this terrestrial organic material is oxidized and biodegraded before it makes it to the

^{9.7} Aliphatic hydrocarbons are any chemical compound belonging to the organic class in which the atoms are not linked together to form a ring. They are divided into three main groups according to the types of bonds they contain: alkanes, alkenes, and alkynes. Alkanes (n-alkanes) have only single bonds and a continuous chain structure, alkenes contain a carbon-carbon double bond, and alkynes contain a carbon-carbon triple bond. Aromatic hydrocarbons are classified as either arenes, which contain a benzene ring as a structural unit, or non-benzenoid aromatic hydrocarbons, which are characterized by special stability but which lack a benzene ring as a structural unit.

final site of deposition on the brine pool floor. In contrast a high algal input is thought to be characterised by n-alkanes in the C₁₆₋₁₈ region.

At its simplest, much of the utility of biomarkers in saline environments comes from salinity-related differences in contribution to organic matter of the general categories of primary producers (autotrophs), namely prokaryotes (cyanobacteria and bacteria) and eukaryotes (higher plants, algae) and archaea. Most triterpanes are associated with prokaryotic sources, whereas steranes tend to be produced by eukaryotes. Thus, the triterpane/sterane ratio can be a rough measure of the prokaryote/eukaryote contribution to the organic material. As salinity increases, the less salinity-tolerant eukaryotic organisms (mostly green algae) give way to more halotolerant bacteria and cyanobacteria (tricyclic and ^{9.8}hopane producers) with a corresponding increase in the triterpane/sterane ratio (e.g. Summons et al., 1999). Thus high alkalinity/salinity settings are characterised by tricyclics (C₂₀-C₂₄; m/z 191), β-carotene (C₄₀H₅₆ compound; m/z 125) and gammacerane (C₃₀ triterpane;

m/z 191), all with prokaryote sources. Hence, high levels of gammacerane and β -carotene in ancient organic signatures are typically associated with nonmarine highly saline environments (Peters and Moldowan, 1993; Peters et al., 2005).

Lipids, entrained as organic residues in modern evaporitic carbonates and gypsums from modern saline pans (mesohaline and lower penesaline waters), are mostly derived from heterotrophic bacteria acting on cyanobacteria and green algae (Figures 9.16, 9.17). The resulting n-alkane distributions show a high predominance of n-docosane. In the modern evaporitic carbonate domain (mesohaline), the C_{20} highly-branched isoprenoid olephines, tetrahymanol (from bacterivorous ciliates) and large amounts of phytol are precursors to most lipids found in buried evaporitic sediments. In contrast, the main lipid contributors to organics preserved in modern halites and bittern beds are the extremely halophilic archaea and their organic signatures are enriched in the isoprenoids, especially phytane (Table 9.4; Barbé et al., 1990; Wang, 1998).

Likewise, Waples et al. (1974) and ten Haven et al. (1986), noted that Tertiary sediments deposited in many saline evaporitic lagoons retain high concentrations of regular C_{25} isoprenoids. They related it to the activities of the photolithotrophic *Chlorobiaceae* sp., an anaerobic green sulphur bacteria, known to flourish at the halocline of modern saline lakes. It is thought to have flourished in similar stratified settings in ancient mesohaline to hypersaline seaways. Its biochemistry leads to the preservation of a series of 1-alkyl-2,3,6-trimethyl benzenes, thought to be derived from the breakdown of its aromatic carotenoids in sulphate- and sulphide-rich brines (Summons and Powell, 1987). Ten Haven et al. (1988) went on to propose that there are a number of biomarkers indicating likely hypersalinity at the time of deposition including; short sidechain steranes, $5\alpha(H)$, $14\beta(H)$, $17\beta(H)$ pregnanes and homopregnanes, as well as high gammacerane indices (gammacerane/ C_{30} hopane). Gammacerane is a pentacyclic C_{30} triterpane thought to be a diagenetic alteration product of tetrahymanol (Table 9.4). The principal source of tetrahymanol are bacterivorous ciliates, such as

protists like *Tetrahymena*. Thus the presence of tetrahymanol is not restricted to any particular environment but the presence of tetrahymanol (and its daughter gammacerane) in large amounts suggests the presence of a stratified water column and possibly hypersalinity in the depositional setting (Table 9.4; Sinninghe Damste et al., 1995; Peters et al., 2005 p.576).

For Archaea, the cell membrane itself, due to its high thermal stability, is a good candidate for a biomarker. Archaeal cytoplasmic membranes do not contain the same lipids that prokaryotes and eukaryotes do. Instead, their membranes are formed from isoprene chains (ether lipids) made up from C_5 isoprenoid units (as for the side chains of ubiquinone) rather than C_2 units (ester lipids) in the normal fatty acids of the non-archaea (Figure 9.19b). Halophilic Archaea do not have fatty acids, rather the cell wall is constructed of lipids, mainly of glycerol, connected to phytanyl chains some twenty carbons in length by ether bonds to form phytanylic diether. Typically these are organized in bilayers that make up the cell wall. In the case of archaea living in extreme conditions, two glycerol molecules can be connected to a double chain of phytanol to create a tetraether structure of forty carbons (Figure 9.19c). Phytane-rich isoprene derivatives indicative of ancient archaea have been found in Mesozoic and Palaeozoic evaporitic sediments, and more generally in older Precambrian sediments (Hahn and Haug, 1986). Interestingly, their chemical traces have even been tentatively identified in sediments from the Isua district of west Greenland, the oldest known sediments on Earth, some 3.8 billion years old. Biomarker evidence for green and purple sulphur bacteria is found in Palaeoproterozoic marine sediments from northern Australia in the form of a new carotenoid biomarker - okenane (Brocks et al., 2005).

Bacterioruberin constitutes the purple patches in the archaeal cell wall and we have already discussed its stability with respect to high temperatures in the living environment. It may well constitute an excellent as yet unrecognised biomarker for haloarchaea in ancient evaporitic sediments that were precipitated in moderate to extreme salinities (Brocks and Summons, 2003). The likely fossil equivalent of bacterioruberin is perhydro-bacterioruberin, but it has yet to be discovered in geological samples. However, it is worth bearing in mind that some high-molecular weight biomarkers may have escaped detection because they are difficult to analyse using conventional GC-MS methods.

^{9.8}Hopanooids are a group of compounds (triterpenoids) produced by prokaryotic organisms, and the diagenetic alteration products of these compounds (found in oils, rock extracts and sediment extracts). Just as steroids (steranes) are a useful group of biomarkers for identifying input from various eukaryotic organisms (e.g., plants and animals), an analogous group of compounds, hopanooids, are a useful group of biomarkers for identifying input from various bacteria. Hopanooids serve the same function in bacteria as sterols do in eukaryotes: they act as cell wall rigidifiers. In petroleum and its source rocks, hopanooid biomarkers exist as a subset of a group of compounds called triterpanes (isoprenoids).

Do biomarkers indicate hypersalinity?

Work in modern hypersaline systems clearly shows that archaea and bacteria can both flourish as heterotrophs in upper penesaline and supersaline waters at salinities higher than 200-250‰ and that cyanobacteria and some green algae can still survive and grow at these salinities (Caumette, 1993; Olivier et al., 1994). Hence, respective biomarker signatures in ancient counterparts will not be mutually exclusive and none of the biomarker indicators listed in Table 9.4 are exclusive indications of hypersalinity.

Also, some of the widely used biomarker-derived maturity indicators for low maturity oils, such as low levels of diasteranes, T_s/T_m ratios < 1, somewhat low homohopane and sterane isomerization values, all historically derived from studies in ancient marine settings, are not as reliable when applied to relatively young saline-lacustrine oils, such as those sourced from hypersaline Oligocene laminites in the northern Qaidam Basin, China (Hanson et al., 2001). These sediments and their outcrop equivalents have vitrinite reflectance values in the range 0.68 - 1.0, all within the oil window (Figure 9.1). The discrepancy between mature indications coming from vitrinite studies and the immature indications derived from various sterane isomerization ratios in these young hypersaline-sourced oils are perhaps explained by a lack of time for various sterane equilibria to develop. Some of these hypersaline oils come from hydrogen-rich type I lacustrine source sediments in the Qaidam Basin fill that may be as little as 3 million years old. But some other so-called maturity indicators, such as the low levels of diasterane probably are better tied to deposition of the source

organics in noncarbonate shales accumulating in hypersaline waters (Philp et al., 1991).

The fluctuating salinities that controls life in the depositional setting of all modern and ancient evaporites means that there is no simple single biomarker indicator for hypersalinity in any ancient sediment. For example, the 2-methyl hopanoids are thought to indicate a cyanobacterial association (Table 9.4) and cyanobacteria are commonplace in mesohaline waters. But the presence of cyanobacteria and hence 2-methyl hopanoids

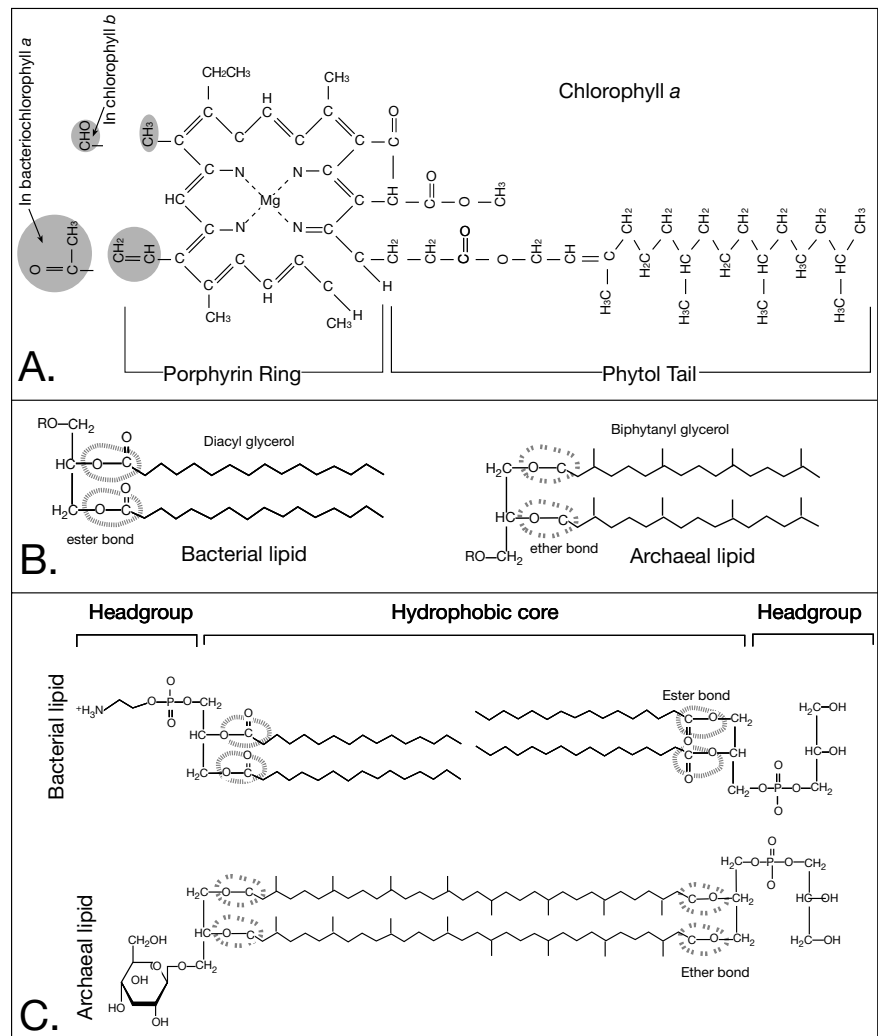

Figure 9.19. Various molecular structures. A) Chlorophyll a structure showing porphyrin ring and phytol tail. Alternate structures from bacteriochlorophyll a and chlorophyll b. B) Phosphatidylanolamine forms a bi-layer lipid in bacterial cells. The acyl chain is usually, but not always straight. Some bacterial lipids have a methyl branch of a cyclohexyl group at the end of the acyl chain, other lipids have one or more unsaturated bonds and the connection of glycerol to the acyl chain is via an ester linkage. C) Lipids are monolayers in Archaea and the phytanyl chain contains isoprenoid-like branches. An ether linkage connects the phytanyl chain. Archaeal membranes also contain bilayer-forming diether lipids.

are not limited to this setting. Likewise, the pentacyclic triterpenoid gammacerane is present in trace amounts in almost all bitumens and oils, but tend to be more abundant in sediments that were deposited under a stratified water column. This is a hydrological condition that is typical of, but not exclusive to, hypersaline lacustrine settings (Sinninghe Damste et al., 1995). A similar argument can be made for low pristane/phytane ratios that are used as indicators of both reducing conditions (assumes a chlorophyll precursor) and halophilia (assumes an archaeal precursor).

All biomarker signatures are indirect and somewhat ambiguous indicators of hypersalinity via assumptions of the relative make-up the original primary producers. In addition all traces of biomarkers from the primary producers preserved in ancient strata have been overprinted by the effects of syndepositional decomposers and likely subsequent mixing from various sources during catagenesis. The overprinting effects of the decomposers in microbial laminites are clearly seen when molecular characteristics of modern hypersaline sediment from the Ejnür salt lake (northern China) are compared to Tertiary (Eocene) core samples from Qianjiang Formation (hypersaline lacustrine) of Jiangnan Basin, central eastern China (Figure 9.20a; Wang et al., 1998). N-alkanoic acids in saline sediments from both areas (Ejnür and Jiangnan) show a pronounced even-over-odd predominance (EOP) and a bimodal distribution. In the lower molecular weight range, the C_{16} and C_{18} components are prominent, with the former dominant. For higher homologues (greater than or equal to C_{20}), docosanoic (C_{22}) and tetracosanoic (C_{24}) acids dominate the n-alkanoic acid homologues in the Jiangnan and Ejnür samples, respectively. Alkanoic acids with an isoprenoid skeleton are more abundant in Jiangnan samples, including C_{20} , C_{21} , C_{24} , C_{25} and C_{30} homologues, with a C_{25} component (3,7,11,15,19-pentamethyleicosanoic acid) most pronounced in the lower part of the Qianjiang Fm. The carbon skeletons of these isoprenoid acids in both units are attributed to archaeal decomposers.

Iso and *anteiso* branched carboxylic acids are prevalent in both the Ejnür samples and in the upper portion of the Qianjiang Formation. They derive from bacteria, probably sulphate-reducing bacteria, and their abundance clearly shows once again the importance of bacterial decomposers, along with haloarchaea, to the biochemical signature of organic matter in modern and ancient saline lake sediments. The presence of hopanoid acids and a 3-carboxy steroidal acid further attest to contributions from bacterial and eukaryotic sources, respectively. The occurrence of particular carboxylic acids in the Jiangnan samples illustrate these compounds, indicators

of halotolerant and halophilic decomposers, can survive as biomarkers in hypersaline source rocks.

Across a broader time and geographic scale, acyclic isoprenoid hydrocarbons are the dominant components in organic matter extracted from sedimentary cores and oils sampling various hypersaline settings in China; the results encompass the Tertiary Jiangnan salt lake basin, the Cretaceous Taian salt lake basin, and the Triassic, Permian and Cambrian Yangtze evaporitic marine platforms (Wang, 1998). Inland saline lake basins in China such as Jiangnan and Songpu are characterized by a tremendous predominance of phytane (C_{20}), which ranges up to 15% of the total extract. The evaporitic marine sediments are also unique in retaining a complete series of super-long-chain acyclic isoprenoids, up to C_{40} (Figure 9.20a). These isoprenoids in the marine evaporites possess head-to-head, tail-to-tail or regular linkages that indicate significant contribution from various archaea to the biomarker signature, i.e. a mixed archaeal contribution from halophiles, methanogens and acidothermophiles. Based on the split in distribution and composition of isoprenoids between the inland salt lakes and the evaporitic marine platform settings, Wang (1998) concluded that the archaeal biota in modern and Cenozoic inland salt lake sediments of China are likely dominated by halophilic archaea, while the halobiotal signatures of Mesozoic and Palaeozoic evaporitic marine sediments were predominantly those of methanogens and acidothermophiles. He also found that the concentration of the various chlorine salts in the sediments is more directly proportional to the abundance of phytane than to sulphate, once again indicating the dominance of halophilic archaea in waters at the halite precipitation stage. He also noted that reduced species of sulphur, sulphide and organic sulphur compounds in the anoxic brines played a key role in the preservation and formation of the abundant phytane in these inland salt lake basins.

A predominance of degraded green algal and cyanobacterial biomarkers in mesohaline settings can be recognised in biomarkers preserved in even older, but organically immature, evaporitic source rocks. The degree of methylation of 2-methyl-2-trimethyl-tridecylchromans (MTTCs) and the abundance of maleimides and bacteriochlorophylls implies a euhaline to mesohaline (≥ 30 -40‰) marine-fed setting for the accumulation and preservation of organics during Kupferschiefer sedimentation in the Permian of NW Europe (Figure 9.20b; Bechtel and Puttmann, 1997; Pancost et al., 2002). These biomarkers are thought to be derived from green/purple sulphur bacteria (decomposers) within organic-rich laminites and suggest that the bottom waters were saturated with H_2S at the time of deposition. Maximum water depths were probably less than 100 metres

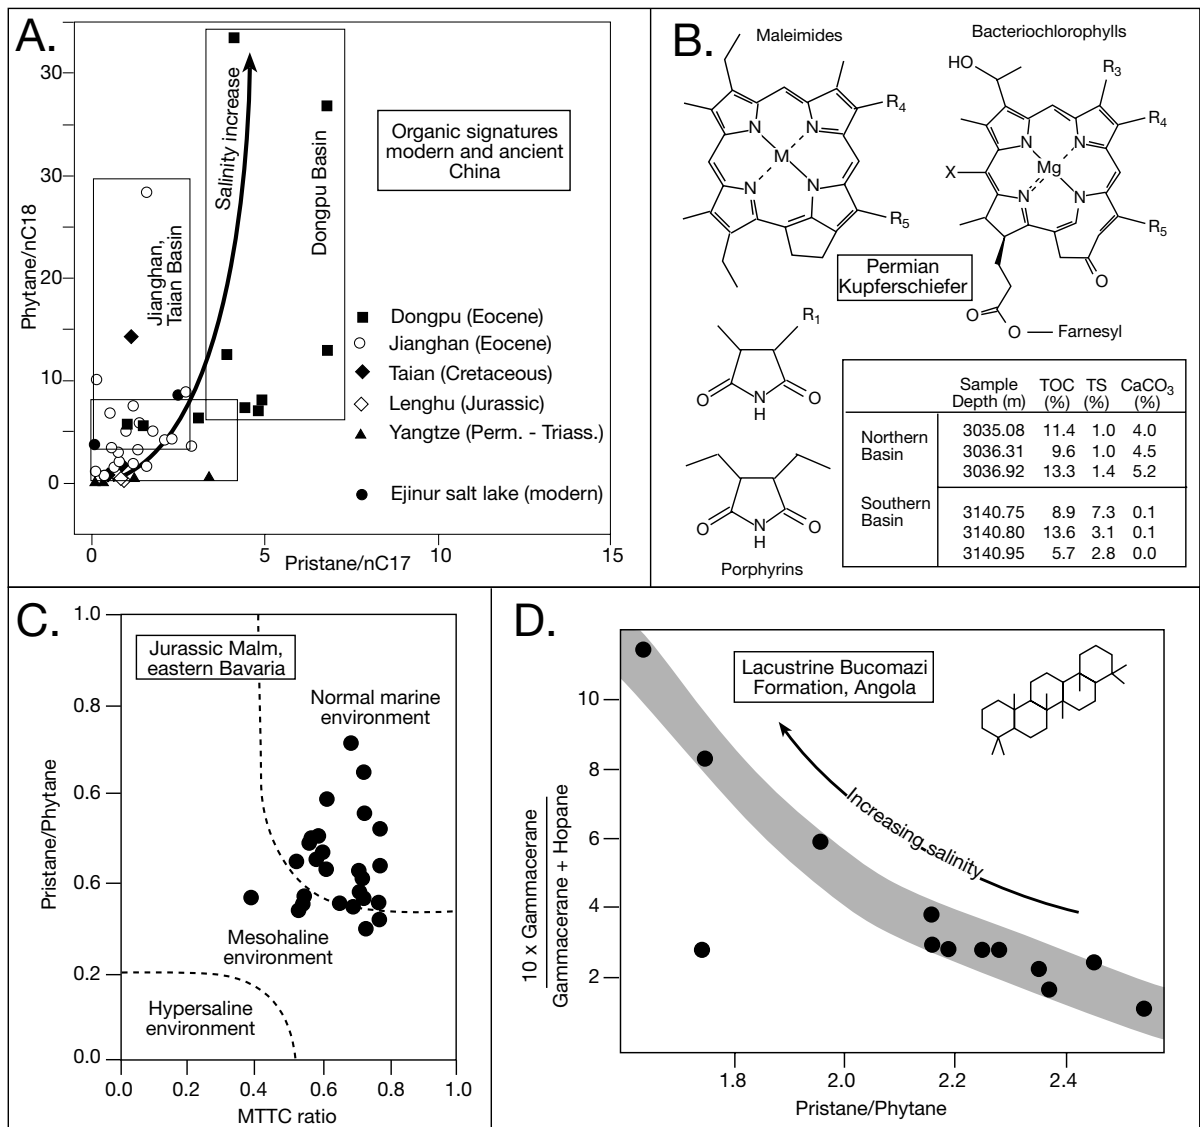

Figure 9.20. Biomarkers. A) Cross plot of Pristane/nC₁₇ versus Phytane/nC₁₈ ratios for various saline/hypersaline settings in China (after Wang, 1998). B) Structure and properties of representative bacteriochlorophylls, maleimides and porphyrins from source rocks in the northern and southern Zechstein basins, offshore NW Europe (after Pancost et al., 2002). Compare with primary structures shown in Figure 9.19a. C) Relationship between pristane/phytane and the methyltrimethyltridecylchroman (MTTC) ratio in Jurassic Malm carbonates of eastern Bavaria (after Schwark et al., 1998). The MTTC ratio is defined as 5,7,8-trimethylchroman/total MTTCs. D) Variations in pristane/phytane ratio and the gammacerane index for oils from lacustrine source rocks in Angola (Inset shows gammacerane structure). Independent biomarker evidence suggests a marine source for the point that lies off the shaded trend (after Peters et al., 2005).

(it was a stratified mesohaline drawdown basin at the onset of Zechstein salinity; see Chapter 5). Decomposers probably lived near the brine boundary between the photic zone and the anoxic (euxinic) bottom water at typical water depths of 10-30 metres below the water surface, as in modern marine-fed density-stratified systems, much like in Lake Mahoney today

(Figure 9.28). Primary production in the upper water column was dominated by photosynthetic cyanobacteria or green algae, while sulphate reduction in the sediment was tied to the availability of abundant sulphate and organic detritus from the overlying water column.

Methanogenesis was also active during Kupferschiefer deposition. This is reflected in the light carbon isotopic composition of organic matter that had originated via recycling of CO₂ generated by methane-oxidizing bacteria in the water column (Bechtel and Puttmann, 1997). Saccate pollen is the only morphologically preserved body fossil in organic matter within this laminated Kupferschiefer sediment, all other traces of cellular morphologies are gone. Euxinic conditions were confirmed by Pancost et al. (2002) over a much larger area of Kupferschiefer deposition than studied by Bechtel and Puttmann. They concluded that almost all of the Kupferschiefer seaway was subject to periods of photic zone euxinia and stratification during the early mesohaline history of the Zechstein Sea.

By themselves, high pristane/phytane ratios, high amounts of gammacerane, and MTTC ratios are not totally reliable indicators of hypersalinity. More reliable determinations can be made when two or more of these biomarkers are crossplotted and the resulting output shows a consistent trend. Figure 9.20c plots pristane/phytane ratio against the MTTC ratio in the Jurassic Malm Zeta laminites of eastern Bavaria in SW Germany (Schwark et al., 1998). The output shows a covariant decrease in the two measures which is interpreted as indicating a trend from normal marine to mesohaline deposition.

A similar covariant trend can be seen in saline lacustrine source rocks when the pristane/phytane ratio is crossplotted against the gammacerane index in mesozoic source rocks from the offshore of west Africa (Peters et al., 2005). Figure 9.20d plots variations in pristane/phytane (a redox and archaeal indicator) and gammacerane index (an indicator of salinity stratification in saline waters) for oils from a set of lacustrine source rocks. Increasing salinity in the depositional setting explains the covariant trend in the plot, whereby higher salinity was accompanied by density stratification and associated reduced oxygen levels in bottom waters. Independent biomarker evidence suggests a marine source for the point that plots off the shaded salinity trend in this figure (after Peters et al., 2005).

Although the levels of entrained organics are very low, similar covariant trends in pristane/phytane and gammacerane occur in C₂₁₋₂₅ isoprenoids, along with relatively heavy δ¹³C signatures, in biomarkers extracted from the Miocene halites of the halokinetic Sedom Formation in Israel. They indicate a predominance of halophilic archaea when the salt was deposited in a CO₂ limited system (Grice et al., 1998; Schouten et al., 2001).

In addition to the signature from their particulate organics, modern brines can also contain large amounts of dissolved organic matter (DOM), with levels that increase with increasing salinity (Hite and Anders, 1991). This liquified organic is

often entrained within brine inclusions in halite and other salt crystals and is not picked up in standard TOC determinations. Levels of volatile fatty acid (VFA), especially acetic acid, are also high in these saline brines. The relative contribution of DOM to the source potential is poorly understood in subsurface evaporitic systems where crossflowing basal brines are dissolving buried halite.

Organic enrichment

The amount of organic matter preserved in an evaporitic sediment, with the potential to become a source rock, is a function of three factors as expressed in the equation (Bohacs et al., 2000):

$$\text{Organic Enrichment} = (P - De)/(Di)$$

where P is production, De is destruction and Di is dilution.

Maximum enrichment occurs when production is maximised and destruction and dilution are minimised. Production at mesohaline salinities is mostly via photosynthetic fixation of CO₂. It includes autochthonous organic matter, formed at or near the site of accumulation and derived from algae, bacteria and aquatic plants, as well as allochthonous organic matter carried in during floods (Bohacs et al., 2000). Katz (1990) showed that varying levels of solar input and water chemistry/stratification exert the largest effects on overall primary production in mesohaline settings. Initial destruction of organic matter is mostly a function of the efficiency of the various scavengers and grazers, which is typically a function of the availability of oxygen (Demaison and Moore, 1980). In increasingly saline settings, bacteria then archaea dominate the scavenger/decomposer population, while the health of the metazoan grazers is largely inhibited by higher salinities (with the possible exception of brine shrimp). Dilution by an influx of minerals to a possible area of organic enrichment can limit levels of organic enrichment by decreasing the proportion of organic matter relative to inorganic matrix. The source of dilution can be detrital clastics or evaporite precipitates.

Dissolved gas levels and temperature changes associated with heliothermal bottoms can create extreme levels of environmental stress in communities attempting to cope with hypersalinity. For example, oxygen is supplied to any water body via exchange with the atmosphere and as a byproduct of photosynthesis of the biota living in the waters. In well-oxygenated water columns most of the organics produced by primary production are de-

stroyed by microbial respiration and the conversion of organic matter back to CO_2 . Much of the improved preservation potential associated with “higher than marine” bottom salinities in mesohaline to hypersaline settings on biotal diversity reflects the effect of increasingly low levels of dissolved oxygen in the bottom and pore waters. Oxygen levels in natural brines tend to decrease with increasing salinity (Figure 9.21a). If not enhanced by the activities of bottom-living aerobic photosynthesizers, natural bottom brines will be dysaerobic to anaerobic by the time salinities reach halite saturation (Kinsman, 1973; Warren 1986). Likewise, all artificial NaCl solutions hold less O_2 at higher salinities and temperatures (Figure 9.21b).

Dissolved CO_2 shows a similar depletion in nutrient-poor waters characterised by little biological activity. Dissolved CO_2 levels in marine-fed modern salt pans decrease to around 50% of the original value as the brine concentration increases from 1.5 to 4 times that of seawater (Lazar and Erez, 1992). CO_2 concentration in brine is also pH dependent; CO_2 content approaches zero in a marine brine at a pH of 8.5-9.0, which is the alkalinity of a brine with a salinity around 70‰ (Moberg et al., 1932). Likewise, measurements of CO_2 in the Dead Sea in 1992 showed its solubility was about 20% of seawater (Barkan et al., 2001). Algae and cyanobacteria, which are dependant on CO_2 for photosynthesis, will suffer shortages at higher salinities.

There can also be increased thermal stress in increasingly hypersaline water bodies. The specific heat of a brine decreases as the salinity increases (Kaufmann, 1960). For example, when the salinity of the surface waters of the Dead Sea increased from 210‰ in the 1940s to 275‰ in the early 1980s, the specific

heat decreased from 3,085 J/kgK to 2,985 J/kgK (Niemi et al., 1997; p. 127). Specific heat is the amount of heat needed to raise one gram of a substance by 1°C. For a given amount of heat input, a unit volume of hypersaline water will show a greater increase in temperature than a less saline water. The resulting greater increase in temperature in a hypersaline water compared to a less saline water can detrimentally effect many thermally-intolerant species. Given the same degree of insolation, it also means density-stratified water columns are heliothermic, with bottom brine tending to be hotter than fresher surface waters. The differences can be substantial, with bottom waters approaching temperatures of 60°C in some

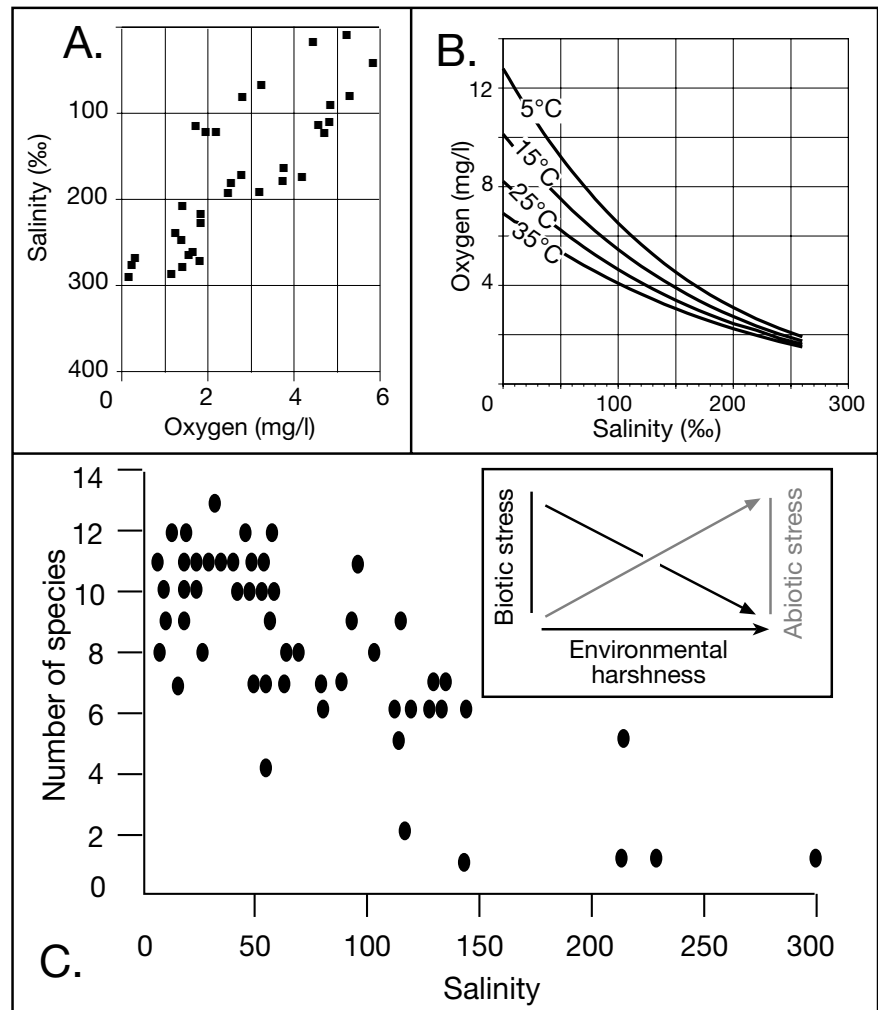

Figure 9.21. Biodiversity and oxygen levels in modern hypersaline settings. A) Measured oxygen levels in present-day surface brines under increasing salinity. Oxygen content of modern seawater ≈ 5.4 mg/l (after Warren, 1986). B) Predicted oxygen values for pure NaCl solutions (replotted from Table 2 in Sherwood et al. (1992)). C) The effect of increasing salinity on metazoan species diversity in the saline lakes of the Coorong region, South Australia (after De Decker and Geddes, 1980).

density-stratified perennial desert lakes such as Solar Lake in the Sinai (Figure 2.48).

An even more interesting association of halophilic microbes comes from the heliothermal lakes of the Vestfold Hills in Antarctica where three hypersaline lakes, Organic Lake, Ekho Lake and Deep Lake, have been studied in some detail (Bowman et al., 2000). The lakes are subsealevel relics of an earlier marine embayment, isolated from the ocean by uplift some 6 ka, but still receiving salt input via marine aerosols. Organic Lake is a shallow meromictic brine lake with waters as much as 7.5 metres deep and an oxycline at 4-5 m. Its surface waters are moderately saline (8 g/l) and their temperature fluctuates between -14 to +15°C. Bottom waters are perennially saline with a TDS of 210 g/l and a near constant temperature of -7°C. Ekho Lake is 42 m deep, meromictic and heliothermally heated with bottom waters maintaining a year-round temperature of 15-16°C. Salinities range from 14 g/l at the surface down to 160-180 g/l on the lake bottom, which is permanently anoxic below an oxycline at 12-20m. The most hypersaline lake is Deep Lake. Its waters are upto 36 m deep, but unlike the other two lakes it is holomictic and aerobic all the way down to the sediment-water interface. Although salinities are around 320 g/l its water temperatures can be as low as -18°C. The biota in holomictic Deep Lake is almost 100% haloarchaeal and it is home to that very robust microbe *Halobacterium lacusprofundi*, (Franzmann et al., 1988; see earlier). The biotal make up of the two meromictic lakes is more complex with varying combinations of the Proteobacteria and Cytophagales. Ekho Lake also contains a number of the Haloanaerobiales, perhaps reflecting its warmer year-round bottom temperature.

But the dominant biomass control in hypersaline and supersaline environments, at least for most multicellular life, is not dissolved gas or even temperature, but the increase in osmotic pressure that comes with increasing salinity. At a concentration of 300‰, sodium chloride brine exerts an osmotic pressure on a cell of more than 100 atmospheres (Bass-Becking, 1928; Reed et al., 1984). Cells of species that typically inhabit marine or brackish waters quickly desiccate in such brines, leading to rapid death (e.g. Geddes, 1975b), hence the adaptations at the cellular level that typify halotolerant and halophilic organisms.

The tendency of bottom waters in many deeper hypersaline water masses to become anoxic, hotter, and osmotically pressured, has helped create many ancient lagerstätte associations (fossil “death communities”), with inherent excellent preservation of fine details in the entrained fossil forms. For example, the widely known Cretaceous Solnhofen micritic plattenkalk

of Bavaria preserves the feathers of the bird-like dinosaur *Archaeopteryx* and many “death-dance” trackways of finely preserved marine crustaceans that once wandered into the hypersaline and anoxic bottom water layers of the Solnhofen lagoon. Similarly, the communities of chemosynthetic mussels, which inhabit nutrient-rich deep dark bottoms about the edges of modern anoxic brine lakes atop dissolving salt allochthons, can suffer mass extermination when sediment slumps occur and mollusc biostromes, carried along by the slump, end up in the anoxic H₂S-rich, death-dealing hypersaline waters of the brine lake (MacDonald, 1992).

High pore water salinities, extreme osmotic stress, a propensity for anoxia in the stratified bottom waters, anoxic pore brines and high bottom temperatures all tend to exclude aerobic burrowing and grazing animals from evaporitic bottom sediments. This minimises a biota that would otherwise oxidise and destroy microbial debris in similar sediments deposited beneath less saline waters.

Biological responses to variably layered brines: Cycles of “feast or famine”

Brines in modern evaporitic depressions are typically layered, with denser more saline waters supporting an ephemeral mass of less dense inflow water (Figure 2.37b). The bottom layer in a perennial brine system tends to be more stable compared to the upper and its physical condition changes little until stratification is lost via mixing of the two water masses (Figure 2.37b). Once mixing occurs the waters in the lake can completely evaporate. Conditions in the floating less dense upper layer are both ephemeral and variable, with wide fluctuations in salinity before desiccation or mixing. When salinities are lowered, this upper layer periodically supports a widespread planktonic bloom (feast). Then, as ongoing evaporation concentrates the upper layer, conditions become increasingly less suitable for life (famine) and a mass die-off occurs, first of the haloxene species, then the halotolerants, then the halophiles. The bloom and the following dieback creates a pulse of organic matter that can swamp the abilities of the anaerobic decomposers in the lower water column to strip it of its hydrogen. Organics can then reach the sediment interface with their long-chain alkanes still largely intact. In conditions where light penetrates to the bottom of the brine column, even when the waters atop the sediment surface are oxygenated, the halotolerant primary producers can be sufficiently productive and the underlying anoxic decomposers sufficiently inefficient that substantial volumes of hydrogen-rich microbial matter can be retained into burial.

Figure 9.22. Organic productivity (maxima) in various saline ecosystems. Typical marine upwelling zone $\approx 250\text{-}500\text{ mg C/m}^2\text{day}$ (the dashed line is world marine maxima based on offshore Peru); tropical shoal water seagrass banks $\approx 500\text{-}1200\text{ mg C/m}^2\text{day}$; open marine waters are less than $100\text{ mg C/m}^2\text{day}$ and average $20\text{ mg C/m}^2\text{day}$ and coastal waters $40\text{-}50\text{ mg C/m}^2\text{day}$. But, preservation is more important than production rate in terms of source potential. Compiled from sources listed in Warren (1986) and this chapter.

When surface water salinities are suitable, evaporite basins have some of the highest measured rates of organic productivity in the world (Figure 9.22; Warren, 1986). When biodiversity is low and salinity is high, a proliferation of well-adapted species can generate productivity levels that are much higher than those observed in most nonevaporitic settings. These saline systems are indicative of general principles seen in all stressed ecosystems, namely, as the harshness or abiotic stress in a system increases the biotic stress decreases on a few well-adapted species (less predators and grazers). The total biodiversity (number of species) decreases, while at the same time the biomass (total mass of organisms in the system) initially increases (Garcia and Niell, 1993). Ultimately, it too declines as conditions become unsuitable for any life (see insets in Figures 9.21c and 9.22)

Salinity change influences organic productivity:
The flamingo connection in East Africa lakes

One of the most visually impressive indications of periodic but very high levels of organic productivity in a well adapted biota in a salinity-stressed layered water body resides in the

“flamingo connection.” This is a connection between flamingoes, mesohaline planktonic blooms and saline lakes, first noted in the geological literature for the east African rift lakes by Kirkland and Evans (1981) and well documented in Lake Nakuru by Vareschi (1982).

Flamingoes are filter feeders thriving on the dense halotolerant cyanobacterial blooms in the shallows of saline lakes around the world. Two species of flamingo flock in huge numbers in the East African rift lakes, namely, the greater and the lesser flamingo (*Phoenicoptus ruber roseus* and *P. minor* respectively), the lesser flamingo has spectacular pink-red coloration. These bright pink waders feed and breed in rift lakes where cyanobacterial blooms can be so dense that a secchi disc disappears within a few centimetres of the lake's water surface (Warren, 1986). Lake Natron is a major breeding ground for flamingoes in East Africa and is the only regular breeding site for the lesser flamingo in Africa (Simmons 1995). It has the highest concentration of breeding flamingoes in any lake in East Africa. Both the greater and the lesser flamingo are found there, with the lesser flamingo outnumbering the greater by a hundred to one. Lesser

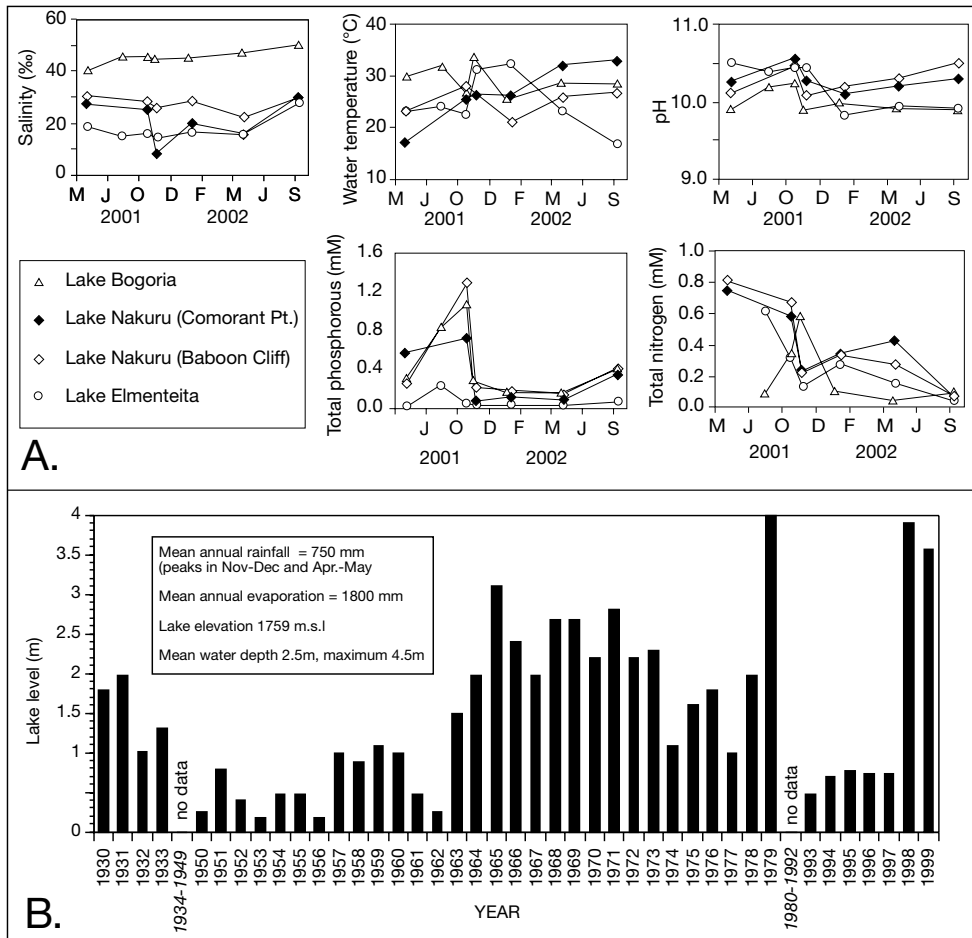

Figure 9.23. Physico-chemical features of saline African Rift valley lakes. A) Physico-chemical changes in soda lake water of the African rift valley lakes from June 2001 to September 2002 (after Ballot, 2004). B) Lake levels in Lake Nakuru from 1930 to 1999. Data are not sufficiently detailed to record times of complete lake drying or drought and there are also substantial times when no data were collected/published (1934-1949 and 1978-1992 (replotted from Vareschi, 1978).

flamingoes bred at Lake Natron in 9 out of 14 years from 1954 to 1967. But while Lake Natron is an essential breeding site, it is not a focal feeding site for flamingoes. Major feeding sites in the rift valley are Lakes Nakuru and Bogoria (formerly Lake Hannington) in Kenya, which are somewhat less saline and so have a greater abundance of mesohaline plankton, especially *Spirulina sp.* (Figure 9.23a). Lakes Nakuru and Bogoria have less than half the areas of Lakes Natron and Magadi, which in turn have small areas compared to most ancient lacustrine evaporites (Figure 5.3)

Millions of flamingoes typically consume more than 200 tons of plankton a day from Lake Nakuru, a shallow saline soda lake with a pH ≈ 10.5 and a typical annual salinity range of 5-30‰ (Figure 9.23a). The lake measures some 6.5 km by 10 km, with eutrophic waters in the lake centre up to 4.5 metres deep

(Figure 9.24a; Vareschi, 1978, 1979, 1982). The feeding style of the birds is to wade through the shallows, with head upside down and beaks waving side to side across the water surface. They are mostly nocturnal feeders and will feed for up to 12-13 hours in a 24 hour period.

The main phytoplankton component in Lake Nakuru waters is the cyanobacterium, *Spirulina platensis* (aka *Arthrospira platensis*). It is the main food component for the lesser flamingoes feeding in both Lake Nakuru and Lake Bogoria (Figure 9.25). In Lake Nakuru it is also consumed by one species of introduced tilapid

fish and one species of copepod and a crustacean. Rotifers, waterboatmen, and midge larvae also flourish in the waters of Lake Nakuru. The mouth-breeding tilapid *Sarotherodon alcalicum grahami* was introduced to the lake in the 1950s to control the mosquito problem and they have flourished ever since, at times displacing the flamingoes as the primary consumers of planktonic algae. Their introduction increased the number of fish-eating birds such as pelicans in the lake (Vareschi, 1978).

Flamingo beaks have evolved to filter plankton from saline to brackish surface waters and are equipped with a feeding system unlike any other bird on earth. By swinging their upside-down heads from side to side and using their tongues to swish water through their beaks, flamingoes siphon the

lake water through the beak filters to trap the cyanobacterium *Spirulina* and other plankton. Flamingoes can filter as many as 20 beakfuls of plankton-rich water a second. Spacings of the filters in the beak of the greater flamingo are wider than those in the beaks of the lesser flamingo. Greater flamingoes feed mostly on zooplankton, while lesser flamingoes feed almost solely on *Spirulina*, thus in any saline lake where the two birds co-exist they do not compete for the same food source.

Spirulina provides high levels of the red pigment phycoerythrin (a protein from the light-harvesting phycobilin family) to the food chain. It accumulates in flamingo feathers to give the birds their world famous coloration (hence the “flamingo connection”). This is not the same pigment that turns waters red in Lake Natron and Lake Magadi. Lesser flamingoes, with their narrower spacings of beak filters survive largely on *Spirulina*, and so have a more intense pink colour than greater flamingoes, a species that sits higher in the lake food chain and so get its feather colour second-hand from the lake zooplankton. As well as possessing very high levels of phycoerythrin in its cytoplasm, *Spirulina* is also unusual among the cyanobacteria in its unusually high protein content (some ten times that of soya). In Lake Chad, and in some saline lakes in Mexico, *Spirulina* accumulates as a lake edge scum that has been harvested for millennia by the local people (including the ancient Aztecs) and used to make nutritious biscuits. A lack of cellulose in the *Spirulina* cell wall means it is a source of plant protein readily absorbed by the human gut, making it a potentially harvestable food source in saline water bodies in regions of desertification.

In 1972 Lake Nakuru waters held a surface biomass of 270 g/m^3 and an average biomass of 194 g/m^3 but, as in most hypersaline ecosystems, Nakuru's organic production rate varies drastically from year to year as water conditions fluctuate (Figure 9.24b; Vareschi, 1978). *Spirulina platensis* was in a long-lasting bloom in 1971-1973, and accounted for 80-100% of the copious phytoplankton biomass in those years. In 1974, however, it almost disappeared from the lake and was replaced by much smaller coccoid cyanobacteria that dealt better with elevated salinities. When the relatively large filaments of *Spirulina sp.* dominate the lake plankton, a flamingo's beak filters between 64 and 86% of the plankton held in each mouthful of lake water (Vareschi, 1978). When the much smaller coccoids come to dominate the filters are much less efficient feeding mechanism. The change in plankton species is also tied to a serious reduction in algal biomass (and protein availability), which in 1974 was down to 71 g/m^3 in surface waters and averaged 137 g/m^3 in the total water mass. As a result the flamingo population feeding

in the lake declined from 1 million to several thousands and the flamingoes moved to other lakes where *Spirulina* were flourishing (Vareschi, 1978).

The lower salinity limit for a *Spirulina* bloom is $\approx 5\text{‰}$ and it does better when salinity is more than 20‰ . The species dominance of *Spirulina* and its higher biomass in somewhat more saline lake waters is clearly in the near unispecific year-round biomass of nearby Lake Bogoria (salinity 40-50‰). Its surface salinity is higher year round than Lake Nakuru (salinity $\approx 30\text{‰}$) and the somewhat fresher Lake Elmenteita (salinity $\approx 20\text{‰}$; Figure 9.23a). Because of this, Lake Bogoria is a more reliable food source for feeding flamingoes compared to either Nakuru or Elmenteita (Figure 9.25). Birds tend to migrate there to feed when conditions for *Spirulina* growth are not ideal in other nearby alkaline lakes (too fresh or too saline). This was the case in 1999 when high rainfall and dilution of lake waters caused the *Spirulina* levels to fall in both Nakuru and Elmenteita.

A driving mechanism for the abrupt change in biomass in Lake Nakuru in the period 1972 -1974 was not clearly defined. It was thought to be related to increased salinity and lowering of lake levels, driving the growth of coccoid species other than *Spirulina sp.* that were better adapted to higher salinity, but offering less protein to the feeding birds (Figure 9.24b; Vareschi, 1978). There is also the simple fact that ever more saline waters cover ever smaller areas on the lake floor. There have been times in the last 70 years when most of the lake has dried up and pools of saline water only a few tens of centimetres deep remained (Figure 9.23b).

During the mid to late 1970s and in the 1980s the lake returned to more typical inherent oscillations in water level and salinity (schizohalinity). The *Spirulina* and flamingo populations in Nakuru returned to impressive numbers. From the 1990s more reliable long-term data sets on physical lake condition and flamingo numbers have been compiled (Figure 9.24d). In 1993, 1995 and 1998 feeding flamingo populations in Lake Nakuru were once again at very low levels and the remaining bird population was stressed. In 1998, unlike 1974, the stress was related to freshening driving the decrease in *Spirulina* biomass, not increased salinity and desiccation. This freshening favoured a cyanobacterial assemblage with strains that possibly also produced toxins. In the preceding bountiful year (1996), the *Spirulina*-dominated biomass had bloomed at times when salinities were favourable and died back at times of elevated salinities and lake desiccation, as in 1974. By 2000 formerly low salinities had once again increased making surface waters

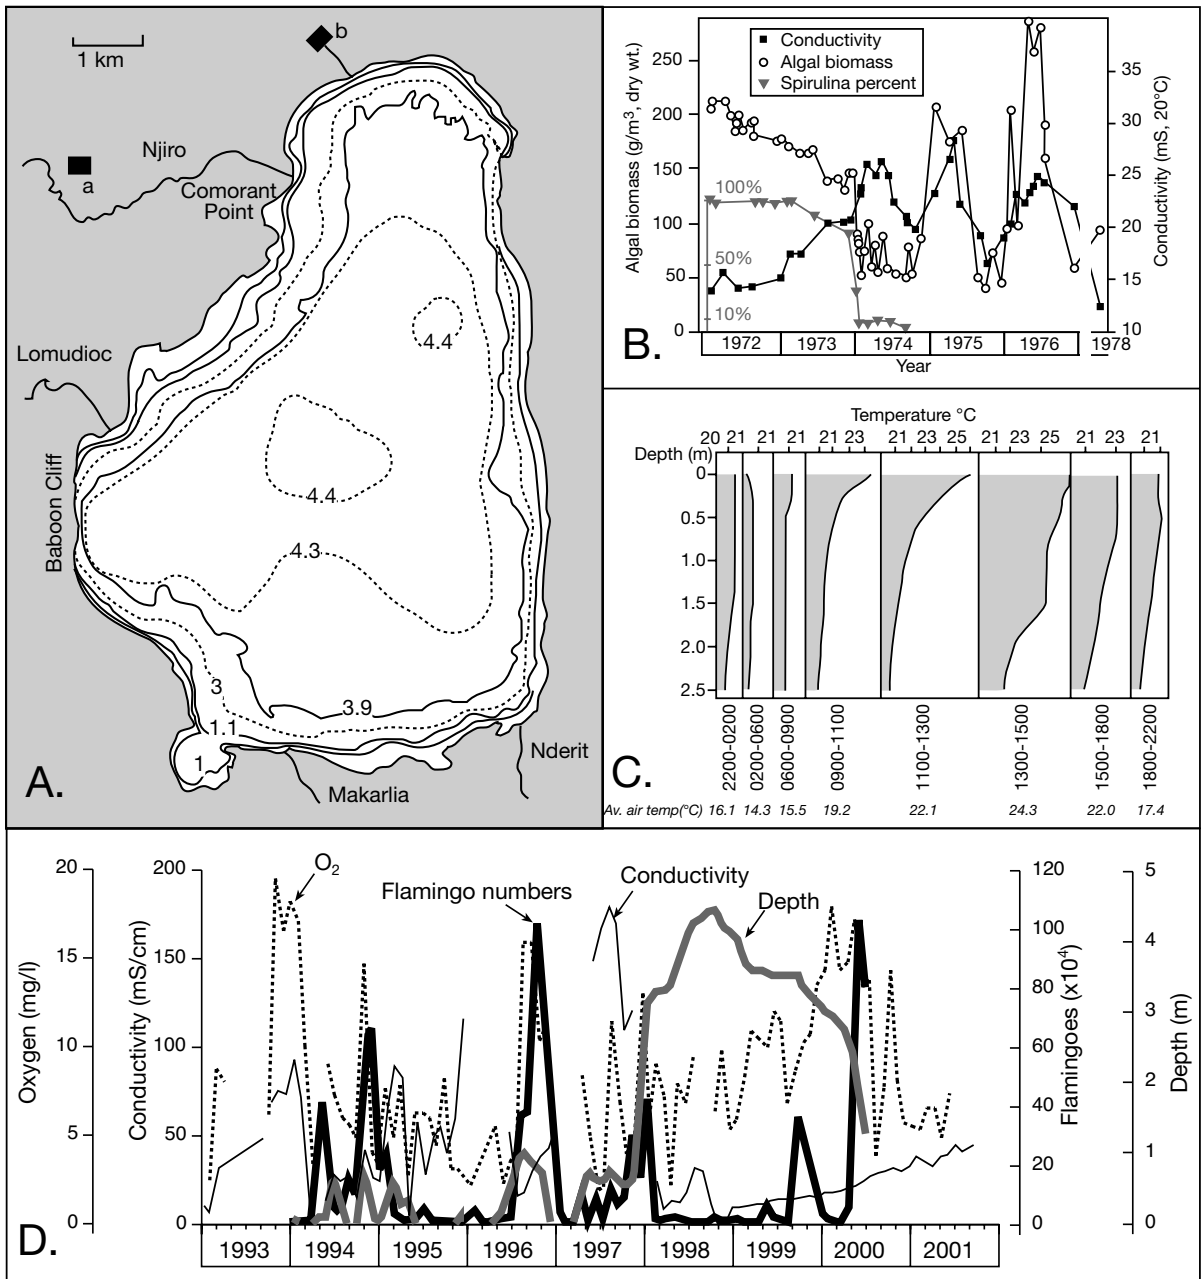

Figure 9.24. Lake Nakuru (A-C after Vareschi, 1982). A) Lake bathymetry (Dec 1979) and strandzone changes. Solid isopleths are actual shorelines at different lake levels over a 20 year period; from outer to inner are December 1979, January 1969, January 1967 and January 1961. Dashed isopleths are based on soundings taken in December, 1971. Two sewage plants are located at a and b. B) Trends of algal biomass and conductivity of lake water during 1972-1978. The percent contribution of *Spirulina platensis* to the total algal biomass is also shown. C) Mean water temperature profiles at different times of day from 1972-1973. D) Monitored water depths, conductivities, oxygen levels and flamingo numbers at Lake Nakuru for the period 1993 to mid 2001. Water depth and flamingo data only available from 1994 to mid 2000. Data is digitised and replotted to a common time scale from data in a progress report by Odadda et al. discussing current conditions in the Lake Nakuru area (downloaded from <http://www.worldlakes.org> on Feb 2, 2004)

suitable for another widespread *Spirulina* bloom and the associated return of high numbers of feeding flamingoes.

And so it seems that breeding flamingoes come to Lake Nakuru to feed in large numbers when there is water in the lake with appropriate salinity and nutrient levels to facilitate a *Spirulina* bloom. In some years when heavy rains occur, lake levels rise significantly and the lake waters, although perennial, stay in the lower salinity tolerance range for *Spirulina platensis*, keeping cyanobacterial numbers and protein levels at the lower end of the spectrum, as in the El Niño period between October 1997 to April 1998. Once lake levels start to fall, salinities and rates of salinity change return to higher levels, then water conditions once again become appropriate for a *Spirulina* bloom. But environmental stress on the flamingoes also comes with elevated salinities and desiccation moving lake waters into salinities at the upper end of *Spirulina* tolerance.

One of the reasons Lake Nakuru is suitable for cyanobacterial and algal growth at times of *Spirulina* bloom is the maintenance of suitable temperatures and oxygenation in the upper water mass. The lake develops a daily thermocline in the upper 1.5 metres of the column that dissipates each day in the late afternoon via wind mixing. Overturn recycles nutrients (derived from decomposition of bird and other droppings) back to the oxygenated surface waters to facilitate an ongoing bloom the next day (Figure 9.24c).

Numbers of flamingoes feeding in Lake Nakuru and Lake Bogoria are used in popular press as indicators of the environmental health of the lakes. Thousands of birds died in Lake Nakuru in 1995 and more than 30,000 birds may have died in Lake Bogoria in the first half of 1999. Some environmentalists argued in the popular press that mass die-offs and their perception of lowered numbers of flamingoes in Lake Nakuru and Lake Bogoria in the 1990s were indicators of uncontrolled forest clearance, an uncontrolled increase in sewerage encouraging eutrophication, and increase in heavy metals from increasing industrial pollutants in the lake and general stress on the bird population from tourists and the drastic increase in local human population centred on the town of Nakuru (third largest in Kenya). Numbers of people in the town, which is the main city in the rift valley, have grown by an average of 10% every decade for the past 30 years.

But like much environmental doomsday argument it is more based on opinionated prediction than on scientific fact (aka the Chicken Little fixation: it sells more newspapers than “good news” stories). When numbers of feeding flamingoes in

Lake Nakuru are compiled across the 1990s it is obvious that flamingo numbers oscillate widely, but it is also obvious that the peak numbers in 2000 are equivalent to the peak in 1996. A longterm fall in numbers of feeding flamingoes in the lake is not based on scientific reality.

Likewise, when studies were done on the cause of the mass die-off in Lake Bogoria in 1999, it was found to have a natural not an anthropogenic cause (Krienitz et al., 2003). The flamingoes had ingested the remains of toxic cyanobacteria that constitute part of the population of the microbial mats that had bloomed to form a floor to the fresh water thermal spring areas about the lake edge. There the mats are dominated by thermally tolerant species; *Phormidium terebriformis*, *Oscillatoria willei*, *Spirulina subsalsa* and *Synechococcus bigranulatus*. The influence of cyanotoxins in the deaths of the birds is reflected in autopsies which revealed: (a), the presence of hot spring cyanobacterial cells and cell fragments (especially *Oscillatoria willei*), and high concentrations of the cyanobacterial hepato- and neurotoxins in flamingo stomach contents and faecal pellets; (b), observations of neurological signs of bird poisoning - birds died with classic indications of neurotoxin poisoning - the ophistotonus behaviour (neck snapped back like a snake) of

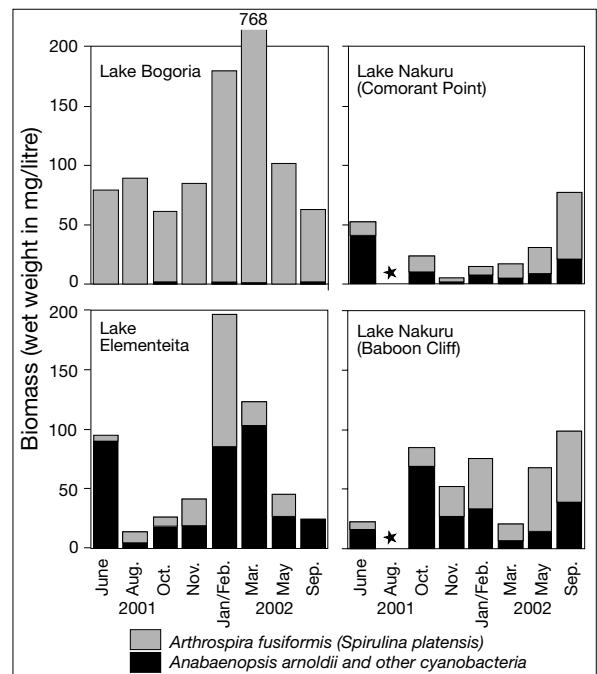

Figure 9.25. Changes in the biomass and the proportion of *Spirulina platensis* in various African rift valley soda lakes from June 2001 to September, 2002. Lake Bogoria is more saline than Nakuru than Elementeita (see Figure 9.23; after Ballot, 2004).

the flamingoes in the dying phase, and the convulsed position of the extremities and neck at the time of death. Cyanobacterial toxins in stomach contents, intestine and faecal pellets were 0.196 g g^{-1} fresh weight (FW) for the microcystins and 4.34 g g^{-1} FW for anatoxin-a. Intoxication with cyanobacterial toxins probably occurred via uptake of detached cyanobacterial cells when birds come daily to the springs to drink and wash their feathers after an overnight feeding session in the saline waters of the lake proper.

When heavy metal studies were undertaken in Nakuru lake sediments, the amount of heavy metals (Cd, Cr, Cu, Hg, Ni, Pb, Zn) were found to be in the typical range of metals in sediments in lakes worldwide. The exception is Cd, which is elevated and can perhaps be ascribed to anthropogenic activity (Svengren, 2002). All other metals are present at low levels, especially if one considers that Lake Nakuru lies within a labile catchment where the bedrock is an active volcanogenic-magmatic terrane.

Rise and fall of lake levels, drastic changes in salinity, a periodically stressed biota, and a lack of predictability in water character are endemic to life in saline ecosystems (cycles of “feast or famine”) and are what controls the number of feeding flamingoes in Nakuru and Bogoria. Oscillations in one or more of these factors are not necessarily anthropogenically induced. In general, sufficient base-line scientific data in this schizohaline ecosystem is not yet available and so accurate determinations of the relative import of increased human activity versus natural environmental stresses on longterm bird numbers are not possible.

Nearby Lake Magadi is also characterised by seasonal freshening, high productivity levels and bright red waters. In this case the colour comes from haloalkaliphilic archaea, not cyanobacteria. Archaeal species belonging to the genera *Natronococcus*, *Natronobacterium*, *Natrialba*, *Halorubrum*, *Natronorubrum* and *Natronomonas*, all occur in soda brines of Lake Magadi. Lake centre brines where this biota flourishes is at trona/halite saturation with a pH up to 12. Stratified moat waters around the trona platform edge are less chemically extreme and moat bottom sediments preserve elevated levels of organics ($\approx 6\text{--}8\%$). Lake Magadi also harbours a varied anaerobic bacterial community in the moat waters, including cellulolytic, proteolytic, saccharolytic, and homoacetogenic bacteria (Shiba and Horikoshi, 1988; Zhilina and Zavarzin, 1994; Zhilina et al., 1996). When the homoacetogen *Natroniella acetigena* was isolated from this environment its pH growth optimum was found to be 9.8–10.0, and it continued to grow in waters with pH up to 10.7 (Zhilina et al., 1996).

Regionally, salinities in the east African rift valley lakes range from around 30–50‰ total salts (w/v) in the more northerly lakes in the rift (Figure 9.23a; Bogoria, Nakuru, Elmenteita, and Sonachi) to trona and halite saturation ($>200\%$) in lakes to the south (Lakes Magadi and Natron). Yet across this salinity range a combination of high ambient temperature, high light intensity and a continuous resupply of CO_2 , makes these soda lakes amongst the highest in the world in terms of their seasonal planktonic biomass (Grant et al., 1999) and also places them among the world’s most productive ecosystems (Figure 9.22; Melack and Kilham, 1974). Organic production is periodic, and pulses of organic product periodically swamp the ability of the decomposers and so accumulate as laminites in the lake centres.

As we have seen, the less alkaline lakes are dominated by periodic blooms of cyanobacteria, while the hypersaline lakes, such as Magadi, can on occasion support blooms of cyanobacteria, archaea and alkaphilic phototrophic bacteria (Jones et al., 1998). Halotolerant and halophilic biota living in the variably saline and layered water columns constitute small-scale “feast or famine” ecosystems, which at times of “feast” are far more productive than either tropical seagrass meadows or zones of marine upwelling (Figure 9.22).

The “flamingo connection” supports a general observation that short periods of enhanced organic productivity are followed by episodes of lessened productivity in various schizohaline lake waters worldwide. It reflects the general principle that increased environmental stress favours the survival of a few well-adapted halotolerant species, to the detriment of others better suited to life in a less saline or less stressed environment. This same general principal of schizohaline ecosystems can be clearly seen in the decrease in invertebrate species (grazers and predators) with increasing salinity in the carbonate lakes of the Coorong of Southern Australia, where only brine shrimp remain alive in waters with salinities in excess of 200‰ (Figure 9.21c).

“Feast or Famine” in the Dead Sea

Effects of occasional freshening on biomass in stratified brine columns that are supersaline, not mesohaline, is clearly seen in the present “feast or famine” productivity cycle of the Dead Sea (Figure 9.26; Oren and Gurevich, 1995; Oren et al., 1995). *Dunaliella sp.*, a unicellular green alga variously described in the past as *Dunaliella parva* or *Dunaliella viridis*, is the sole primary producer in the Dead Sea waters. Then there are several types of halophilic archaea of the family Halobacteriaceae, which utilise organic compounds produced by the algae.

Two distinct periods of organic productivity (feast) have been documented since the lake became holomictic in 1979 (Oren, 1993, 1999). The first mass developments of *Dunaliella* sp. (up to 8,800 cells/ml) began in the summer of 1980 following a dilution of the saline upper water layers by the heavy winter rains of 1979-1980. The rains drove a rapid rise of 1.5 metres in lake level and an increase in the level of phosphates in the lake's surface waters (Figure 4.42b). This bloom was quickly followed by a blossoming in the numbers of red halophilic archaea (2×10^7 cells/ml), *Dunaliella* numbers then declined rapidly following the complete remixing of the water column and the associated increase in salinity of the upper water mass. By the end of 1982 *Dunaliella* had disappeared from the main surface water mass. Archaeal numbers underwent a slower decline.

During the period 1983-1991 the lake was holomictic, halite-saturated and no *Dunaliella* blooms were observed. Viable halophilic and halotolerant archaea were probably present in refugia about the lake edge during this period, but in very low numbers. Then heavy rains and floods of the winter of 1991-1992 raised the lake level by 2 metres and drove a new episode of meromictic stratification as the upper five metres of the water column was diluted to 70% of its normal surface salinity. High densities of *Dunaliella* reappeared in this upper less saline water layer (up to 3×10^4 cells/ml) at the beginning of May 1992, rapidly declining to less than 40 cells/ml at the end of July 1992 (Figure 9.26). An associated bloom of haloarchaea (3×10^7 cells/ml) continued past July and continued to impart a reddish colour to the surface and nearsurface waters.

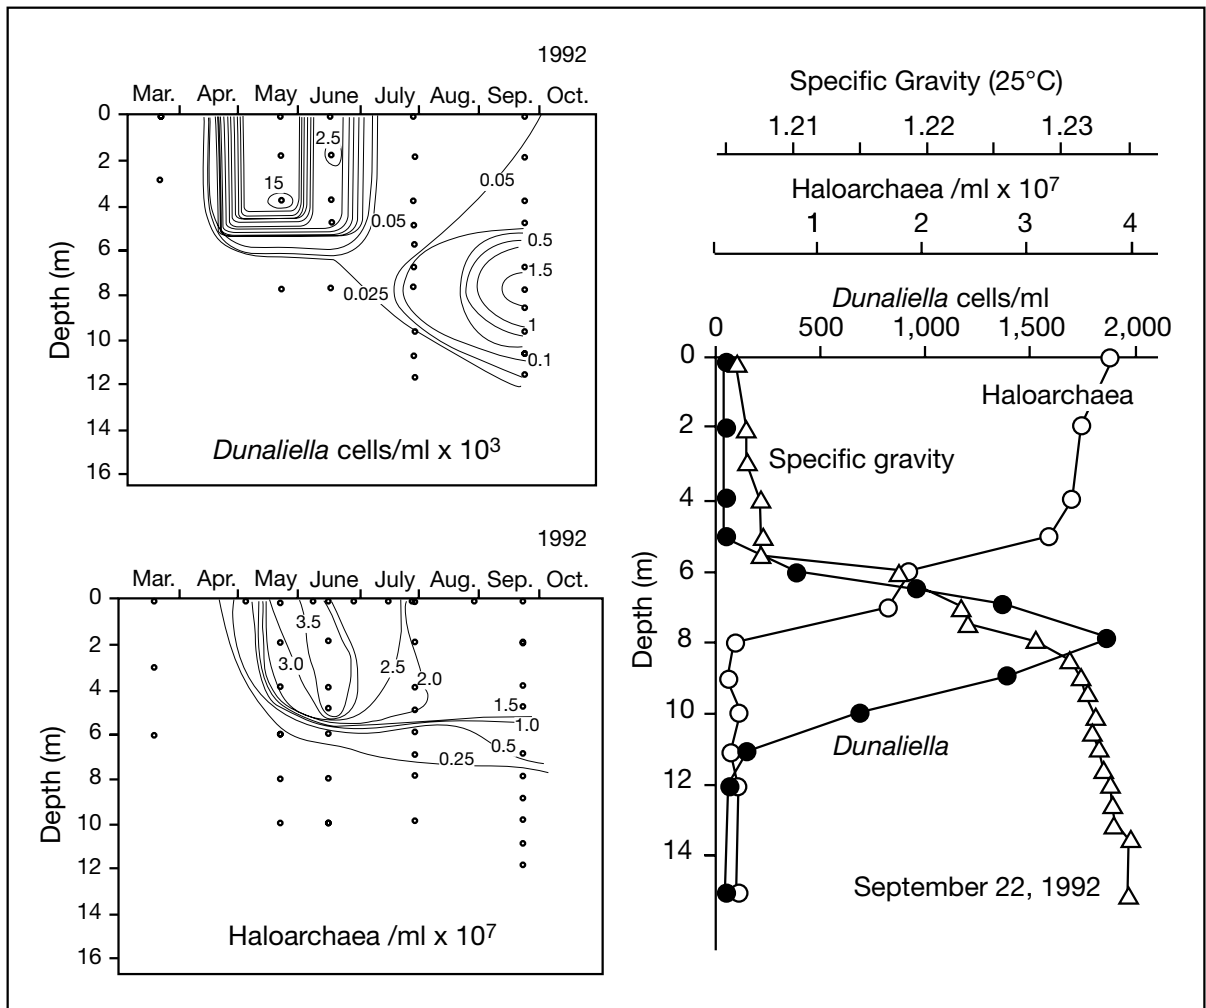

Figure 9.26. Changes in the vertical distribution of *Dunaliella* and halobacteria during the flood-induced density stratification of the Dead Sea in 1992 (after Oren, 1993). Note the vertical distribution of *Dunaliella* and haloarchaea relative to the halocline on September 22, 1992.

Much of the archaeal community was still present at the end of 1993 but the amount of carotenoid pigment per cell had decreased two- to three-fold between June 1992 and August 1993 (Oren and Gurevich, 1995). No new algal and archaeal blooms have developed since the winter floods of 1992-1993. A remnant of the 1992 *Dunaliella* bloom maintained itself at the lower end of the pycnocline at depths between 7 and 13 m (September 1992- August 1993), perhaps chasing nutrients rather than light. Its photosynthetic activity was low, and very little stimulation of archaeal growth and activity was associated with this algal community. It seems that once stratification ends and the new holomictic period begins, the remaining Archaeal community, which was largely restricted to the upper water layers above the halocline, spreads out more evenly over the entire upper water column until it too dies out.

Coloration of the Dead Sea waters from the initial algal bloom allowed Oren and Ben Yosef (1997) to use Landsat images, collected in May 1991 and in April and June 1992, to plot the development of the *Dunaliella sp.* bloom. In contrast, the carotenoids of the subsequent archaeal bloom did not produce a recognizable signal in the images. The April 1992 image obtained at the time of the onset of the algal bloom, prior to its lakewide spread, suggested it originated in the shallow areas near the shore of the lake where light penetrated to the bottom of the brine column. It was probably instigated by resting cells that had survived in near surface sediment of the shallow lake margin.

The ultimate decline of the lakewide bloom of halophilic archaea in the Dead Sea appears to be related to viral infection (Oren et al., 1997). For example, in October 1994, during the decline of the halophilic archaeal population in the upper 20 m of the Dead Sea water column, there were between 0.9 and 7.3×10^7 virus-like particles per ml of brine. Virus-like particles outnumbered archaea by a factor of 0.9-9.5 (averaging 4.4). Water samples collected during 1995 contained low numbers of both archaea and virus-like particles ($1.9-2.6 \times 10^6$ and $0.8-4.6 \times 10^7 \text{ ml}^{-1}$ respectively in April 1995), with viral numbers sharply declining afterwards (less than 10^4 ml^{-1} in November 1995-January 1996). Oren et al. (*op cit.*) suggest that viruses play a major role in the decline of halophilic archaeal communities in many other hypersaline environments where protists and metazoa are absent.

The Dead Sea and the African Rift Valley are examples of “feast or famine” in planktonic submersed settings. Enhancement of productivity (feast) during periodic freshening is also seen in halotolerant microbial mats in marine-margin mudflats. A study

of benthic mats in Storr’s Lake in the Bahamas showed that a reduction in brine salinity from 90‰ to 45‰ significantly enhanced CO_2 and N_2 fixation rates, but additions of inorganic nutrients and dissolved organic carbons (DOC) did not show any significantly enhanced rates compared with the salinity controls (Pinckney et al., 1995). That is, dissolved organic carbon/dissolved organic nitrogen uptake in the mats was not influenced over the entire range of salinities (45-90‰) seen in this study of mesohaline growth. Rather, abiotic stress, induced by hypersaline conditions in these Bahamian lagoons, created lower productivity in the saline-tolerant (haloxene) microbial mats, even when nutrient levels were high. When the osmotic stress on the biota was relieved by a lowering of salinity, mats underwent enhanced primary production and nitrogen fixation. Changing nutrient levels were far less significant than changing salinity levels as controls on mat productivity. Salinity-induced stress in these halotolerant microbial mats outweigh nutrient level, which is the typical limiting factor regulating phototrophic growth in normal marine and brackish waters.

Feast or Famine in the Messinian

“Feast or famine” cycles as just noted in the African rift lakes and the Dead Sea suggest that periodic freshening of surface waters in stratified brine bodies (usually by meteoric water or seawater influx) should facilitate the accumulation of organic-rich pulses to the bottom sediments in similar stratified brine bodies in the past. The notion that subsequent accumulation of a thick salt seal atop mesohaline source rocks, once the basin was cut off from a surface marine connection, helps explain the intimate association between evaporites and hydrocarbon seen in the many occurrences listed in Table 9.1. Now we shall test this notion by considering a likely ancient counterpart.

Organic-rich evaporitic marls were deposited beneath stratified brines in the Lorca Basin, located within the tectonically evolving Betic Cordillera of southeastern Spain. It was a rapidly subsiding basin in an open-marine setting during much of the Miocene (Benali et al., 1995). By the Upper Miocene (Messinian) the basin was accumulating thick diatomite-bearing sediments (Tripoli Unit), which are overlain by the Main Messinian Evaporite series. This evolution from marls to gypsum/halite beds records the onset of the “salinity crisis” throughout the Mediterranean region (Figure 5.40). Restriction by the time of the deposition of the Tripoli Unit in the Lorca Basin led to intercalations of thin precursor evaporitic layers, mostly subaqueous and sabkha Ca-sulphates, with diatomites (Figure 9.27; Rouchy et al., 1998). Prior to the main salinity crisis, the alternation of evaporites and diatomite cycles indicates periodic

Figure 9.27. Lorca Basin, Spain, showing organic character of normal marine, mesohaline and evaporitic sediments (after Benali et al., 1995).

restriction and the development of mesohaline conditions, followed each time by an episode of marine reflooding.

Schizohalinity drove both the varying levels of primary production in surface waters and the preservation of organic matter in the hypersaline bottom sediments, finally culminating in widespread evaporative sedimentation in the latest Miocene. As basin waters evolved toward perennial hydrographic isolation and holomixis there were unusual evaporative conditions that heralded the main salinity crisis. These were a number of salinity-stratified mesohaline surface floods when the resulting anoxic bottoms accumulated oil shales with up to 25% TOC (Figure 9.27; expanded section). When oil shales were accumulating, the system was meromictic; upper water mass was nutrient-rich and mesohaline with near normal marine salinities, while the bottom waters were anoxic and somewhat more saline than surface waters (Benali et al., 1995). Later in the basin history, when mixed gypsum marls and clastic gypsum sequences were accumulating, the oil-prone quality of any potential kerogen in the basin was diluted by rapid deposition of gypsum precipitates and an influx of oxidised organic detritus.

The formation of organo-sulphur compounds, replacement of sulphates by carbonates and the high levels of elemental

sulphur are other byproducts of early diagenetic/microbial processes occurring in the Lorca oil shale. The high abundance of phytane, 2,3-dimethyl-5-(2,6,10-trimethylundecyl)-thiophene, mid-chain C_{20} isoprenoid thiophenes and bithiophenes and bis-O-phytanyl and O-phytanyl-O-sesterterpanyl glycerol ethers indicates that the organic matter in these sediments was deposited under anoxic hypersaline conditions (Table 9.4; Russell et al., 1997). Isopranyl glycerol ethers occur in sulphur-bound macromolecular matter, which contrasts with the low concentrations of these compounds as free lipids. However, the distribution of these isopranyl glycerols is paralleled by the occurrence of free phytanic acid in both the oil shales and intercalated laminated carbonates and by 3,7,11,15,19-pentamethyleicosanoic acid in the laminated carbonates. A high level of input from bacterial decomposers is indicated by 2-hydroxytetracosanoic acid, n-octadec-11-enoic acid, hopanoic acids and the distributions of iso- and anteiso- C_{15} and C_{17} homologues and minor amounts of iso- C_{16} and anteiso- C_{14} . These branched fatty acids are characteristic of sulphate-reducing bacteria, which would have inhabited the anoxic bottom brine. The relative proportions of the iso- and anteiso-compounds in the total fatty acid distributions are tied to the proportion of reduced sulphur in the sediments.

As in Lake Nakuru and the Dead Sea, cyanobacterial and halotolerant algal blooms in freshened surface waters created these organic-rich Messinian carbonates. Blooms of halotolerant species, followed by die back, drove cycles of “feast or famine” in the Lorca oil shales.

The where and when of productivity

Most biological studies in freshwater lakes and in the oceans have found that the highest levels of organic productivity (primary productivity) occur annually within the zone of maximum light penetration in the upper few metres of the water column. Long term salinity stratification or meromixis in the perennial waters of an evaporite basin, can change the locus of maximum organic productivity, especially in situations where the required nutrients lie at or below the halocline. Haloarchaea in the Dead Sea can survive by facultative photosynthesis long after their primary food source has died back (Figure 9.26). But is there a more general layering of the halobiota in stratified brines where the chemical interface created by the coming and going of the halocline allows life to flourish via chemosynthesis, not photosynthesis? If so, then bacterial productivity in upper fresher waters of a layered brine column may come to rely on nutrients supplied from permanently saline and anoxic bottom waters.

Mahoney Lake is a small 30m deep meromictic salt lake in British Columbia, Canada, with a halocline that separates a variably oxygenated mixolimnion⁹⁹ from a permanently anoxic monimolimnion at a depth of around 6 m in the lake brine column (Figure 9.28a). It has been a saline meromictic/holomictic system for the last 9,000 years, with some meromictic episodes lasting as long as 1,100 years (Overmann et al., 1996). Heterotrophic bacterial production in the lower mixolimnion at times exceeds concomitant primary production in the upper waters of the same mixolimnion by a factor of 7 (Figure 9.28b). In this highly productive interval lives an extremely dense population of the phototrophic purple sulphur-oxidising bacterium *Amoebobacter purpureus*, which is present year round along the lake halocline. The Mahoney Lake halocline harbours the densest population of phototrophic sulphur bacteria ever reported in a natural body of water. It is sufficiently abundant to form the base of a food chain where it constitutes 70% of the diet of planktonic copepods living in the upper water mass.

Each year, following ice melt, a layer of freshened water enters the lake, creating a well defined uppermost oxygenated layer in the mixolimnion, which disappears within a few months. For example, the stability of the mixolimnion declined sharply

between May and July 1993, in parallel with the disappearance of the low-salinity uppermost surface water layer, the warming of the lower waters of the mixolimnion, and the resulting loss in density stratification (Overmann et al. 1996). This allowed mixing across the perennial halocline and the release of nutrients into the lower parts of the mixolimnion. For most of an annual cycle any bacterial growth in the lower mixolimnion is limited by the supply of inorganic phosphorus or nitrogen, which can come from above or below. In Mahoney Lake, liberation of phosphorus from upwelling of the remains of purple sulphur bacteria in the lower waters, and degradation of allochthonous dissolved organic carbon floating at the halocline, act as a carbon source for the bacteria and so render heterotrophic bacterial production largely independent of photosynthetic phytoplankton cycle in the overlying waters of the uppermost mixolimnion.

Similar purple bacterial layers cap the haloclines of brine lakes on the deep seafloor of the Urania Basin in the Mediterranean Sea. This bacterial community utilises sulphur compounds crossing the brine interface from anoxic waters below and thrives many thousands of metres below the euphotic zone (Sass et al., 2001). Sulphur-oxidising bacterial communities, independent of light penetration, probably occur atop marine suprasalt brine-lake haloclines worldwide.

The effect of salinity stratification on productivity in many saline lakes does not follow the predictable annual cycle seen in Lake Mahoney and in most freshwater temperate dimictic lakes (dimictic = seasonally mixed). This lack of annual cyclicality in

⁹⁹ Jargon of lacustrine stratification

Mixolimnion: the upper, low density, freely circulating water layer of a meromictic lake.

Monimolimnion: the deep, usually salty, layer of a meromictic lake, typically it is a perennially stagnant or noncirculating water mass.

Meromixis: a condition in a lake (meromictic lake) where the bottom noncirculating water mass is adiabatically isolated from the upper water mass.

Holomixis: a condition in a lake describing complete overturn and mixing of the lake water mass.

Hypolimnion: is the lowermost water mass in a lake, characterised by a generally uniform temperature (or density) profile.

Eutrophic lake: a lake characterised by an abundance of nutrients and a seasonal deficiency of oxygen in the hypolimnion. Waters are usually shallow and sediments are organic-rich laminites.

Oligotrophic lake: a lake characterised by a deficiency in nutrients and an abundance of oxygen in the hypolimnion. The bottom sediments typically contain low levels of organics and the water column is deep.

Monomictic Lake: –A lake which undergoes one period of complete mixing during the year separated by one period of thermal stratification.

the organic production is clearly seen in the timing of meromictic stages of the Dead Sea (Figure 9.26). Multiple years of stratification without breakdown is also characteristic of Mono Lake, California where photosynthetic activity was measured in its hypersaline and stratified waters during an 8-yr period from 1982 to 1990 (Jellison and Melack, 1993). Exceptionally large volumes of freshwater runoff in 1982 and 1983 led to a 2.6-m rise in surface elevation of Mono Lake and the onset of a new period of meromixis in the lake (Figure 4.21). In 1984 chemical stratification accounted for a density difference of $1.2\text{--}1.5 \times 10^{-2}$ gm/cc between the 2 and 28 m water depths. At the same time the midsummer density difference between 2 and 28 m depths that was due to temperature was approximately 0.5×10^{-2} gm/cc. Salinities ranged from 77 to 98 gm/l across the interface and sodium, chloride, sulphate, and carbonate were the major ions in both the upper and lower water mass.

This eight-year time frame in Mono Lake spans the onset (1983), persistence (1984–1987), and breakdown of meromixis (1988). Following the onset of meromixis, the algal biomass in the lake each spring and autumn decreased from 1984 to 1986: annual primary photosynthetic production was reduced from $269\text{--}462 \text{ gC m}^{-2}\text{yr}^{-1}$ (1984–1986) compared to nonmeromictic conditions of $499\text{--}641 \text{ gC m}^{-2}\text{yr}^{-1}$ (1989 and 1990). A gradual increase in photosynthetic production then occurred, even before meromixis ended, because of increased vertical flux of ammonium from the anoxic saline bottom, due to deeper mixing and the buildup of ammonium in the monimolimnion. Annual primary production in the lake was greatest in 1988 ($1,064 \text{ gC m}^{-2}\text{yr}^{-1}$) when the weakening of chemical stratification and eventual breakdown of meromixis in November of that year allowed a large upward influx of ammonium (source of nitrogen) into the euphotic zone.

Another transition from monomixis to meromixis occurred in Mono Lake from 1994 to 1995 (Figure 9.29; Melack and Jellison, 1998). During the preceding monomictic conditions in 1993 and 1994, the lake had thermally stratified in March and

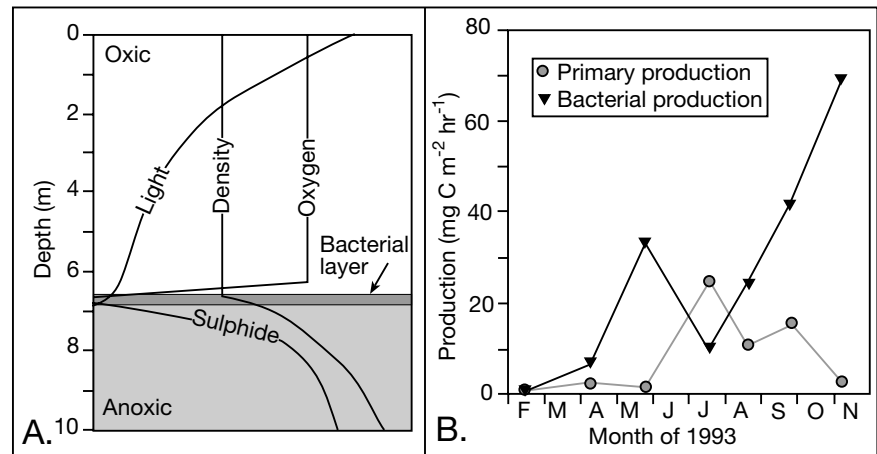

Figure 9.28. Lake Mahoney, Canada. A) Stratification in the brine column showing the position of the purple sulphur-oxidising bacterial community at the halocline. B) Integrated primary production and bacterial production in the mixolimnion during 1993. Both were measured simultaneously during incubation around solar noon (after Overmann et al. 1996).

had mixed to the bottom by each December. During meromictic conditions in 1995, 1996 and 1997, the absence of holomixis during winter once again resulted in persistent anoxic conditions beneath the chemocline, the accumulation of ammonium in the monimolimnion, its depletion in the mixolimnion, and low mixolimnetic chlorophyll concentrations in the spring and autumn. The meromictic state continued until mixing in 2003 and was preceded by a trend of year-to-year deepening of the chemocline, which indicates increasing lability to mixing in a meromictic lake (Figure 9.29). The same deepening of the halocline marks the transition to holomixis in the Dead Sea (Figure 4.43).

The TOC content of a core through the laminites of Mono Lake, sampling the last 300 years, shows an overall tendency toward increasing TOC content in the period 1700–1800, then a consistent trend hovering around 6% but with wider variations in TOC in the last 60 years, since the diversion of the inflow to the Los Angeles water supply in 1941 (Figure 9.30; Benson et al., 2003). The highest values of TOC in the core occur in this time frame, 14% around 1970, as do some of the lowest, e.g. around 4% in 1943 and 1980. Clearly, the perennially anoxic saline bottom waters of the lake, with a pulse of productivity (a time of feast) in those years when the lake transitions from meromictic to holomictic, have facilitated the preservation of organics at levels that in ancient counterparts would characterize a source rock. Whether the fluctuations in TOC levels in the bottom sediments reflect varying intensities in algal blooms or some other factor related to the volume of organics reaching the bottom is not yet defined.

Figure 9.29. Mono Lake, California, conductivity profiles in December for the years 1994-2000 (figure was redrafted from a database downloaded from file://www.monobasinresearch.org/toc.htm, last accessed Dec. 28, 2004).

Predicting preservation of benthic organics

Predicting how organic productivity in surface waters relates to organic preservation under a variable layered brine column is difficult. It is commonly assumed in source rock modelling that saline waters at the base of a stratified saline water column are anoxic and will always favour the preservation of organic matter produced by plankton (Demaison and Moore, 1980). The effectiveness of stratified brines in the preservation of pelagic organic matter originally produced in photic and oxygenated water is especially obvious when comparing open marine and density-stratified hypersaline environments. Estimates for the preservation efficiency of primary organic matter in the modern shallow open-marine oxygenated bottoms centre around 0.1% (Menzel and Ryther, 1970), while on the floor of the anoxic Black Sea it is about 4% (Deuser, 1971). In contrast, preservation efficiency beneath density-stratified hypersaline lakes and epeiric seaways subject to times of feast or famine can be as high as 85% (Hite and Anders, 1991). This vast improvement in preservation in part reflects the “salting effect” of a perennial dysaerobic to anoxic saline bottom brine

layer and the periodic proliferation of a photosynthetic biomass in a freshened upper brine body. Plankton that is blooming in a stratified brine column is liable to mass mortality as ongoing evaporation increases nearsurface salinities to intolerable levels (“feast or famine”). Schizohaline surface waters means most organic-rich evaporitic mesohaline sediments are deposited as laminites, facilitated by repetitive “life and death cycles” in the halobiota (Warren, 1986).

Yet mesohaline to moderately penesaline bottom waters of some density-stratified shallow modern brine lakes are oxygenated, not anoxic. Bottom microbial mat communities below such waters are dominated by halotolerant oxygen-producing photosynthesising benthic cyanobacteria.

These benthic primary producers create and maintain elevated oxygen levels in the well-lit bottom waters immediately above the mat and are the hypersaline equivalents of marine seagrasses. But, benthic microbial mats tend to be anoxic no more than a few millimetres below such photosynthesising surface layers of microbes (Figure 9.18). Burial via mat aggradation tends to quickly move newly created cyanobacterial organics into an anoxic regime, where organic preservation is much more likely

Figure 9.30. TOC and carbonate proportions in a core through Mono Lake laminites deposited in the last 300 years (after Benson et al., 2003).

(Figure 9.6). Unlike marine seagrass banks, the association of permanent bottom hypersalinity and anoxia a few mm below the sediment brine interface, tends to prevent most burrowers from entering the bottom sediment. Burrowing is a major mechanism for maintaining oxygenation in normal marine sediment, where it tends to prevent substantial accumulations of organic matter in bottom sediments.

Lake Hayward, Australia is meromictic and a good case in point; it is a shallow perennial hypersaline coastal salina filled by brines less than 2 metres deep. Photosynthesis via its benthic microbial mat community, is normally sufficient to supersaturate the bottom with dissolved oxygen, even during periods of brine column stratification, yet bottom sediments contain 5-7% TOC (Burke and Knott, 1997). Laminated microbial mats in the permanently submersed mesohaline centre of the lake are dominated by photosynthesising cyanobacteria *Cyanothece sp.*, while *Microcoleus sp.* are dominant in the biolaminites of the lake's seasonally desiccated strandzone. In daylight the oxygen saturation can be as high as 270% in the uppermost photosynthesising mat and the immediately overlying bottom waters (Burke, 1995). However, after an unusually dry year in 1987, the lake salinity in the upper waters increased to 260 g/l and gypsum precipitated across the lake (Figure 9.31; Burke and Knott, 1997). Turbidity generated by gypsum crystallisation in the brine mass was sufficient to obscure the benthos completely, despite the shallowness of the lake (secchi curve in Figure 9.31). As a result, the amount of benthic oxygenic photosynthesis was greatly reduced and benthic mats degraded. During brine stratification in the following winter (1988), bottom waters became anoxic and supported a healthy population of purple sulphur-oxidising bacteria.

However, during the next few years, after each subsequent brine column overturn, healthy cyanobacterial mats

were re-established and they were able to again supersaturate the bottom waters with oxygen year round. The development of a healthy microbial mat community in Lake Hayward prevents periodic bottom anoxia, whereas nearby meromictic lakes, that do not contain a healthy halotolerant microbial benthos, tend to annual anoxia during stratification. The lake illustrates a general principle that healthy halotolerant microbial mat functions as a strong homeostatic mechanism in allowing longterm stability of elevated oxygen levels in bottom waters of the shallow brine lake, but an increase in salinity can make the bottom anoxic.

Figure 9.31. Effect of gypsum precipitation on benthic microbial communities and oxygenation in Lake Hayward, West Australia (compiled from data in Burke and Knott, 1997).

benthic mats in low nutrient systems formed from salinities

Gypsum precipitation in the brine column is not the only cause of brine column turbidity and bottom anoxia in shallow waters. Planktonic blooms (a time of feast) can also substantially reduce light penetration to the bottom of a shallow brine lake (Horsfield et al., 1994). If the bloom is intense it can prevent benthic cyanobacteria from photosynthesising. The shaded part of system eutrophies as decomposing planktonic remains rain down through the now dark brine column. Decomposition in the upper portions of the column uses up all the oxygen in the water column. The oxic-anoxic interface rises from the sediment into the brine column, killing off any oxygen-requiring benthic species. Such hypertrophication overwhelms the delivery of oxygen to the bottom by the photosynthetic benthos and facilitates higher levels of organic delivery to bottom sediments than occurs with the benthic mats. This eutrophic and slimy bottom style of deposition naturally characterises the central portions of Solar Lake, Egypt (Figure 4.11). It may explain why the TOC of its bottom sediments, accumulating beneath pore waters that are perennially anoxic, are elevated compared with microbially-bound bottom sediments of Lake Hayward (Figure 9.6; 15-20% versus 5-6%).

In a study of eutrophication in modern saltfields Javor (2000) found that in shallow gypsum and the pre-gypsum ponds there was an interesting inverse relationship between the level of nutrients (nitrates and phosphates) in the brine column and the development of microbial mats on the water covered pan floor. In a high nutrient brine system (eutrophic or well-nourished) the algae and bacteria flourished as planktonic forms and the biomass buildup in the upper parts of the brine column tended to shade the sediment surface so that there was little or no development of a microbial mat and bottom waters were dys-aerobic to anoxic. In a low nutrient system there was little or no planktonic development of algae or bacteria and microbial mats tended to flourish on the perennial pond floor. She found

Figure 9.32. Sedimentation rate versus percent of total organic carbon content (TOC) in laminite marls from the Oligocene evaporites of the Mulhouse Basin, Europe. Inset shows the scale and mineral /organic distribution in the laminae (varve couplets) of the sampled intervals (after Hofmann et al., 1993b).

of 50,000 ppm to gypsum saturation. At lower salinities mats were destroyed by the feeding activities of invertebrates and fish (Figure 9.9).

Most benthic microbial mats beneath hypersaline waters depend, in large part, on nutrients recycled by the bacterial decomposers that make up the underside of the living part of the mat. Even if nitrogen and phosphorus levels in the overlying brines are low, there may be sufficient nutrient recycling within the mats to allow the bottom mats to continue to grow. Javor (*op. cit.*) found that once a gypsum crust becomes well established over the floor of a crystalliser pond there was little recycling of nutrients from beneath the crust. From this point downstream in the crystalliser pans, nitrate and phosphate nutrients concentrated by evaporation were recycled into the biomass living in the brine column and not within the benthic mat. In oligotrophic gypsum ponds the gypsum crust is stable and the bottom waters are oxygenated. In eutrophic gypsum ponds at the same salinities the bottom waters become anoxic and sulphate-reducing bacteria flourish. In these systems the gypsum dissolves and the bottom is typically covered by a black slimy organic-rich mud containing no more than a few

embayed and dissolved gypsum remnants, much like the central facies in Solar Lake (Figure 4.11). If portions of this slimy bottom become suspended and are flushed into the next stage of the crystalliser brine stream they create a problem in the final product known as “black spot.” Brine shrimp are often added to the mesohaline ponds of a saltworks to control planktic blooms and so minimise “black spot.”

That organic enrichment occurs naturally in the mesohaline carbonate stage and not in subsequent gypsum or halite layers is clearly seen in the evaporitic marls and salts of the Oligocene Mulhouse Basin (Figure 9.32; Hofmann et al., 1993b). This deposit is one of a few ancient evaporitic settings where organic chemistry has been studied in a logical and detailed fashion, rather than as spot samples. Organic matter occurs mostly in finely laminated carbonate marls (varves), which can contain up to 7% TOC, anhydrite beds contain 0.08-0.78% TOC, halite beds 0.01-0.25% TOC and the potash beds <0.1% TOC. The marls are characterized by thin, continuous bedding parallel laminae that are not disturbed by any bioturbation.

They are interpreted as seasonal varves with the clay and carbonate forming alternate layers in the couplet (see inset in Figure 9.32). In spring and summer the increased temperature in surface waters favoured precipitation of micritic carbonate, in autumn and winter the phytoplankton died back and rain-fall/runoff transported clastic debris into the basin. On the basis that the laminar couplets are varves, Hofmann et al., (1993b) were able to plot the relationship between sedimentation rate and TOC content in the marls (Figure 9.32). Marls deposited during times of low sedimentation rate tend to be organic-rich, while marls deposited at times of higher sedimentation tend to contain lower amounts of organics. They concluded that the even lower levels of organics in the more saline salt beds (anhydrite and halite) indicate even more dilution because of inherently higher sedimentation rates.

Proximity of organic-rich mesohaline laminites to ancient bedded evaporites has lead some geologists to postulate that bedded salts are potentially also organic-rich sediments with the same level of source potential as mesohaline carbonates. This is not borne out by TOC analysis of evaporitic salts in the Mulhouse Basin. Likewise, worldwide measurements of total organic matter levels in ancient CaSO_4 and NaCl lithologies tend to be normal or depleted (Katz et al., 1987). Mesohaline carbonates, not higher salinity salts, are the source rocks to ancient reservoirs (Figure 9.3). But, levels of dissolved organic matter and volatile fatty acids rise in increasingly saline brines

and may be considered potential mobile or liquid sources if caught up in intercrystalline interstices and inclusions (Anders and Hite, 1991). Levels of DOM and VFA may be high in such penesaline salts and could be released in the subsurface when halite beds are dissolved by crossflows of surface brines. But in general the typically low levels of solid organic matter in bedded halite reflects the higher depositional rates of evaporitic salts when compared with evaporitic carbonates (dilution effect). Under the same rate of supply of detrital organics, the higher rate of halite accumulation dilutes the associated organic content compared to carbonate sequences.

Whatever the finer controls on accumulation levels, observations of organic accumulations in modern and ancient mesohaline saline systems show that peaks or pulses in primary production (“feasts”) in density-stratified brine lakes are controlled by two factors; 1) the occasional presence of an ephemeral less saline surface water mass, and 2) a periodic supply of nutrients (nitrate/ammonia and phosphate), possibly from a combination of inflow/runoff and leakage from the lower hypersaline water mass. The biota contributing the organic pulse, which ultimately reach the bottom sediments to form organic-rich laminae, are largely dependant on the timing of photosynthetic activity. Modern saline lakes with a well defined annual freshening of surface waters will deposit varved evaporitic carbonates (e.g. Lake Tanganyika with up to 7-11% TOC in deep bottom laminites; Cohen, 1989), while other brine lakes and seaways, with less predictable stratification, may form similar carbonate laminites, but the organic layering may not be annual (Dead Sea, Mono Lake).

Populations of purple-sulphur oxidising bacteria define the position of the oxic-anoxic interface in hypersaline settings. They reside a few millimetres below the mat surface beneath shallow brines with healthy cyanobacterial mats on the bottom. In deeper brines they reside at the halocline. Shading of a healthy cyanobacterial mat, either by planktonic blooms or mineral saturation in the brine column, allows the oxic-anoxic interface to rise from within the mat into the brine column and bring with it its healthy population of purple bacteria. If organic debris from a planktonic bloom settles to the sediment surface at this time there is less likelihood it will be broken down by fermenters and decomposers before it is buried. Hence, elevated TOC levels from times of planktonic feasting are more likely to be preserved.

Life, brine seeps and dissolving salt allochthons

There is an association between chemosynthetic communities, saline anoxic bottom brines, organic-enriched laminites, metal sulphides and salt allochthons in some modern marine slope and rise settings (Warren, 2000b). Historically, a relatively deep

open marine setting was not considered an area where hypersaline bottom brines facilitated the accumulation of organic and metal sulphide-rich mesohaline sediments. Yet it is in seafloor settings where shallow salt allochthons are actively flowing and dissolving and, as such, is a zone of potential mesohaline source rocks (Figure 9.3).

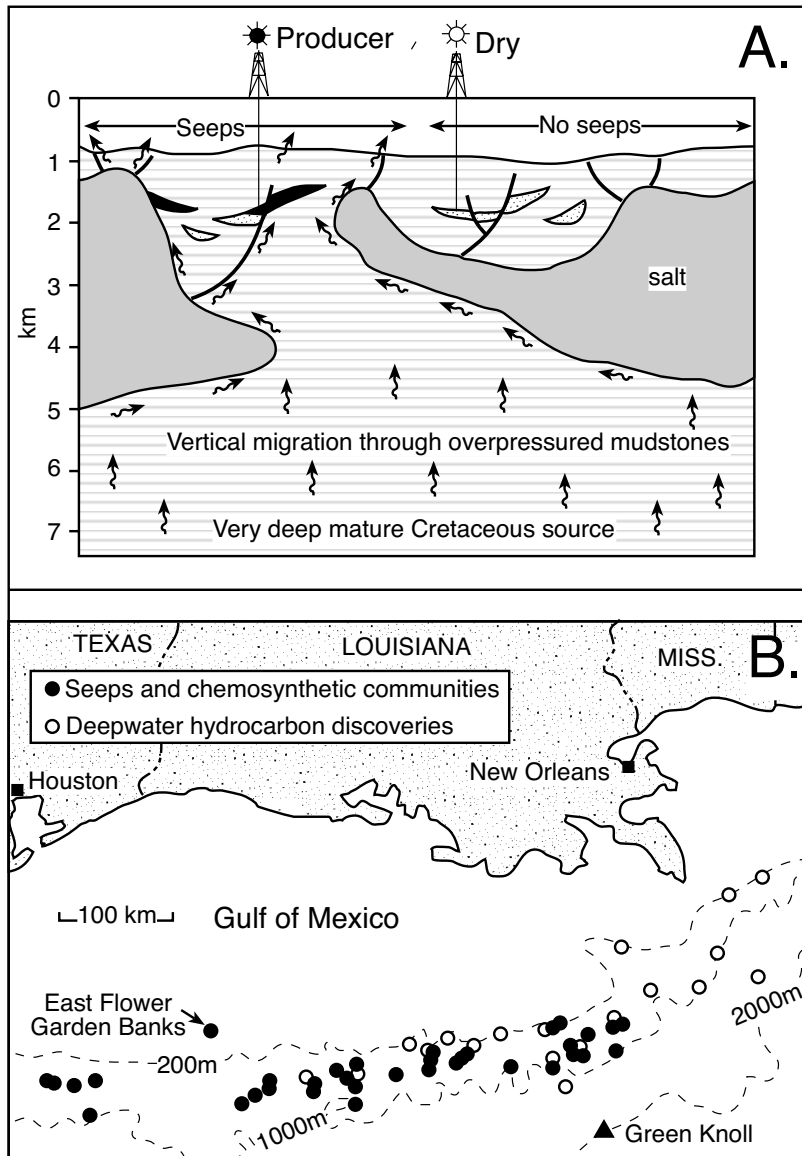

Figure 9.33. Brine seeps. A) Model of hydrocarbon migration and seepage in the deepwater Gulf of Mexico. Seepage indicates a change in the salt continuity in an intrasalt basin, but it does not indicate the presence of an effective migration pathway to a specific hydrocarbon trap. B) General association of seeps, chemosynthetic communities and hydrocarbon discoveries in the deepwater Gulf of Mexico (after Thrasher et al., 1996).

When an allochthonous salt sheet lies just beneath the seafloor it dissolves from the edges inward as it releases and focuses chloride-rich brines into its surrounds. Any subsalt brine forms a dense chloride-rich plume that sinks into the underlying sediments to become caught up in subsalt convection cells (Figures 8.2, 8.23). As it convects it mixes with escaping basal brines, whereby upward brine passage is focused along the dissolving undersides and edges of the salt mass, before it finally seeps and vents to the seafloor (Figure 9.33a). Such brine-issuing vents occur at 1920m-deep seafloor on top of Green Knoll, an isolated salt diapir rising seaward of the Sigsbee Escarpment in the northern Gulf of Mexico. Methane- and chloride-rich vent brines are supplied in part by congruent seawater dissolution of the underlying Louann salt, and in part by hydrocarbon-rich basal waters escaping from deeper within the salt sealed sediment column (Table 9.5; Aharon *et al.* 1992). In the Gulf of Mexico the venting Na-Cl brines are up to seven times saltier than ambient seawater and the geometry of their subsurface passage to the seafloor largely reflects breaks in the continuity of allochthonous salt sheets that underlie much of the continental slope (Figure 9.33b; Thrasher et al., 1996).

Venting of hydrocarbon-rich (methane) hypersaline anoxic brines onto the seafloor, both by lateral flow and by diffusion upward through the underlying clastic sediments, gives rise to seafloor seeps, methane hydrates and methane-

saturated anoxic brine lakes ranging in diameter from 1m to 20km. Only microbes (extremophiles) can inhabit the bottom waters and sediments of the brine lakes, while spectacular chemosynthetic mollusc-tube worm biotopes form in normal marine waters about the brine lake edges. Venting brines can either seep and dissipate via mixing with oxygenated marine bottom waters on the open ocean floor to form spectacularly red braided channelways or can seep into closed depressions on the seafloor to form lakes of density-stratified anoxic bottom brine. It is here on the floor of these brine pools that organic- and sulphide-enriched laminites accumulate.

Seepage and drainage onto an open ocean bottom creates loosely consolidated red-orange iron-oxide deposits, with surfaces characterised by anastomose and braided patterns (Aharon et al. 1992). Similar iron-oxide deposits are found about the edges of the Red Sea brine pools. The ferric iron now in the seafloor oxides was originally extracted during the flushing of buried sediment by salt-dissolution-driven convection of anoxic pore waters in the peridiapiric and salt sheet surrounds (Hanor, 1994a). Once vented onto the oxygenated seafloor, the dissolved iron precipitates as haematite and other ferrous hydroxides. In this scenario the seafloor surface itself constitutes a redox front between the reduced basin brines and oxygenated marine waters. Figure 9.34a and b, shows clearly that red iron oxides are stable in the oxygenated conditions that typify the open seafloor (see also Sheu and Presley, 1986a, b).

In contrast, in the more reduced conditions in highly saline subsurface waters and bottom waters of brine pools, precipitated iron phases are dominated by pyrite, siderite and other ferroan carbonates. The pH does not vary widely in such reduced saline settings (Figure 9.34b), and the relationship between pyrite and siderite becomes clearer when activities of dissolved sulphur or dissolved bicarbonate are plotted against Eh. Pyrite is the

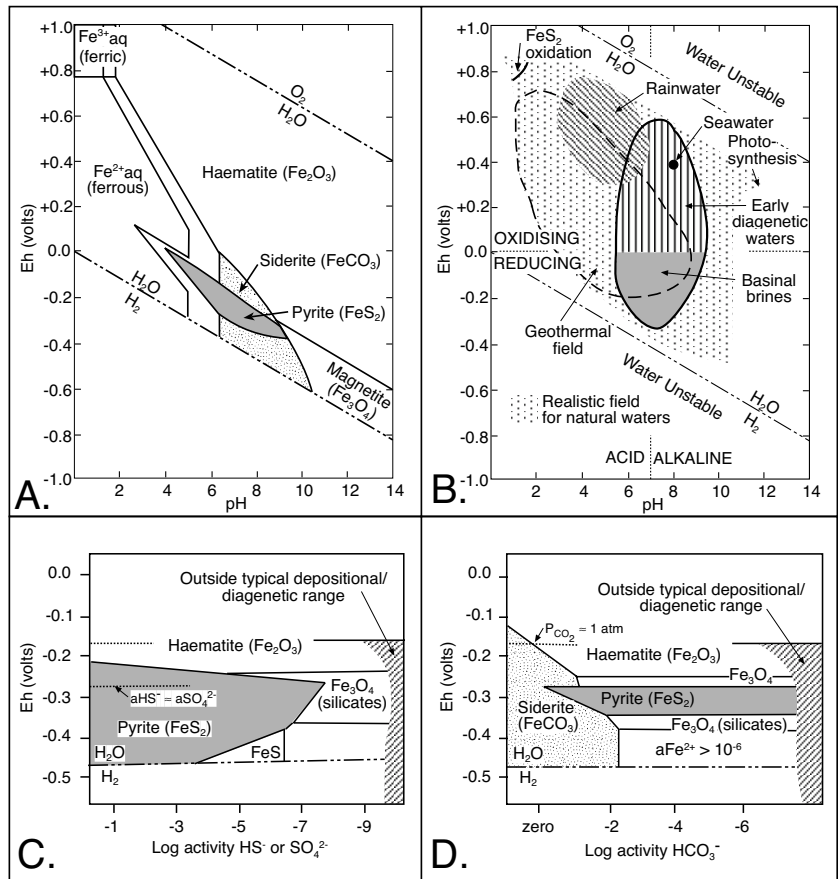

Figure 9.34. Iron stability: phase diagrams showing the stability of iron mineral phases with respect to A) and B) Eh and pH, C) Eh and sulphide/sulphate activity and D) Eh and bicarbonate activity (after Garrels and Christ, 1965; Hesse, 1986; Taylor and Curtis, 1995).

stable phase in anoxic conditions where levels of dissolved sulphide are high (Figure 9.34c), while siderite and other ferroan carbonates are the stable phases under anoxic conditions where the activities of dissolved sulphide are very low and bicarbonate activities are high (Figure 9.34d).

On its way to the surface the same brine chemistry precipitates the pyrite and ferroan carbonate cements in peridiapiric sands as around the Hackberry dome and in the Carrizo sand outcrop (Figure 8.24). It also explains the formation of iron silicates, such as chamosite and berthierine (the Fe_3O_4 silicates in Figure 9.34c, d), in anoxic environments where the activities of both sulphide and bicarbonate are very low. This siliceous Fe-phase chemistry has important implications in terms of the reduction state of Archean and Proterozoic seawater chemistry and the precipitation of banded iron ores (Chapter 2).

Table 9.5. Chemistry (mmol/kg) of two venting Green Knoll brines versus surface and deep seawater from the Gulf of Mexico - GOM (after Aharon et al., 1992).

Dense anoxic brines pond in lakes on the modern deep seafloor wherever vented brines can seep into closed depressions. The lows tend to form via local subsidence atop dissolving shallow allochthonous salt sheets or atop areas of salt withdrawal where the underlying salt is flowing into adjacent growing salt structures (growth-fault and rim syncline depressions). The redox interface in such seafloor pools is located at the halocline and so is some metres or tens of metres above the seafloor.

For example, the Orca Basin in the Gulf of Mexico is a closed intraslope depression at a depth of 2,400 metres, some 600m below the surrounding seafloor (Figure 9.35a). Its bottom is filled by a 200m column of highly saline (259‰) anoxic brine that is more than a degree warmer than the overlying seawater column (Figure 9.35b). The pool is stable and has undergone no discernable change since it was first discovered in the 1970s. It is a closed dissolution depression fed by brines seeping from a nearby subsurface salt allochthon (Addy and Behrens, 1980). A large portion of the particulate matter settling into the basin is trapped at the salinity interface between the two water bodies. Trefry et al. (1984) noted that the particulate content was 20-60 μg/l above 2,100m and 200-400 μg/l in the brine column below 2,250m. In the transition zone, the particulate content was up to 880 μg/l and contained up to 60% organic matter.

A core from the bottom of the Orca brine pool captured laminated black organic-enriched pyritic mud from the seafloor to 485 cm depth and entrains 3 intralaminite turbidite beds of grey mud with a total thickness of 70cm (Addy and Behrens, 1980). This is underlain by grey mud from 485 cm to the bottom of the core at 1079 cm. The laminated black mud was deposited in a highly anoxic saline environment, while grey mud deposition took place in a more oxic setting. The major black-grey boundary at 485 cm depth has been radiocarbon dated at 7900 ± 170 years and represents the time when escaping brine began to pond in the Orca Basin depression. Within the dark anoxic laminates of the Orca Basin there are occasional mm- to cm-thick red layers where the iron minerals are dominated by haematite and other iron hydroxides and not by pyrite. These layers represent episodes of enhanced mixing across the normally stable oxic-

anoxic halocline and indicate the short-term destruction of bottom brine stratification.

Brine pools also form in the salt-floored compressive terrain of the accretionary complex of the Mediterranean Ridge where sheets of Miocene evaporites have been folded and thrust to shallow depths below the deep seafloor. The consequent dissolution of Messinian evaporites creates saline brine pools such as the Bannock, Tyro, Discovery, L'Atalante, and Urania brine lakes and basins (Westbrook and Reston, 2002). The Discovery, L'Atalante, and Urania brine lakes constitute what is sometimes referred to as the "anoxic lake region" of the Mediterranean Ridge. The "anoxic lake region" and the brine lakes of the Tyro Basin lie on the growing front of the Hellenic side of the accretionary wedge, while Bannock Basin is located

atop the toe of the accretionary complex (Figure 9.36). Brine lakes on the Hellenic side of the ridge are a response to sediment deformation with a strong diapiric component. Fluids are driven out of the compacting pre-Messinian sediments as it is overridden by the growing Messinian wedges (Figure 5.51). Rising fluids dissolve and breach the evaporite cover wherever it is thin, leading to the escape of hypersaline fluids both ahead of the deformation front and through the pre-Messinian wedge. In contrast, the brine lakes of the Bannock Basin are a result of a seamount as it was dragged into the accretionary complex by the subducting African plate. The disturbance created as it ploughed through evaporites of the accretionary complex allowed hypersaline fluids to escape to the seafloor.

All these lakes occur on the deep-sea floor of the Mediterranean, thousands of metres below the euphotic zone, within depressions that entrain bottom waters more than ten times as saline as Mediterranean seawater. In the Bannock Basin the various brine-filled depressions or sub-basins create a closed outer moat around a central seafloor mound that is 10 km across (Figure 9.36a). The chemical composition of the Tyro Basin bottom brine is related to the dissolution of the underlying halite-dominated evaporites, while the chemical composition of the Bannock Basin (Libeccio Basin in the Bannock area) implies derivation from dissolving bittern salts (de Lange et al., 1990). In the “anoxic lakes region”, sodium chloride is predominant source in the L’Atalante and Urania lakes, but L’Atalante is much richer in potassium chloride than the other lakes. The Discovery basin brine is almost exclusively the product of dissolution of magnesium chloride (bischofite)

salts. It has a density of 1330 kg/m³ which makes it the densest naturally occurring brine yet discovered in the marine environment (Wallmann et al., 2002). Its concentration profile in sediment beneath the brine lake shows the age of this lake is between 700 and 2000 yr. The high concentration of magnesium chloride drives dissolution of biogenic calcium carbonate, but facilitates excellent preservation of siliceous microfossils and organic matter.

Biomarker associations of the organics accumulating in these brine lakes define two depositional styles: typical marine and hypersaline (Burkova et al., 2000). Algal and bacterial biomarkers typical of saline environments were found in layers 0.60 to 0.75 m below the sediment surface in the Tyro Lake Basin, as well as normal marine indicators derived from pelagic fallout (“rain from heaven”). Saline indicators include; regular C-25

isoprenoids, squalane, lycopane, isolycopane, tetraterpenoid and tetrapyrrolic pigments, monoalkyl-cyclohexanes, tricyclic diterpanes, steranes, hopanes, bio- and geohopanes. According to Burkova et al. (2000), the saline organic signatures come from microbial mat layers, redeposited from a Messinian source into the sapropels of the modern depression. Alternatively, they may indicate the activities of a chemoautotrophic community, which flourishes at the halocline or around active brine vents. As in the Orca Basin, the organic content of the bottom sediments of the Mediterranean brine pools is much higher than is found in typical deep seafloor sediment (Figure 9.37a).

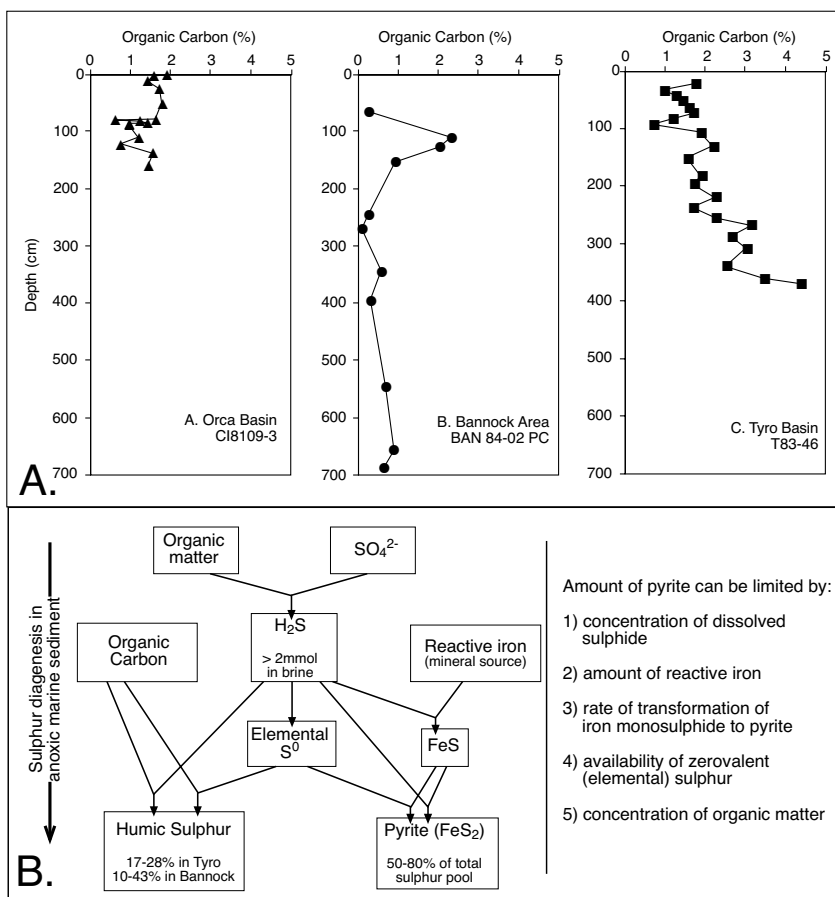

Figure 9.37. Organic characteristics of brine pool bottom sediment. A) Total organic carbon as % dry weight versus depth (plotted from Tyro and Orca data in Table 1 of Sheu, 1987, and Bannock data from Hennecke et al., 1997). B) Modes of occurrence of sulphur in brine pool bottom sediments (after Hennecke et al., 1997).

Anoxic hypersaline brines in Mediterranean brine lakes are highly sulphidic and among the most sulphidic bodies of water in the marine realm, with H₂S concentrations consistently greater than 2-3 mmol (Figure 9.37c; Henneke et al., 1997). The brine body below the Urania chemocline contains up to 11 mM hydrogen sulphide, making it the most sulphidic water body in the known marine realm.

Region of brine occurrence	Salinity (‰)	pH	O ₂ (μM)	H ₂ S (mM)	SO ₄ (mM)	Ca (mM)	Cl (mM)	PO ₄ (μM)	NH ₄ (μM)
Urania Basin (Mediterranean)	200	6.8	0	8.6-11	85	34	2,830	41.2	ND
Libeccio Basin (Bannock area - Medit.)	321	6.5	0	1.67	99	21	5,333	12	3,080
Tyro Basin (Mediterranean)	ND	6.75	0	2.15	49	34	5,350	10	1,260
Orca Basin (Gulf of Mexico)	258	5.5	0	0.60	47	32	5,000	82	500
Seawater (Mediterranean)	39	8.2	200	0	31	11	660	0.2	0.2

Table 9.6. Chemical make-up of various salt allochthon-associated brine pools compared to oxygenated seawater from the Mediterranean (after Sass et al., 2001).

In contrast, there is little to no H₂S in the anoxic bottom brine of the Orca Basin (Table 9.6). There the iron concentration is 2 ppm, a value more than 1000 times higher than in the overlying Gulf of Mexico seawater. Such high levels of reducible iron in the Orca Basin are thought to explain the lack of H₂S in the bottom brine and a preponderance of framboidal pyrite in the bottom sediments (Sheu, 1987). Both the Orca Basin and the brine pools on the floor of the Mediterranean show sulphate levels that can be more than twice that of the overlying seawater.

Pyritic sulphur is the main phase of inorganic reduced sulphur in the Tyro and Bannock basins, where it makes up 50-80% of the total sulphur pool. It is also present at the same levels in cores from the two basins, that is, around 250 μmol per gram dry weight (Figure 9.37b; Henneke et al., 1997). Humic sulphur accounts for 17-28% of the total sulphur pool in the Tyro Basin and for 10-43% in the Bannock Basin. Sulphur isotope data show negative δ³⁴S values for both pyritic sulphur, with δ³⁴S = -19‰ to -39‰; and for humic sulphur, with δ³⁴S = -15‰ to -30‰; indicating that both pyritic and humic sulphur originated from microbially produced H₂S within the brine column.

Marine sediment fills in all the active brine lakes of the Mediterranean Ridge range in age from Holocene to Late Pleistocene and are typically made up of turbidites interlayered with laminated intervals composed of alternating green gelatinous muds and grey reduced oozes. Usually, the density of the bottom brine layer in the Bannock region is high enough to support a layer of finely dispersed organic debris, allowing substantial bacterial mats to float at the seawater-brine interface (halocline) and so form suspended deep mid-water bacterial mats (Erba, 1991). While the organics float on the oxic side of the halocline they are subject to oxidation and biodegradation (Figure 9.8). Owing to the high density of the bottom brines, moving this floating organic material to the floor of density-stratified brine pools appears at first to be a difficult proposition. Bottom sediments in the Urania Basin for example contains very little particulate organic matter (>1% TOC). Yet, organic contents in the anoxic

bottom muds beneath Tyro and Orca basins can be as high as 4-5% organic carbon (Figure 9.37a). The propensity for organics to remain suspended at the halocline can be overcome when mineral crystals, including pyrite, precipitate at the interface via diffusive brine mixing in combination with bacterial sulphate reduction. Newly formed crystals attach to organic matter floating at the halocline to create a combined density that carries the suspended pellicular organics to the pool floor. In such a brine pool scenario, the redox front that fixes pyritic sulphur occurs at the halocline, and not at its more typical marine position located at or below the sediment-seawater interface.

Organic debris, first formed at the halocline, then accumulated as pellicle layers within the pyritic bottom muds (laminites). Pellicular debris is also carried to the bottom during the emplacement of turbidites when the halocline is disturbed by turbid overflow (Figure 9.38; Erba, 1991). Hence, pellicular layers are typically aligned parallel to lamination, or are folded parallel to the sandy bases of the turbidite flows, or line up parallel to deformed layers within slumped sediment layers. Individual pellicle layers are 0.5 to 3 mm thick and dark greenish-grey in colour. Similar pellicular layers cover the surface of, or are locked within, recent gypsum crystals recovered from bottom sediments of the Bannock area. This gypsum is growing today on the bottom of the Bannock Basin, atop areas about the brine pool margin that are directly underlain by dissolving Miocene evaporites (Corselli and Aghib, 1987). Other than the Dead Sea, it is one of the few modern examples of a deepwater evaporite, but its seepage-fed genesis means it is a poor analogue for deepwater basinwide salt units.

The community of bacteria and archaea flourishing at the halocline in sulphidic marine brine pools is quite diverse and largely independent of primary production in the euphotic zone. Bottom brine in the Urania brine lake has a salinity of 162‰ and the chemocline of the brine lake is some 3490m below the ocean surface, so only a very small amount of phytoplanktonic organic carbon ever reaches the 20m thick chemocline. Yet the oxic waters of the upper part of the chemocline support a rich

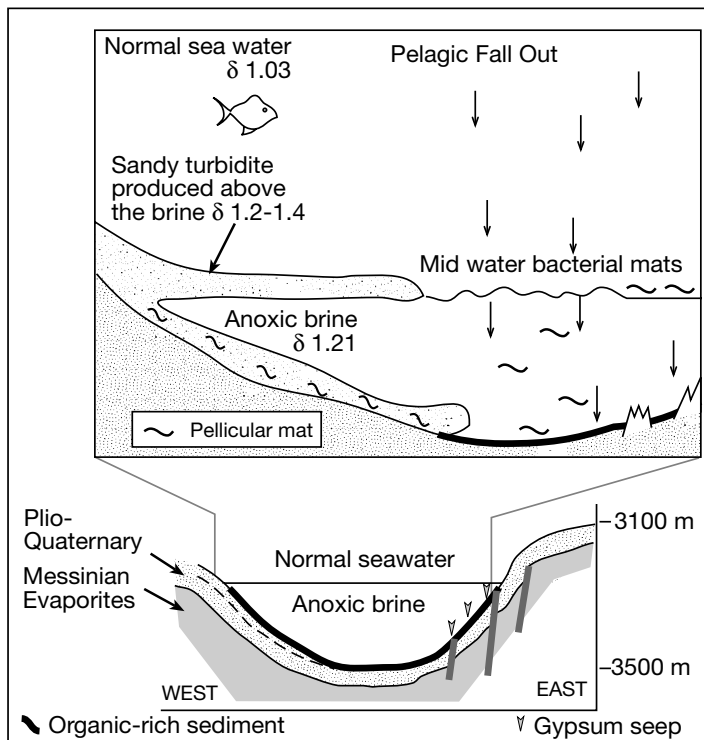

Figure 9.38. Formation and sedimentation model for pellicles in Mediterranean seafloor brine lakes. Bacterial (pellicular) mats grow mid-water at the interface between normal seawater and anoxic brine and trap biogenic and inorganic particles. When pelagic sedimentation prevails, pellicles sink to the basin floor after load increases to breach levels at the halocline interface (right side). Occasional turbidity currents and sediment slumping disrupts the interface, destroys the floating mat layer and transports fragments of pellicles to the basin bottom as part of coarser sandier layers (after Erba, 1991).

bacterial assemblage in the interface between the hypersaline brine and the overlying seawater, much like the bacterial community atop the halocline in Lake Mahoney (Figure 9.39; Sass et al., 2001). Sulphide concentration increases from 0 to 10 mM within a vertical interval of 5 m across the interface. Within this chemocline, the total bacterial cell counts and the exoenzyme activities are elevated. Bacterial sulphate reduction rates measured in this layer are $\approx 14 \text{ nmol SO}_4 \text{ cm}^{-3} \text{ d}^{-1}$ and are among the highest in the marine realm. They correspond to the zone of maximum bacterial activity in the chemocline. Particulate organic content is 15 times greater than that in the overlying normal marine waters. Employing 11 cultivation methods, Sass et al. isolated a total of 70 bacterial strains from the chemocline. These strains were identified as the flavobacteria, *Alteromonas macleodii*, and *Halomonas aquamarina*. All 70 strains could grow chemo-organoheterotrophically under oxic

conditions. Twenty-one of the isolates could grow both chemo-organotrophically and chemo-lithotrophically (decomposers and fermenters). While the most probable numbers in most cases ranged between 0.006 and 4.3% of the total cell counts, an unusually high value of 54% was determined above the chemocline with media containing amino acids as the carbon and energy source.

In another brine lake, the Kebrut Deep on the deep floor of the Red Sea, halophilic archaea flourish in hypersaline waters below the chemocline. Under strictly anaerobic culture conditions, novel halophiles were isolated from samples of these waters and belong to the halophilic genus *Halanaerobium*. They are the first representatives of the genus obtained from deep-sea, anaerobic brine pools (Eder et al., 2001). Within the genus *Halanaerobium*, they represent new species which grows chemoorganotrophically at NaCl concentrations ranging from 5 to 34%. They contribute significantly to the anaerobic degradation of organic matter, which formed at the brine-seawater interface and is slowly settling into the bottom brine.

Neither Tyro or Bannock Basin bottom sediments show a significant correlation between pyritic sulphur and the organic carbon in the bottom sediments, suggesting predominantly syngenetic pyrite formation in bottom sediments of these brine lakes (Henneke et al., 1997). That is, both pyritic and humic sulphur preserved in the bottom sediments formed either in the lower water column or at the sediment-brine interface, not in the sediment itself. Ongoing diagenetic processes within the bottom sediments only form an additional 5% of the total pyrite. Van der Sloot et al. (1990) clearly showed that metal sulphides, as well as organics and other minerals, precipitate at the brine-seawater interface in the Tyro Basin. They found extremely high concentrations of Co (0.015%), Cu (1.35%) and Zn (0.28%) in suspended matter at the halocline. These high particulate Co, Cu and Zn concentrations correspond to sharp increases in dissolved sulphide across the interface (a redox front), and indicate precipitation of metal sulphides at the interface (Figure 9.36c). Humic sulphur in the bottom sediments correlates with the pyritic sulphur distribution and is related to the amount of gelatinous pellicle derived from bacterial mats growing at the halocline between oxic seawater and bottom brine (Erba, 1991, Henneke et al., 1997).

Additionally, the degree of pyritisation in the sediments (DOP ≈ 0.62) indicates that present-day pyrite formation is limited by the reactivity of Fe in the Bannock and Tyro basins and not by the availability of organic matter, the latter being the process that limits pyrite formation in most normal marine settings. The degree of pyritisation (DOP) is defined as [(pyritic iron)/(pyritic iron + reactive iron)]. Raiswell et al. (1988) showed that DOP in ancient sediments can distinguish anoxic from normal marine sediments. Anoxic sediments show DOP values between 0.55 and 0.93, while normal marine sediments have DOP values less than 0.42. The DOP levels in the Bannock and Tyro basins confirm observations made in ancient anoxic sediments. Thus, although the Tyro and Bannock basin brines differ in their major element chemistry, reflecting a different salt source, their reduced sulphur species chemistry appears to be similar, but significantly different from normal marine systems and capable of precipitating metal sulphides above the sediment surface.

Pools of hypersaline, anoxic brines, underlain by laminated pyritic organic-rich sediments, are far more widespread in halokinetic terrains than just in the Orca, and Mediterranean Ridge basins. For example, similar brine seeps and pools have now been documented atop and adjacent to numerous salt allochthons along much of the continental slope of the Gulf of Mexico. In the Green Canyon area, wherever shallow allochthonous salt sheets are dissolving just beneath the seafloor, organic-enriched pyritic sediments are also commonplace (Figure 9.40a, b; Reilly et al., 1996). Similar cool-seep systems are active today along the foot of the Florida Escarpment and the Blake Ridge, where they are focused and in part fed by subadjacent dissolving salt allochthons (Paull et al., 1992).

Edges of salt allochthons do not just focus the upward flow of escaping subsurface waters into brine lakes along minibasin margins, they also focus the upward escape of gaseous and liquid hydrocarbons. Where sea bottom temperatures are suitable, gas hydrates can form atop focused outflow zones.

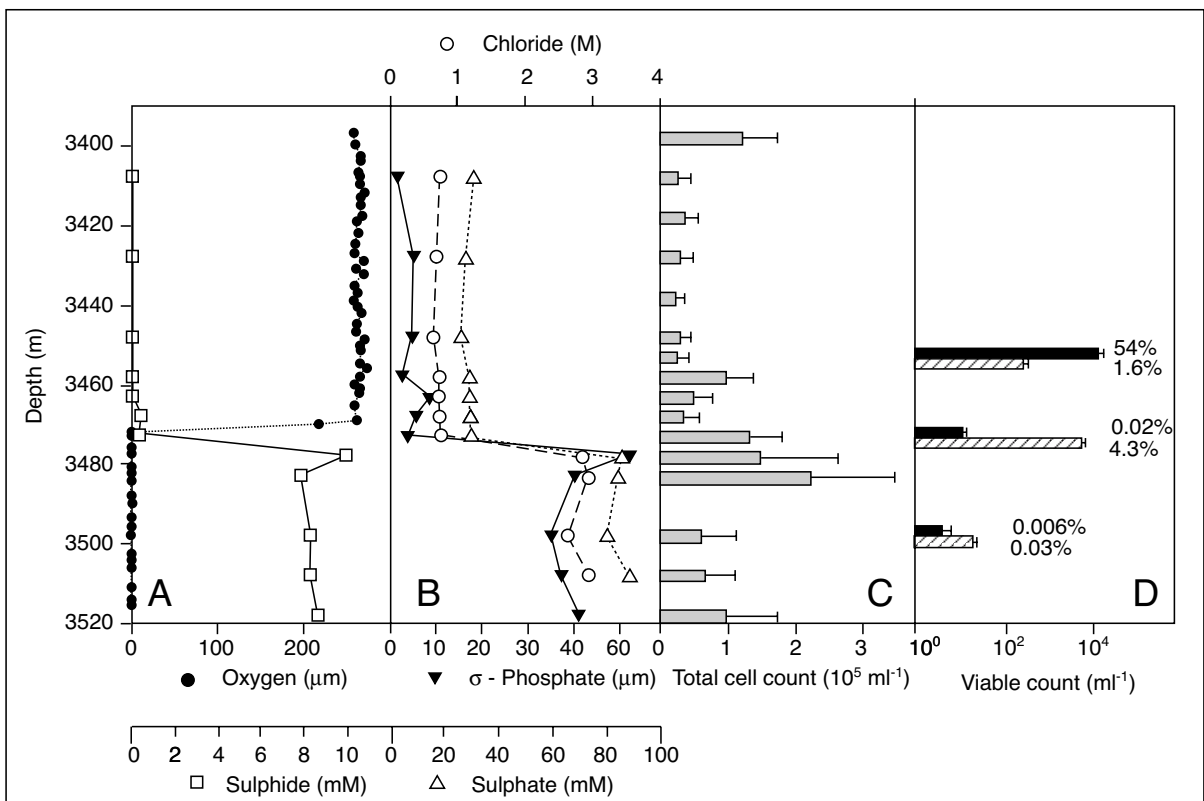

Figure 9.39. Physicochemical parameters, total cell counts, and MPN across the oxic-anoxic boundary of the Urania Basin, Mediterranean Ridge (after Sass et al., 2001). A) Oxygen and sulphide concentrations; B) Sulphate, orthophosphate and chloride concentrations; C) Total cell counts; D) Viable cell counts in anoxic media containing the amino acid mixture (solid bars) and in oxic media containing thiosulphate (cross-hatched bars). The percentages are relative to the total cell count and the error bars indicate standard deviation.

A light-independent chemosynthetic seep biota can grow and flourish in regions of hydrocarbon (methane) and H_2S focused outflow (Figure 9.40b).

Gas hydrate or clathrate is an ice-like crystalline mineral in which hydrocarbon and nonhydrocarbon gases are frozen within rigid molecular cages of water. They can be thought of gaseous permafrost. Their occurrence is not just tied to the cold temperature portion of the deep seafloor; clathrates are the dominant seals to large gas reservoirs in the permafrost regions of Siberia. Methane hydrates are commonplace associations where methane (often biogenic) occurs just below the deep cold seafloor and can accumulate in many seafloor regions independent of any evaporite occurrence. Clathrate formation on the seafloor requires bottom temperatures not encountered until the seafloor bottom lies beneath a water column 450-500 m deep.

Beneath the clathrate covered seafloor, temperature increases with depth and this limits the depth at which gas hydrates will occur; below it an accumulation of free gas is likely.

Thus, clathrates are not unique to, but are often very obvious about, salt allochthon edges where salt flow induces extensional faulting (Chapter 6). This in turn acts as focusing mechanism for escaping thermogenic and biogenic methane and other gases (Figure 9.40; MacDonald et al., 2000, 2003). Rapid burial of organic-entraining sediments in supra-allochthon minibasins encourages the creation of biogenic methane that sources much of the gas escaping to the seafloor. Hence, in the salt allochthon province of the northern Gulf of Mexico there is a definite association between brine pool chemosynthetic communities, thicker gas hydrates and the edges of minibasins (Figure 9.40; Reilly et al., 1996; Milkov and Sassen, 2001).

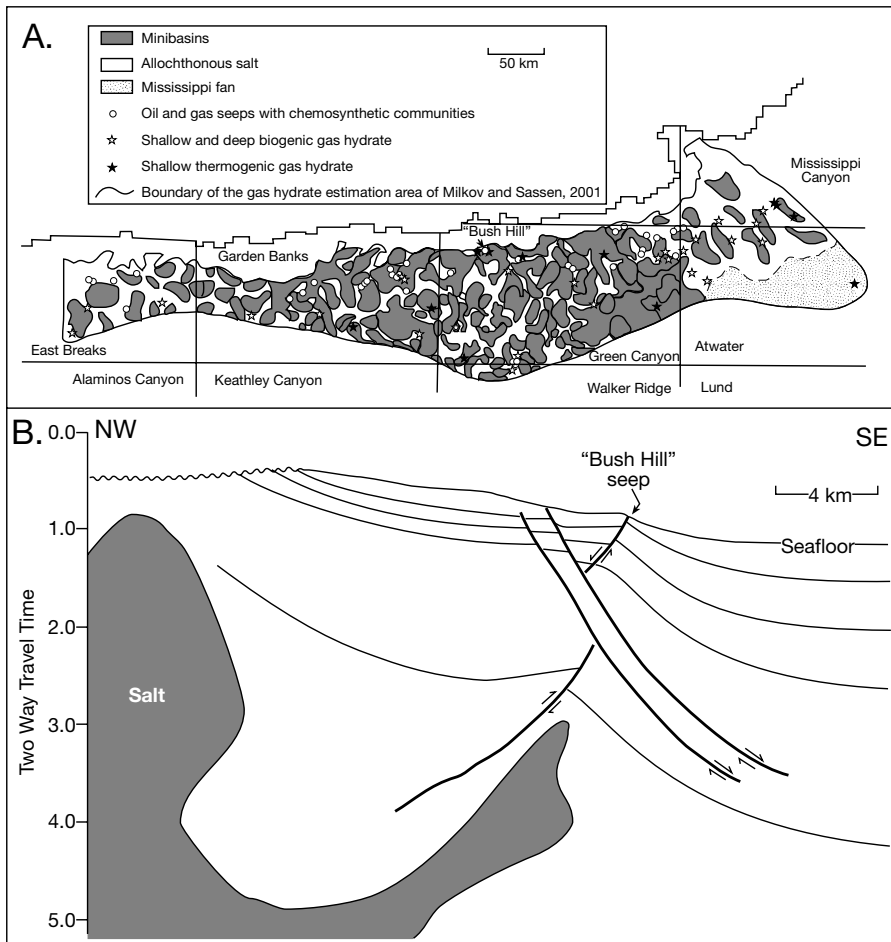

Figure 9.40. Seeps in the northern Gulf of Mexico. A) Documented occurrences of seeps and methane hydrates (after Milkov and Sassen, 2001). B) Interpretation of seismic line showing strong structural control on location of the chemosynthetic seep at "Bush Hill" (after Reilly et al., 1996).

The escape of nutritive methane and H_2S from these brine-filled pockmark pools and lakes supports symbiont-containing mussel and tubeworm communities, which can construct dense biostromes around the brine pool rims. This mussel-tubeworm dominated biota is the cold water equivalent of the chemosynthetic hydrothermal communities flourishing in the vicinity of black smoker vents (MacDonald, 1992; MacDonald et al., 2003). In both settings it is methane and sulphide, not light, that provides the energy source for the bacteria and archaea that make up the base of the food chain. Methanogenic archaea live symbiotically on the mussels' gills, take in methane and convert it to nutrients that nourish the mussels. Seep mussels (*Bathymodiolus childressi*) continually waft methane-rich water through their gills to help the archaea grow and periodically harvest some

of the excess growth. Their lifestyle means that seep mussels need to live near a supply of dissolved gas, they may inhabit isolated zones on the floor where gas is bubbling out but do best about the edges of methane-saturated brine pools and will grow in any fringe area to the pool, wherever they can keep their siphons above the halocline.

Likewise, the polychaete tubeworms (*Hesiocaeca methanicola*) are chemotrophs with a microbe-dependant metabolism. Microbial sulphate reducers live in the anoxic sea-floor sediments near seeps as they convert escaping hydrocarbons and seawater sulphate into H_2S . Tubeworms take up this hydrogen sulphide, along with oxygen, and provide them as nutrients to sulphur-oxidising bacteria living symbiotically in trophosome structures that extend for up to 75% of the length of the tube worm.

Interestingly, when they were first collected, figuring out what these giant tubeworms (*Riftia pachytila*) lived on in deep dark waters was especially mystifying because they had no mouths, guts, or anuses! They were first thought to be absorbing tiny food particles through their skin. The function of the trophosome was unknown but thought to be related to dealing with toxicity not feeding, after all these structures were lined with what was thought to be extruded sulphur crystals. It is now known that the sulphur-oxidising bacteria, which inhabit the trophosome cells, use H_2S to produce nutrients in the form of organic carbon for the tubeworms to metabolise. Elemental sulphur is the common metabolic intermediate in sulphur-oxidising bacteria (Figure 9.11a). Tubeworm colonies or “bushes” in cold seep regions of the Gulf of Mexico are typically rooted in the H_2S -rich muds giving the colony a morphology similar to a tree or shrub, with “roots” extending into the earth and branches extending above. Growing individuals actively extend down into the H_2S -rich mud as well as up into the O_2 -rich water column. It seems that these tubeworm shrubs can absorb H_2S through their “roots” and O_2 through their “branches” (Freytag et al., 2001).

Although individuals may live for more than 300 years, vagaries in the rate of brine and nutrient supply to the seafloor mean many mussels and tubeworms colonies can be overwhelmed by a rising halocline and so die in a short space of time. Their partially decomposed remains can spread out as part of the organic-rich debris atop the halocline, along with bacterial, algal and faecal residues, where it is acted upon by a rich community of aerobic and anaerobic decomposers. If it is mineralised it sinks to the anoxic bottom, where it is largely preserved and protected from further biodegradation. The inherently unstable nature of the seafloor in the vicinity of active salt allochthons and brine lakes means parts of the biostrome are periodically

killed “en masse” as sediment about a brine pool edge collapses, slumps and slides into anoxic pool waters, carrying with it the chemosynthetic community. As well as further elevating levels of preserved organics in the brine pool bottom sediments, this process also creates potential fossil lagerstätte (“death communities”). Cretaceous counterparts to these methanogenic brine systems have been documented in the Canadian Archipelago where methane-rich mound seeps, dominated by fossiliferous fibrous calcite and aragonite hardgrounds, grew atop growth faults activated by salt diapirism in the Sverdrup Basin (Savard et al., 1996).

If the evaporite indicators in ancient counterparts of all these brine pool/seep systems are not recognised, then, once the associated allochthonous salt sheets have dissolved or moved on, the evaporites that focused the accumulation of organic-rich pyritic brine pool sediments will become an enigma (Warren, 2000b). In the Phanerozoic, any remaining organic constituents will be made up primarily of marine plankton, a benthic marine biota and bacteria from a normal marine setting. Sediments above and below the pyritic pellicular laminites are also made up of normal marine deepwater deposits. There will be little geochemical evidence to show that these organic-rich pyritic sediments were preserved in a hypersaline deep marine environment. Evidence of the significance of evaporites in creating such a sequence will only come from sedimentological and structural analysis of core or outcrop from below and adjacent to the laminites, and the recognition of halokinetic breccias, salt welds, chemosynthetic biostromes and marine-cemented hardgrounds within a deeper water marine sediment matrix.

Subsurface organic-sulphate reactions

As organic matter in evaporitic sediments is buried it becomes hotter, it can also be anomalously heated locally by intrusions and crossflows of fault-focused hydrothermal fluid. It is altered in a number of ways, all tied to rates of temperature increase in the presence or absence of oxygen in the pore fluids (Figure 9.41). The subsurface interface between hypersaline waters (typically with reducing dysaerobic to anaerobic chemistries) and less saline waters (typically with more oxidised and oxygenated chemistries) creates redox fronts in aquifers adjacent to subsurface evaporites and is often defined by a colour transition from green (reduced) to red (oxidising) in the sediment matrix. Less saline waters tend to dissolve evaporites and create secondary porosity (mostly vuggy and collapse fracture), while

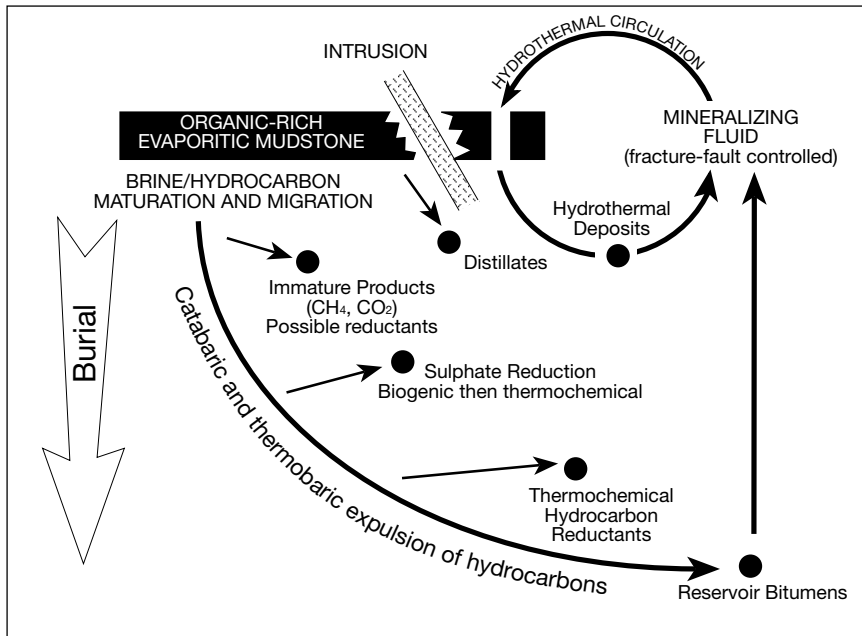

Figure 9.41. The role of organic-rich evaporitic mudstones in burial diagenesis. The mudstones can act as a source of hydrocarbons and as a reductant for metals.

at the same time chloride or sulphate passes into solution. Where the sulphate in solution interacts with the organics in the vicinity of the redox interface, H_2S is generated via sulphate reduction. It can dissolve any adjacent carbonate, which is reprecipitated as calcite cement, along with pyrite and other metals on the reducing side of the interface (Figure 9.41). Much of the H_2S that is found in elevated amounts in an evaporitic basin is bacterially or thermochemically generated by sulphate reduction from sulphate carried by brine and derived from dissolving sulphate beds. Additional H_2S in an evaporite basin can be generated from local magmatic and biogenic sources.

Any association of dissolved sulphate and hydrocarbons (organic matter) is thermodynamically unstable in all diagenetic settings and the chemical response is sulphate reduction (Machel, 2001). Sulphate reduction reactions can be bacterially mediated through the activities of sulphate-reducing bacteria (bacterial sulphate reduction-BSR) or inorganically mediated under conditions of increased temperature and pressure (thermochemical sulphate reduction - TSR). Both scenarios require the presence of preserved organic matter, or its more evolved subsurface equivalent in the form of hydrocarbons (oil or gas), and result in similar but not identical carbonate cements, mostly calcite. The bacterially mediated system operates at lower burial temperatures

<110°C, mostly <60–80°C, in a temperature range equivalent to vitrinite reflectances R_o of 0.2–0.3. Thermochemical sulphate reduction processes require temperatures of more 120°C and R_o values ranging from 1.0 to 4.0 (Figure 9.42).

Bacterial sulphate reduction (BSR)

BSR takes place in surface and nearsurface environments where sulphate-reducing bacteria utilise dissolved sulphate and organics/hydrocarbons to produce H_2S (Figure 9.42a, c; Trudinger et al., 1985; Machel, 1987, 2001; Hill, 1995; Riciputi et al., 1996; Aref, 1998b). So far we have discussed bacterial sulphate reducers in the context

of stratified brine columns, where they flourish in anoxic waters beneath the halocline, or in benthic cyanobacterial mats where they occupy the low anoxic portions of the mat. In this section we will look at the nature of BSR in the subsurface.

Bacterial sulphate reduction occurs at temperatures typically <80°C, although hyperthermophilic archaeal sulphate-reducers (*Archaeoglobus* sp.) can grow around hydrothermal vents on the deep ocean floor at temperatures up to 110°C. In regions with normal geothermal gradients the temperature range <60–80°C corresponds to burial depths from the surface down to 2000–2500m. BSR processes and bacterial sulphate reducers are widespread in many other anoxic subsurface sediments unrelated to evaporites. But the discussion in this section concentrates on those types of sulphate reduction that are commonplace in regions of dissolving evaporites and saline pore waters. Such systems tend to form bioepigenetic limestones and cements with textures and isotopic signatures indicating its evaporite precursor or association.

Bacterial sulphate reduction is usually expressed by the equation;

At pH<6-7 the produced H₂S is undissociated; at pH>6-7, H₂S dissociates so that H₂S → H⁺ + HS⁻ (Hill, 1995). In this equation, SO₄ indicates dissolved sulphate, which is derived either from shallow phreatic refluxing brine/seawater or from dissolving sulphate evaporites such as gypsum, glauberite, or anhydrite. CaCO₃ represents bioepigenetic limestone products, which typically precipitate as cements or replacements of precursor evaporite sulphates. CH₄ represents a host of possible organic compounds or hydrocarbons, mostly organic acids and other products of aerobic or fermentative biodegradation.

There are two well established genera of sulphate-reducing bacteria, *Desulphovibrio* and *Desulphotomaculum*, they seem to be quite unrelated to each other and their relation to other bacterial groups is also obscure.

Members of better known genus, *Desulphovibrio*, are mesophilic (prefer a moderate temperature range) and can be moderately halophilic (Figure 9.11b); the genus is thought to contain seven species at the present time. *Desulphotomaculum* species are somewhat more difficult to isolate and purify. They are characterised by spore formation and are sometimes thermophilic; only one moderately halophilic strain has been reported in the five recognised *Desulphotomaculum* species (Postgate, 1984).

Mesophilic isolates of the genus *Desulphovibrio* will typically not grow above 45°C. Thermophilic isolates of the *Desulphotomaculum* genus have been grown at temperatures as high as 70°C - the most common species of thermophile being *Desulphotomaculum nigrificans*. However, Rozanova and Khudyakova (1974) isolated an apparent *Desulphovibrio* sp. having a

maximum growth temperature of 85°C, while Zobell (1957) claimed that he had isolated viable sulphate-reducing bacteria from an oil-bearing reservoir where growth was occurring at 104°C under a pressure of 1000 atm. Both these higher temperature reports were not biologically documented under noncontaminated conditions. The upper temperature limit for subsurface biogenic sulphate reduction is usually considered to be 80-85°C (Trudinger et al., 1985), a reasonable estimate for documented sulphate reducers in most evaporitic and shallow subsurface settings. It means the most vigorous bacteriogenic reduction (>50°C) typically extends from any nutrient-rich brine column oxic-anoxic interface down to redox fronts at burial depths of a kilometre or so.

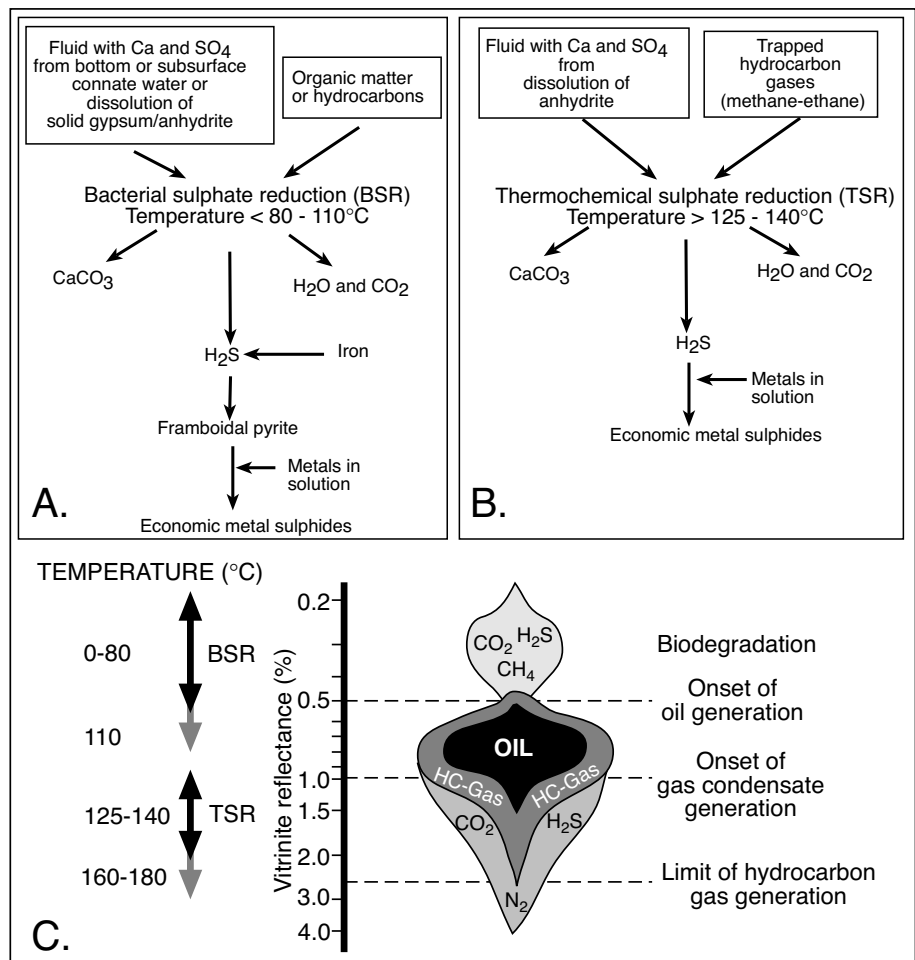

Figure 9.42. Chemical pathways and thermal regimes associated with sulphate reduction. A) Bacterial sulphate reduction - BSR. B) Thermochemical sulphate reduction - TSR. C) Thermal regime and hydrocarbon generation stages tied to characteristic values of vitrinite reflectance (in part after Machel, 2001; Warren, 2000b) Note that there is a lack of biogenically produced pyrite framboids during thermochemical sulphate reduction.

Under suitably pressurized deep-sea bottom conditions, and perhaps some subsurface conditions, biogenic sulphate reduction may extend into higher temperature regions. Work in the anhydritic deep-sea hydrothermal vent sediments of the Guaymas Basin in the Gulf of California has revealed biologically-mediated sulphate reduction by hyperthermophilic Archaea at temperatures up to 110°C, with an optimal rate at 103-106°C (Huber et al. 1989; Jørgensen et al., 1992). But such hyperthermophilic sulphate reducers are not recovered from formation brines of most subsurface hydrocarbon-rich settings, otherwise sweet oils would be a rare style of oil occurrence at temperatures less than 110°C (Machel, 2001).

Bacterial sulphate reduction in evaporitic settings typically occurs near an aerobic/anaerobic interface. It may be a density interface in a layered brine column, it may be at the aerobic-anaerobic interface just below the sediment surface, it may be at an oil/water contact at greater depths, or it may be a subsurface diffusion or mixing zone, focused by faults, fractures and bedding boundaries. Wherever hydrocarbons are involved, most sulphate-reducers cannot directly digest long chain n-alkanes (paraffins) as nutrients. Instead, they depend on metabolic residues of hydrocarbon biodegradation, such as the various organic acids produced by aerobic biodegradation of oil (Davis and Kirkland, 1970; Machel, 1987). Thus, sulphate reducers are anaerobes but typically depend on aerobic bacteria to create suitably biodegraded hydrocarbon substrates.

Sulphate-reducing bacteria then oxidize the biodegraded hydrocarbons to HCO_3 and bitumen residues, while simultaneously reducing the dissolved sulphate to H_2S . Where methane is the main carbon source, all the methane is oxidized into HCO_3 , and no bitumen residue forms (Machel, 1989). Production of H_2S favours the precipitation of carbonate cement or the replacement of dissolving sulphates by calcite. H_2S may escape into the atmosphere or come into contact with dissolved oxygen in an aquifer or a diffusion zone, where it is oxidized into elemental sulphur, as in most shallow sulphur deposits (Chapter 11; Berner, 1980).

Growth of sulphate-reducing bacteria is typically restricted to anoxic pore waters with a pH of 5 - 9. The creation of anoxic microniches means there are many saline depositional situations where the bacterial sulphate-reducers flourish locally, usually within millimetres of oxygenated seawater or brine. For example, at the local scale much of the micrite precipitated as marine stromatolite laminae in metre-high structures in tidal channels of the Bahamas (Chapter 1) are a byproduct of bacterial sulphate reduction. This BSR-induced precipitation

occurs within millimetres of normally oxygenated seawater (Visscher et al., 2000). Likewise BSR controls the precipitation of microbial carbonate in mm-layered mats in a modern hypersaline lake on Eleuthera Island in the Bahamas (Dupraz et al., 2004) and primary dolomites in Brazilian coastal salines (Figure 4.16). At broader subsurface scales, anoxic interfaces suitable for BSR tend to form near the dissolving margins (top or bottom) of shallow salt beds and allochthons, or within diapir caps, or near fractures and other breaches in dissolving calcium sulphate beds. These are all sulphate-rich environments where focused crossflow and mixing occurs between reduced basinal waters and more oxic waters.

Sulphate-reducing bacteria are responsible for the laminar vuggy bioepigenetic limestones that make up the caprocks of the Gulf Coast and Zechstein diapirs (Kyle and Posey, 1991; Peckmann et al., 1999), the Castile Formation mounds (castiles) of the Gypsum Plain, Culberson County, west Texas, the Messinian Gessoso Solifera of Sicily, as well as numerous other calcitic limestones that replace sulphate evaporites worldwide (Figures 6.63, 7.9, 7.45a, 11.58, 11.59). Subsequent weathering of the encasing gypsum means calcitic buttes can form irregular steep-sided hills in areas, as in the Castiles rising 3 to 30 m above the Gypsum Plain of west Texas (Kirkland and Evans 1980). Castile calcite masses did not precipitate at the surface, they originally formed hundreds of metres below the surface (Figure 7.45a). The bacterial/hydrocarbon association of these bioepigenetic limestones is clearly seen in their negative $\delta^{13}\text{C}$ signatures (Figure 9.43a). Carbon in calcite making up a Castile is sourced by the breakdown of organic matter or hydrocarbons and does not come from dissolution of marine limestone. Sulphate-replacing calcites formed by BSR are typically ^{13}C depleted, and this isotopic signature, along with their more negative sulphur isotope signature (compared to marine sulphates), is used to characterise BSR-induced calcites worldwide (Figures 9.43 and 7.48).

Widespread bioepigenetic limestone buttes or castiles today outcrop in areas of exhumed Miocene evaporites along the margin of the Red Sea (Aref, 1998b; Pierre and Rouchy, 1988). There the carbonate masses are vuggy and form irregularly stratiform limestones within or capping beds of sulphate evaporites. As in the Castiles of west Texas and the diapir caprocks of the Gulf Coast, the Red Sea buttes are stained by hydrocarbon residues and smell of hydrocarbons when broken with a hammer. Associated natural sulphur (S_2) is usually yellow, but may be brown to black due to bitumen staining. The carbonate masses replacing the gypsum or anhydrite are made up of varying amounts of aragonite, calcite, or dolomite. $\delta^{13}\text{C}_{\text{PDB}}$ mean values

Figure 9.43. Stable isotope signatures of bacterial calcite. A) Outcropping samples from calcite buttes of the Castile Formation, Delaware Basin, west Texas, various Middle Miocene outcrops along the Red Sea coast and aragonite inclusions in gypsum of Zechstein, Germany. B) Bioepigenetic carbonates from Miocene of Gulf of Suez, caprocks in the Gulf of Mexico, sulphur deposits of Sicily and Castile Fm. buttes in west Texas. Thin line indicates range, thick line plots standard deviation about mean (Both figures replotted from data in Aref 1998b; Jassim et al., 1999; Kirkland and Evans, 1976; Peckmann et al., 1999; Pierre and Rouchy, 1988 and references therein).

for carbonate minerals typical of organic-derived signatures and ranging from -3.3 to -31.3 ‰ (Figure 9.43a). There is some overlap, but most are heavier than the $\delta^{13}\text{C}$ values of nearby crude oils (-28.1 to -29.3 ‰). Oxygen values from the Red Sea castiles define two groups. One is clustered around 0 ‰ and is dominated by aragonitic mineralogies with lesser calcite and is thought to indicate BSR replacement of gypsum that occurred soon after deposition. The other group is mostly calcite and dolomite, its $\delta^{18}\text{O}$ values range from -6 to -11 ‰ and is interpreted as a later meteoric-influenced BSR, occurring during halokinetic uplift and flushing of rising diapir caps by fresher groundwaters, this stage is akin to that forming the patchy BSR limestones in caprocks atop coastal plain diapirs in the Gulf of Mexico.

Microbial creation of stratiform bioepigenetic limestone is a widespread but under-recognised process at the dissolving edges of many gypsum/anhydrite masses. It typifies near surface seeps in the Fergana and Amudarya depressions of central Asia and the Mesopotamian depression in Iraq (Jassim et al., 1999). Bedded examples of coarsely crystalline gypsum replaced by texturally similar bioepigenetic calcite characterise contacts of some Upper Miocene gypsum outcrops in the Lorca Basin (Rouchy et al., 1998). Likewise the Ratynsky Limestone, with its characteristic light carbon signature and sulphur association, is a bioepigenetic limestone bed that defines the top of outcropping and subcropping artesian gypsum karst in the western Ukraine (Andrejchuk and Klimchouk, 2001).

Thermochemical sulphate reduction (TSR)

During thermochemical sulphate reduction, H_2S is produced as sulphate is inorganically reduced, via inorganic reactions with hydrocarbons, at temperatures typically in excess of 140°C, which is much too hot for any life (Figure 9.42b, c; Worden et al., 1995; Heydari 1997; Machel, 2001). Reactive hydrocarbons caught up in the TSR reaction are mostly branched and n-alkanes, followed by cyclic and mono-aromatic species in the gasoline range. Historically, the efficiency of thermochemical sulphate reduction in producing H_2S was inferred from experimental evidence or from levels of sour gas (H_2S) in deep oil and gas wells, rather than direct observation of subsurface processes (Trudinger et al., 1985; Noth, 1997). This has now

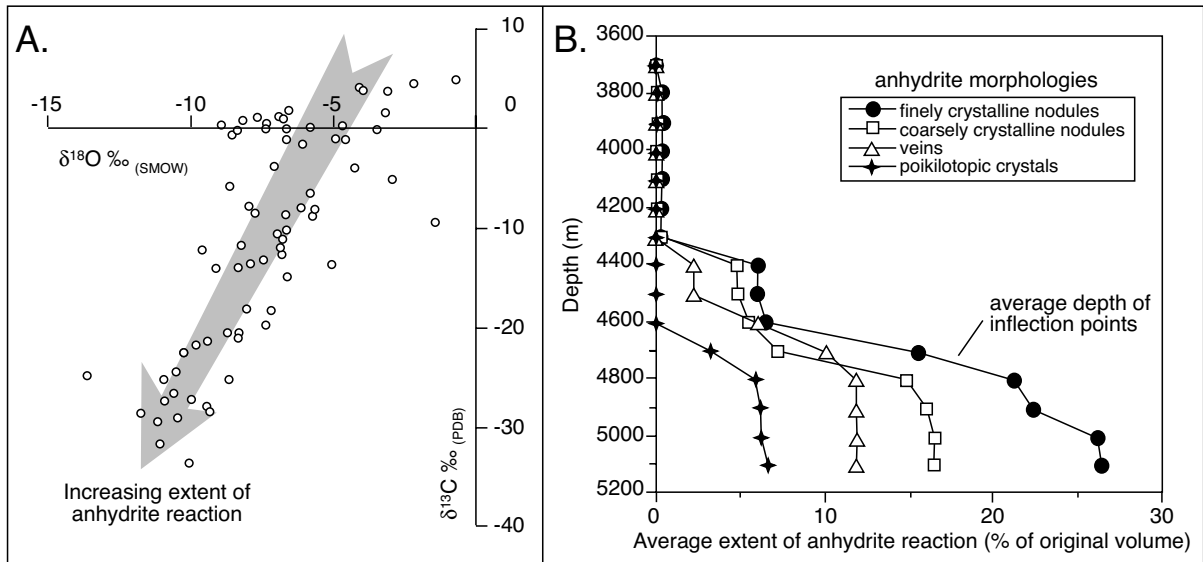

Figure 9.44. Thermochemical sulphate reduction in the Permian Khuff Fm., UAE. **A)** Stable isotopes of thermochemical calcite. Arrow shows trend of increasing calcite reaction. **B)** Depth versus the average extent of anhydrite replacement by calcite for the different types of anhydrite. Anhydrites with smaller crystal sizes are more reactive at any given burial depth. (after Worden et al., 2000).

changed with the direct documentation of TSR-produced H_2S (sour gas) in gas reservoirs in the Permian Khuff Formation of Abu Dhabi (Worden et al., 1995, 1996; Worden and Smalley, 1996). In Khuff reservoirs hotter than 140°C , anhydrite has been partially replaced by calcite, and hydrocarbon gases have been partially or fully replaced by H_2S . That is, anhydrite and hydrocarbons have reacted to produce calcite and H_2S .

Worldwide, the lowest temperature at which TSR occurs may be lower than the 140°C seen in the Khuff Fm. Machel (1998) suggests that the onset of TSR occurs in a range from $100\text{--}145^\circ\text{C}$ depending on variations in chemical kinetics, which will differ from basin to basin. If so, then one can expect TSR-derived H_2S to form at shallower depths than the 4000 m suggested by the work of Worden et al. (1995) or Heydari (1997).

Carbon and elemental sulphur isotope data from the gases and minerals in the Khuff Fm. show that the dominant general reaction is (Worden et al., 1995, 1996; Worden and Smalley, 1996; Heydari, 1997):

Gas chemistry and isotope data also show that C_2+ gases react preferentially with anhydrite via reactions like:

Sulphur is generated by this reaction and is locally present, but is also consumed by the reaction:

The frequently quoted and experimentally observed reaction between anhydrite and H_2S with CO_2 to produce calcite and sulphur:

has been shown, by gas chemistry, calcite $\delta^{13}\text{C}$ and sulphur $\delta^{34}\text{S}$ data, to be insignificant in the Khuff Formation.

Rather, a direct reaction between hydrocarbons and anhydrite occurs in solution. It takes place within residual pore waters that are initially dominated by carbonate dissolved out of the marine carbonate matrix. The first-formed replacive calcite thus contains carbon that was derived principally from a marine dolomite matrix with a $\delta^{13}\text{C}$ signature of 0 to $+4\text{‰}$. Continuing reaction leads to the progressive domination of pores water derived by TSR carbonate, with a minimum $\delta^{13}\text{C}$ of about 30‰ (Figure 9.44a). The spread of carbon isotope values in the replacive calcite shows that in the earliest stages of TSR the ambient formation water was dominated by bicarbonate derived from dissolution of the matrix dolomite. As TSR commenced, the first-formed aqueous carbonate species plus the newly dissolved calcium from the dissolving anhydrite led to

supersaturation with respect to calcite. However, this calcite was initially dominated by the dolomite-derived carbonate and thus inherited the dolomite's heavier carbon isotope signature. As TSR proceeded, the methane-derived carbonate came to dominate, leading to ever more negative $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values in the resulting calcite (Fig. 9.44a).

When petrographically determined amounts of replacive calcite in the Khuff Formation are plotted as a function of depth (Figure 9.44b) it shows that TSR starts around 4300 m depth (corresponding to a present-day temperature of 140°C) for all of the anhydrite types apart from the coarsest (poikilotopic variety), which shows signs of reaction only below 4500m. This implies that availability of sulphate from anhydrite is the rate-limiting step during the earlier stages of reaction when

anhydrite is replaced *in situ* by calcite on the very edges of anhydrite nodules and crystals (Worden et al., 2000). Later, as TSR proceeds, and the thickening calcite rind begins to isolate the anhydrite from the dissolved methane, the reaction becomes transport controlled. TSR ceases once calcite has effectively armour-plated (totally isolated) the remaining anhydrite. Finely crystalline anhydrite underwent more extensive and more rapid TSR than coarser anhydrite crystals because these had a greater ratio of surface area to volume, allowing more and faster dissolution and requiring more calcite to isolate them from methane. Localized loss of H_2S occurs in the Khuff reservoir by reaction with indigenous Fe-bearing clays. Consequently, Khuff reservoirs with a relatively high siliciclastic content have less H_2S than would be expected from the advanced state of anhydrite replacement with calcite in these units.

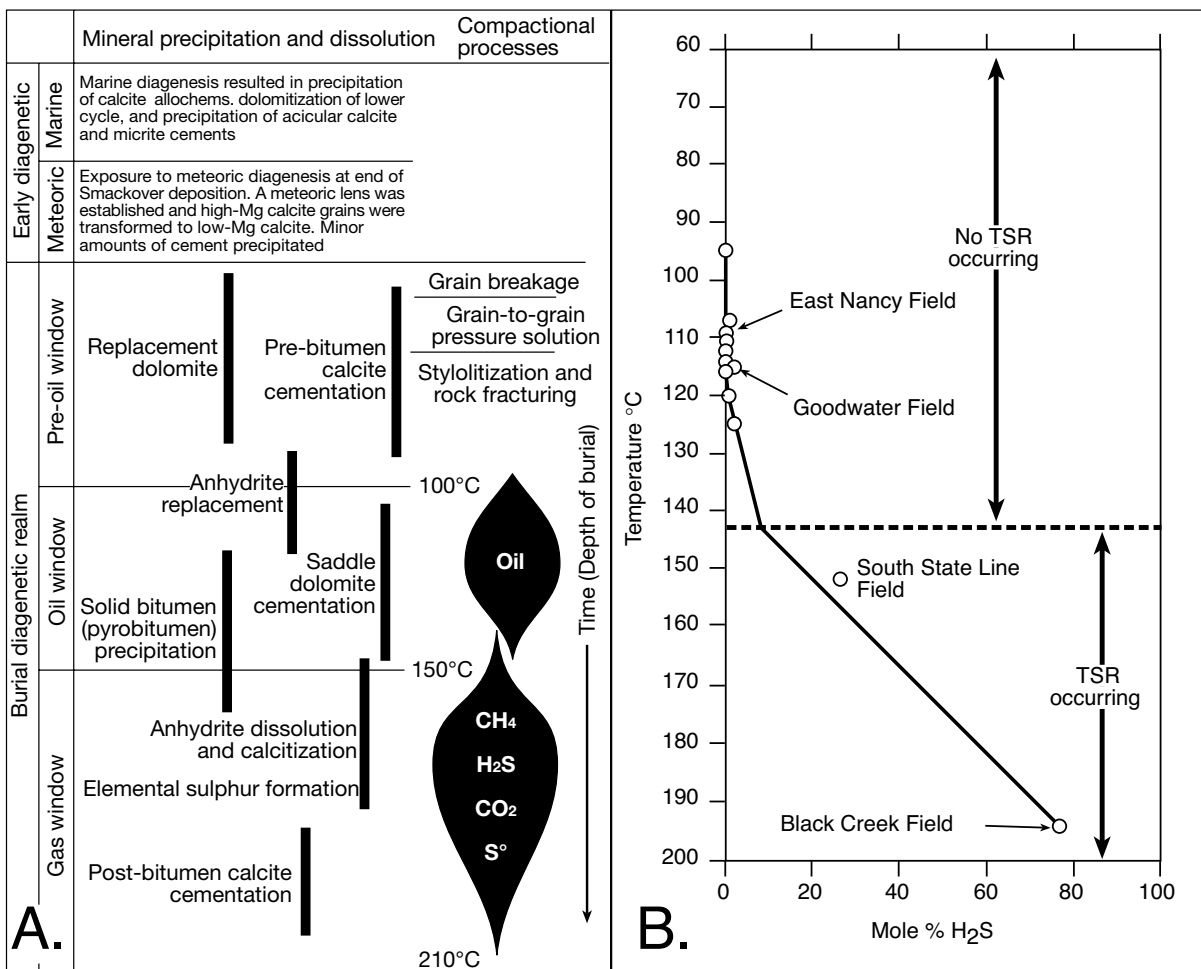

Figure 9.45. Thermochemical sulphate reduction in the Smackover Formation, Gulf of Mexico. A) Paragenetic sequence of the Smackover Formation at Black Creek Field summarizing major products of marine, meteoric, pre-oil window, oil window, and gas window diagenetic stages. B) Concentrations of H_2S in Mississippi Smackover reservoirs vary consistently with temperature (after Heydari, 1997).

Thermochemical sulphate reduction produces substantial volumes of very low salinity subsurface water in the vicinity of the reaction zone. Locally, the salinity of formation water in evaporite lithologies undergoing TSR is, therefore, not necessarily high. In the Khuff reservoir the water salinity and isotope data show that the original formation water was locally diluted between four and five times by water from TSR (Worden et al., 1996). A typical Khuff gas reservoir rock volume calculation suggests that initial formation water volumes can only be increased by about three times as a result of TSR. The extreme local dilution shown by the water salinity and $\delta^{18}\text{O}$ data in the Khuff must, therefore, reflect transiently imperfect mixing between TSR water and original formation water. Dissipation of this water into surrounding lithologies may aid further dissolution of adjacent evaporites. TSR is believed to cause the dilution of formation waters by up to 50% locally and up to 30% on a reservoir scale (Worden et al., 1996; Yang et al., 2001). On the other hand, there might be other reactions involved in TSR, some of them consuming water, so that the amount of water produced is probably highly variable and, according to Machel (2001), negligible at a regional scale.

Anhydrite dissolution and calcitisation in the Jurassic Smackover Formation in Mississippi, USA, does not occur below temperatures of 140–150°C, suggesting that, as in the Khuff, it is a thermochemical process (Figure 9.45a). Gas window diagenesis in deeply buried dolomitized Smackover reservoirs is largely driven by thermochemical sulphate reduction. Reaction of sulphate with H_2S generated S^0 that, in turn, reacts with CH_4 to form more H_2S in a self-reinforcing cycle (Heydari, 1997, 2001). Closed-system diagenesis prevents the escape of H_2S and, with sulphate abundantly available (Buckner Anhydrite). Without Fe^{2+} to remove H_2S by pyrite precipitation, the reaction continues until all hydrocarbons are consumed. TSR-generated CO_2 results in precipitation of postbitumen calcite with low $\delta^{13}\text{C}$ compositions.

Concentration of H_2S in Mississippi Smackover reservoirs varies consistently with temperature (Figure 9.45b; Heydari, 1997). Reservoirs studied are of the same age (150 Ma), similar lithology (clean oolitic limestone), and bounded by impermeable layers (Buckner anhydrite above and lime mudstones below). Heydari (1997) found that concentration of H_2S is very low in reservoirs that have experienced temperatures of 120°C for more than 50 m.y. It suggests that TSR has not occurred, and therefore it is not a time-dependent process (not kinetically driven). High H_2S concentrations occur in reservoirs with temperatures in excess of 140°C and increase with temperature, suggesting TSR is occurring and so it is a temperature-dependent process (thermodynamically driven).

Where anhydrite and methane remain in reservoirs warmer than 140°C, thermochemical sulphate reduction continues into the low temperature end of the metamorphic realm (>200°C). Alonso-Azcarate et al. (2001) documented vein deposits containing native sulphur, gypsum, quartz and rare sphalerite in the very low-grade metasediments of Cervera del Rio Alhama in the Mesozoic Cameros Basin of NE Spain. In outcrop the veins are hosted by lacustrine evaporites, which now comprise alternations of dolomite and recrystallised gypsum (which was anhydrite during metamorphism) layers. Fluid inclusion homogenization temperatures and quartz-sulphate oxygen isotope geothermometry indicate formation of the veins around 225°C. Fluid inclusions contain sulphur along with a gas phase comprising H_2S , N_2 , CO_2 and minor CH_4 . These are all reactants and products of sulphur generation via thermochemical sulphate reduction (TSR) in the anchizone, which utilised organic matter, followed by a partial re-oxidation of some H_2S by SO_4 to produce sulphur. These TSR reactions differ from those observed in most petroleum-related sour gas settings in that there is no evidence for secondary carbonate precipitation and in that significant S isotopic fractionation exists between sulphate (around + 20‰) and reduced products (sulphur is around - 11‰).

H_2S , natural gas and metallogeny

H_2S (sour gas) is bacterially produced from organic matter by BSR at lower temperatures and nonbiogenically by TSR at higher temperatures (Figures 9.42). In deep evaporite-sealed oil and gas provinces, the proportion of bacteriogenic H_2S that becomes one of the many constituent of the trapped natural gas is negligible compared to that produced by TSR (Hunt, 1996). However, further updip, the proportion of bacteriogenically-produced H_2S can be much higher. H_2S is one of the ^{9,10}deadliest gases produced naturally in large amounts. At nearsurface conditions it is almost three times as soluble as CO_2 and more than 70 times as soluble as methane (Figure 7.47). Its critical temperature of 100.4°C is also much higher than that of CO_2 . Above this temperature all undissolved H_2S is in the gas phase. Large quantities of both CO_2 and H_2S gas are thermochemically generated at temperatures greater than 120°–140°C in mature to overmature source rocks. Peak generation for methane is around 140°C, while H_2S has not yet reached its peak generation at temperatures of 170°C (Figures 9.42c, a). H_2S forms best at temperatures beyond where petroleum geochemists have already lost interest, but its genesis is of great importance in the formation of base and precious metal deposits (Warren, 2000b).

Because of its high reactivity, it is difficult for H₂S to migrate from its source to a distant reservoir (Hunt, 1996). Away from direct contact with deeply buried and reactive anhydrite, H₂S in most oil and gas reservoirs is largely the product of sulphate reduction from sulphate ions in solution or the thermal decomposition of sulphur-containing oil. Interestingly, all the natural gas reservoirs with high thermochemical H₂S contents, listed in Table 9.7, are interbedded with anhydrites, or have anhydrite above or below the reservoir horizon. At its critical temperature of 104°C and a pressure of 14 MPa (2,000 psi), H₂S is forty times more soluble in water than at surface conditions.

Wherever H₂S in solution comes into contact with metalliferous chloride brine it is likely to be involved in a number of metal sulphide forming reactions. Sulphide products range from the cool shallow biogenic precipitation of syngenetic framboidal pyrite to the formation of hot, hydrothermal sulphides, which often also involve dissolution and alteration of the adjacent rock matrix. For example, in a Mississippi Valley type (MVT) scenario, a metal sulphide phase typically coprecipitates with hydrothermal or saddle dolomite in bathyphreatic or vuggy porosity at temperatures in the range of 60 - 180°C (Hill, 1995):

^{9.10} At very low concentrations of less than 10-100 ppm it smells like rotten eggs and there is a common misapprehension that its foul odour is a warning. At 100 ppm the gas kills the sense of smell in 3-15 minutes and will cause you to cough or your eyes to water. Over 100 ppm your eyes and throat may begin to sting. At 200 ppm, your eyes and throat will begin to burn and you will get headaches. Only 600 ppm, or 0.06 of 1% will cause death, if you are not treated very quickly. Over 1,000 ppm causes respiratory paralysis and a sudden agonizing death from asphyxiation.

H₂S is also heavier than air, invisible, highly explosive and can destroy steel and rubber seals very quickly. Modern drill rig floors are all fitted with sniffers.

Region	Reservoir Age	Lithology	Depth (m)	% H ₂ S in total gas

Table 9.7. Regions of natural gas deposits with high H₂S contents. In all these the deposit is stored in a carbonate reservoir that is interbedded with anhydrite, or there is an anhydrite unit above or below the deposit (after Hunt, 1996).

The formation of metal sulphide from hydrogen sulphide generated by TSR can be expressed in the general reaction;

Such reactions create acid, which in turn is capable of forming secondary porosity in a deeply buried limestone host. It is why bathyphreatic vuggy porosity with sphalerite stalactites are found in many MVT ore deposits, such as Cadjebut in Western Australia where these metalliferous dripstones formed in methane-rich bathyphreatic vugs and pores (Figure 7.51; Warren and Kempton, 1997).

When considering the association of sulphate evaporites with mineralisation it is important to realise that it is not the sulphate evaporites that are directly responsible for the precipitation of metal sulphides during sulphate reduction (Warren 2000b). Rather, evaporite dissolution or reaction places sulphate/sulphide in a fluid medium so that it can react with liquid or gaseous hydrocarbons. It is this sulphate-entraining solution that is reduced in the presence of organic matter or hydrocarbons

to form H_2S . And it is the H_2S in solution that then precipitates the metal sulphides at or near a redox interface, which is a zone where slightly more oxidised metalliferous chloride brines can interact with a H_2S buildup on the reduced side of the interface.

Thus, ore textures in areas where sulphate evaporites are dissolving and metal sulphides are precipitating are most likely to be open space or porosity-fill textures. Ore textures and the degree of layering will depend on a number of factors including: the size of the dissolution front (interpore versus laminar versus vug versus solution-collapse cavern), the rate of fluid crossflow at the interface, the degree of stability of the redox interface, and the distance the sulphate ion travels before it is reduced (Warren and Kempton, 1997). Precipitation of the metal sulphides may occur directly across from a dissolving sulphate evaporite where it is producing H_2S on the other side of a fluid-filled interface. Or it may occur after H_2S derived from TSR has seeped and migrated into a closed structure (aka prepared ground) higher in the sedimentary succession.

When H_2S accumulates at an interface where oxygen is present and large volumes of metalliferous brines are absent, it can form accumulations of native sulphur, rather than metal sulphides, via the reactions:

Elemental sulphur can form and persist near a redox interface where $\text{Eh} \approx -0.2$ to $+0.2$. This is thought to be the mechanism that generated the economic evaporite-associated sulphur deposits in hydrocarbon leakage haloes within the Gulf of Mexico diapir caprocks and the stratiform sulphur of Culberson Co. west Texas (Figure 11.59). The presence of abundant free sulphur (S°) in peridiapiric Pb-Zn deposits such as Bou Grine is used by some workers to argue that in such situations the supply of metals to a sulphate/sulphide reduced environment was the reaction-limiting step (Bechtel et al., 1996).

Sulphur sourced from TSR in the deep subsurface may not all be consumed by the reaction of methane and water, especially where metalliferous fluids are not present in sufficient quantities to form metal sulphides. However, as sulphur melts at temperatures between 113° and 120°C , any such sulphur formed during TSR (requires temperature $> 140^\circ\text{C}$) will be molten. Such sulphur occurrences typically occur in deep stratigraphic zones dominated by carbonate and calcium sulphate lithologies

(Hunt, 1996). For example, molten sulphur was recovered from a depth of 6,098 m (20,000 ft) in the Jurassic Smackover carbonate-evaporite sequence in southern Mississippi on the US Gulf Coast. It was also recovered from the Cambro-Ordovician Arbuckle limestone-dolomite at a depth of 9,586 m (31,441 ft) in the Bertha-Rogers well in the Anadarko Basin, Oklahoma. Wells in the Permian Zechstein dolomites in western Germany have recovered molten sulphur from depths between 3,000 and 4,300 m (10,000 - 14,000 ft).

Elemental sulphur reacts with H_2S to form polysulphides, which are powerful oxidants that quickly convert any saturated hydrocarbons to thiopenes, thiols and sulphides (Hunt, 1996). This reactivity means that all the hydrocarbons from pentane, through butane, propane, ethane and finally methane are oxidised to CO_2 at elevated temperatures in the presence of H_2S . Hence, it is no surprise that whenever molten sulphur is recovered on a drillstem test, no appreciable amounts of methane or the higher hydrocarbons are present.

Importance of mesohaline organics and sulphate reduction in stratiform base metal ores

In order to illustrate the commonplace association between mesohaline organics, bedded evaporites and stratiform base metal mineralisation we shall consider only one such style - the giant Lubin copper deposit of Poland. It is an example of a basinal subsalt bedded setting in what is a widespread diagenetic association of base metals and evaporites. But it is only part of the much broader evaporite-base metal-salt allochthon association, which controls the occurrence of many significant base metal deposits through time. The interested reader is referred to Warren (2000b) for a more detailed discussion of this topic.

Sulphate reduction in the Permian basal Zechstein sediments has focused the deposition of large quantities of Cu, Pb and Zn ores in Kupferschiefer-style deposits in Poland and smaller scale deposits in Germany. The Kupferschiefer mining districts of southwestern Poland (Cu deposits of the Fore-Sudetic Monocline and the North Sudetic Trough) are ranked among the largest productive Cu deposits of the world (Bechtel et al., 2002). For example, the Lubin deposit in Poland has estimated ore reserves of 2600 Mt at grades $>2\%$ Cu, 30–80 g Ag/t, and 0.1 g Au/t (Kirkham 1989). Annual production of the district in 1999 was 520,000 t Cu, 1351 t Ag, and 13,800 t crude lead. Additional metals recovered include 66 t technical selenium, 1722 t Ni sulphate, approx. 490 kg Au, 30 kg Pt, 15 kg Pd and, depending on the price, As, Re, and Zn. Economic reserves con-

Deposit, Location (Age of Host)	Reserve (10 ⁶ tonnes)	Cu (%)	Pb (%)	Zn (%)	Evaporite Role	Evaporite Association
BEDDED OR STRATABOUND DEPOSITS						
Kupferschiefer-style, Lubin, Poland (Permian)	≈2,000	>2	-	-	Subsalt, stratiform with brine focus creating the Rote Faule contact and adjacent redox precipitates	Anhydrite and halite in Zechstein hangingwall and anhydrite in Rotliegende footwall
Kupferschiefer-style, Mansfeld, Germany (Permian)	≈7.5	≈2.9	-	±1.8	Subsalt, stratiform with brine focus	Anhydrite and halite in Zechstein hangingwall and anhydrite in Rotliegende footwall
Redstone River, Canada (Neoproterozoic)	small	2.7	-	-	Intrasalt stratabound with subsalt focus to upwelling brine	Algal limestone host with abundant nodular CaSO ₄
Creta, Oklahoma, USA (Permian)	1.9	2	-	-	Intrasalt bedded (breccia), adjacent redox precipitates	Redbed - evaporitic mudflat host with abundant nodular CaSO ₄
Corocoro, Bolivia (Tertiary)	≥7	≈5	-	-	Intrasalt bedded (breccia), brine reductant	Redbed - greenbed host with gypsum and baryte in veinlets and disseminated nodules
Gays River, Nova Scotia (Carboniferous)	2.4	-	8.6	6.3	Subsalt with subsalt focus to upwelling brine. Local supplier of sulphur via TSR	Anhydrite both within main ore zone and as cement in disseminated ore
Nanisivik, Baffin Island (Proterozoic)	6.5	-	1.5	12	Intrasalt?, bedded	Host is a stratiform karst cavern: evaporites and pseudomorphs in lateral equivalent beds
San Vicente, Peru (Triassic - Jurassic)	12	-	1	12	Intrasalt, bedded. Local supplier of sulphur via TSR	Ore hosted in cryptalgal laminites with pseudomorphs after CaSO ₄ in barrier-lagoon host
Cadjebut, NW Australia (Devonian)	3.8	-	17% (Pb+Zn)		Intrasalt, bedded (breccia). Local supplier of sulphur via TSR	Bedded anhydrite as lateral equivalent to each ore lense and linked by evaporite dissolution breccias
Largentière, France (Triassic)	9.6	-	0.7	3.7	Intrasalt	Disseminated CaSO ₄ cements and nodules within evaporitic lagoonal beds
ALLOCHTHON-ASSOCIATED DEPOSITS						
Atlantis II Deep, Red Sea (Holocene)	150-200	0.8	yes	5-6	Suprasalt allochthon acts as focus to resurging Cu-Zn-Cl brine (salt partially covers ridge basalts)	Dissolving allochthon underbelly supplies Cl-rich metalliferous brine to deep seafloor brine lake. Hydrothermal anhydrite is interbedded with laminites
Dzhezkazgan, Kazakhstan (Carboniferous)	≈400	1.5	0.1-1.0	-	Suprasalt diapiric, anticlinal focus to brine flow	Interbedded redbed and greybed host with CaSO ₄ and halite in underlying salt anticline and lateral equivalents
Dongchuan deposits, China (Mesoproterozoic)	10-100	1.0-1.5	-	-	Suprasalt allochthon or intrasalt breccia. Allochthon acts as focus to resurging metalliferous brine	Stratabound ore in cryptalgal laminites adjacent to diapiric breccia
Lisbon Valley, Utah, USA (Cretaceous)	small >0.15	1.4	-	-	Suprasalt allochthon, salt movement creates ore-hosting faults in overburden	Ore in vein and pore fills adjacent to faults created by halokinesis
Jubilee, Nova Scotia (Carboniferous)	Not economic	n/a	n/a	n/a	Subsalt allochthon (tectonic breccia) stratiform, subsalt focus to brine flow	Interstratified fractured carbonate and anhydrite ore host created by regional salt-induced gravity slide
Bou Grine, Tunisia	7.3	-	2.4	9.7	Suprasalt, peridiapiric, brine focus via halokinesis	Ore in peridiapiric organic-rich pyritic laminates adjacent to halite allochthons
Gulf Coast USA (Tertiary)	Not economic	n/a	n/a	n/a	Suprasalt allochthon capstone, brine focus via halokinesis	Anhydritic caprock undergoing bacteriogenic alteration in association with reservoired hydrocarbons

Table 9.8. Some of the many base-metal deposits formed in the diagenetic realm in association with bedded, dissolving and flowing evaporites (after Warren, 2000b).

sist of 31 million t Cu and 81,000 t Ag. The average content of the reduced Cu–Ag ore is 2.1% Cu, 59 ppm Ag, 550–2000 ppm Pb, 33–71 ppm Ni, 20–140 ppm Co, 25–84 ppm Mo, 56–242 ppm V, 20–60 ppb Au, 11–15 ppb Pt, and 10 ppb Pd.

Some mineralisation in the Kupferschiefer was early and associated with bacterial sulphate reduction (especially in the

Kupferschiefer itself, as indicated by syndeositional framboidal pyrite) but much of the economic Cu mineralisation is later. It is a burial diagenetic product, typically precipitated at a redox front created at an interface between dissolving Zechstein evaporites and upwelling basinal waters (metalliferous chloride brines). Mineralisation occurred in an association of evaporite-capped beds at the top of a thick continental volcanic

and redbed sequence, which were deposited atop a Permian continental rift basin passing up into sag filled with basinwide evaporites (Figure 9.46a).

Stratabound Cu–Ag Kupferschiefer deposits were long considered classic examples of syngenetic mineralisation driven by bacterial sulphate reduction (e. g. Wedepohl, 1964). However, detailed work in Poland in the last two decades has shown that the Cu mineralisation cuts depositional boundaries. Richest intervals of mineralisation define low-angle transgressive metal zones associated with the redox edge of diagenetic Rote Faule units (Figure 9.46b; Jowett et al. 1987; Jowett 1992; Oszczepalski, 1994; Large and Gize 1996).

Rote Faule (literally ‘red rot’) actually describes a nonmineralised burial diagenetic zone and loosely encompasses any barren red-coloured rocks typically found near high-grade ore. It is defined by various types of red colour created by the diagenetic formation of disseminated authigenic haematite and goethite in an oxidised haematitic interval adjacent to reduced highly-mineralised intervals. Pyrite and the original organics of the Zechstein carbonate and the Kupferschiefer mudstones, are oxidised and largely removed in Rote Faule intervals (Oszczepalski 1989; Bechtel et al., 2002). The isotopic and organic signatures in its diagenetic precipitates indicate mother fluids fed by deep basin circulation (Bechtel et al., 2002). Rote Faule is not formation specific and occurs in the Weissliegende, Kupferschiefer and Zechsteinkalk strata (Figure 9.46b, c).

Ore sulphides in the Kupferschiefer were largely precipitated in zones where H_2S , carried by brines flushing the TSR zone along the dissolving underside of the Zechstein evaporites, mixed with the rising metalliferous waters. That is, the Rote Faule indicates redox interfaces where ascending slightly-oxidising chloride-rich basinal brines, which carried Cu, Pb and Zn, mixed with dissolution-fed brines carrying TSR-derived H_2S . Base metal precipitation occurred on the far side of subhorizontal oxidation–reduction front indicated by the edge of the Rote Faule.

Sulphides are arranged in three distinct haloes around ‘Rote Faule’, in the order Cu, Pb and Zn (Figure 9.46b, c). Thus, around and above the Rote Faule, the base metals are zoned laterally and vertically in successive mineralisation belts of chalcocite, bornite, chalcopyrite, galena and sphalerite. The overlying evaporitic Zechstein sediments enhanced and focused the precipitation of Cu, both by forming prepared ground at the time of deposition (pyritic and organic-rich

evaporitic laminite host) and during diagenesis by creating a stable dissolution hydrology, which held back hydrocarbons and through dissolution of the Werra Anhydrite Fm. created H_2S by thermochemical sulphate reduction. The thickness of the basinwide evaporites of the Zechstein meant the dissolution front was a stable subsurface interface that focused the large volumes of economic mineralisation into a redox zone immediately adjacent to the Rote Faule boundary.

Levels of mineralisation in the Kupferschiefer adjacent to a Rote Faule interval are typically far higher than background levels in the Kupferschiefer shale (Figure 9.46c). Mineralisation transgresses depositional boundaries as it is tied to the Rote Faule/saline brine interface and not to the depositional pattern and distribution of the Kupferschiefer shale. Thus copper ore is not just hosted in the organic laminites of the Kupferschiefer and the Zechsteinkalk, it also occurs in parts of the Weissliegende aeolian sandstone, a unit that at the time of deposition was exceptionally free of organics, laminites and pre-ore sulphides (Figure 9.46c). To the dismay of many syngeneticists, this positionally clean aeolian sandstone hosts half the economic Cu-sulphides in the Lubin district.

Methane was likely an ephemeral component in the Weissliegende sands, as was authigenic anhydrite cement. Jowett (1992) demonstrated that the widespread sparry anhydrite cements in the Weissliegende at Lubin, along with the trapped methane beneath the evaporite seal, set up burial chemistries suitable for thermochemical sulphate reduction and the precipitation of Cu-sulphides in the Weissliegende host. As well as acting as a seal to the methane, the overlying Zechstein evaporites were also a likely source for the anhydrite burial cements. Clearly, Cu, Pb and Zn mineralization at Lubin is a basinal pore water process, not directly tied to the occurrence of organics or pyrite in the Kupferschiefer. Rather, mineralisation occurred wherever hydrocarbons or organics came into contact with calcium sulphate and thermochemical H_2S was formed. Either the hydrocarbons or the sulphate-forming H_2S could arrive at the mineralisation site in solution. Metals other than the original framboidal pyrite present at the mineralization site were carried in by the basinal waters ascending through the thick underlying redbeds.

Geometries of mineralisation suggest that the dissolving underside of the Zechstein sediment pile acted as a long-term fluid focus and seal; it maintained an ongoing interface with upwelling metal-rich slightly oxidising chloride-rich basinal waters and could be located either in the mesohaline Kupferschiefer or its lateral equivalents in the Weissliegende. Tight Zechstein salts also created a pressure seal that aided hydrofracturing in the

maturing organic laminates of the Kupferschiefer, as evidenced by numerous sulphide–calcite veinlets in the Kupferschiefer. An inherent lack of permeability in widespread thick evaporites also meant the upper side of the Zechstein salt beds prevented downward percolation of fresh oxygenated waters, which would otherwise have destroyed the stability of the redox front at the edge of the Rote Faule.

Mineralisation at Lubin underlines the longterm impervious nature of any thick evaporite unit and its underlying salt-plugged halo, even as it dissolves in the subsurface. It means that until

it is breached its underside is an excellent seal to migrating hydrocarbons (both liquid and gaseous). Thus the organics required for the sulphate reduction process may not only be locally derived from organic-rich sediments, they may have seeped and flowed into the subsalt interval as a hydrocarbon charge trapped directly beneath the evaporite seal. The requirement for organics in the sulphate reduction process and the ability of evaporite beds to act as a seal explains, at least in part, the ubiquitous worldwide association of evaporites, hydrocarbons/ organic matter, and diagenetically created (TSR) base metal deposits. Put simply, bedded sulphate salt beds, chloride-rich

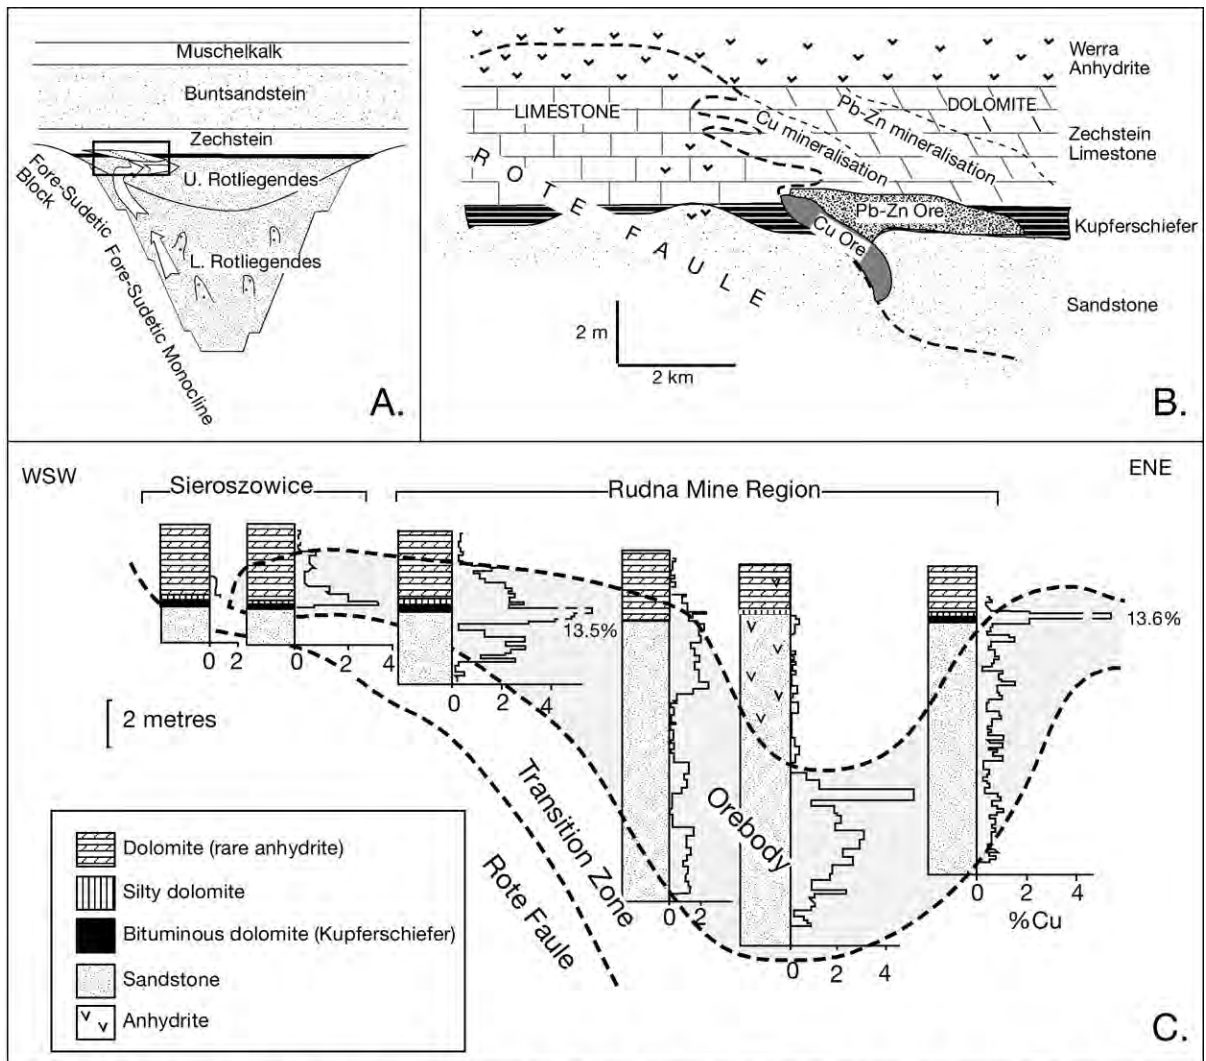

Figure 9.46. Rote Faule and its relation to the Kupferschiefer (after Warren, 2000b and references therein). A) Regional cross-section showing the focusing of the upwelling basinal water beneath the Zechstein evaporites. B) Enlargement of region of Rote Faule [see box in (A)] showing how the mineralisation and its zonation is tied to the Rote Faule not the Kupferschiefer. C) Distribution of Cu in the ore zone showing higher Cu enrichment (≈13%) in the Kupferschiefer, but by far the greater volume of ore resides in the sandstones beneath the Zechstein evaporite seal.

Figure 9.47. Model of salt-allochthon-controlled base-metal (sedex) accumulations. Note the importance of the subsalt lithologies in controlling the mineralogy of the precipitates. Cu is not easily transported too far from its source beds whereas Pb-Zn can be carried much further. The volume of sediment being leached of its metals beneath the focusing salt unit is controlled by the continuity of the salt bed. Also listed are various Cu and Pb-Zn deposits associated with bedded evaporites (after Warren, 2000b).

salt beds, autochthons and allochthons are transient features in most sedimentary basins that through dissolution and flow can dissolve, focus and fix base metals.

This is so not just for base metals associated with bedded platform sulphates, but also for deposits in halokinetic basins (Table 9.8). In Chapter 8 we saw that upward escape of chloride-rich metalliferous basinal brines is typically focused along the underside of thick basinwide evaporite units. Deeply circulating metalliferous subsalt brines typically escape into overlying strata at breach points in the salt body. Such breach points may be the feather-edge of the evaporite bed or extensional faults that cross-cut the flowing and deforming salt body or zones of halokinetic touchdown. Some of these faults may be induced by the basinward flow of salt; others may be large regional basin-defining structures. Any calcium sulphate bed, or an evaporitic carbonate bed rich in mesohaline organics, can act as a supplier of reductants to fix base metals carried by the escaping metal-rich chloride brines (created deep in the basin by halite dissolution). Mineralised redox fronts can occur in subsalt, intrasalt and suprasalt positions and in both bedded and allochthonous salt associations (Figure 9.47).

In all these evaporite-associated low-temperature diagenetic ore deposits there are four common factors that can be used to recognise suitably prepared ground and so improve the ability of an exploration model to predict likely sites of ore occurrence within a basin (Warren, 2000b): (i) a dissolving evaporite bed acts either as a supplier of chloride-rich basinal brines capable of leaching metals, or as a supplier of sulphur and organics that can fix metals; (ii) where the dissolving bed is acting as a supplier of chloride-rich brines, there is a suitable nearby source of metals that can be leached by these basinal brines (redbeds, thick shales, volcanoclastics, basalts); (iii) there is a stable redox interface where these metalliferous chloride-rich waters mix with anoxic waters within a pore-fluid environment that is rich in organics and sulphate/sulphide/H₂S; and (iv) there is a salt-induced focusing mechanism that allows for a stable, long-term maintenance of the redox front, e.g. the underbelly of the salt bed (subsalt deposits), a dissolution or halokinetically maintained fault activity, the overburden (suprasalt deposits), a stratabound intrabed evaporite dissolution front (intrasalt deposits).

Metal sulphide ores formed by TSR and BSR fixation can have near identical textures, both are typically pore or vug-filling cements or evaporite replacements (Machel et al., 1995). One way to help differentiate the origin of the precursor H_2S is via sulphur isotope analysis of ore sulphides that, if possible, is tied to $\delta^{13}C$ and $\delta^{18}O$ analysis of the various gangue carbonate cements and matrix signatures that bracket the ore minerals. H_2S derived via bacterially mediated sulphate reduction tends to be isotopically light and so tends to exhibit more negative δ values (Figure 9.48). This is true of both the sulphur in the sulphides and of the carbon in any late stage dolomite or calcite cements. Unlike carbon and sulphur isotopes, oxygen is more thermally sensitive below $200^\circ C$ and is better used as a geothermometer (Emery and Robinson, 1993).

For example, isotopic values of bacterially reduced sulphide in subsurface waters of the Permian Basin west Texas, is typically in the range -32 to 0 ‰ on the CDT scale. These values are significantly lower than the isotopic composition of sulphate from Permian marine sulphate evaporite, which lie in the range $+9.6$ to $+13$ ‰ (Figure 2.23a). Reoxidation of sulphide to sulphate or sulphur by oxygen in the fluid mixing zones does not cause significant fractionation. Lighter isotopic values in modern cave sulphur in Guadalupe Mountain caves ($\delta^{34}S_{CDT} = -25.8$ to -20 ‰) and in the Culberson mine (-4.7 ‰) indicate bacterial sulphate reduction reactions, rather than abiogenic precipitates (Figure 7.48; Hill, 1995). A hydrocarbon source is indicated by the light carbon isotope character of associated biogenic calcite in the Culberson mine ($\delta^{13}C_{PDB} = -44.2$ to -18.6 ‰; Hill, 1995). The depleted $\delta^{13}C$ values are significantly lower than would be expected in marine carbonates, which normally fall in the range of -4 to $+4$ ‰. The scatter in the data could arise from mixing in varying proportion of fluids. More depleted values (less than -30 ‰) probably reflect oxidation of source hydrocarbons, whereas the heavier ^{13}C was perhaps derived from isotopically heavier fluids of the deep basin.

H_2S from thermochemical reduction is not biologically fractionated, and so $\delta^{34}S$ values of the ore sulphide tend to reflect the isotopic signature of its evaporite precursor (Worden et al., 1997). Limited experimental work on deeply buried anhydrite undergoing thermochemical reduction suggests

that the sulphur isotopic composition of the derived H_2S is isotopically similar to, or a few per mille lighter than, the precursor anhydrite (Krouse et al., 1988). Thus $\delta^{34}S$ and $\delta^{13}C$ values under TSR are much higher (more positive) than its BSR equivalent, while the $\delta^{18}O$ reflects elevated temperatures of late stage diagenetic spar formation (more negative).

But this isotopic distinction between bacterial and thermochemical sources is not as clear cut as it first appears; sulphur need not have come from the reduction of evaporitic sulphate, it may also come from organically derived sulphur in oil trapped in the host rock. Under this scenario the sulphur has low $\delta^{34}S$ values, similar to any associated hydrocarbons (Kesler et al., 1994). The range of values for these hydrocarbon systems is similar to that from bacterially mediated sulphate reduction. This overlap underlines the need for matrix characterisation, which ties stable isotope determinations to detailed petrographic and sedimentological understanding of the ore host. For example, if the ore sulphur was locally sourced, then calcite may have replaced the precursor anhydrite. This calcite should be sampled for carbon and oxygen isotope analyses to see if its genesis parallels that of any ore sulphides. In addition, even though sulphate salts no longer remain, the “salt that was” textures should still be present.

Hydrothermal cracking in saline rift lakes

Not all the hydrocarbons found in evaporitic sediments have necessarily evolved from millions of years of kerogen burial into depths where temperatures exceed $60^\circ C$. In some evaporitic situations the heating and evolution is much more rapid, driven

Figure 9.48. Typical ranges of naturally occurring sulphur isotopes under thermochemical and bacterial sulphate reduction (after Emery and Robinson, 1993).

by the near surface circulation of hydrothermal waters. Such heating may be commonplace in evaporite accumulating areas where the evaporite depression was tectonically induced. Hence, hydrothermal hydrocarbons may be an integral part of source rock evolution of the early brackish to mesohaline lacustrine fill of evaporite-sealed rift successions, with organics typically accumulating on the bottom of density/salinity stratified lakes (Tiercelin et al., 1993).

One such example is the oil seeping onto the lake floor off Cape Kalamba in Lake Tanganyika at the south end of the Ubwari Peninsula (Simoneit et al., 2000). The area lies at the intersection of faults controlling the morphology of the northern basin of the Tanganyika Rift. Oil samples collected at the surface of the lake 3-4 km offshore from Cape Kalamba lack typical suites of polynuclear aromatic hydrocarbons. This indicates an origin via hydrothermal alteration of immature biomass in the organic-rich mesohaline sediments of the lake bottom. Based on the constituents of the modern bottom sediments, the prime producers were diatoms and cyanobacteria, which constitute most of the 6% TOC that is found in sediments on the modern deep lake floor. Compositions of the oils and nearby tar balls demonstrate a $<200^{\circ}\text{C}$ temperature during formation/generation, similar to the fluid temperatures identified at the Pemba

hydrothermal site some 150 km north of Cape Kalamba. Hydrothermal petroleum generation seems to have occurred in the lake depression slightly before 25 Ka, during a drier climatic environment when the lake level was lower than today. Hydrothermal smokers or chimneys also occur on the subaqueous floor of the Lake Tanganyika (Barrat et al., 2000). It may well be that the deposition of any future overlying evaporite seal in this underfilled lacustrine situation may focus the flow of micropetroleum into more appropriate landward sands, but ancient economic lacustrine counterparts of this style of hydrothermal oil have yet to be documented.

Not all hydrothermally-cracked oil is found in rift-valley fills or is associated with sedimentary CaSO_4 . More impressive in terms of hydrocarbon volumes and origins are the oils forming in the hydrothermally-flushed deepwater sediments on floor of the Guaymas Basin in the Gulf of California (Figure 9.49a). Radiocarbon dates show this oil forms in association with thermochemical sulphate reduction in less than 5,000 years (Didyk and Simoneit, 1989; Peter and Scott, 1991). But unlike the rift association of east Africa, the anhydrite in this hydrocarbon system is hydrothermal and is created by the convective heating of seawater (retrograde solubility). The isotope signatures of the anhydrite, as well as the hydrothermal baryte

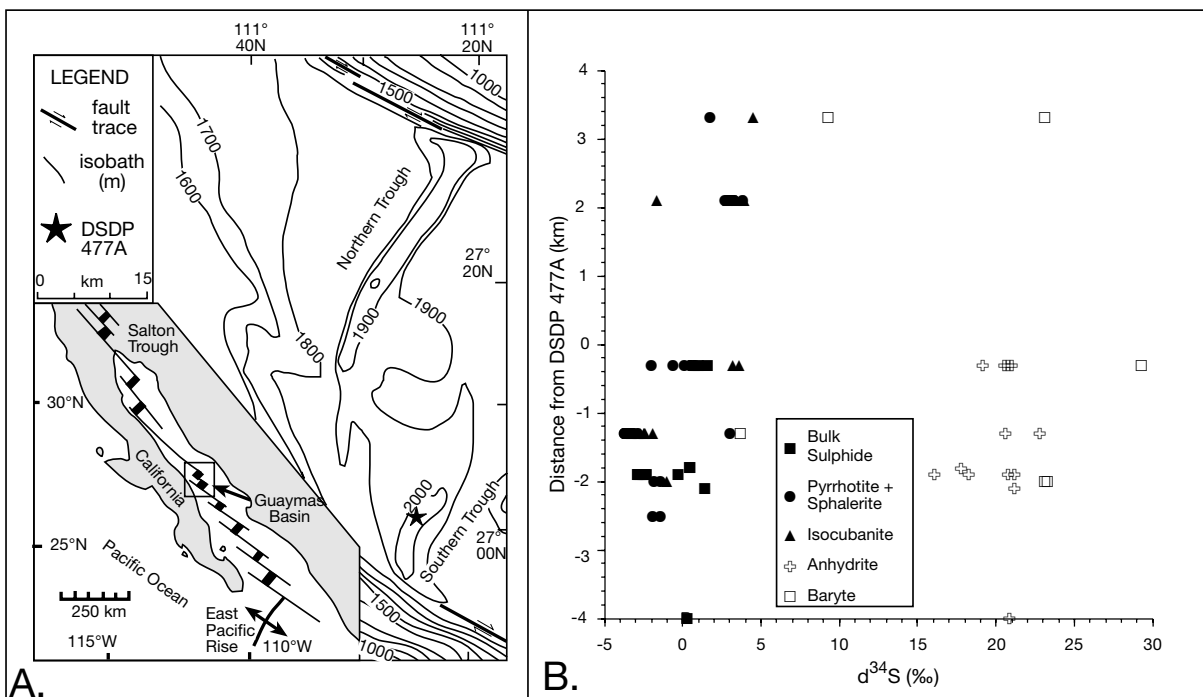

Figure 9.49. Guaymas Basin. A) Location of DSDP drill hole 477A. B) Sulphur isotopes from hydrothermal anhydrite and baryte and various sulphide phases in seafloor samples from the Southern Trough in the vicinity of DSDP 477A (replotted from isotope data in Peter and Shanks, 1992).

and metal sulphide phases show sulphur signatures reflecting their genesis from hydrothermally heated seawater. Notably, the sulphur isotope field of this hydrothermal anhydrite is the same as that of modern evaporitic anhydrite and gypsum (Figure 9.48 c.f. 9.49b).

Although the evidence is clear for hydrothermally-cracked hydrocarbons migrating through sediments at active spreading centres, the inherent association with active faulting and tectonism in modern ocean spreading centres means most hydrocarbon product is lost to the overlying seawater column through a lack of appropriate long-term traps and seals (Kvenvolden and Simoneit, 1990). Perhaps such systems are more likely to trap oils in areas where there is a fortuitous association between hydrothermal circulation and downdip end of salt allochthons flowing basinward across the deep seafloor, as in some parts of the Red Sea troughs.

At the older end of this hydrothermally-cracked oil spectrum are oil remnants in the 3.2 Ga Early Archaean deep-sea volcanogenic massive sulphide deposits of northwest Australia (Rasmussen and Buick, 2000). Archean seawater lacked sufficient sulphate or Ca to form anhydrite. There the oil was preserved in fluid inclusions within hydrothermal baryte, and as pyrobitumens intergrown with polymetallic sulphides. Petrographic textures show that the oil was emplaced and thermally altered (cooked) before late-stage sulphide mineralization. Its presence implies subseafloor hydrothermal petroleum generation was active during the Early Archaean, possibly providing an energy and carbon source for a subsurface microbiota that was metabolizing hydrothermal sulphur species.

Summary

Source rocks accumulate beneath density-stratified saline water and sediment columns in evaporitic settings with layered hydrologies subject to oscillations in salinity and brine level (Figure 9.3). Saline-associated organic matter is not produced at a constant rate. Rather, it is produced as pulses by a halotolerant community responding to relatively short times when less stressful near- or at-surface conditions prevailed in the layered hydrology (Figure 9.50). This happens in any layered brine lake or epeiric seaway when an upper less saline water mass forms atop nutrient-rich brines or in wet mudflats when pore waters freshen in and atop the uppermost few millimetres of a microbial mat.

The resulting bloom (a time of “feasting”) by halotolerant algal, bacterial and archaeal photosynthesizers is a time of exponential growth characterized by very high levels of organic productivity (Figure 9.50). In mesohaline waters where light penetrates to the bottom, the organic-producing layer is typically the upper algal and bacterial portion of a benthic laminated microbialite (typically characterized by elevated numbers of cyanobacteria). In stratified brine columns (oligotrophic and meromictic) the typical producers are planktonic algal or cyanobacterial communities inhabiting the upper water mass. Halotolerant autotrophic microbial communities, living off the remains of this plankton, float mid-water at the halocline of the density-stratified brine columns. Similar communities of aerobic and anaerobic biodegraders also constitute the living layers below the mm-thick primary producing layers of benthic microbialites beneath oxygenated bottom waters.

Short pulses of extremely high productivity in turn create a high volume of organic detritus settling through the water column and/or building up in benthic microbial mats. Then, with the end of the freshening event, the ongoing intense aridity that characterizes all evaporitic depressions means salinities, temperatures and osmotic stresses increase rapidly in the previously freshened water mass, first leading to a slowing of growth, followed by a time of mass die-off in the once flourishing community (“famine;” Figure 9.50). These increasingly salty surface waters can at first no longer support haloxene forms. Then halotolerant life dies back and finally, by the halite pre-

Figure 9.50. Typical growth curve as a population expands into a vacant ecological niche. In a layered brine system it is created by the freshened surface water and ends with holomixis.

cipitation stage, only a few halophilic Archaea remain (typically acting as heterotrophs and fermenters).

The pulses of organic matter created during a freshening event create a laminated bottom sediment. Hydrogen-rich algal and bacterial debris is best preserved within sediments where pore waters are anoxic and remain so until this kerogen is sufficiently buried to generate liquid and gaseous hydrocarbons. Increasing rates of mineral precipitation at higher salinities means levels of hydrogen-prone organics are highest in sediments deposited in schizohaline waters that remain in the mesohaline field. Once ambient salinities pass into the penesaline and supersaline, the proportion of organics accumulating in the bottom sediment becomes insignificant as it is overwhelmed by the large volumes of gypsum and halite reaching or accumulating on the bottom (or trona and glauberite in some continental penesaline/supersaline waters).

Feast and famine is a response of the biota to environmental conditions that are first eminently suitable and then increasingly adverse (Figure 9.51). It is a biological response to rapid niche creation and expansion as the freshened water layer sets up in the evaporitic depression. This creates a vacant ecological niche in to which microbial life rapidly expands, flourishes and then once more dies back as drying or brine concentration shrinks suitable niche space. Longterm stability in any ecosystem leads to domination by “specialist” species that are well adapted, diverse and efficient in terms of energy flow-nutrient utilisation. This biodiverse community takes up and recycles carbon very efficiently through the system and the potential for large volumes of carbon passing into the burial realm is low and hence source potential is also low (a good

example is a tropical coralgal reef). In contrast a schizohaline system is one defined by high habitat instability, a lack of habitat permanence that encourages opportunistic lifestyles (cycles of “feast or famine”). Opportunists expand rapidly into any suitable niche space, but then just as quickly die back as conditions become adverse. Such systems are characterised by high biomass pulses and low species diversity leading to pulses of organics accumulating in the evaporitic depression, with the remains likely to be buried and “pickled” beneath anoxic bottom brines and pore waters, giving such systems a higher source rock potential (Figure 9.51).

Some hypersaline settings are intermediates in that their waters are constantly hypersaline, stressful to most life but suitable to a few well adapted species. These are usually populated by a few very specialized species (e.g. “high-salt-in” halophiles) that can survive and flourish in conditions where most life dies. They photosynthesise and metabolise successfully in these hypersaline conditions (often for example living near haloclines), but do so at rates that are much slower than the growth rates attained by “opportunists” at times of “feast.” Even though heterotrophic, these well-adapted halophiles cannot ingest all the debris raining down on them at times of feasting in the waters above.

Once we attempt to take our understanding of microbial community dynamics from modern into ancient saline systems we must also account for changes in both scale and depositional diversity. Put simply, there are no modern same scale analogs for large ancient marine fed evaporite depressions (Figure 5.27). We can show that organic-rich carbonate laminites forming in the African rift valley lakes today have similar counterparts in

Figure 9.51. Schematic summary (‘halomancy’) of the interrelationships between habitat stability, environmental stress or adversity, biodegradation, anoxia and source rock potential in an evaporite basin.

the ancient rift valley source rocks, for example in the Cabinda Basin of Angola and the Mesozoic lacustrine basins of South America (Table 9.1). Likewise, we are in the early stages of documenting ancient counterparts of supra-allochthon brine lakes with anoxic bottoms rich in organics.

But these are small-scale features. There are no modern counterparts for most ancient large-scale evaporite depressions. They required varying combinations of greenhouse eustasy (epeiric seaways) and tectonics-climate in order to create huge subsealevel depressions filling with evaporitic carbonates and salts (marine-seepage rifts, soft collision belts and far-field intracratonic sags). Yet it was in the resulting salinity-layered intraplatform epeiric depressions and restricted basin centres that schizohaline waters and stable longterm brine plumes formed across time scales that allowed evaporite source rocks to accumulate (Figure 9.3 and Table 9.1). As for most ancient evaporite styles, the present is not a suitable time for studying scales of evaporite development, but process and texture can be seen in small-scale Holocene deposits.

Chapter 10: Oil and gas associations

Introduction

Worldwide, bedded and allochthonous evaporites are highly effective seals. Even though evaporites constitute less than 2% of the world's sedimentary rocks, one-half of the world's largest oilfields are sealed by evaporites, the other half are sealed by shales (Figure 10.1; Grunau, 1987). Kirkland and Evans (1981) argued that evaporites overlies or seal carbonates containing an estimated 50% of the world's known total petroleum reserve. Of the world's 25 largest oil fields, Grunau (*op. cit.*) found that 17 fields are capped by Mesozoic seals, six by Tertiary seals and only two by Palaeozoic seals. Eleven are situated in the seal depth-interval of 1,000-2,000 m; ten are in the 2,000-3,000 m interval; three in the 0-1,000 m interval; and one at a depth greater than 3,000 m.

Of the world's 25 largest gas fields, nine are sealed by evaporites and sixteen by shales and hydrates. Sixteen are capped by Mesozoic seals, 7 by Palaeozoic seals, and only two by Tertiary seals. Fourteen are in the 1,000-2,000 seal-depth interval, nine in the 2,000-3,000 m interval; and two in the 0-1,000 m interval. As one would expect, more gas fields than oilfields

are sealed by Palaeozoic caprocks, and more oilfields than gas fields by Tertiary caprocks. Surprisingly, the seal depth intervals for the 25 largest oil and gas fields do not differ significantly. However, Grunau argues many "supergiant" gas accumulations below depths of 3,000 metres have either not yet been discovered, or have not yet been put in production (e.g. much of the Khuff gas in North Dome in the Middle East).

The exemplary ability of evaporites to act as seals holding back large hydrocarbon columns is clearly seen in the Middle East, where Ghawar, the world's largest oil field, is sealed by bedded evaporites of the Arab Formation and the overlying Hith Anhydrite seal. This seal holds back an estimated remaining reserve of more than 100-200 billion barrels. Evaporites also seal Safaniya the world's largest offshore field, also in Saudi Arabia, with estimated reserves of more than 25-30 billion barrels of oil and 5 billion cubic feet of natural gas. Likewise evaporites are the seal to North Field in offshore Qatar, the world's largest single gas field (non-associated gas) with more than 500 tcf of reserves (Alsharhan and Nairn, 1997). This gas is reservoir and sealed in the evaporitic dolomites of the

Figure 10.1. Seal type and ultimate recoverable reserves in 25 of the world's largest oil and gas fields (in part after Grunau, 1987).

		Effect of evaporite on nearby reservoir		Effect of seal itself	
		Depositional	Subsurface/diagenetic	Depositional	Subsurface/diagenetic
Bedded salt	Suprasalt	Presence of brine, either from salt dissolution or deposition of nearby salt can prevent accumulation of carbonates or siliciclastics containing a normal marine biota.	Solution of bedded salt creates collapse sinks and fronts that can enhance deposition of porous sediments or encourage collapse fracturing in overlying beds	Not applicable	Dissolution of salt creates a dense brine plume that aids in the formation of hydrodynamic traps
	Intrasalt		Solution of surrounding salt creates fractured and brecciated intrasalt beds that can stack into porous solution breccias	Not applicable	Permeable intervals are encased in bedded salt
	Subsalt	Evaporite bed acts as a source of Mg-rich brine that improves permeability of underlying or adjacent bed (creation of mouldic porosity and brine reflux dolomite)		Evaporite bed acts as top seal and/or lateral seal to reservoir (well documented)	Evaporite bed acts as a source of saturated brine for cement plugging of underlying or adjacent unit
Halokinetic	Suprasalt	Shallow halokinetic salt focuses the deposition of porous sediment around areas of uplifted seafloor or land surface. Can also influence the formation of slumps and CCD-related sedimentation	Dissolution of the upper salt surface creates a caprock reservoir	Salt flows carries blocks of anhydrite/dolomite and allochthon dissolution creates salt ablation (retreat) breccias	Passage of salt allochthon creates adjacent zones of alteration/cementation that may continue to act as a barrier to fluid flow even when the salt is no longer present (weld)
	Intrasalt	Not applicable	Salt flow can break up, fracture and rotate organic-rich intrasalt beds, allowing them to become self-sourcing reservoirs encased in a halokinetic salt seal	Brecciation of intrasalt bed leads to overpressured blocks within the salt mass	Salt flow allows salt unit to maintain seal integrity
	Subsalt	Not applicable	Brine plume created on the underside of a dissolving salt allochthon can alter underlying beds, which in some situations (eg fluid breakthrough) can enhance permeability of underlying beds via dolomitisation/fracturing	Salt allochthon acts as top seal or lateral seal to reservoir sands (well documented). The ability of salt to maintain seal integrity under both extension and compression is significant	Passage of salt allochthon creates adjacent zones of alteration/cementation that may continue to act as a barrier to fluid flow even when the salt is no longer present (weld)

Table 10.1. Role of evaporites in creating hydrocarbon reservoirs and traps.

Permian Khuff Formation and recent announcements (2003) by the Qatari Government have documented more than 900 tcf of certified non-associated gas in the structure.

According to Klemme (1983) all the supergiant^{10.1} gas fields in the world are overlain directly, or somewhat directly, by laterally extensive evaporite beds or by permafrost carapaces with their attendant gas hydrates. Most of the giant Russian gas fields (mostly in Siberia) have hydrate seals, while those of the Middle East are mostly sealed by evaporites. In 53% of the gas fields that have a net recovery of 3.5 tcf or more, evaporites are either associated with the reservoirs or form the trap (Billo, 1996). All of the giant gas fields in thrust belts have an evaporite seal (Downey, 1984) reflecting salt's ability to maintain seal integrity as it deforms, while underlying sediments fracture into salt-sealed reservoirs. Deforming shallow salt allochthons in

the Gulf of Mexico and elsewhere, not only control the seafloor topography focusing deposition of nearby sand and carbonate buildups, but later can flow over these deposits to create the seal (Figure 6.63). Halokinesis creates both suprasalt and subsalt traps. The presence of an impervious salt bed or allochthon also helps maintain higher than expected porosities and pressures in underlying reservoirs (Figure 8.14).

^{10.1}A giant oil field contains more than 0.5×10^9 barrels of expected ultimate recoverable oil, while a supergiant contains more than 5×10^9 barrels (Fitzgerald, 1980). The equivalent separation between giant and supergiant gas fields is 0.5×10^9 and 5×10^9 BOE, respectively.

BOE is barrels of oil equivalent on a BTU basis; 1 barrel of oil = 5.61 ft^3 , so the respective cutoffs for giant and super giant gas fields are 3 and 30 tcf (trillion cubic feet).

In the gently folded belt in front of the main Zagros deformed zone in Iran and Iraq an intimate association exists between sediment deposition, salt flow and the creation of salt-sealed reservoirs. This foreland basin is an area undergoing compression and syndepositional folding where crests are still growing at the surface (growth folds) and so controlling the distribution and structuration of both reservoir and seal. The same collision system also created the restriction that allowed the Fars-Gasharan seal to precipitate. It is an area with a great deal of potential for future evaporite-associated discoveries, as evidenced by the 1999 discovery of the Azadegan oil field, near Ahwaz in the Zagros Fold Belt of southern Iran. As announced by the NIOC (National Iranian Oil Company) in September 1999 the structure holds a possible 24-26 billion barrels of oil in place over an area of more than 520 km², with something like 5-6 billion barrels of recoverable oil. If the size of the projected field is confirmed by ongoing drilling, it will become one of the world's supergiant fields. To put this level of reserves into some perspective, 26 billion barrels of oil in place is more than the total known reserves in China.

Predicting the position and quality of potential reservoirs in evaporite terranes is difficult without integrating notions of feedback between deposition, diagenesis and structural evolution. Therein lies the difficulty in placing evaporite-associated reservoirs and traps in classic terms of structural, stratigraphic and diagenetic traps. When classifying a field with an evaporite trap, the fact that salt is so mobile, so soluble, and so diagenetically active, separates it from other trap styles in a petroleum system. It means that a salt unit, by its comings and goings, plays ongoing and multiple roles in generating reservoirs and traps from the time of deposition through diagenesis to structuring. Tying the resulting oil and gas field to a static and categoric breakdown is near impossible as salt-induced structuring, diagenesis and deposition are often penecontemporaneous and in a state of intimate feedback.

Over the years, I have come to regard such pigeonholes for salt-associated traps as next to useless in predicting likely positions of hydrocarbons in evaporitic provinces. Rather, as a salt unit is typically the most obvious feature on a seismic section, especially in carbonate terrains, I use a much simpler classification of; "Where's the salt?" At their simplest, evaporite-associated reservoirs all occur adjacent to either bedded or halokinetic salt (or their solution residues; Table 10.1). With bedded or halokinetic salt or solution breccias, there are three possible positions of potential reservoir, namely; subsalt, intrasalt and suprasalt (Figure 10.2). Within a single hydrocarbon fairway there may be reservoirs sitting in more than one position. Where I can, I further classify each reservoir in terms of the relative roles of deposition, diagenesis and structure as controls on the position of the targeted hydrocarbon accumulations.

Consider this, when a seal bed with a vertical permeability of 10⁻⁸ darcies is a mile long on each side and is cut by a single fracture 6 μm wide, then the drainage through that single fracture is equivalent to the total fluid flux through the square mile of

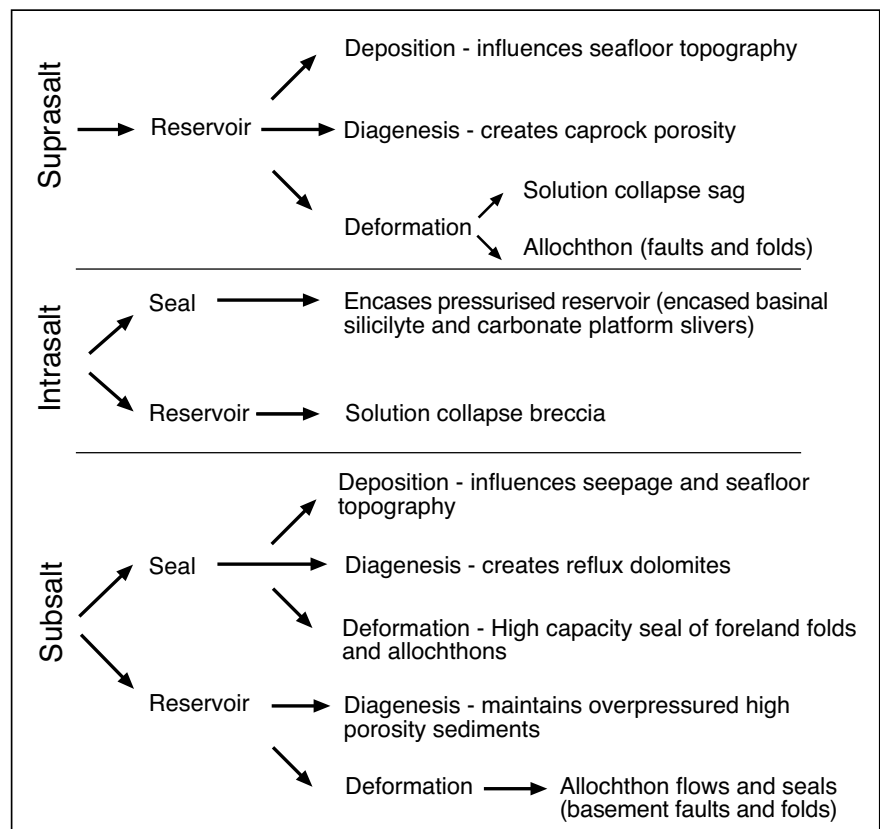

Figure 10.2. Classification of evaporite seals and associated reservoirs relative to the salt body position and the dominant mechanisms.

seal. Downey (1984) calculated that a single fracture 25 μm wide atop a 150 m oil column would leak oil at rate of more than 150 million barrels per million years. Understanding and predicting lateral continuity of both bedded and halokinetic salt seals is an important exploration and development tool.

Continuity of ancient saltern and mudflat seals and their ability to resist fracturing via reannealing means salt beds can gather and constrain subsalt hydrocarbons over large drainage areas. In suprasalt traps, the role of salt in creating reservoirs and traps ranges from stratigraphic seal through diagenetic trap to a creator of structural traps (anticlinal [halokinetic], fault and drape traps). The key factor in assessing the capacity of any seal, including salt, is timing of any microfracturing or fracturing relative to hydrocarbon emplacement in an underlying or adjacent potential reservoir. In other words, does any loss of seal capacity precede or postdate possible storage of hydrocarbons in the reservoir? We shall soon examine a number of examples from various bedded and halokinetic reservoir associations. First, we need to consider why salt units are excellent seals; it's a discussion where salt's inability to maintain ongoing penetrative fractures cannot be overestimated.

Seal capacity of evaporites

In Chapter 9 we saw there is a depositional association between evaporites and some types of organic-rich oil-prone source rocks. In Chapter 6 we saw how salt flows created structures capable of trapping substantial volumes of hydrocarbons. But, of the various reasons for the evaporite-hydrocarbon association (source, trap and seal), the most commonly cited is the efficiency of evaporite layers in holding back substantial hydrocarbon columns for lengthy periods of time, even as adjacent nonevaporite strata fracture and leak. Using a worldwide database of 350 giant oilfields, Macgregor (1996) showed oil pools are dynamic short-lived phenomena, with a median age of 35 Ma. A third of them show evidence for post-entrapment destructive processes, particularly erosion, fault leakage, gas flushing and biodegradation. Biodegradation began in many cases prior to complete filling of the trap. Re-entrapment of oil released from spilling or breached traps was common to all regions. He found the main controls on oilfield preservation to be post-entrapment tectonism and seal type, with temperature and hydrodynamic regimes being secondary factors. He concluded the potential for giant oilfields is greatest in tectonically quiescent basins with evaporite seals. As areas for the best development of this association he cites as the Middle East centred on Saudi Arabia/UAE and the Permian Basin of the

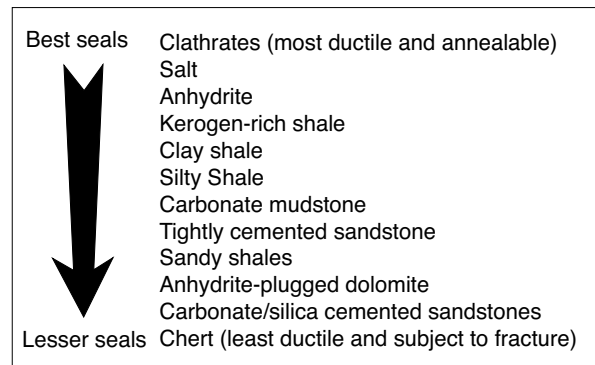

Figure 10.3. Differing ability to form a seal is related to a rock's inherent ductility in the subsurface (in part after Downey, 1984).

southwest USA. Billo (1996) noted a similar association when discussing the same areas.

So why do evaporites seal?

In terms of seal capacity and resistance to fracturing, the most effective sedimentary seals are gas hydrates, followed by evaporites, then shales (Figure 10.3; Downey, 1984). To seal an economic accumulation of hydrocarbons, any sealing surface or lithology needs to be laterally continuous, maintain a constancy of properties over large areas, be relatively ductile, and be widespread over a sedimentary basin. A fundamental requirement for any effective seal is that the minimum^{10.2} displacement pressure of the lithologic unit comprising the sealing

^{10.2}The minimum capillary pressure required to force oil or gas from one water-filled pore to the next.

^{10.3}Gas or methane hydrates (more precisely called clathrates) are the solid form of mostly methane trapped in a crystalline framework of ice and are only found in low temperature seafloor or permafrost conditions. They seal the onshore supergiant fields of west Siberia and the Timan-Pechora basins of Russia and occur also as solid bacterial-associated products in the seafloor in many of the world's oceans where water depths exceed 500 m. Seafloor clathrates are thought to contain more than 20 quadrillion cubic metres of methane. In oil equivalents this is around 15 trillion m^3 (116 trillion barrels), more than 30 times the volume of oil and gas reserves thought to exist in the world (Hunt, 1996).

^{10.4}Synonymous with minimum displacement pressure.

^{10.5}In most oilfield applications the millidarcy (md), which is 0.001 darcies, is used as a measure of permeability. Permeability is fundamentally a L^2 unit. In SI it is expressed in μm^2 , which is 10^{-12}m^2 . In conventional metric use it is expressed in m^2 (metres squared) or cm^2 . The conversion between oilfield and SI units is 1 darcy = $9.869 \times 10^{13} \text{m}^2$. In practical terms, 1 md and $1 \mu\text{m}^2$ are essentially equivalent, while in terms of hydraulic conductivity, 1 darcy = 10^{-5}m/s .

surface be greater than the buoyancy pressure of the hydrocarbon column in the subjacent accumulation. Hence, the size of the pore throats and the density of entrained hydrocarbons and water are of great importance in determining whether or not a particular lithology can act as a seal. Density/buoyancy differences between oil and gas means there are fields, such as some evaporite-cemented San Andres Formation mudstones in the Permian Basin of Texas, where dolomitic mudstones act as a seal to liquid hydrocarbons, yet flow gas.

Any lithology can be a seal, but other than ^{10.3}clathrates, evaporites are the most effective, regardless of hydrocarbon type and structural setting (Figure 10.3). Unlike the low temperatures requirements for a clathrate seal, evaporite seals, with their extremely high ^{10.4}entry pressures, very low permeabilities and large lateral extents, can maintain seal integrity over wide areas, even when exposed to a wide range of subsurface temperature and pressure conditions. A typical shale seal has a permeability $\approx 10^{-1}$ to 10^{-5} md, with rare values as low as 10^{-8} md (Figure 10.4a). Quantitative measurement of evaporite permeability is beyond the capacity of standard instruments used in the oil industry and is mostly a topic of study for engineers working with waste storage caverns (see Chapter 12). Their work shows halite has permeabilities^{10.5} that are less than 10^{-21} m² (10^{-6} md) with some of the tighter halites $\approx 10^{-7}$ to 10^{-9} md and massive anhydrite $\approx 10^{-5}$ md (Beauheim and Roberts, 2002). Cement bonds behind well casings are much more permeable than any evaporite bed that an oil well

intersects. If an oil well is abandoned without appropriate well completion, water seeping into the cement bond behind degraded casing can access the salt and the associated salt leaching can lead to problems in long term ground stability (Table 12.4). Concerns in terms of long term stability of a sealed access well,

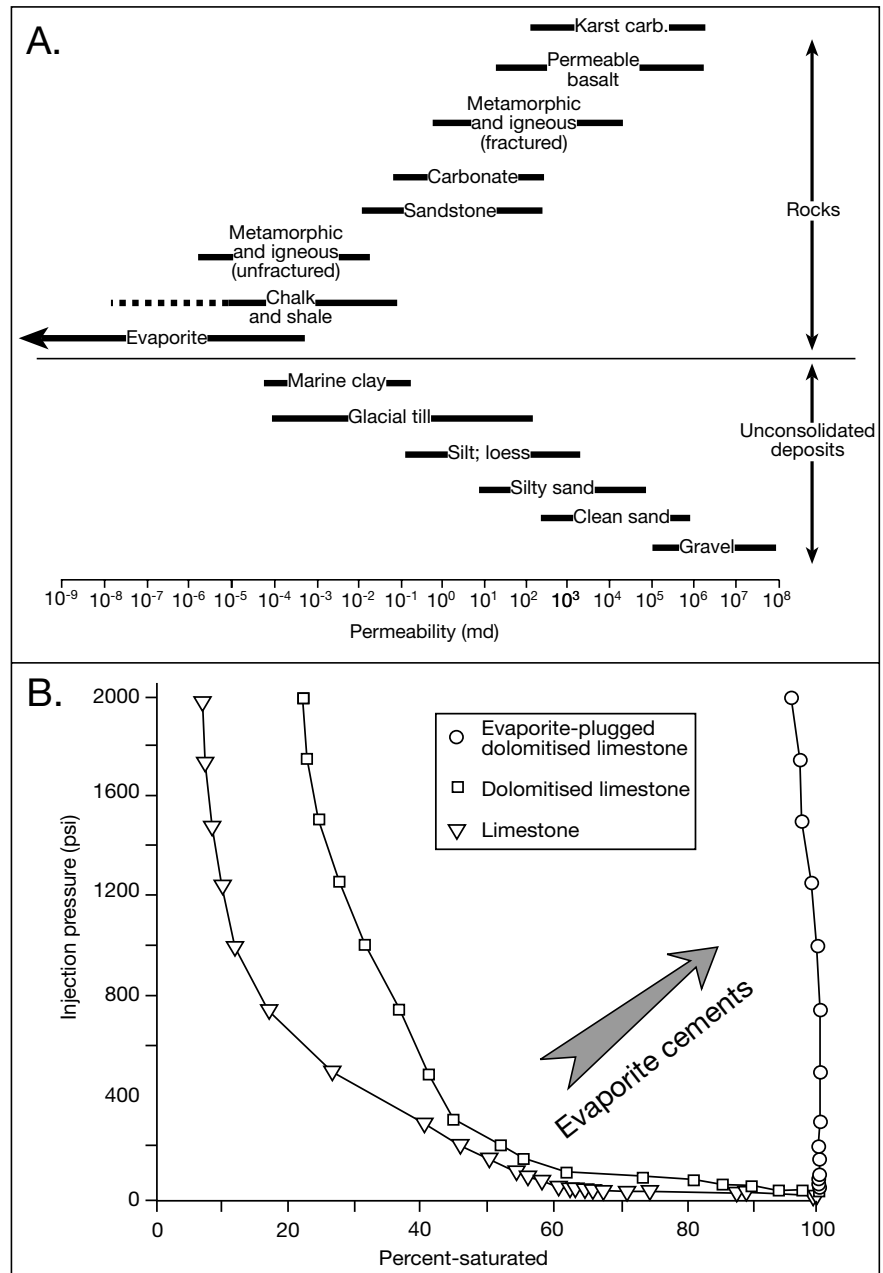

Figure 10.4. Seals. A) Relative ranking of permeability of various lithologies (in part after Beauheim and Roberts, 2002) B) Hg-injection curves from representative lithologies in a sequence undergoing reflux dolomitisation and overdolomitisation (from Warren, 1992).

rather than leakage through the salt itself, is the most important issue to be addressed in the longterm storage of radioactive materials and other high level hazardous waste within purpose-designed isolation cavities in salt (Table 12.5).

Little or no leakage will take place through a laterally continuous evaporite seal when the reservoired hydrocarbon is oil. Even when the reservoired hydrocarbon is methane, little or no loss occurs, even by diffusion. The much greater efficiency of evaporite seals is clearly seen in the total hydrocarbon volumes held back by the two lithologies. Total worldwide shale sediment volume in the crust is more than an order of magnitude greater than that of evaporites, yet the split between reservoired hydrocarbons below a shale or an evaporite seal is roughly 50:50 (Grunau, 1987).

Typical bedded evaporites, especially beds composed of monomineralic assemblages such as massive nodular anhydrite or massive halite, have entry pressures in excess of 3000 psi. Most impure evaporite beds have entry pressures greater than 1000 psi, as do many evaporite-plugged reflux dolomites (Figure 10.4b). Contrast this with most shales, which tend to be water-bearing (mostly bound and structural water) and have typical entry pressures between 900 and 1500 psi. Even though such shales are respectable seals, over time shale allows substantial diffusive leakage of methane and even liquid hydrocarbons via inherent microporosity, less so if the shales are organic-rich. Even ignoring salts ability to reanneal under stress, an evaporite seal has much lower intrinsic permeability that helps maintains its integrity. With permeabilities of 10^{-7} md, a hydraulic gradient of 0.01, and a porosity of 0.01, a brine would take somewhere between 3 and 30 million years to flow 1 metre into an unfractured halite seal, while anhydrite, which has permeability some 100 times higher, a brine would take between 30,000 and 300,000 years to flow 1 metre into the seal (Beauheim and Roberts, 2002). Evaporites are excellent longterm seals to substantial hydrocarbon columns.

With the likely exceptions of clathrates, thick halites and perhaps anhydrites, almost all fine-grained subsurface rocks will at some time in their burial history be subject to microfracturing and leakage. Otherwise, organic-rich mudstones and shales could not act as source rocks and there would be no primary migration of hydrocarbons. In contrast, rather than fracturing, most salt seals tend to lose their seal integrity either through dissolution windows or through salt-flow-induced breaches, which are defined by areas of overburden touchdown and focused subsalt leakage. Thick salt beds experience brittle fracture only at very shallow nearsurface and typically vadose conditions, such as Salar Grande in South America (Figure 3.47).

Halite's very high ductility and its ability to flow, reanneal and re-establish lattice bonding by solution creep (Figure 6.3b) when subject to stress give it a low susceptibility to fracturing. The ability of a halite unit to maintain seal integrity, and so prevent the escape of hydrocarbons, reflects a combination of an ability to flow and reanneal under stress, and the small size of molecular interspace in its ionically-bonded NaCl lattice. Massive bedded halite units contain few, if any, interconnected pore throats. The distance between NaCl lattice units is 2.8×10^{-10} m, while the smallest molecular diameter of a hydrocarbon molecule (methane) is 3.8×10^{-10} m. In reality, the only way that hydrocarbons can migrate through an unfractured halite bed, even by diffusion, is if the halite contains impurities that render it locally porous and make it brittle during deformation.

Whether buried halite beds that enclose organic intrabeds can release volatiles during catagenesis is still a matter of some discussion among organic geochemists. The longterm lack of fracture or pore throats in buried salt beds is why organic-rich intrasalt carbonate or shale laminites tend to be inefficient source rocks in style 1a source rocks (Figure 9.3). Likewise, possible flushing and maturation effects are poorly understood in subsurface situations where encased organic-rich beds are in contact with hydrated salts converting to their anhydrous equivalents (such as gypsum to anhydrite or carnallite to sylvite, mirabilite to thenardite). Loss of water of crystallisation has the potential to allow organic-rich fluids to escape as the hydrated salts transform to their anhydrous forms. But such burial transformations typically occur in the first few hundred metres of burial and may only allow immature hydrocarbons to escape into adjacent more porous sediments (Hite and Anders, 1991). There they must be stored, mature and remigrate in later burial if they are to act as source rocks on encased organic-rich beds (Warren, 1986). Many intrasalt organic-rich beds survive well into the metamorphic realm and evolve into graphitic quartzites and marbles encased in meta-evaporitic albitites and scapolites. However, some thin impurity-rich salt beds may fracture when overpressured (e.g. Figure 6.4).

As a general rule, even as a halite bed fractures, its inherent lack of strength and the consequent ability to flow means any microscale intercrystalline fractures quickly reanneal by a combination of flow and pressure solution induced recrystallisation. Current consensus is that some thin impurity-rich salt beds interlayered with carrier beds do leak small amounts of volatiles, but much less efficiently than thicker organic-rich mudstones and shales; whereas organics encased in thicker salt beds probably cannot leak until the enclosing salt dissolves. Evaporite beds and allochthons constitute some of the strongest longterm

subsurface barriers to the vertical migration of hydrocarbons in a sedimentary basin.

Environments favouring seal continuity

When assessing any hydrocarbon accumulation the top, lateral and bottom seals must be identified and evaluated. Theoretically, the thickness of a seal does not contribute to seal capacity: a clay shale (4-10 μm particle size) with an entry pressure of 600 psi is theoretically capable of sealing a 900 m oil column. In reality, it is unlikely a shale bed only a few cm thick is a laterally continuous, unbroken, unbreached unit capable of maintaining stable lithic character over a sizeable area. A thin evaporite perhaps could be, but a thicker seal provides many layers of contingent sealing beds and so gives a larger probability of a sealing surface being continuous over an entire prospect. Evaporite seals more than 30 m thick are considered excellent, while shale seals more than 50 m thick and evaporite seals more than 10 m thick are considered adequate.

Seal continuity rather than measured seal capacity is the most important factor in assessing seal quality. In the laboratory, one can measure the displacement or entry pressure necessary to force a given hydrocarbon mixture through a rock sample under given conditions of temperature and pressure. However, there are many difficulties in extrapolating quantitative data from a capillary pressure test on a 4-8 inch (10-20 cm) diameter core into a reliable prediction of the seal character across the entire sealing surface. A simple domal closure of 2,950 ha (6,400 acres) provides a ratio between a typical seal sample (4-inch diameter whole core) and the area of top seal of 1 to 3.5 billion. Average values of seal properties measured from core without a reliable geological model for the reservoir are next to useless in quantifying seal integrity. What is needed is knowledge of the likeliest weakest points in the seal across the structure of interest. It's the difference between a guarantee that you will on average survive if you swim in these shark- and stinger-infested waters, versus you are advised not to swim in this lagoon. Most of us prefer the second option, it's the same when investing tens of millions of dollars in exploration and development wells.

Saltern and deepwater evaporite beds make excellent seals because the density-stratified hydrology of their depositional setting guarantees there was little lateral variation in depositional rock properties over large areas of the salt-covered basin floor (Chapters 2 and 5). Evaporite-plugged mudflat units also make effective seals, as do platform carbonates plugged by evaporite cements precipitated from dense reflux brines. But high levels of entrained impurities, less predictable depositional topography

and lateral variations in early diagenetic fluid flux rates means both these seal types are more subject to problems with lateral continuity as well as stress fracture and failure.

Deposition of saltern evaporites atop the various Arab cycle carbonate reservoir sands of Saudi Arabia and the Emirates not only formed the highly effective Hith seal (Figure 10.5a), but aided in the preservation of underlying reservoir porosity and permeability by preventing later entry of meteoric waters (from above) capable of precipitating eogenetic carbonate cements.

Once dissolution starts to thin a previously effective seal, it begins to leak. Even the Hith Anhydrite can leak once it is less than 10 m thick, as can be seen by the migration of Jurassic-sourced oil in Cretaceous reservoirs along the edge of the Hith Anhydrite (Figure 10.5a; Hawas and Takezaki, 1995). In my opinion, this leakage in the thinned Hith can be tied to increasing proportions of dolomite residues near the dissolutional feather edge of the Hith and a consequent propensity for brittle responses near this edge, with local faulting tied to collapse fracturing. There would be little loss of seal capacity in an anhydrite bed as thin as 10 metres if it remained as relatively pure nodular anhydrite.

Leakage is obvious in Al Rayyan Field, Qatar, where the upper Arab anhydrite, the intra "C" anhydrite, and the intra "D" anhydrite of the Arab Formation do not form effective seals and only the Hith acts as a regional seal for the field (Brown and Loucks, 2001). The intra "C" and intra "D" beds are interpreted as depositionally discontinuous with relatively high dolomite contents. This reflects original shoalwater carbonate deposition in the cycle capstones, which were deposited as thinned, and perhaps pinched-out, evaporitic mudflats onlapping the carbonate shoal. Likewise, the intra "C" sabkha unit, with its higher fraction of intercalated porous dolomite intrabeds, promotes seal failure via fracturing and faulting. The discontinuous salina deposits in the intra "D" anhydrite also lack sufficient lateral continuity to form an effective seal over the structure. Brown and Loucks (op. cit.) found that the major cause of seal failure in the thin, upper anhydrite is fault offset, whereby fault throw exceeds seal thickness. The high fraction of brittle dolomite in these anhydrite intrabeds results in wider seal damage zones, allowing greater potential for along-fault leakage. In contrast, where fault throw in the field does not exceed the thickness of the Hith, nor the thickness of the middle, and lower anhydrites in the Arab cycles in the field, the evaporites capping the various intra-Arab cycles remain as intact seals. Faults intersecting these beds also cause less structural (brittle fracture) damage due to the higher anhydrite fractions of the beds, so that along-fault leakage from connected intrasalt beds is minimal.

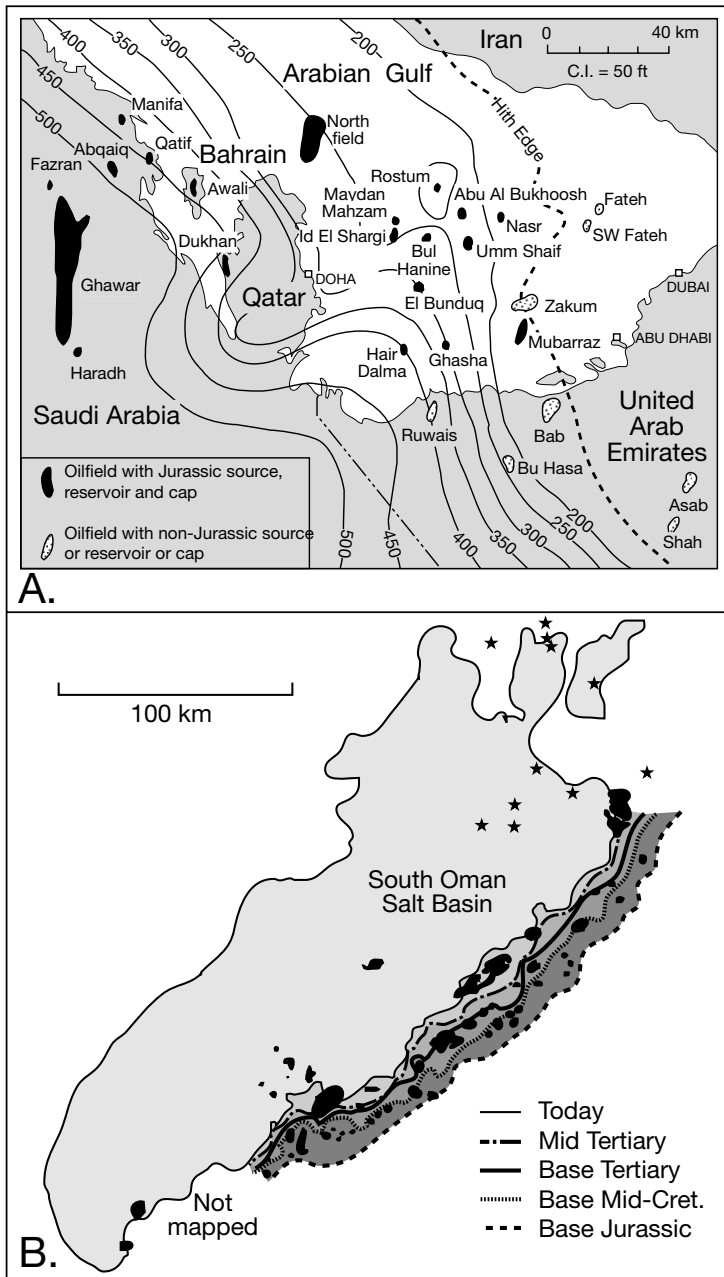

Figure 10.5. Evaporites as seal and a control of charge distribution. A) Hith Anhydrite isopach showing thickening from the UAE west into Saudi Arabia and some of the main fields producing from Jurassic reservoirs in this region (in part after Alsharhan and Kendall, 1994). Note the lack of Jurassic reservoirs to the east of the Hith erosional edge showing the effectiveness of the saltern evaporite in holding back substantial oil and gas columns sourced in Hanifa mudstones (see Figure 9.4). B) Distribution of charge in the oil and gas fields along the highly productive eastern margin of the South Oman Salt Basin is controlled by the retreating dissolution edge of the Neoproterozoic Ara Salt and the underlying Huqf Fm. source rock, which became mature in the Cretaceous. Oil fields shaded black, stars indicate gas fields (after Terken et al., 2001).

Hydrocarbon migration and trapping in the south Oman salt basin, with its subsalt Neoproterozoic Huqf source rock, is strongly controlled by the continuity of the Neoproterozoic Ara Salt. In the centre of the basin, where the salt is still present, there is an additional substantial volume of oil still trapped in intrasalt organic-rich siliceous stringers of the Athel silicilyte (Amthor et al., 1998; Terken et al., 2001). In the peripheral syncline along the east flank, salt dissolution is the controlling parameter of structural style and trap formation (Heward, 1990), and retreat of the salt edge is the main factor for charge timing (Figure 10.5b). Traps in Palaeozoic clastics in the eastern basin margin were initially formed by halokinetic structuring, and subsequently filled by salt dissolution breaches driving dissolution drape and oil emplacement. The subsalt Neoproterozoic Hufq source rock began to generate oil in the middle of the Cretaceous and the retreat of the salts dissolution edge can be mapped in the successive fillings of the various fields that define the productive eastern margin of the basin.

Salt dissolution has today removed most of the salt along the east flank of the south Oman salt basin, and its timely removal is largely responsible for the present-day hydrocarbon-filled structures (Figure 10.5b). Oil accumulations mimic a negative image of the salt structures first formed during the earlier halokinetic stage as early salt withdrawal basins then became inverted into oil bearing turtle structures. Anticlines resulted from drape of strata over Haima and Al Khalata turtle structures and drape over deeper laterally discontinuous siliceous and carbonate stringers floating in the Ara Salt. Where salt dissolution occurred, formerly salt-encased stringers leaked and became the grounded remnants that now form chaotic solution residue horizons both in outcrop and in the subsurface (Terken et al., 2001; Peters et al., 2003).

Wherever marine carbonate reservoir sands are sealed by salterns or basinwide salt beds, the width of the subeconomic transition zone from economic reservoir into an overlying depositional seal is typically narrow and sharp.

Such seals are created as basin isolation drives rapid platform or basinwide drawdown (e.g. anhydrites capping the Arab cycles in Ghawar or Salina Fm. salt seals of the Michigan Basin). The narrow transition reflects hydrographic isolation that typifies the onset of marine fed saltern and basinwide evaporite precipitation (Chapter 5: a corollary of Walther's Law).

In contrast, a continuous depositional transition from reservoir to seal generates an uneconomic hydrocarbon-filled gradational passage into a seal. Such gradational transitions from reservoir to seal characterise many nonevaporite sealed stratigraphic traps, such as reef-grainstone shoals drowned beneath onlapping lagoonal shales, or point bar sands buried beneath floodplain muds. Likewise, some brine reflux traps beneath evaporitic mudflats are created by salt plugging of platform carbonates. They tend to show subeconomic transitions from reservoir to seal both vertically and laterally. Much of the hydrocarbon can lie in partially plugged porous dolomites that are "not quite reservoir, hardly seal" (Figure 10.4b). Compared to pure-evaporite seals, both salt-plugged and shale seals are much more prone to longterm leakage and the creation of thicker transition zones from reservoir to seal. Understanding and predicting the distribution of salt plugging is a significant problem in reliably modelling reserves and production estimates in evaporite-sealed reservoirs worldwide.

The transition from a potential dipping reservoir sand into a near vertical diapir stem or a subhorizontal salt allochthon also forms sharp effective lateral and top seals. The passive mode of salt emplacement creates a sharp rather than a transitional boundary. Syndepositional stacking of reservoir sands against a passive diapir stem seal in the Gulf of Mexico has created some of the most productive acreage anywhere in the world (in terms of recovered bbl/acre; Halbouty, 1979). Sharp contacts also create potentially hazardous sharp transitions into zones of high overpressure (see Chapter 8).

Reservoirs and traps

At its simplest, evaporite-associated reservoirs occur adjacent to either bedded or halokinetic seals (or their solution residues) in subsalt, intrasalt or suprasalt positions (Table 10.1). Bedded salt seals are further subdivided into lacustrine, platform or basinwide settings, while halokinetic salt seals are either autochthonous or allochthonous.

Bedded salt seals

The main function of bedded evaporites in the evaporite hydrocarbon association is as a seal to subsalt accumulations of oil and gas (Table 10.2). In many cases, high levels of primary intergranular porosity in grain-dominated limestones are preserved beneath a salt seal (e.g. Jurassic Arab cycles on the Arabian Peninsula) or intercrystalline porosity forms in variably dolomitized subsalt limestones (e.g. San Andres reservoirs on the Central Basin Platform fields of west Texas). Impermeable evaporite beds and salt-plugged dolomites capping various upward-shoaling platform cycles, effectively seal off underlying porous carbonates from later surface-driven influxes of freshwater or sulphate-bearing fluids. The evaporite horizon is never a potential reservoir, unless it dissolves into a solution breccia or if intergranular salt cements are leached from previously salt-plugged sands or dolomites.

In the early stages of salt deposition, especially of gypsum salterns atop a marine platform, there is usually an associated hydrological system of basinward flushing dense brines (reflux). Circulation is driven by gravitational instability, set up by an updip dense brine plume or brine curtain that typically forms below accumulating evaporites (Figure 2.50). At its periphery this refluxing plume mixes with and displaces less dense subsurface and connate waters to create or enhance the reservoir properties of adjacent subsalt limestones via reflux dolomitization.

As dense Mg-rich brines seep downdip from the platform saltern or mudflat they create intervals of porous dolomites in more distal zones, located seaward of overdolomitised evaporite-plugged areas. In some cases the most extensively dolomitised carbonates in these more distal zones are high-energy, shallow water grainstones and packstones. These were the sediments with the higher permeabilities at the time of dolomitisation. However, in areas of pervasive syndepositional marine cementation, some originally porous carbonates may have already lost much of their intergranular permeability via overgrowths of isopachous rim cements. In this situation the less cemented platform mudstones act as aquifers to the refluxing brines and so are preferentially dolomitised. Likewise, in more restricted portions of an epeiric carbonate platform where the only sediment beneath a salt seal is lagoonal mud, it is dolomitised and sometimes converted into a reservoir with intercrystalline permeability (e.g. the Levelland-Slaughter trend in the San Andres Fm, west Texas and New Mexico). In some muddy platform carbonates, only the pelletal and sandy burrow fills retain sufficient permeability to be dolomitised, while their muddier surrounds are not (e.g. Red River Dolomite of North

Dakota). Whatever the setting, the rule of thumb is that refluxing brines will preferentially dolomitise whatever carbonate facies is capable of acting as an aquifer at the time of reflux.

The economic significance of reflux dolomite was first noted in the 1960s in the various evaporite-associated Permian dolomite reservoirs of west Texas (Adams and Rhodes, 1960). Reflux dolomitisation also controls porosity/permeability distribution in the finer-grained parts of some Jurassic Arab Formation reservoirs in Saudi Arabia, as well as the Permian Khuff Formation in the Arabian Gulf, the Smackover Formation carbonates of the Gulf of Mexico, and many other oil and gas fields across the globe where dolomites occur beneath an evaporite seal (Sun, 1995; Warren, 2000a). Yet, in other depositionally similar evaporitic settings, some of the mesohaline laminites that underlie bedded salts are not dolomitised, typically because they were evaporite-cemented in the strandzone prior to the onset of reflux flushing. They were too tight to transmit the volumes

of Mg-rich brine needed for dolomitisation. Syndepositional permeability in units deposited immediately after a transition into widespread evaporite deposition, controls the type and extent of brine reflux.

Worldwide, Phanerozoic dolomite reservoirs are defined by four syndepositional associations (Sun, 1995; Warren, 2000a): (1) evaporitic mudflats in a carbonate platform, most often a ramp profile (roughly equivalent to peritidal-dominated carbonate of Sun, 1995), (2) saltern-sealed platform carbonates with mudflat development over palaeotopographic highs - this system typically develops across an epeiric platform behind a rimmed shoal profile (roughly equivalent to subtidal carbonate associated with evaporitic tidal flat/lagoon of Sun, 1995), (3) basinwide evaporite seal (subtidal carbonate associated with basinal evaporites of Sun, 1995), and (4) nonevaporitic carbonate sequences associated with topographic highs/unconformities: platform-margin buildups or burial related fault/fracture

Field or area	Reservoir and age	Reservoir	Trap Type	Seal	Reference
Gulf of Suez	Rudeis and Belayim Middle Miocene	Cyclic shallow ramp lagoonal carbonates deposited within a restricted embayment	Dolomites created by brine reflux	Massive basinwide evaporites	Orszag-Sperber et al., 1998 Sun and Estaban, 1994
Mesopotamian Platform	Euphrates-Jeribe Early Miocene	Locally dolomitised and packstones, with red algae, mollusks and benthic foraminifers	Reflux dolomites, skeletal buildups and biostromes	Saltern and mudflat evaporite cap	Buchbinder, 1996 Sun and Estaban, 1994
Oolitic to siliciclastic ramp reservoirs, offshore Angola	Pinda Group (Albian)	Littoral sandstones with interparticle porosity to various types of dolomitised marine shelf to shoreline carbonates with mouldic, vuggy, and intercrystalline porosity	Late Cretaceous segmentation of the reservoir series by salt tectonic gravitational gliding into halokinetic "turtle-back" and raft	Evaporitic mudflats/shales	Eichenseer et al., 1999
Sunniland Field, Southern Florida	Sunniland limestone, Early Cretaceous	Dolomitised bank margin grainstones and mudstones	Low relief anticlinal trap, possibly halokinetic	Massive saltern anhydrite	Halley, 1985 Loucks and Crump, 1985
Walker Creek Field, Chatom Field, and Mt Vernon Field, Gulf of Mexico Basin, Arkansas, USA	Smackover Formation, Jurassic (Oxfordian)	Oolitic-pisolitic dolomitised limestone retaining varying levels of primary intergranular porosity and calcite cement	Up-dip and down-dip depositional pinchout of oolitic grainstone bars, modified by halokinetic faulting (underlying Louann Salt)	Saltern and mudflat (Buckner Anhydrite)	Chimene, 1991; Feazel, 1985; Druckman and Moore, 1985
Appleton Field, Gulf of Mexico Basin, Alabama, USA	Smackover Formation, Jurassic (Oxfordian)	Dolomitised algal peloid ooid grainstone with intercrystalline and vuggy porosity	Combination structural-stratigraphic trap Up-dip and down-dip depositional pinchout of oolitic grainstone bars on high of crystalline basement	Saltern and mudflat (Buckner Anhydrite)	Haywick et al., 2000 Petta and Rapp, 1990
Ghawar, Qatif, Uthmaniya and other Arab Fm. fields in Saudi Arabia	Arab Formation, Late Jurassic (Tithonian and Kimmeridgian)	Partially dolomitised skeletal, peloidal and oolitic grainstone (Arab D), peloidal/oolitic/ skeletal grainstone (Arab C)	Low amplitude anticlines related to basement faulting and possible halokinesis of Hormuz Salt	Nodular anhydrites and tight mudstones of Arab cycles and the overlying Hith Anhydrite	Cantrell et al., 2001 Saner and Sahin, 1999, 2000 Meyer et al., 1996 Wilson, 1985
McElroy Field, Central Basin Platform, Texas, USA	Grayburg Formation, Permian (Lower Guadalupian)	Dolomitised shelf carbonates ranging from mudstones to fusilind wackestones	N-S trending asymmetrical anticline with steeper eastern limb. Permeability pinches out to west due to increasing evaporite plugging (anhydrite and gypsum)	Evaporites and siltstones of the Queen Formation; Anhydrite plugged porosity is heterogeneous.	Harris and Walker, 1990

Table 10.2. Some of the many Tertiary to Permian platform reservoirs and fields sealed by bedded evaporites.

Field or area	Reservoir and age	Reservoir	Trap Type	Seal	Reference
Ghawar, Qatif, Uthmaniya and other Khuff Fm. fields in Saudi Arabia	Khuff Formation (Members A-C), Permian	Dolomitised and leached peloidal grainstones, wackestones and mudstones, variable anhydrite cements	Low amplitude anticlines related to basement faulting and possible halokinesis of Hormuz Salt	Saltern cap and varying development of evaporitic mudflats	Al Jallal, 1995; Dasgupta et al., 2002
Reeves Field, Midland Basin and Levelland-Slaughter trend, Northern Platform, Permian Basin, Texas USA	San Andres Formation, Permian	Dolomitised skeletal wackestones and mudstones	Stratigraphic with structural assist via draping over former shelf edge	Strandline anhydrites of the San Andres Formation	Chuber and Pusey, 1985
Pecos Slope Field, Permian Basin, New Mexico, USA	Abo Formation, Permian (Leonardian)	Fluvial sandstone	Tectonically fractured stratigraphic wedge-out of fluvial clastics	Anhydrite of the Yeso Formation	Bentz, 1992
Tarchaly, Rybaki, Sulecin, Barnowko--Buszewo fields, west Poland and Thuringian basin fields, East Germany	Zechstein main dolomite; Early Permian	Dolomitised oolitic/pisolitic grainstones and mudstones	Shelf margin buildup beneath evaporite seal, structurally assisted	Zechstein anhydrite cap (basinwide)	Depowski and Peryt, 1985; Peryt and Dyjaczynski, 1991; Gorski et al., 1999; Karnin et al., 1996
Aneth Field, Paradox Basin, Utah	Hermosa Formation (one main reservoir, several semi-isolated intervals), Pennsylvanian	Leached and recrystallized oolitic limestone and dolomitised mudstone	Dolomitised carbonate mound	Evaporitic organic-rich dolomitic shale	Peterson, 1992
Lisbon Field, Utah, USA	Leadville Formation; Mississippian	Dolomitised (sucrosic) and karstified platform carbonates (wackstone-packstone)	Faulted anticline beneath supra-unconformity halokinetic evaporites of the Paradox Basin	Paradox Salt (basinwide)	Miller, 1985
Stanley Field, Williston Basin, North Dakota, USA	Mission Canyon Formation; Mississippian	Pisolitic-oolitic limestone with local skeletal marine grainstone. Fenestral porosity with primary interparticle and intraparticle	Updip facies change to fractured evaporitic mudflats and porous grainstones from downdip wackestone and mudstone	Massive platform anhydrite of the Rival Member top seal	Beach and Giffin, 1992
Elkhorn Ranch Field, Williston Basin, North Dakota, USA	Mission Canyon Formation; Mississippian	Dolomitised skeletal mudstones and wackestones	Hydrodynamic trap where structure assists in localising accumulation, but trap stratigraphic passage is into an anhydrite seal	Massive platform anhydrite top seal of the Mission Canyon Formation	DeMis, 1992
Glenburn Field, Williston Basin, North Dakota, USA	Mission Canyon Formation; Mississippian	Pisolitic limestone exhibiting subaerial exposure and vadose diagenesis with porosity pinchouts via evaporite plugs	Solution collapse anticline in underlying Devonian Salt	Massive saltern anhydrite and ferruginous shale caps, structurally assisted (anticlinal)	Borchert et al., 1990 Gerhard, 1985
Little Knife Field, Williston Basin, North Dakota, USA	Red River, Duperow, Mission Canyon; Ordovician, Devonian, Mississippian	Dolomitised shallow shelf to evaporitic mudflat carbonates	Combination anticlinal nose and porosity pinchout	Massive Mission Canyon platform anhydrite top seal, lateral change to nonporous carbonates	Wittstrom, 1990 Lindsay and Kendall, 1985
A and E pools, Rainbow Field, Canada	Keg River Formation, Rainbow Member, Middle Devonian (Givetian)	Dolomitised limestone and limestone	Pinnacle reef enclosed in evaporites and bituminous carbonates	Muskeg Member evaporites	Schmidt et al., 1985
Pinnacle reef fields, Michigan Basin, SE Michigan USA	Guelph Formation and equivalents; Middle Silurian	Dolomitised and karstified pinnacle reefs	Pinnacle reef enclosed in evaporites and bituminous carbonates	Salina Group evaporites	Gill, 1985; Obermajer et al., 2000

Table 10.2 cont'd. Some of the many Palaeozoic platform reservoirs and fields sealed by bedded evaporites.

controls. Three of the four worldwide dolomite-hydrocarbon associations show an intimate association with evaporites. Brine reflux is the dominant process in dolomite creation in all three, although it can be overprinted by later burial dolomites.

Dolomite reservoirs created by brine reflux can be subdivided using the dominant depositional style of the evaporite capstone, namely, platform and basinwide (Figure 5.7). In platform-evaporite-sealed dolomite associations, the evaporite seal is typically ≈ 5 –10 metres thick (although it can be 20–30m thick) and is usually anhydrite interlayered with shoaling platform carbonates. This evaporite cap can be further subdivided into evaporitic mudflat or saltern-dominated. Basinwide seals to carbonate reservoirs tend to be thick (>100 m) and halite prone in the basin centre and to cap carbonate buildups about the basin edge. Such buildups grew prior to the saline giant stage. Ongoing or longterm reflux beneath accumulating evaporites in both platform and basin settings can “overdolomitise” the reservoir and encourage evaporite plugging leading to occlusion of effective porosity (Warren, 2000a for summary). In platform settings such porosity-depleted overdolomitised zones tend to be most common in regions of restricted carbonate deposition beneath leaky evaporitic mudflats (these are the typical caps to Sun’s peritidal association). These sediments tend to accumulate in the more updip evaporite-dominated portions of a carbonate platform, where underlying carbonates have been flushed for extended periods by hypersaline brines. With basinwide-sealed associations, a later burial overprint and pervasive intra-reservoir karst/fracturing event seem to be needed to create and maintain economic porosity levels.

“Peritidal” muddy carbonate with evaporitic mudflat seals

Evaporitic mudflats dominate the ephemeral water portions of an evaporite basin. As discussed in Chapter 5, the use of a tidal nomenclature is not appropriate in highly restricted to hydrographically isolated epeiric setting where evaporites are accumulating. Strandzone rather than the intertidal and supratidal of the peritidal is more appropriate, but peritidal terms are used in the following discussion to conform to historic subdivisions. Strandzones can create dolomite-forming hydrologies within stacking muddy epeiric platform carbonates whereby highly saline Mg-rich brines, sourced in the mudflats, seep into adjacent restricted lagoonal marine carbonates (Figure 10.6). Without subsequent fracturing, leaching and other diagenetic enhancements to their permeability, such fine-grained mimetic sydepositional dolomites constitute few economic reservoirs. Those intervals that do constitute reservoir tend to

be low permeability systems, which are patchily distributed in a host formation that is extensively plugged with variable levels of evaporite cement. Enhancements to this generally low and patchy permeability can occur if karst, fracturing or burial leaching subsequently modify the host lithology. Early diagenetic permeability tends to increase where the dolomitised marine mudflat was located further out on the platform and away from areas of most intense dolomitisation and evaporite plugging.

Ordovician Red River Fm., Williston Basin, USA and Canada

The Red River Formation was deposited in an epeiric sea-way that occupied the Williston Basin in the Middle to late Ordovician. The Williston Basin is located on the southern edge of the Canadian Shield, straddling the US-Canadian border and centred on Saskatchewan and North Dakota. The basin itself is circular, about 800 km across, and is filled with up to 4600 m of Phanerozoic sediments. The Palaeozoic succession is predominantly carbonate and up to 2 km thick. It is overlain by a Mesozoic succession of mainly fine terrigenous clastic rocks up to 1.5 km thick and a Tertiary succession of mostly coarse terrigenous clastics that is less than a kilometre thick. The maximum thickness of the Red River Fm. occurs in the basin centre close to Bismarck, North Dakota, and where it is slightly more than 200m thick (Pu and Qing, 2003; Longman and Haidl, 1996).

Within the basin are several major epeirogenic structures, of which the Cedar Creek anticline and Nesson anticline are the most prominent. Both anticlines have long episodic histories of farfield tectonic movement. Elsewhere in the basin, the subsurface dissolution of Palaeozoic evaporites resulted in collapse and inversion structures in post-Middle Devonian strata, such as the Birdbear structure (McTavish and Vigrass, 1987).

Red River strata consist of three carbonate-evaporite depositional sequences known as the A, B and C cycles (Figure 10.6a, b; Pu and Qing, 2003). Each sequence starts with a burrowed, normal-marine mudstone to wackestone and packstone at the base, followed by a laminated mudstone representing more restricted mesohaline deposition, which in turn is overlain by a bedded to enterolithic evaporative mudflat anhydrite which can be traced over much of the basin. Industry terminology informally defines these evaporites as capstones to the “A,” “B,” and “C” cycles. Some workers also distinguish a lower “D” zone that lacks an anhydrite cap (Figure 10.6b). In ascending order, a typical Red River cycle consists of: 1) locally dolomitized burrowed carbonate mudstones and skeletal wackestones that define a

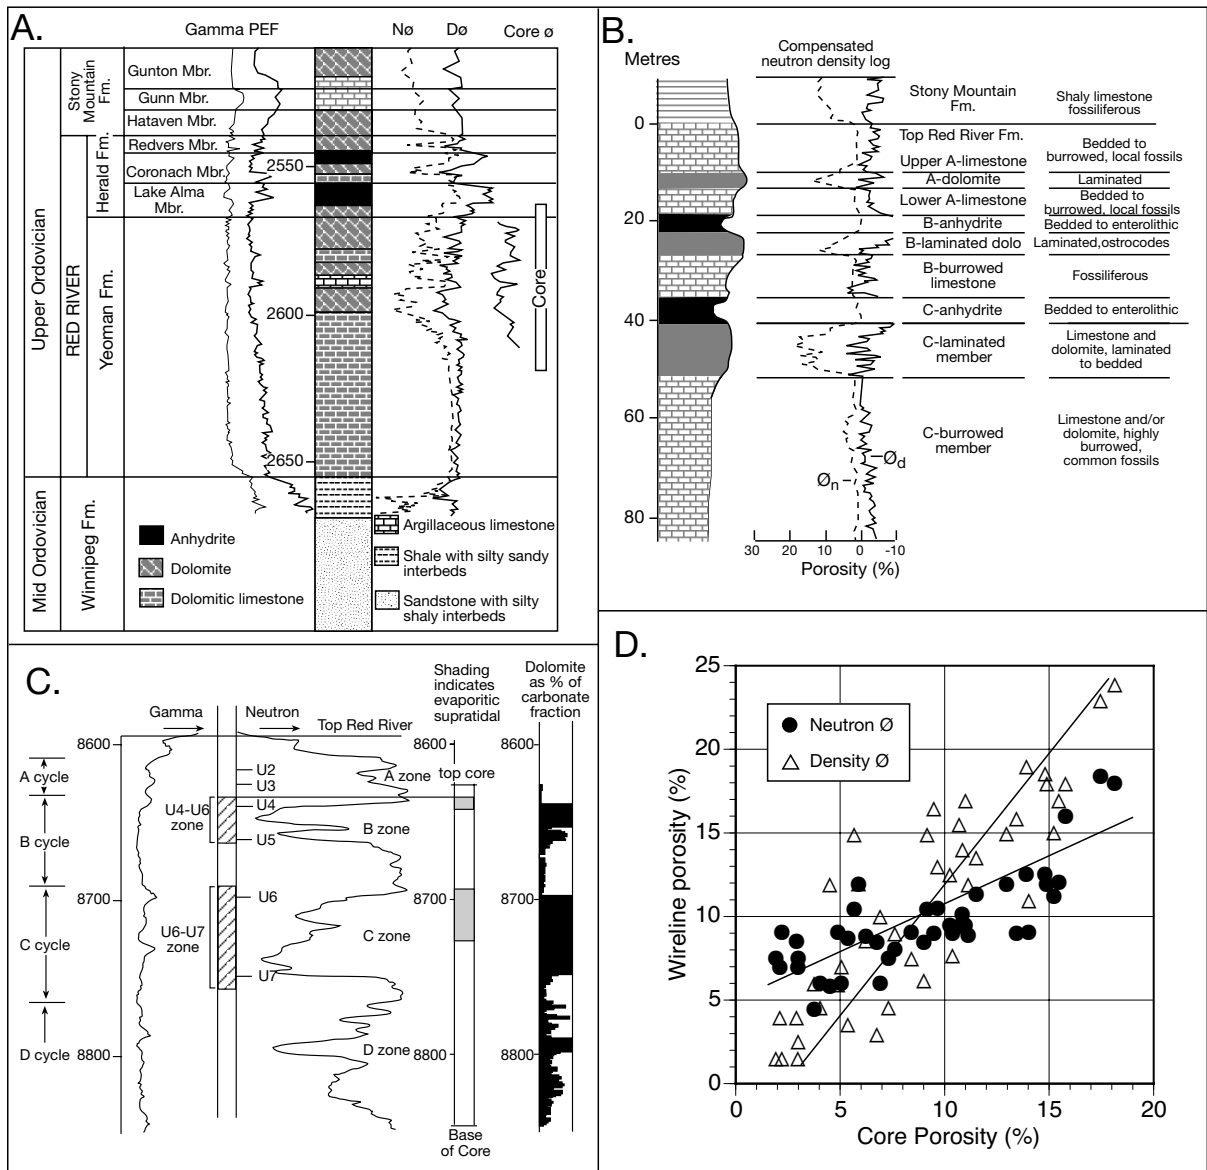

Figure 10.6. Evaporitic mudflat (peritidal) style of deposition in the Ordovician Red River Dolomite, North America. A) Red River stratigraphy with wireline data from well 7-3-7-11W2 in Midale area, Saskatchewan (after Pu and Qing, 2003). B) Typical section showing detailed sedimentary character of the main cycles (after Longman et al., 1983). C) Core section in the Cabin Creek Field, shows the close relationship between dolomite occurrence and evaporite beds (after Clement 1985) D) Relationship between core porosity, neutron log and density log porosity in well 14-16-7-11W2 in Midale area Saskatchewan (after Pu and Qing, 2003).

“Burrowed Member,” which is around 9 m thick in the B zone and up to 90 m thick in the C zone; 2) irregularly laminated carbonate mudstones that constitute a 3-12 m-thick “Laminated Member;” and 3) an impure 3-6 m capping anhydrite showing nodular-mosaic, nodular, or enterolithic textures (Figure 10.6c). All members thin toward the edge of the basin where the anhydrites disappear completely.

Subtidal lithologies in each cycle are classic Zone X sediments composed of partially dolomitized burrowed biomicrite wackestones with fragments of echinoids, brachiopods, bryozoans, trilobites, molluscs, ostracodes, and gastropods, and lesser amounts of solitary corals and stromatoporoids (Figure 5.16). These subtidal dolomitic units are poorly bedded and heavily bioturbated and were laid down in a quiet-water epeiric platform setting.

The Red River Formation is 90 to 180 m thick in Cabin Creek Field on the Cedar Creek anticline in Montana, on the southwest side of the Williston Basin. Its lower part is a tight bioturbated marine limestone (Ruzyla and Friedman, 1985). The average depth to pay across Cabin Creek Field is 2750 m, with a 15.2 m net pay thickness, a productive area of 30.5 km² (7620 acres), and an estimated 224 million barrels of oil in place. Here, and throughout much of the Williston Basin, economic porosity is largely restricted to bioturbated and partially dolomitized platform limestones.

The overlying strandline (intertidal?) portions of a cycle are dolomitic biomicrite wackestones, deposited under somewhat more energetic bottom conditions (Zone Y). These deposits are still muddy but contain graded beds, crossbeds, ripple marks, imbricate shell lags and conglomerates. They also contain allochems characteristic of strandlines, such as oncolites, ooids, intraclasts, and peloids. The overlying anhydritic sediments in each cycle (Zone Z) include wavy-laminated micritic dolomites and organic-rich mudstones, along with evidence of completely restricted and at times subaerial conditions in the form of desiccation cracks, erosion surfaces, intraclast breccias, solution collapse breccias, and nodular anhydrites. This capstone in the vicinity of the Cabin Creek anticline was deposited on the platform in a mosaic of sabkhas and salinas within an evaporitic mudflat.

Figure 10.7. Cross plot of core porosity and permeability in the Red River Formation in well 3-8-1-11W2, Midale Field, Saskatchewan. Clearly shows the improvement in porosity and permeability associated with dolomitisation (replotted from Pu and Qing, 2003).

Evaporitic strandzone sediments in the reservoir interval in Cabin Creek Field show evidence of subsequent leaching; they contain empty gypsum and anhydrite moulds, corroded anhydrite crystals and solution collapse breccias. Early micritic dolomites of the supratidal are mimetic but units tend to be overdolomitised and salt plugged and so are relatively poor quality reservoirs. Upper contacts of the evaporite-cemented dolomite intervals are typically sharp, often erosional and pass abruptly up into the limestones of the next cycle suggesting exposure prior to the passage into the next cycle. This style of transition also characterises sediments in modern evaporite mudflats and sabkhas. In contrast, the bases of the various dolomite intervals are transitional and conformable with the underlying marine limestone interval, typical of brine transition driven by an early reflux hydrology.

As in Cabin Creek Field, Red River dolomite throughout the rest of the Williston Basin is mostly of two types; a) a mimetic evaporitic-mudflat reflux mesohaline dolomite, which is primary and precipitated penecontemporaneously as wavy-laminated or peloidal mudstones intercalated with the strandline (supratidal) carbonates; and b) an associated, perhaps slightly later, somewhat coarser-grained brine-reflux dolomite, which dolomitized underlying portions of the intertidal and subtidal sediments immediately below and downdip of the micritic mudflat dolomite (Pu and Qing, 2003; Clement, 1985; Longman et al., 1983). The proportion of dolomite decreases downward from the base of each evaporitic mudflat (supratidal) unit due to the sinking and mixing of dense hypersaline waters, which originated in the strandzone (supratidal?). Brine reflux dolomites selectively replace skeletal fragments and burrows of the marine carbonate platform. Within productive areas, dolomitised limestones consistently show improved porosity and permeability compared to nearby undolomitised limestones (Figure 10.7).

Red River reservoirs throughout much of the Williston Basin are not hosted in mesohaline mudflats, but in porous dolomitised marine lenses some 27 to 43 metres below the "C" Anhydrite Member. Permeable lenses vary in thickness from less than 3 metres up to 60 metres thick and are up to 1.5 km across (Figure 10.8). The lateral extent of these porous lenses and the possible interconnections between them is poorly understood because most producing fields are small and consist of only a few wells. Most cored reservoir intervals are dominated by *Thalassinoides-like* burrow networks, with individual dolomitised burrows 1-2 mm to >1 cm across within a less dolomitised matrix. Reservoir porosities are typically less than 15% and permeabilities less than 30 md, with most wells showing a poor relationship between porosity and permeability (Figure 10.7). Porosity development seems to be related to the degree of dolomitization,

with some porosity enhancement of partially dolomitised intervals occurring during later burial by partial dissolution of residual calcite matrix. The initial formation of dolomite may well have been bacterially mediated and focused along organic-rich linings of the burrows (Gingras et al., 2004). The mechanism was perhaps similar to that of the sulphate-reducing bacteria forming modern dolomites in the mesohaline salinas of Brazil (Figure 4.16). Dolomite-lined burrow meshworks acted as a focus for subsequent dolomitisation.

There is general agreement that dolomites of the mottled Red River C member are genetically related to Mg-rich brines seeping through restricted marine muddy carbonates. These dense hypersaline basin waters were depleted of their calcium and sulphate, either through attendant deposition of aragonite and gypsum, or perhaps by ongoing bacterial sulphate reduction. What is not agreed is whether the dolomitising brines were descending or ascending at the time of widespread dolomitisation. Longman et al. (1983) argued that brine migration was localised by “holes” in the anhydrite mudflat seal (Figure 10.8a). Fracturing, minor faulting, or early expulsion of subsurface waters from the carbonate host probably formed the “holes.” When the descending Mg-rich hypersaline brines first entered the underlying carbonate sediments beneath the “holes” they were oversaturated and precipitated cryptocrystalline dolomite (overdolomitisation), but as they migrated away from the holes they lost their potency and produced rhombs floating in a dissolving calcitic matrix. This calcite may have been precipitated as an early diagenetic phase or left as unreplaced vestiges of original calcite (or aragonite subsequently altered to calcite) during dolomitization.

Figure 10.8. Models explaining the occurrence of patchy diagenetic dolomite that characterises much of the reservoir in the various fields in the Red River Formation. A) The descending hole model of Longman et al., 1983. B) the ascending megapolygon model of Kendall (1983). See text for discussion.

Perkins (1991) agreed with the brine reflux model for the widespread mimetic dolomite fabric but went on to argue that following further burial, limestones tended to chemically compact through pressure solution, whereas late stage fractures were localized in the more brittle dolomitised portions of the Red River Formation. These fractures served as conduits for late stage leaching fluids, possibly associated with hydrocarbon generation, which locally enhanced porosity in dolomite intervals adjacent to active fractures through the removal of associated calcite. On the scale of individual burrows, late-stage leaching is reflected in “overly porous” dolomite haloes

around cemented burrow centres and highly porous dolomite seams along stylolitic contacts.

Kendall (1983) also agrees with a brine reflux model but argues that once the gypsum cap was deposited (prior to its burial conversion to anhydrite) it was an aquifer not an aquitard and that the brine flux could just as easily been upward and focused via brine resurgence through more permeable intervals in the gypsum bed. He goes on to suggest that the control on the dolomite intensity was a series of megapolygonal sutures, much like the resurgence of saline groundwaters seen atop giant polygonal cracks in Pleistocene playas (Figure 2.41).

The complexity of dolomite-reservoir to seal interrelationships in the Red River Dolomite is symptomatic of similar relationships in many other mudflat-associated dolomite reservoirs (Warren, 2000a). The dolomitization process is ongoing from deposition through burial and uplift. Likewise, the burial

evolution of the adjacent evaporite seal is also ongoing from first deposition until complete subsurface dissolution. The evaporitic interval can act as both as a source of fluids, as in reflux dolomites and dissolving salt beds, or as a focus to fluid access as when rising basinal fluids pool and spread beneath a laterally extensive evaporite seal, or where a breached salt bed or allochthon facilitates the ingress of fluids either from below or above the breach. Generally, dolomite reservoirs contain multiple styles of dolomite created at different times in the hydrological evolution of the adjacent evaporite seal (Warren, 2000a).

Platform carbonates with saltern seals

Porosity in saltern-sealed carbonates typically occurs as multiple zones within stacked shallowing-upward evaporitic cycles that pass into mudflats near the basin edge or intrabasin highs (Warren 2000a). The saltern evaporite platform reservoir

Figure 10.9. Late Jurassic Tithonian palaeogeography of the Arabian Gulf (after Al-Husseini, 1997). Deposition of the four carbonate-anhydrite cycles of the Arab Formation and the overlying Hith Anhydrite constitute the dominant regional reservoirs and caprocks. The western Rub' Al-Khali and Gotnia basins were inland salterns characterised by halite rather than platform-wide anhydrite, which is the dominant evaporite salt in the Arab and Hith formations.

grouping in part corresponds to the “subtidal carbonate associated with evaporitic tidal flat/lagoon” grouping of Sun (1995). Each economic zone is formed by porous, partially to completely dolomitized subtidal limestones. Reservoirs are typically capped by tight, dominantly saltern evaporites, with local highs indicated by seal transitions from saltern into evaporitic mudflat. Reservoir quality in the subtidal carbonate is related to depositional facies and varying intensities of diagenetic overprint.

Reflux dolomitisation is a common permeability enhancing mechanism beneath many leaky pans and saltern seas (as in the reef-rimmed Permian Basin of west Texas). But retention of relict primary porosity in epeiric limestones beneath tight sub-salturn units, rather than intensity of reflux dolomitization near the platform edge, is a significant control on reservoir quality in the Middle East (as evidenced by the

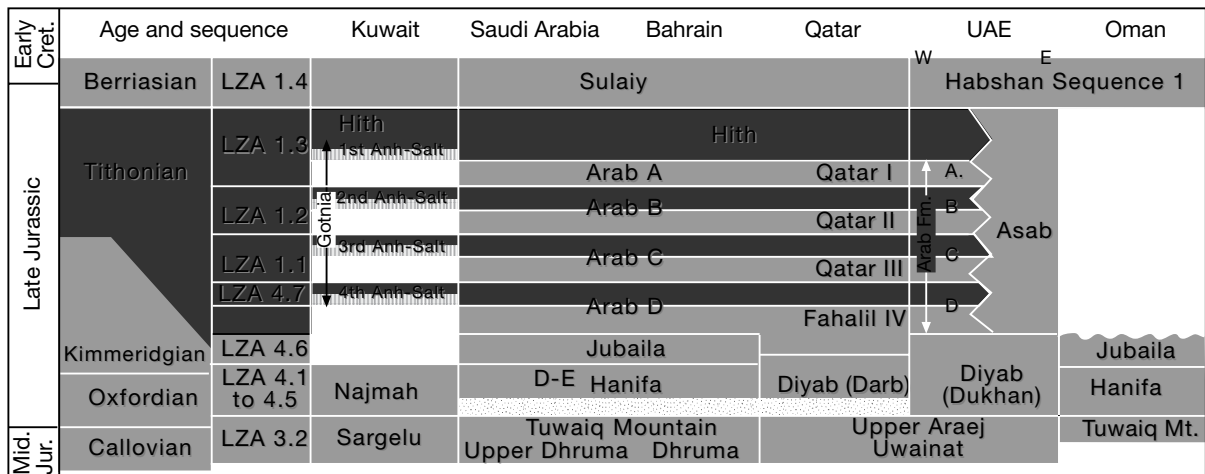

Figure 10.10. Stratigraphy of the Late Jurassic sediments of the southern Arabian Gulf (after Al-Husseini, 1997).

many saltern-sealed interior mounds and shoals making up the main Arab D reservoirs across the Arabian Peninsula; Figure 10.9). In both settings, better quality reservoirs tend to occur in higher energy, grain-dominated limestones (oolitic/peloidal/pisolithic packstones) or dolostones, but quality reservoirs can also form in lower-energy lagoonal dolomudstone/wackestone with an overprint of coarsely crystalline dolomite.

Finely crystalline, mud-dominated mimetic dolomites typically form a thin cap beneath a saltern seal or stacks in updip evaporitic mudflat positions, where they lie nearer the brine source. Such mudflat dolomites are typically low permeability sediments that require further diagenetic enhancement to attain reservoir quality (see previous section).

Jurassic Arab Formation, Arabian Gulf

The Late Jurassic (late Kimmeridgian) Arab Formation within and around the Arabian Gulf hosts some of the most prolific oil fields in the world, including Ghawar and Safaniya fields (Lucia et al., 2001; Sahin and Saner, 2001; Meyer et al., 2000; Cantrell et al., 2001; Alsharhan and Kendall, 1994; Wilson, 1985). This prolific petroleum system includes several regional organic-rich source rocks, stacked reservoirs and multiple seals (Al-Husseini, 1997). Jurassic strata were deposited across a broad platform (Murriss, 1980) that is sometimes characterized as “layer cake.” Chronostratigraphic correlation from outcrops to wells, well to well, and from country to country, defines a late Jurassic regional anhydritic sealed carbonate platform encompassing large intrashelf basins with grainier rims. At times of hydrographic isolation, the platform evolved into a widespread saltern that with further isolation was characterised

by halite-filled depressions known as the Gotnia and Rub Al-Khali salt basins (Figure 10.9; Al-Husseini, 1997).

The proposed regional stratigraphic framework for the Jurassic, as defined by Al-Husseini (1997), is as follows; 1) Upper Triassic-?Lower Jurassic continental clastics (Minjur Formation and equivalents) and the subsequent pre-Toarcian unconformity indicating regional erosion and non-deposition over the Arabian platform. 2) A Toarcian sequence (Marrat Formation and equivalents) providing a basal Jurassic regional datum, except in Oman. 3) Late Toarcian and Aalenian corresponding to a substantial sea-level lowstand and a regional depositional hiatus. 4) The Middle Jurassic Dhruma Formation corresponding to four different sequences with a major intervening hiatus. The Upper Dhruma Member, together with the Tuwaiq Mountain Member, forms the topmost sequence (Figure 10.10). The correlation between the Dhruma, Tuwaiq Mountain, Hanifa and Jubaila formations, to their equivalents in other Arabian Gulf countries, still requires clearer definition. 5) The Arab and Hith Anhydrite formations are Tithonian, based on their sequence assignment, while the Sulaiy Formation is Berriasian and straddles the Jurassic- Cretaceous boundary. The four Tithonian Arab Formation carbonates (A-D members) were deposited as transgressive to early highstand deposits, while the Tithonian Arab, Gotnia and Hith anhydrites are perhaps late highstand deposits which overstep inland salterns (Gotnia and western Rub’ Al-Khali basins). Each carbonate and overlying anhydrite cap in the four Arab cycles (Arab A-D) are interpreted as complete third-order cycles (Al-Husseini, 1997). The equivalents to the Kimmeridgian Jubaila Formation and Tithonian Arab carbonates are absent because of non-deposition in Kuwait. The Tithonian Hith Anhydrite provides a regional stratigraphic datum in the Arabian Peninsula, except in Oman

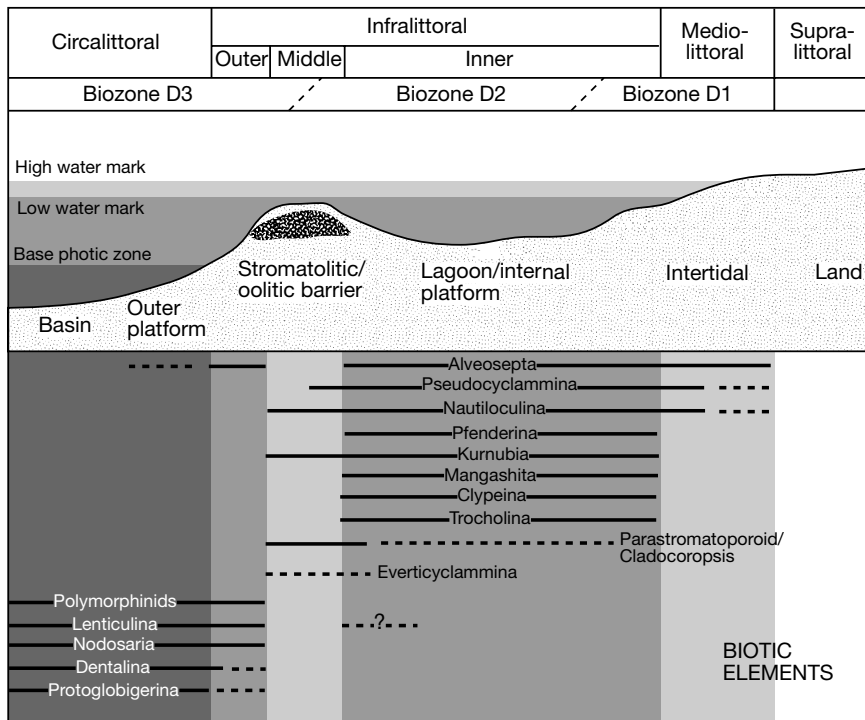

Figure 10.11. Palaeoenvironmental distribution of various biotic elements within the Arab-D reservoir (Wyn Hughes, 1996).

and the eastern United Arab Emirates (UAE). There the Arab and Hith Anhydrite formations are absent as they have been eroded or were never deposited, so the former eastern and southeastern extent of the Hith is not well understood.

The main reservoirs within this prolific petroleum system are oolitic-peloidal grainstones and dolomitized limestones, within a regionally extensive, mostly muddy, carbonate platform that is now called the Arab Formation. The Arab Formation is typically divided into four cycles (A through D from base to top); all cycles can produce, but the Arab D is the most productive over much of the Gulf. Each cycle shoals up from a more marine base to restricted-marine, variably dolomitised, limestone to mudflat dolomites and evaporites. The lower portion of the Arab D is typically a bioclastic lime mudstone or wackestone with normal marine fossils. Away from topographic highs, local organic-rich mudstones were deposited in intrashelf basins and are lithologically identical to similar intrabasinal successions in the underlying Diyab Formation. The lower Arab D is overlain by a middle unit of clean washed calcarenite, largely composed of sorted and rounded skeletal particles and ooids (grainstone-packstone), and an upper variably developed thin dolomitic mudflat sequence, which grades across a metre or two of anhydrite-plugged carbonate into massive to nodular anhydrites

of the Arab D capstone. This anhydrite was deposited within a regional sulphate saltern/pan with local, but still widespread, evaporite mudflats atop local highs. Evaporitic mudflats also encircled the depositional edges of the basin. Microfossil and macrofossil content in the marine portion of the Arab D is a useful discriminant of water depth and restriction (Figure 10.11; Wyn-Hughes, 1996)

Atop the anhydrite-capped marine-dominated limestone and dolomite of the Arab D are the more restricted cyclic carbonates-anhydrites of the Arab A-C. These sediments in the United Arab Emirates show depositional relationships that correspond to the outline of the current and possibly the late Jurassic edge of the evaporite basin, although exact detail has

been obscured by edge dissolution and erosion (Figure 10.12). Wireline signatures in the anhydrite caps to the various A-C cycles in oil fields in both Saudi Arabia and eastern Abu Dhabi indicate evaporite mudflats made up of mosaics of sabkhas, ephemeral brine pans and salinas (personal observation) and are very similar to signatures in shoal water portions of the Arab D capstone. As in the Arab D cap, the proportion of subaqueous anhydrite increases in the capstone away from the crests of many fields, showing that many current highs were also highs in the Jurassic. Unbreached anhydrite caps in all Arab D cycles are highly effective seals, for example the anhydritic cap to the Arab D holds back a 400m-oil column in Ghawar Field, Saudi Arabia. Wireline signatures in the crest of the field indicate a mosaic of salinas and sabkhas.

The Asab Formation in the eastern United Arab Emirates is laterally equivalent (although not necessarily time equivalent) to the Arab Formation (Figure 10.12). Definitions of Arab-A, -B, and -C vary from field to field across the Gulf and do not necessarily represent the same chronostratigraphic unit. The combined Arab-ABC is defined by Grötsch et al. (2003) as a lithostratigraphic unit composed of high-frequency dolomite-anhydrite shallowing-upward cycles capped by the massive

Lower and Upper Hith Anhydrite. The top of the underlying Arab-D reservoir in the eastern UAE is typically picked at the top of a clean gamma-ray trend, which is usually an oolitic and bioclastic grainstone section. Its top typically coincides with the first occurrence of a gamma kick, indicative of a black marker limestone that commonly contains pyrite. However, in my opinion, this marker is not always a depositional unit and may be a dissolution residue created by fluid crossflow along the underside of the anhydrite sealing the Arab D. Although a useful correlative marker of the reservoir top, it probably does not represent a time-line.

If we assume the Arab D is the base of the section throughout the Arabian Peninsula, then the difficulty in breaking out three separate cycles (Arab A-C cycles) atop the Arab D reflects the high degree of textural similarity of all restricted and dolomitised evaporite-capped shoaling cycles. The inherent lack of an entrained time-significant fossil assemblage and the vagaries of syndepositional evaporite dissolution in all evaporitic mudflats makes detailed well-to-well correlation at the level of the

Arab A-C very difficult. There are more than three anhydrite beds in the A-C interval (Figure 10.12). Short but significant episodes of subaerial exposure and freshening characterised the brine sheets depositing these marine-fed mudflat cycles. Intraformational evaporite dissolution residues, sometimes show high gamma kicks and without reference to core can be easily misinterpreted as maximum flooding surfaces.

Capping the cycles of the Arab Formation is a thick regional unit of subaqueous saltern anhydrite, the Hith Anhydrite, which extends over much of the Arabian Gulf region. In Saudi Arabia and the eastern UAE, it holds back almost all of the oil and gas sourced in Jurassic mudstones. It is only at the edge of the Hith in the central and western UAE that Jurassic sourced oil is found as widespread accumulations in the overlying Cretaceous succession (Figure 10.5a, 10.12).

Deposition of the various widespread anhydrite caps in the Arab Formation across the Arabian Plate indicate higher order sealevel falls, within what was a second order sequence ac-

Figure 10.12. Schematic east-west cross-section of the Arab and Hith formations, offshore Abu Dhabi. Note: Datum is possibly affected by erosion and evaporite dissolution with the amount of truncation increasing to the east. Facies relationships between wells are schematic (after Al Silwadi et al., 1996).

cumulating during the late Kimmeridgian. For much of this time, when evaporites were not accumulating, open-marine to restricted-marine epeiric carbonates were the dominant sediments (Figure 10.12; Sharland et al., 2001; Al-Saad and Sadooni, 2001). During the preceding Hanifa and Jubaila time (middle Oxfordian and early Kimmeridgian, respectively), local organic-rich intrashelf basins deposited starved-basin sequences of laminated organic-rich dark-coloured marls and mudstones (Figure 9.4; Ayres et al., 1982).

Prior to hydrographic isolation that marked the end of the Arab D, oolite/peloidal shoals and patchy coral-algal stromatoporoid banks were deposited as local higher energy shoals across the muddy epeiric platform that typified marine stages of Arab Formation deposition across the Arabian Peninsula (Figure 10.11). Regionally, similar but more laterally continuous Kimmeridgian equivalents to these higher energy marine carbonates lined the epeiric platform margin. This band of shelf-edge shoals was a hydrodynamic barrier that periodically restricted free surface exchange between Arabian Platform waters and deeper open-marine (Tethyan) waters to the east and facilitated deposition of the various anhydrite capstones (Figure 10.9). This shoal-rimmed margin thus separated a muddy interior epeiric platform, with its intrashelf depressions, from the deeper openwater marine slope carbonates. Edges of the various intrashelf basins of the epeiric shelf behind the main shelf margin shoal were ramp-style progressions around somewhat deep ($\approx 30\text{m}$) intrashelf basins (Sharland et al., 2001). Much of the regional platform-margin shoal rim was destroyed during later continental collision.

Regionally, much of the reservoir quality in the undolomitised or poorly dolomitised limestone reservoirs in the Arab D can be directly tied to partially-preserved primary porosity in grainstone (oolid, skeletal and peloid) shoals and local reefal (stromatoporoid) debris aprons in the epeiric interior seaway. In many parts of the platform interior (e.g. the offshore UAE) the shoaling of the Jurassic seafloor and the formation of seafloor shoals in the Arab Formation was facilitated by salt structures sourced in the Precambrian Hormuz salt.

After deposition of the Arab D, ongoing higher order eustatic changes formed the numerous parasequences that make up the widespread A-C cycles of the Arab Formation in the epeiric shelf interior. Eustatic fluctuations drove periodic marine flooding episodes on the platform, followed by filling of accommodation space, hydrographic isolation and capping by evaporites and exposure surfaces. With each transgression another more open marine platform unit defined the base of a cycle and

was deposited as marine to mesohaline, skeletal-poor peloid wackestones/mudstones. Local shoaling on the epeiric platform led to progressively higher bottom energies culminating in thin local buildups of ooid and peloid grainstones that are now producing intervals in the Arab ABC.

Progressive platform restriction followed, via a combination of active carbonate aggradation and high order falls in relative sealevel (3rd to 5th order), which periodically exposed the shelf margin within an environment of net evaporation across the arid platform. This drove numerous brining-upward depositional cycles in the Arab ABC, with most, but not all culminating in the deposition of mudflat gypsum. Gypsum beds were porous at the time the various Arab ABC sulphates were deposited and brine reflux drove the formation of mimetic dolomites in the immediately underlying limestones. Dolomitisation is less pervasive, but still significant, in terms of reservoir quality in the underlying Arab D (Figure 10.13b). Thus syndepositional reflux dolomitisation occurred many times during the accumulation of evaporite caps to the various muddier units of the Arab Fm. and each probably indicates platform restriction related to higher order sealevel falls or local halokinetically- or basement fault-induced seafloor uplift. Some evaporite beds associated with these higher-order relative sealevel falls were leached by a subsequent rise in sealevel, so that all that remains of some of these higher order evaporite deposits are nodules cementing carbonate remnants in thin dolomites, along with widespread cm-scale dissolution surfaces and residues, often associated with gamma peaks in the wireline log (pers. obs.).

Any model explaining reflux dolomitisation on the Arabian Shelf as only occurring during the deposition of the four major cycle caps in the Arab Formation is too simplistic, as is the notion that the reservoir sediments of the Arab D cycle are the same as those of the subsequent A-C cycles. Given that the Arab D is the dominant producer throughout the Arabian Peninsula, we shall now focus on the detail of its reservoir characteristics and any relationship to diagenesis, perhaps tied to reflux and vertical crossflows that were focused by its evaporite seal.

The best-documented and regionally largest accumulation of hydrocarbons in the Arabian Peninsula occurs in Ghawar Field in Saudi Arabia (Figure 10.1). It not only stores hydrocarbons in the Jurassic section, but also entrains rich gas reserves in the underlying Permian Khuff Formation and with more than 150-200 billion barrels of recoverable oil is the world's largest single oil-filled structure. The following discussion will only deal with the Jurassic section in Ghawar. Detailed studies of various aspects of Ghawar and its outcrop equivalents in Saudi

Arabia have been published by Cantrell et al., 2001; Cantrell and Hagerty, 1999, 2003; Douglas et al., 1996; Lucia et al., 2001; Meyer et al., 1996, 2000; Powers, 1962; Saner and Sahin, 1999; Stenger et al., 2003; Wyn Hughes, 1996. The following section is a summary of aspects of this work, along with some comments of my own.

Ghawar Field, Saudi Arabia

The Arab-D carbonate reservoir of the Upper Jurassic Arab Formation in the onshore Ghawar Field was discovered in 1948. Following further separate discoveries in culminations along the structure's main axis, five production areas were quickly identified as parts of a single giant Ghawar oil field (Stenger et al., 2003). From north to south Ghawar is made up of Ain Dar, Shedgum, Uthmaniyah, Hawiyah and Haradh (Figure 10.13a). At the Arab-D level, the field is a NNE-trending composite anticline, 230 km long and about 30 km wide, with a productive area of more than 693,000 acres in a single, pressure-continuous reservoir. Ghawar accounts for more than half of Saudi Arabia's cumulative oil production.

Within the Jurassic section the Ghawar produces from the evaporite-sealed Arab D, with the reservoir section extending down into mudstones of the uppermost Jubaila Formation. Production layering is typically broken out into 4 zones

with the main production intervals broken into further finer subdivisions (Figures 10.14). Limestones of Zone 1 and 2 typically constitute the best quality Arab D reservoirs (Figure 10.13b). Arab-C, Hanifa and Fadhili oil reservoirs are also present in parts of the field, but the Arab-D reservoir accounts for nearly all of the oil reserves and production. Production began in 1951 and reached a peak of 5.7 million barrels per day in 1981. This is the highest sustained oil production rate achieved by any single oil field in world history. At the time that this record was achieved, the southern areas of Hawiyah and Haradh had not yet been fully developed. Production was restrained after 1981 for market reasons, but Ghawar remains the world's most important oil field. Cumulative production by year end 2000 was about 51 billion barrels of oil.

Across the field the Arab-D reservoir is comprised of a series of stacked shallow water, platformal carbonate sediments deposited as a cleaning-up and a shallowing-up carbonate succession stacked into metre-scale cycles or parasequences. The bulk of the reservoir is comprised of limestone, though some dolomite is present. Anhydrite is present in the reservoir as cement, but typically in minor amounts (Table 10.3). The cleanest and most porous rocks - hence the most favourable in terms of production - are situated in the grainier upper portion of the reservoir (Zone 2) Interparticle porosity predominates in the various reservoirs, though locally, other porosity types are important; for example, mouldic and intercrystalline porosity

Figure 10.13. Poroperm crossplot of typical Zone 1 and 2, Zone 3 and 4 and dolomites from cores in the Arab D reservoir of Ghawar Field, Saudi Arabia (after Cantrell and Hagerty, 2003).

in dolomitized portions of the reservoir. Each of the major upward-shoaling cycles that make up the Arab D was initiated in deeper subtidal water that shoaled to near sea-level. The proportion of skeletal grainstones and packstones, along with ooid grainstones, increase within each cycle and within the Arab

D overall. The top of the Arab-D carbonate is characterized by a thinner unit of dolomitized carbonate mudstone (Zone 1), capped by an evaporite seal.

By far the most abundant reservoir rock texture in the Arab-D is packstone; likewise, the most abundant reservoir lithofacies is skeletal-oolitic (SO; Tables 10.3, 10.4; Cantrell and Hagerty, 2003). The other significant lithofacies in the Ghawar reservoir are: *Cladocoropsis* (a characteristic finger-shaped and sized stromatopoid) lithofacies (CLADO), stromatopoid-red algae-coral lithofacies (SRAC), bivalve-coated grain-intraclast lithofacies (BCGI), micritic lithofacies (MIC) and dolomite lithofacies (DOLO), all of which are described in detail by Mitchell et al. (1988). Similar, if not identical, lithofacies make up Arab D reservoirs in other fields in Saudi Arabia and the western United Arab Emirates. In a detailed petrographic and petrophysical characterisation of the Ghawar Arab D reservoir Cantrell and Hagerty (2003) defined seven related limestone reservoir rock types based on the values of: (1) the amount of cement, (2) the amount of matrix (lime mud), (3) the grain sorting/grain packing, (4) the dominant pore type, and (5) the size of the largest moulds (Tables 10.4, 10.5; Figure 10.15).

At the broadest scale of reservoir classification the Arab D reservoirs are either limestone or dolomite (Table 10.5). In terms of porosity and permeability in the limestones, the amount of matrix is the most important of these five parameters and breaks down into three reservoir types (I-III). Cantrell and Hagerty (op cit.) break our two broad families, A and B in each of the three reservoir types (Table 10.5), Family, A, is relatively coarse-grained and poorly sorted rock with relatively large moulds. Family, B, is a generally fine to medium-grained, well-sorted rock with few or small moulds. Together this constitute 6 families of reservoir rock in the Arab D. Reservoir rock type IV is a seventh limestone family in Ghawar. Type IV limestones contains more than 10 percent cement, this modifies pore size distribution enough to warrant a separate limestone reservoir family (Figure 10.15). Each of the seven limestone types are characterized

limestone family in Ghawar. Type IV limestones contains more than 10 percent cement, this modifies pore size distribution enough to warrant a separate limestone reservoir family (Figure 10.15). Each of the seven limestone types are characterized

Lithofacies	Skeletal-Oolitic (SO)	<i>Cladocoropsis</i> (CLADO)	Stromatoporoid Red Algae-Coral (SRAC)	Bivalve-Coated Grain-Intraclast (BCGI)	Micritic (MIC)	Dolomite (DOLO)

by distinctive porosity-permeability relationships (Figure 10.15). Similar matrix-lean limestone reservoir characterise better quality reservoirs in Abqiq Field in Saudi Arabia and the Jurassic Arab Formation reservoirs of Qatar (Figure 10.16 and 10.17, respectively).

Dolomites in Ghawar constitute reservoir rock type V and are further subdivided according to their dolomite crystal texture, although stratigraphic position and porosity can also be effective pointers in their classification (Table 10.5; Figure 10.18a; Cantrell and Hagerty, 2003). The four dolomite textures are: fabric preserving (Vfp), sucrosic (Vs), intermediate (Vi) and

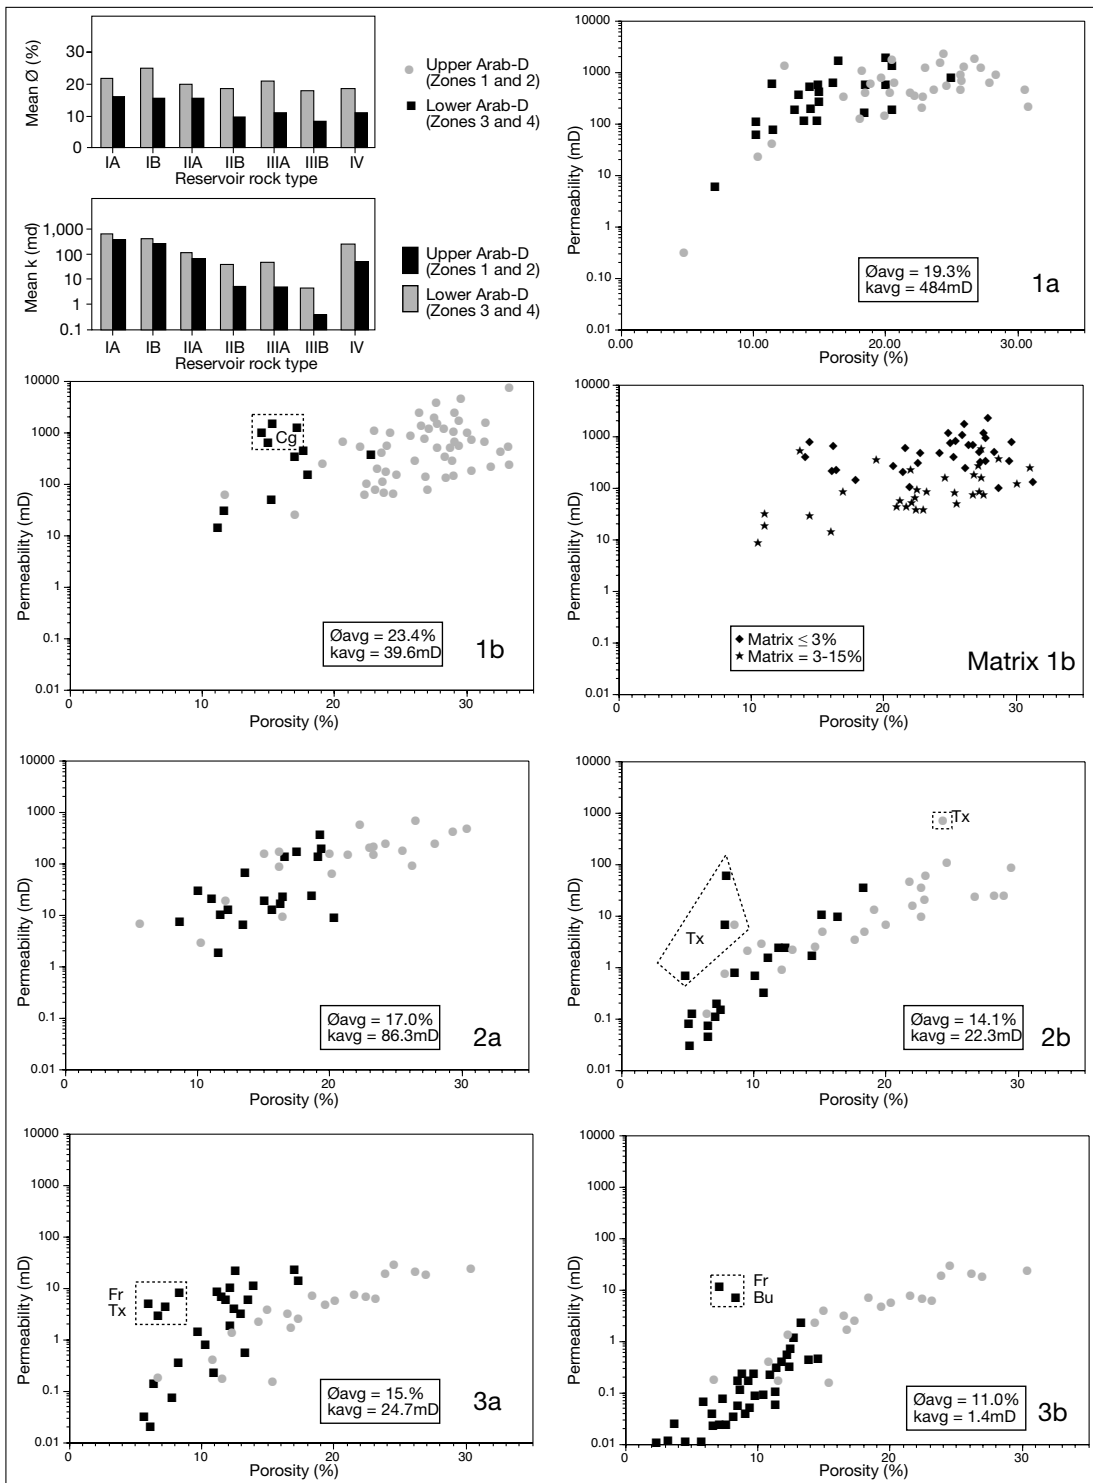

Figure 10.15 Porosity-permeability cross plots of individual limestone reservoir rock types as defined in Table 10.5 (after Cantrell and Hagerty, 2003). Outliers from the main poroperm trends are labeled according to their non-uniformity or textural characteristics (Bu=burrows; Cg=coarse grained; Fr=microfractures; Tx=textural variations; kavg=average permeability, in millidarcies; Øavg=porosity, in percent bulk volume).

Texture	Lithofacies						Total
	SO	CLADO	SRAC	BCGI	MIC	DOLO

mosaic (Vm). The mimetic Vfp dolomite is only found in Zone 1 of the Arab-D (immediately below the anhydrite cap) where it is the major dolomite type. Sucrosic (Vs) dolomite occurs in dolomites with more than 12% porosity, Vm less than 5% and Vi between 5 and 12%. Vfp dolomites have pore systems similar to their precursor limestone, but the pore systems of the other dolomite types are unique.

Powers (1962) and Lucia et al. (2001) concluded that once an interval in the Ghawar Field of Saudi Arabia is dolomitised, its reservoir quality is tied to the proportion of dolomite and dolomite crystal size (Figure 10.18b, c). In general, when dolomites are compared to limestones in the Arab D they show lower porosities (Figure 10.13). This is clearly seen in wireline-based porosity histograms of Zone 1 in the Arab D from Abqaiq Field, a supergiant field with 17 billion barrels of proven reserves, in eastern Saudi Arabia (Figure

10.16; Sahin and Saner, 2001). In part, this decrease in porosity with dolomitisation is a reflection of the originally lower precursor porosity in muddier transitional sediments that typically underlie a mudflat or saltern seal (mimetically dolomitised Zone 1 carbonates - Vfp).

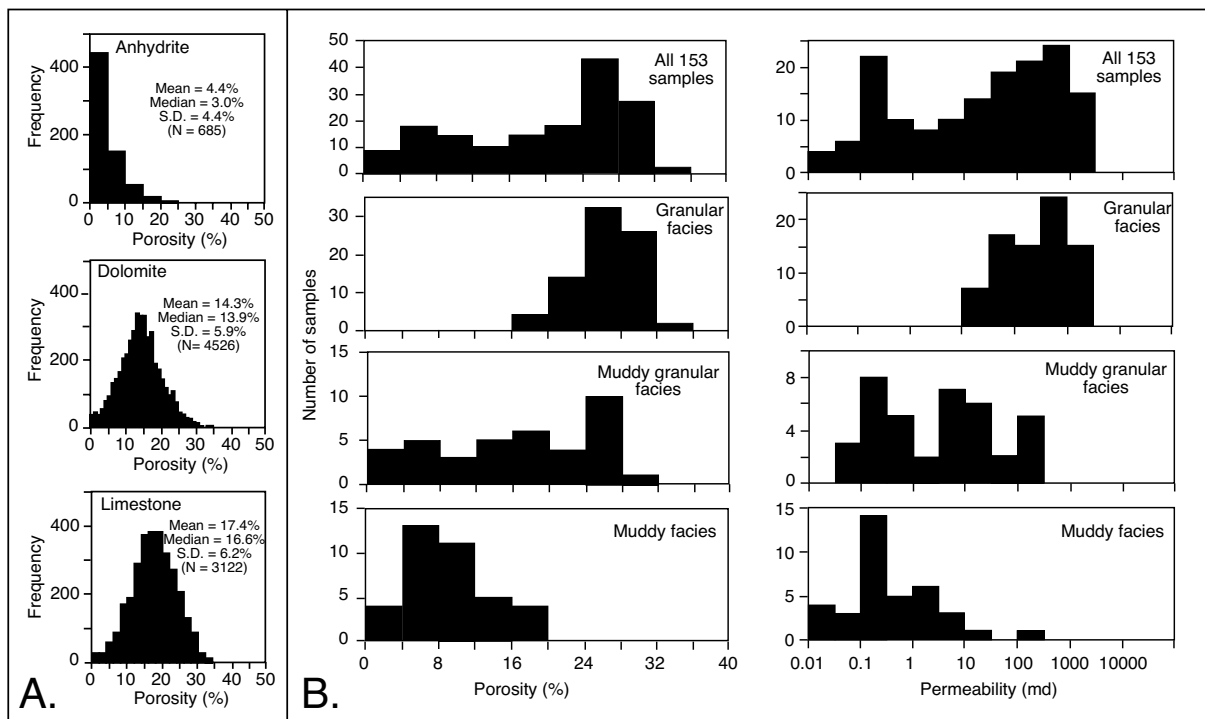

Figure 10.16. Petrophysical character of the Arab D, Abqaiq Field, eastern Saudi Arabia (after Sahin and Saner, 2001). A) Well log porosity for each of the three wireline defined lithologies in Zone 1 of the Arab D. B) Core plug-defined distribution of porosity and permeability in the various limestone dominated lithofacies of the Arab D.

Table 10.5. Classification of reservoir rocks, Arab-D reservoir, Ghawar Field (after Cantrell and Hagerty, 2003).

Anhydrite-derived, corrected porosity in wireline-defined anhydrites in Zone 1 is greater than zero in Abqaiq Field, eastern Saudi Arabia (Figure 10.16a; Sahin and Saner, 2001). This value comes not from the actual anhydrite beds, which are tight, but from the thin dolomite stringers that are intercalated within the anhydrite; they sit at the limits of vertical resolution of the wireline tool in such finely layered sequences. Controls on the Arab D reservoir are similar to those in Ghawar, with limestone matrix type rather than dolomitisation as the prime control (Figure 10.16b). Once the proportion of dolomite in a muddy succession attains 80-90%, the reservoir character substantially improves compared to its muddy limestone precursor (Figure 10.18b).

In many fields the dolomitisation process is most pervasive in lime mudstones below an evaporite unit or its former solution residues (e.g. Zone 1 in Ghawar). The reason why dolomites can form excellent reservoirs in tight mud-rich lime precursors

in many mudstone of the Arab cycles (and the Permian Khuff of Saudi Arabia and San Andres of west Texas) is the development of intercrystalline porosity. Hence, within the muddier facies of Ghawar there is a significant tie of reservoir quality to dolomite percent and crystal size, as in the coarsely crystalline sucrosic intervals in the dolomitised interval of Ghawar. Crystal size in the dolomites is related to reservoir quality with coarser crystals defining the higher porosity/permeability intervals, probably reflecting a propensity for larger pore throats and remnant dissolution voids in the more coarsely crystalline dolomites (Figure 10.18c). Locally such coarsely crystalline dolomite can create high permeability “super-k” layers (Meyer et al., 2000).

But dolomites in the Arab Formation in Saudi Arabia are not from a single generation of reflux dolomite, nor are the dolomitized units laterally homogenous. When dolomite is subdivided by texture and stratigraphy (not porosity as was done in Table

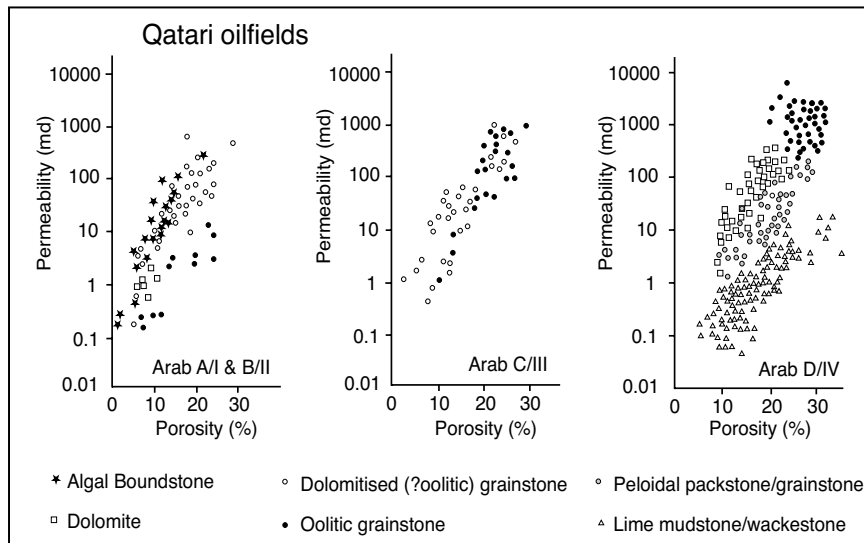

Figure 10.17. Porosity and permeability in the Arab A through D in Qatari oilfields showing the importance to reservoir quality of graininess in the limestones and dolomitization in the Arab D (Alsharhan and Nairn, 1993).

10.5) then five types of dolomite occur in the Arab D reservoir in Ghawar Field, namely (Figure 10.19; Cantrell et al., 2001):

- 1) Finely crystalline, non fabric preserving (NFP) dolomite in Zone 3 (lower Arab D) with considerable preserved calcite, low oxygen isotope values and generally poor reservoir quality. Dolomite is typically associated with hiatal surfaces.
- 2) Medium crystalline NFP dolomite with elevated oxygen isotope values and very poor reservoir quality in Zone 2 (upper Arab D). Occurs essentially as dolomite beds with little or no reservoir quality.
- 3) Medium to coarsely crystalline (NFP) dolomite with low

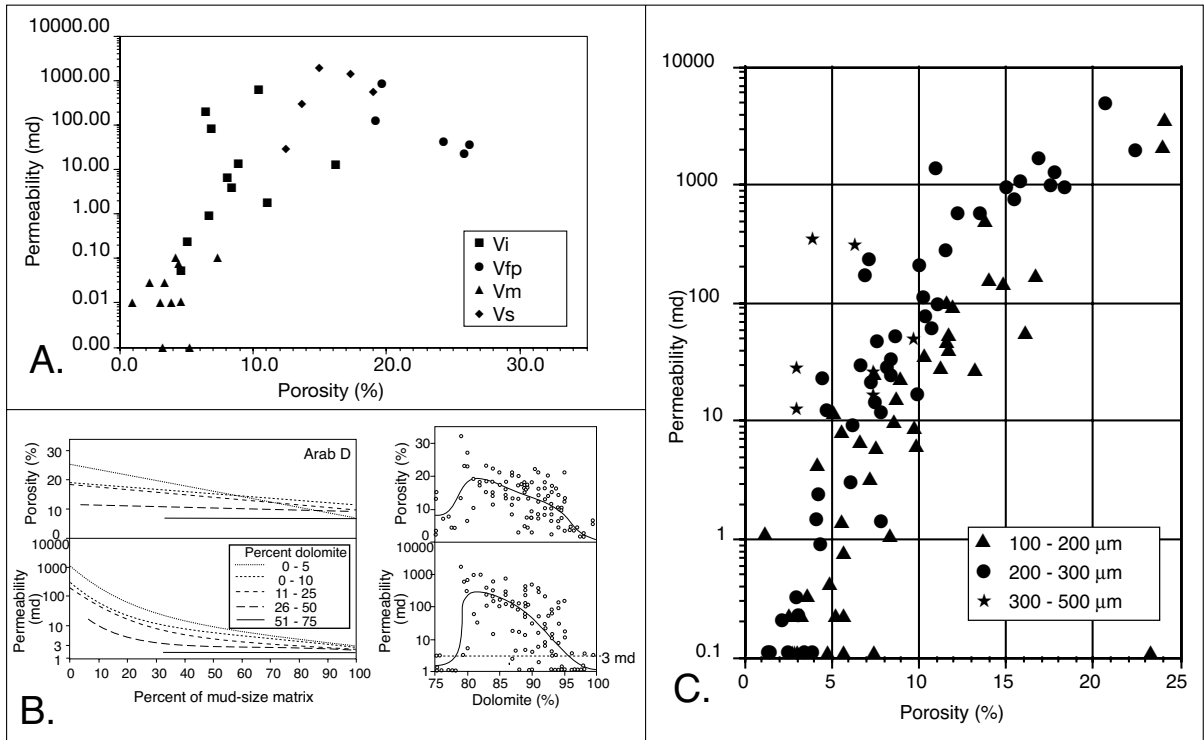

Figure 10.18. Reservoir properties of dolomites in the Arab D, Ghawar Field, Saudi Arabia. A) Textural-petrophysical classification of dolomite reservoirs (after Cantrell and Hagerty, 2003). B) Effect of mud size and dolomite percentage on porosity and permeability in the Arab D in Ghawar Field. There is a drastic increase in permeability when the dolomite proportion is between 80 and 90% (after Powers, 1962). C) Interparticle porosity permeability crossplot for dolomites of various crystal sizes (after Lucia et al., 2001).

oxygen isotope values and very good reservoir quality in Zone 2. Petrographically it is similar to medium-crystalline NFP dolomite but shows a lighter isotopic signature. It is an important reservoir component as it occurs in ‘super k’ intervals (Meyer et al., 2000). It is characterised by a high degree of intercrystalline porosity and locally retains leached mouldic porosity (typically after *Cladocoropsis*).

4) Finely crystalline fabric preserving (FP) dolomite in Zone 1 (uppermost Arab D) with elevated oxygen isotope values and generally fair to poor reservoir properties. It is minor in terms of overall reservoir volume in the Arab D and also occurs in association within and below the overlying C-D anhydrite transition. Typically it forms layers or thin sheetlike beds in Zone 1. Reservoir quality typically reflects the characteristics of the overprinted limestone facies, most of which were relatively mud free and partially cemented mud-lean packstones.

5) Rare locally occurring saddle dolomite (not sampled in the Cantrell et al., 2001 study).

Overall, dolomite comprises around 14% of the Arab D in Ghawar, with the highest proportion in Zone 1 below the anhydrite cap (Figure 10.20, 10.21; Cantrell et al., 2001). Zones

Figure 10.19. Isotopic compositions of dolomites in Arab D, Ghawar Field, Saudi Arabia, based on textures (after Cantrell et al., 2001).

Figure 10.20. Block diagram shows average percent dolomite in different Arab D reservoir zones for each field area of Ghawar Field, Saudi Arabia. The table summarises dolomite percent for all Arab D in Ghawar Field (data re-charted from Cantrell et al., 2001).

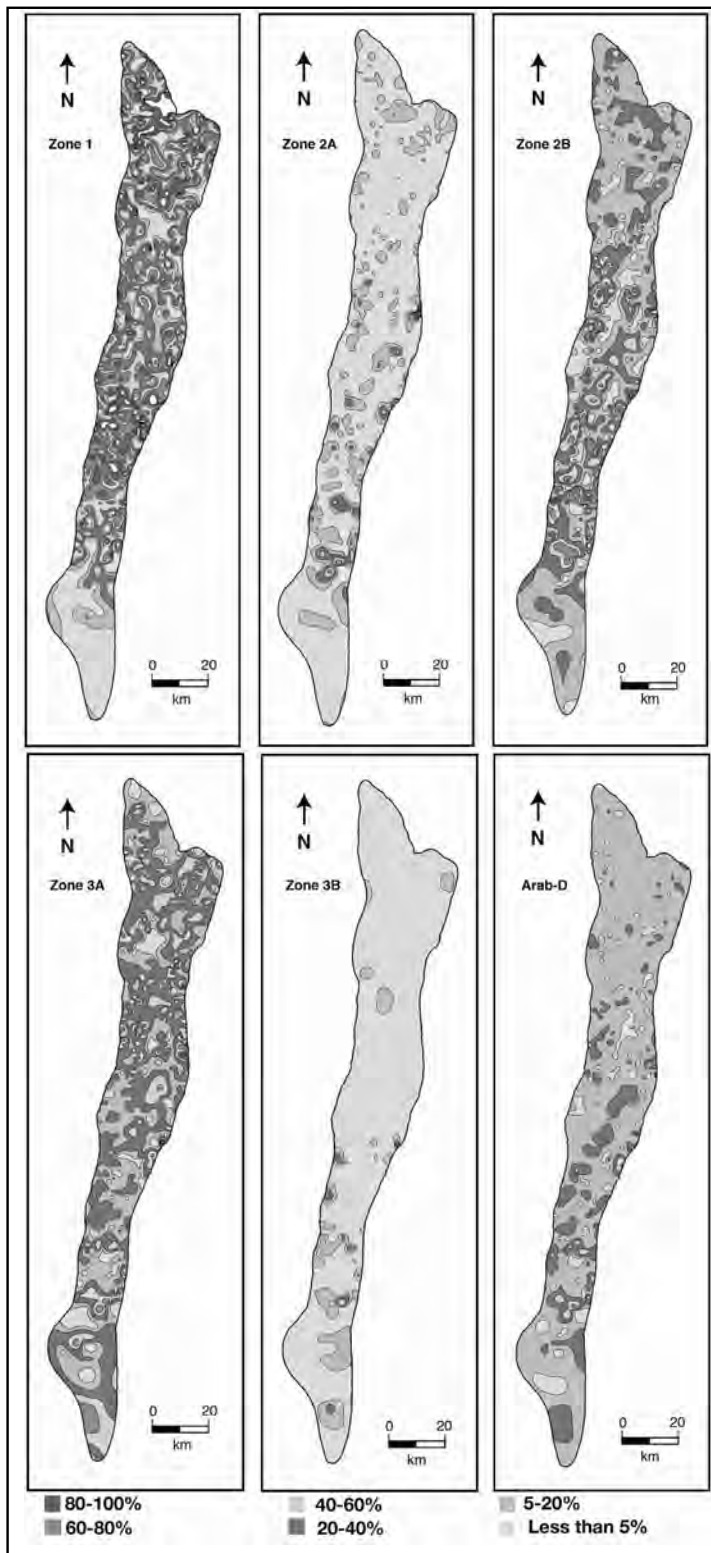

2B and 3A have less dolomite, but it is still a significant fraction of the reservoir matrix. Dolomite is a relatively insignificant contributor to reservoir matrix in Zones 3B and 2A. Within each reservoir zone much of the total dolomite percentage in a well comes from individual layers, which are intercalated with limestones. Laterally many of these dolomite layers can vary greatly in the proportion of dolomite (e.g. Zone 2B). On a Ghawar-wide basis dolomite increases systematically from north to south in Zones 2A and 2B, but zone 3A displays an inverse trend by generally decreasing from north to south (Cantrell et al., 2001).

When Cantrell et al. (2001) mapped dolomite distribution over Ghawar Field they identified a series of parallel linear trends of high dolomite content that extended for tens of kilometres along northeasterly trends (Figure 10.21). These trends are especially obvious in Zone 2B but are also discernable in Zones 2A and

3A. Locally the trends connect areas of pervasive dolomitisation, where much of the section (virtually 100% of Zones 1, 2A, 2B and 3A) is replaced by dolomite. There may also be some saddle dolomite in these same areas, but it is rare. Northeast trends are present, but less obvious, in southern Ghawar. The trends suggest some structural control to the dolomite distribution and, according to Cantrell et al. (2001), indicate diagenetic patterns that are responses to a series of underlying fractures or faults. These structural features facilitated movement of dolomitising fluids into the reservoir.

As for the dolomites in the Red River Formation discussed previously, what is not clear in Ghawar is whether the dolomitising fluids (other than zone 1 dolomites) were ascending or descending when they drove the dolomitising process. Similar fault- and fracture-controlled distributions of dolomite have been documented by Warren and Kempton (1997) in metalliferous evaporite-sealed Devonian carbonates of the platform margin of Canning Basin, Australia and by Hurley and Budros (1990) in the Silurian Scipio Albion Trend in Michigan. Dolomite's propensity for ongoing alteration and replacement in Ghawar, and its proximity to a fluid-focusing evaporite layer (first as a fluid source and then as a seal) throughout its burial history, means the origin of the Ghawar dolomites is probably not a simple unidirectional fluid flow story (Warren, 2000a). Fractures in the host carbonates may have been conduits for descending reflux fluids early in the burial history, but may have then acted as conduits for upwelling fluids later in the field's burial history. During this upwelling stage, various unbreached evaporite seals acted to pond and store escaping basinal fluids. Such flow reversals would overprint early formed dolomites with later burial signatures.

Partially preserved primary pore spaces in the Arab D limestones throughout the region typically remain as well-defined relicts in evaporite-sealed banks of weakly dolomitised coral-stromatoporoid reefs and skel-oid grainstones and grain dominant packstones. These build-ups and shoals are also characterised by leached moulds of stromatoporoid and coral branches and other aragonite allochems. Yet there is little evidence of meteoric diagenesis or karst and little or no evidence of later pervasive diagenesis and calcite cementation once the overlying evaporite cap was deposited. Much of the leaching in the reservoir seems to have been early and perhaps was an integral part of the same reflux hydrology that was dolomitising portions of the Arab Formation adjacent to evaporite beds. Considering their age (≈ 150 Ma) and relatively deep current burial (1200 - 3000 m), this preservation of widespread primary void skeletal moulds in any limestone is unusual.

Wilson (1985) argued the early emplacement of the evaporite capstones atop limestone buildups and the subsequent deposition of the Hith Anhydrite was what preserved economic porosity levels into the burial realm. Burial beneath saltern and mudflat sediment in an environment that was consistently arid and hot meant that once all the gypsum had converted to tight nodular anhydrite beds within the first few hundreds of metres of burial, the resulting seals slowed fluid flow and largely prevented further influx of suprasalt subsurface waters, which would otherwise drive pervasive shallow subsurface cementation in most of the carbonate.

The relatively pristine relict porosity in the reservoir limestones, with solution-mouldic and variably-dolomitised overprints that characterises the Arab D in Ghawar, is a reservoir style that is part of a wider association seen in many evaporite-sealed limestone and dolomite reservoirs worldwide. Such reservoirs tend to show widespread leaching of aragonite allochems without associated karst surfaces or meteoric calcite cements. High Mg-calcite allochems (red algae, echinoids, crinoids) in the same sequence are relatively unaltered or mimetically replaced by dolomite. The process driving this precompaction leaching was not entry of meteoric waters, but flushing and brine mixing driven by early burial throughflushing of hypersaline marine brines (Sun, 1992). As well as the enhancing porosity in the Arab cycles, such evaporite-associated reflux waters have enhanced porosity levels in formerly aragonitic sediments of the Permian San Andres Fm. of west Texas, and the Miocene carbonates of the Middle East and SE Spain.

Slaughter-Levelland Trend, west Texas and New Mexico

Another region of variably dolomitised limestone forming high-volume evaporite-sealed reservoirs within an epeiric carbonate platform is the Slaughter-Levelland trend of New Mexico and Texas

Figure 10.21. Map of the percent dolomite in the various reservoir zones of the Arab D in Ghawar Field, Saudi Arabia (after Cantrell et al., 2001). Clearly shows a linear fracture-related distribution Zone 2 and in the total plot for the Arab D (right hand side of figure).

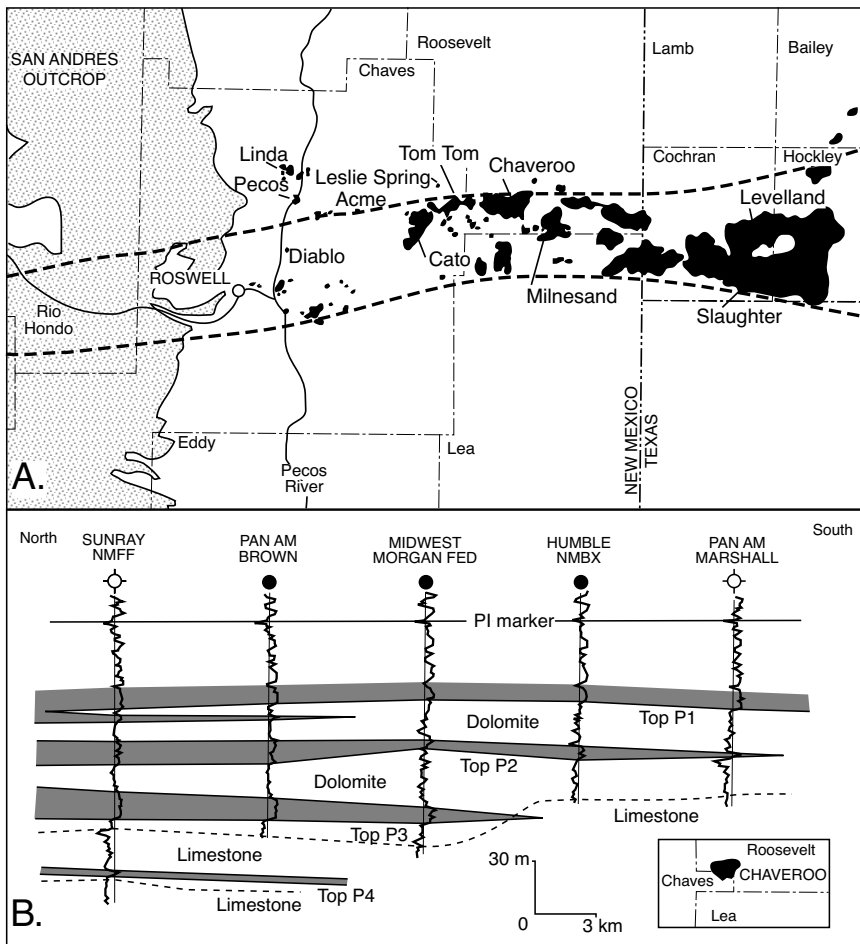

Figure 10.22. San Andres Formation in the Levelland-Slaughter trend near Roswell, New Mexico (after Elliott and Warren, 1989; Warren, 1991). A) North-south section through Chaves and Roosevelt counties in the vicinity of Chaveroo Field. B) Map of the Levelland-Slaughter trend and its equivalents in the San Andres outcrop belt west of Roswell.

(Figure 10.22a). There the main play is in the Permian San Andres Formation with the occurrence of better quality reservoir defined by the transition from platform carbonates in the south into updip massive anhydrites and halites in the north. The lower member of the San Andres contains two evaporite-sealed intervals (P_1 and P_2) that form the main reservoirs (Figure 10.22b). The producing style is a stratigraphic-diagenetic trap defined by updip pinchout (to the north) from a porous dolomite into nonporous evaporite-plugged dolomite beneath regionally extensive evaporite seals. Production from most dolomite reservoirs in the trend is slow but constant.

Cleaning-upward cycles in the lower member can be divided into 5 lithofacies groupings (P_1 to P_5) stacked into shoaling upward successions, with each cycle being 15 -50 m thick

(Elliott and Warren, 1989). Shaly carbonate mudstones define the base of each cycle; they are the initial low-energy deeper water deposits formed atop a flooding surface. These laminar mudstones are overlain by more massive biomicritic packstones and wackestones (≈ 10 m thick) containing brachiopods, bryozoa, crinoids, molluscs, and cephalopods, sometimes forming what may be local low relief bioherms with phylloid algal debris. These various mudstones were deposited on an open marine shelf, initially below wave base and under low-energy conditions.

Next comes the dolomitized intervals (typical matrix porosities 10-12%; permeabilities 20-30md), which constitute the main reservoir in the trend (Figure 10.23a). It is by far the most variable carbonate unit and in places retains remnants of primary texture, giving three variably dolomitised subtypes:

1. Wispy laminated to microstylolitized biomicrites, intramicrites, and peloidal micrites and packstones that entrain poorly preserved open marine faunas. Skeletal material is typically preserved as moulds, which near to the anhydrite cap are filled or partially filled with anhydrite cement. This is the most common reservoir unit in the Slaughter-Levelland trend.
2. Oolitic peloid-foram grainstones, which were deposited as localized shoals (uncommon unit in the Slaughter-Levelland trend).
3. Inter- to supratidal mudstones with fenestra, pisolites, biolaminites, and possible desiccation cracks (uncommon unit in the Slaughter-Levelland trend).

Next comes a massive to laminar anhydrite unit that historically was interpreted as a sabkha deposit (Ward et al., 1986). It is metres-thick in the Slaughter-Levelland trend and is made up of a dm-scale interbedded nodular anhydrite and laminated

Figure 10.23. Lithofacies of the San Andres Formation. A) Dolomitised pel-mouldic wackestone/packstone showing angular highly altered peloidal outlines, moulds can be plugged by anhydrite (image is about 2 mm wide). b) Elongate nodules of anhydrite typical of the seal facies showing remnant subaqueous gypsum ghosts with internal swallowtail-V's still visible (scale bar in cm).

anhydrite. Some cores immediately to the north of the field preserve vertically aligned anhydrite nodules (gypsum “ghosts”), which pass downward into laminated and bedded nodular mosaic anhydrite (Figure 10.23b). The alignment, the lamination, the purity, the thickness of the units, and the fact that it is laterally equivalent to subaqueous platform gypsum to the north implies that in the Levelland–Slaughter area this unit was laid down near the depositional edge of a saltern (Elliott and Warren, 1989). In the Palo Duro Basin, situated further to the north of the Slaughter-Levelland trend, the equivalent to the various saltern anhydrite caps are overlain by saline-pan halites.

To the west of Roswell the outcrop equivalents to the anhydrite seals are dissolution breccias, which can be used as a regional mapping datum in the vicinity of the Rio Hondo outcrops (Elliott and Warren, 1989). Lateral facies changes can be seen in each outcropping cycle, showing the carbonate intervals were deposited as facies mosaics on an extensive relatively low energy muddy carbonate marine platform, with each cycle separated by evaporites.

The mosaic distribution of the reservoir carbonates and a lack of grainstone and shoreline/strandline shoals either in outcrop or the subsurface, led Elliott and Warren (1989) and Warren (1991) to revise the reservoir model for San Andres deposition the Levelland-Slaughter

Trend. In contrast to previous models that saw the reservoirs in the Slaughter Levelland trend as sabkha-sealed depositional pinchouts, they argued sabkhas are a relatively minor component in the widespread subaqueous saltern seal. Rather than a stratigraphic control the reservoir dolomites were created by brine reflux through relatively muddy epeiric platform carbonates via brines fed from up dip salterns (Figure 10.24; Warren, 1991).

This saltern edge model of San Andres deposition offered a different exploration strategy for the San Andres reservoirs on the Northwestern Shelf of the Permian Basin and elsewhere (Warren, 1991). Generally, saltern-associated reservoirs do not form by updip pinchout of marine grainstones and mudstones

Figure 10.24. Reflux brines drive dolomitisation in marine carbonates some distance downdip from intervals of more restricted shoreward carbonate that tend to be overdolomitised and evaporite plugged (after Saller and Henderson, 1998 and Elliott and Warren, 1989).

into stacked sabkhas. Rather, the reservoir trend marks the transition from an updip, evaporite-plugged, partially-dolomitized subtidal–intertidal section into a dolomitized, subtidal–intertidal sequence characterized by intercrystalline and relict interparticle porosity. Unlike areas closer to the source of the reflux brines and beneath the saltern proper, these regions are not pervasively plugged with evaporite cements. This dolomitised zone passes down-dip into more tightly-cemented open marine subtidal

limestones. Updip plugging was driven by episodes of widespread evaporite deposition and the associated sluggish reflux of supersaturated brine into the underlying newly forming dolomites. The down-dip subtidal–intertidal section saw some evaporitic plugging, but it did not suffer the longterm massive influx of evaporite cements experienced further updip. Its more marine-marginal position allowed the porosity to remain open and magnesium-rich solutions associated with brine reflux to

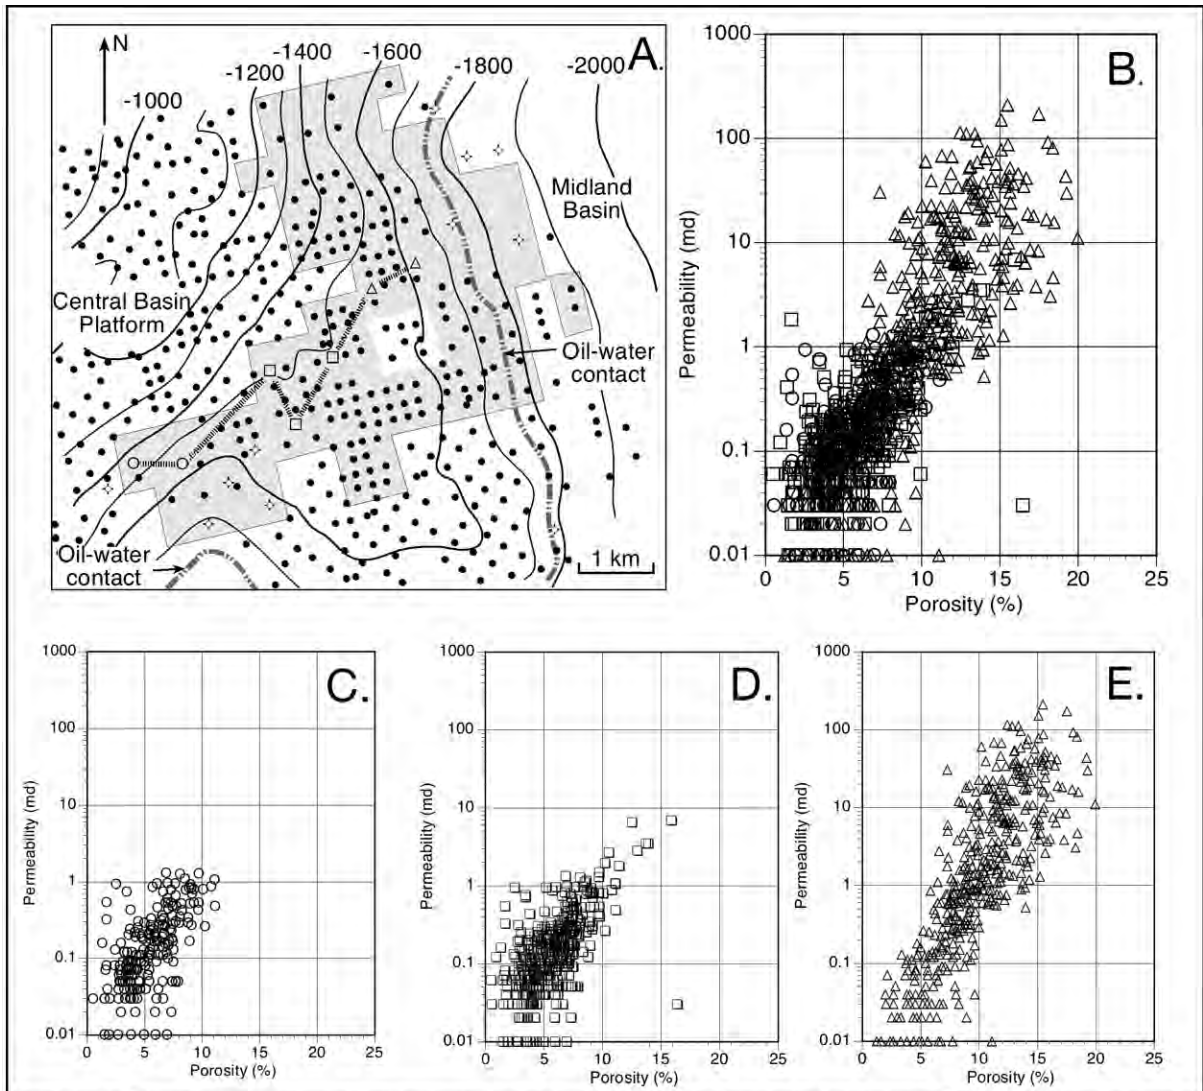

Figure 10.25. Porosity and permeability increase in the Moss unit of the Grayburg Formation in South Cowden Field, west Texas (redrafted and replotted from Saller and Henderson, 1998). A) Map of distribution of wells used in data compilation. The dolomitised transect used to compile data in B-E runs from the overdolomitised evaporite-plugged platform (O) to a dolomitised transitional zone (□) to the more basinward partially dolomitised platform wells with minor evaporite plugging (Δ) B) porosity permeability from all measured plugs in wells along the transect. C) Porosity-permeability from evaporite plugged platform interior wells, D) Transition zone wells. E) Porosity permeability from reservoirs in wells more distal to the evaporite-plugged platform interior. The plots B to E show an obvious increase in reservoir quality in the crossplots that corresponds to a decrease in evaporite plugging and an increase in dolomite crystal size along the downdip reflux pathway (as shown in Figure 10.24).

enter the carbonates to evolve into more coarsely crystalline dolomites. The Levelland-Slaughter reservoir trend is not a palaeoshoreline, nor is it a stratigraphic pinchout trap. It is a diagenetic front and trap with the best reservoir quality defined by the zone immediately down-dip of the thinning edge of the San Andres saltern (Warren, 1991).

Dolomitised limestones Central Basin Platform, west Texas

The same diagenetic control to reflux dolomite intensity seen at the regional scale in the Levelland Slaughter trend is also true at the oil field scale on the Central Basin Platform to the south. Saller and Henderson (1998) noted similar variations in reflux-related "dolomite intensity" controlling reservoir properties in the evaporite-sealed North Riley Field at the northern margin of the Central Basin platform and in South Cowden Field on the east-central margin of the Central Basin platform, Texas (Figure 10.25a, b). The main reservoir units in North Riley Field are permeable dolomites of the Leonardian (Permian) Clear Fork Formation, while dolomites of the Grayburg Formation (Guadalupian, Permian) are the main reservoir in South Cowden Field. Replacive dolomitization and the creation of intercrystalline porosity in both fields was driven largely by the reflux of evaporatively concentrated seawater circulating shortly after deposition of the original limestone matrix.

Ongoing reflux-driven evaporite plugging means porosities and permeabilities are lower in platform-interior dolomites and higher in dolomites near the platform margins in both fields (Figure 10.25c through e). Reservoir porosity and permeability are not strictly facies dependent in either field. As in the Slaughter-Levelland trend, Saller and Henderson (*op cit.*) found the distribution of porosity and permeability is largely the result of location within the diagenetic dolomitising system and to a lesser extent reflects the original depositional permeability of the limestones.

Due to inherently higher brine densities beneath an evaporite-depositing lagoon or saltern, the dense saline dolomitising brines, generated by evaporative concentration of seawater in restricted evaporitic mudflats and salterns, percolated downward and seeped basinward (refluxed) through the sediments. Refluxing brines, supersaturated with respect to dolomite and calcium sulphate, precipitated large quantities of dolomite and anhydrite cement in the proximal parts of the reflux system. This lowered dolomite saturation in waters flowing into distal portions of the reflux system. Lower dolomite saturations resulted in less dolomite, fewer nuclei and larger crystals (not

overdolomitised) along with more intercrystalline porosity and permeability retention in distal parts of the system (Figure 10.24). Many platform-interior wells in both fields are structurally higher than wells near the platform margin, yet structurally lower wells near the platform margin are more porous and permeable, and have produced three to ten times more oil than the platform-interior wells (Saller and Henderson, 1998).

Reservoirs in the Jurassic Smackover Fm., Gulf of Mexico

More than 1 billion barrels-equivalent of oil and gas has been discovered in the Smackover of the northeastern Gulf Coast Basin (Prather 1992a, b). The majority of these hydrocarbons are found in a few large fields such as Jay, Big Escambia Creek, Blackjack Creek, Chunchula, and Hatter's Pond, and the fields in the Mobile Bay complex. Except for the fields in the Mobile Bay complex, which have Norphlet Sand reservoirs, the Smackover Formation is the primary hydrocarbon reservoir in the large fields and many smaller fields, such as Vocation, Barnett, Uriah, and Appleton. Like the Arab D in the Middle East, the richness of Smackover hydrocarbon system in the region is a result of the co-occurrence of microlaminated lime mudstone source rocks, dolostone reservoir rocks, and an evaporite cap, all within an overall shoaling depositional package (Moore, 1984; Heydari, 1997).

The Smackover Formation forms a subsurface arc about the Gulf of Mexico and was deposited in a transgressive-regressive event during Upper Jurassic (Oxfordian) time (Figure 10.26a). It is underlain by the siliciclastic eolian-wadi Norphlet Formation in more marginward areas and by the Louann Salt Formation further out in the Basin. The Smackover, and the overlying Buckner Anhydrite Member of the Haynesville Formation, were deposited in three depositional stages that correspond to periods dominated by marine transgression, aggradation, and ultimately progradation. The Buckner Evaporite and its equivalents, which form the seal to the various upper Smackover fields was interpreted as sabkha until the mid 80s (Lowenstein, 1987). But in the 90s its interpretation changed to an evaporitic mudflat, a mosaic of sabkhas and salinas passing up and laterally into a saltern (Mann, 1990, 1992; Prather 1992a, b; Benson et al., 1996).

The Smackover is a combination of platform dolomites, shelf-margin oolitic and peloidal grainstones, and slope and basin limestones. It can be subdivided into three informal units, the lower, middle, and upper Smackover (also known as Smackover C, B and A, respectively). Each unit was deposited

Figure 10.26. Smackover Formation, Northern Gulf of Mexico. A) Generalised map of Smackover distribution along the coast of the United States (after Melas and Friedman, 1992). B) The downdip limit of reflux and shallow burial mixed water zones occurs between dolostone reservoir rocks and nonporous lime grainstones (after Prather, 1992a).

in a different depositional setting on a gently shoaling carbonate ramp. Lower Smackover deposition accompanied a rapid sea level rise that inundated most palaeohighs in the basin to produce a depositional system that was first transgressive and then aggradational in nature (Benson et al., 1996; Prather, 1992a, b). Most sediments in the lower Smackover are basinal and consist of laminae of dark brown to black mudstones, alternating with laminae of pyrite and siliciclastic silt or sand. Locally they are organic rich and have acted as widespread source rocks for the hydrocarbons in the overlying Smackover sands (Heydari, 2000). The style of the laminae in the lower Smackover changes upward from very thin parallel laminae near the base to slightly thicker irregular laminae higher in the section. Algal patch reefs grew in lower Smackover time around the periphery of some palaeohighs, driven by the rising sea.

The middle Smackover is composed of sediments deposited on a low-energy, open-marine platform, laid down as sedimentation caught up with relative subsidence. Short-term sea level fluctuations produced numerous shallowing-upward packages (parasequences) in the middle Smackover. Two lithofacies are typical of the middle Smackover: a wispy-laminated, crustacean-pellet carbonate mudstone containing a sparse pelagic fauna and a densely burrowed skeletal-pellet wackestone containing a benthic fauna. Tidal flat, lagoon, and shoal complexes formed in

topographically higher parts of the northern Gulf, while sub-wavebase sediments were deposited in deeper waters and away from salt structure-induced seafloor shoals.

The upper Smackover consists of several grain-supported lithofacies deposited in shoal settings ranging from strandzone (tidal) bars and channels to beaches, islands, and algal-stromatoporoid reefs. Burrowed pellet and oncolite packstones and algal-stromatoporoid boundstones formed as moderate-energy outer shoals, and sequences of crossbedded mixed allochem, oolite, and oolitic grainstones comprised the current-reworked inner shoals. During upper Smackover deposition, sea level was relatively stable allowing the Smackover to aggrade and prograde. Upper Smackover deposits are peritidal or strandzone dominated. Short-term sea level fluctuations produced shallowing upward packages capped by exposure surfaces in crestal locations and deposited widespread syndepositional isopachous marine cements of aragonite (now calcite).

During lower Buckner deposition, evaporitic mudflats formed over the crests of the palaeohighs and passed off-structure and landward into salterns. Short-term sea level fluctuations produced a series of higher-order shallowing-upward evaporitic mudflat cycles behind the main oolite shoal. Development of subaqueous gypsum increased during ongoing restriction of the northern Conech Embayment and ultimately led to widespread deposition of the subaqueous saltern evaporite seal that defines the upper Buckner Anhydrite. This unit seals most Smackover reservoirs.

Dolomitised upper Smackover facies constitute the most productive reservoirs. In fact, dolomitisation and leaching are critical to the preservation of economic levels of porosity throughout the Smackover in the northern Gulf of Mexico (Figure 10.27). Historically, a minimum of 4% porosity and 0.1 md permeability in Smackover carbonates is considered to be reservoir grade (Becher and Moore, 1976). Economic Smackover porosity is of three main types:

1. Partially preserved primary interparticle porosity
2. Leached mouldic porosity
3. Intercrystalline porosity within coarsely crystalline dolomites

Most reservoirs are found in: a) grainstone shoals, b) fractured and dolomitised sediments of the inner-shelf and, c) algal stromatoporoid buildups (Mancini et al., 2000). The best reservoirs in Arkansas, Louisiana and eastern Mississippi are in dolomitized intervals that preserve incompletely cemented interparticle and mouldic porosity (Figure 10.26a). The updip

Smackover close to the palaeoshoreline in this region often contains leached mouldic porosity due to mixed-water flushing. In east Texas, Alabama, and Florida, the precipitation of dolomite with intercrystalline porosity has enhanced the reservoir potential of the Smackover grainstones.

Dolomitization is almost always required to form a reservoir in inner-shelf Smackover sediments and enhances the reservoir character in the grainier shoal sediments. A rule of thumb in the region is that a minimum of 80% dolomite is necessary for consistently good reservoir quality (Figure 10.27), but rocks that are 100% dolomite, or dolomites with pervasive evaporite cements, are not good reservoirs. Individual reservoirs can be as thick as 10 metres, with porosities as high as 26%, and matrix permeabilities as great as 6.5 md. Although enhanced reservoir quality is often related to reflux dolomitization, the distribution of dolomite, like that of the interparticle porosity and the mouldic porosity, is in large part inherited from porosity trends in the original depositional setting.

Geochemical and petrographic data suggest that calcite/aragonite alteration and dolomitization took place in: (1) phreatic seawater-seepage, (2) brine reflux, (3) nearsurface mixed-water, (4) shallow-burial mixed-water, and (5) deeper burial environments. These settings overlapped in time and space to form a

Figure 10.27. Relationship between porosity and the degree of dolomitisation in Jay Field, Conech Embayment. The lower Smackover facies in the field shows low porosity and are relatively less dolomitised compared to the upper Smackover grainstones, which have high porosity and are extensively dolomitised (data from point count data and are replotted from Melas and Friedman, 1992).

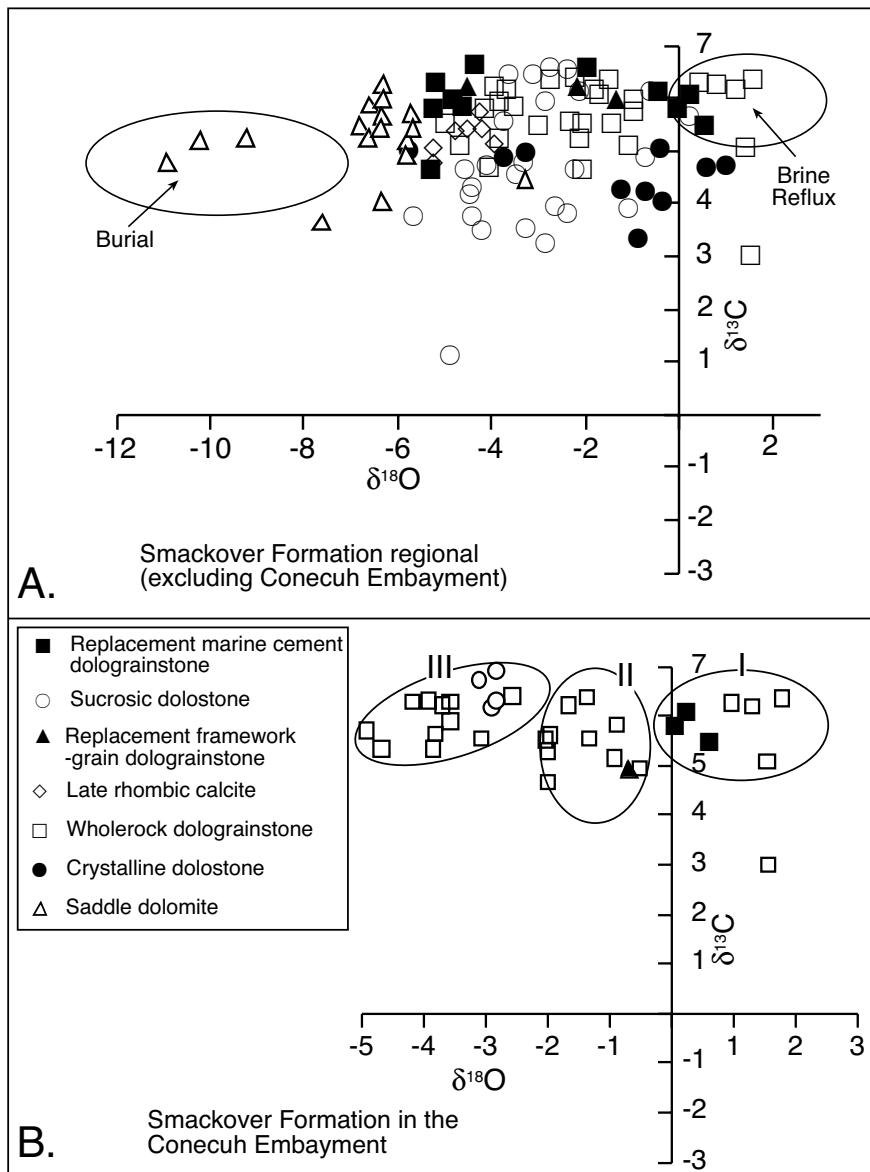

Figure 10.28. Stable isotopic signatures of the Smackover Formation, Northern Gulf of Mexico (after Prather, 1992a). A) Plot of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ of dolomites from the Northern Gulf of Mexico, excluding the Conecuh Embayment and deeper burial dolomites. B) Plot of $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ of dolomites from Conecuh Embayment.

“platform-scale” dolostone composed of a complex mixture of dolomites and authigenic cements (Prather, 1992a). Of the five, the brine reflux and the deeper burial settings can be thought of as end members of a diagenetic spectrum creating dolomites. They are also the most easily separable of the five using isotopic signatures (Figure 10.28a). The other three form a related but overlapping group of subsurface alteration features.

Texturally, without isotopic data and with the exception of early isopachous rim cements, it is very difficult to assign origins to the various replacements and cements that typify the Smackover reservoirs.

Brine reflux dolomitization of the upper Smackover was largely driven by movement of hypersaline brines during deposition of the overlying Buckner Anhydrite member of the Haynesville Formation. Flushing by dense brine explains the distribution of early dolomite in southeastern Alabama and western Florida (Barrett, 1986; Saller and Moore, 1986; Worrall and Warren, 1986). Such beds show an enrichment in $\delta^{18}\text{O}$ indicative of precipitation from evaporated brines and constitute thin zones within the upper 5-7 m of the Smackover throughout the Conecuh Embayment. Replacement of precursor marine cements by dolomites rich in ^{18}O places this phase of dolomitization early in the paragenetic sequence, consistent with a reflux origin. Thicker zones (5-15 m) of isotopically-enriched reflux dolomite occur locally around the Conecuh Ridge, Pensacola Arch, and over the Chunchula Platform (Figure 10.26b). Time-slice lithofacies maps show that these thicker dolomite zones correspond to the locations of coastal evaporitic mudflats, which were first established on palaeotopographic highs within a pericontinental setting (Prather 1992a). These zones show aggradational geometries produced during an early regressive phase of Smackover/Haynesville deposition. Thicker zones of enriched dolostone probably formed in these areas because of the ongoing aggradation of the reflux dolostone host through time.

Texturally, without isotopic data and with the exception of early isopachous rim cements, it is very difficult to assign origins to the various replacements and cements that typify the Smackover reservoirs.

Brine reflux dolomitization of the upper Smackover was largely driven by movement of hypersaline brines during deposition of the overlying Buckner Anhydrite member of the Haynesville Formation. Flushing by dense brine explains the distribution of early dolomite in southeastern Alabama and western Florida (Barrett, 1986; Saller and Moore, 1986; Worrall and Warren, 1986). Such beds show an enrichment in $\delta^{18}\text{O}$ indicative of precipitation from evaporated brines and constitute thin zones within the upper 5-7 m of the Smackover throughout the Conecuh Embayment. Replacement of precursor marine cements by dolomites rich in ^{18}O places this phase of dolomitization early in the paragenetic sequence, consistent with a reflux origin. Thicker zones (5-15 m) of isotopically-enriched reflux dolomite occur locally around the Conecuh Ridge, Pensacola Arch, and over the Chunchula Platform (Figure 10.26b). Time-slice lithofacies maps show that these thicker dolomite zones correspond to the locations of coastal evaporitic mudflats, which were first established on palaeotopographic highs within a pericontinental setting (Prather 1992a). These zones show aggradational geometries produced during an early regressive phase of Smackover/Haynesville deposition. Thicker zones of enriched dolostone probably formed in these areas because of the ongoing aggradation of the reflux dolostone host through time.

Thin zones of enriched dolostones similar to those over most of the Conecuh embayment also occur sporadically around the flanks of the Chunchula Platform, Manila Basin rim, and the flanks of the Hatchatigbee Platform (Figure 10.26b). The downdip limit of thin reflux dolostones tentatively, inferred from very limited well control, appears to parallel depositional strike. Thinness or absence of enriched dolomite zones updip of this line may be associated with rapid progradation of the shoreface/coastal-sabkha couplet resulting in rapid lateral shifting of reflux zones, which prevented aggradation of reflux zones and allowed little time for refluxing brines to circulate deeper into the upper Smackover grainstones.

Brine reflux was driven by Buckner deposition and was tied to regional drawdown hydrology in the region behind the oolite shoals. Drawdown driving the reflux also influenced porosity evolution in the adjacent Smackover shoals that formed the isolating sill. For example, the drop in relative sea level in the Conecuh Embayment during the Oxfordian (Prather, 1992b) exposed thick submarine oolite sand bars of the upper Smackover on the southern flank of the Conecuh Basin. It created a subaerial sill, which separated the Conecuh Basin from the Gulf, as more than 100 m of Buckner salts were laid down as a saltern within the isolated intraplatform sag. The sill today consists of a thick (18–55 m) lower unit of medium to finely crystalline sucrosic dolostone and oolite dolograinstone overlain by a thinner upper unit of finely crystalline oolite dolograinstone. $\delta^{18}\text{O}$ analysis indicated that the dolostone in the sill is composed of three populations of dolomite. Two populations of dolomite depleted in ^{18}O occur in the lower sill (Figure 10.28b, groups II and III). A third population found in the upper part of the sill is relatively enriched in ^{18}O (Figure 10.28b, group I). The contact between the upper and lower units is gradational over about 1 m and has no apparent relationship to stratal boundaries. This contact was first noted by Vinet (1982) in wells from Jay, Blackjack Creek, and Big Escambia Creek fields, and was subsequently located in more wells by Prather (1986).

The association of a relatively abrupt localized geochemical and lithologic discontinuity within rocks beneath a sill that was subaerial during a sea level lowstand suggests the discontinuity may represent a fossil water table (Prather 1992a). If this is the case, the following events must have taken place: (1) partial dolomitization of the lower unit as seawater seeped through the sill to recharge the saltern brines in the Conecuh Basin, (2) complete dolomitization of the upper unit by reflux processes as the upper sill was buried during aggradation and progradation of Buckner evaporites (fill and spill sedimentation of the basin),

and (3) continued burial dolomitization of the lower unit by ^{18}O -depleted dolomitizing fluids. Each of these events gave rise to each of the three isotopic groups of dolomite from the sill: (1) seawater seepage dolomite with $\delta^{18}\text{O}$ values of -0.6 to -1.9 ‰, (2) reflux dolomite with $\delta^{18}\text{O}$ values of 2.0 to 1.0 ‰, and (3) later burial dolomites with $\delta^{18}\text{O}$ values of -2.6 to -4.6 ‰ (Figure 10.28b).

An earlier nearsurface mixed-water environment, locally affected sediments from the surface to several tens of metres thick in the vicinity of local freshwater entry points. Freshwater entered the Smackover either through groundwater sinks (exposed palaeohighs or islands) or via the updip part of the regional groundwater flow system. Under these conditions, freshwater supply to coastal areas of the Northern Gulf, such as the Conecuh embayment, probably was limited to what was supplied by the updip drainage system between the Conecuh ridge and Pensacola arch. These waters leached aragonite allochems, leaving behind hollow grains preserved only by their micrite envelopes. The $\delta^{18}\text{O}$ contents of these replacement dolomites are slightly depleted relative to seawater-seepage dolomites, slightly enriched relative to later rhombic dolomite cements, and closely associated with freshwater-phreatic calcite cements, suggesting a nearsurface mixed-water origin. Dolomite-replaced precursor marine cements, with only slightly depleted $\delta^{18}\text{O}$ compositions relative to seawater-seepage dolomites, have been encountered only in the Conecuh embayment. This is consistent with the notion that they are connected to isolated mixing zones. Their localized distribution probably reflects the limited extent of freshwater environments in such an arid climate.

Rhombic dolomite crystals of the shallow-burial mixed-water environment typically have cloudy cores and clear rims. These rhombic dolomite cements overgrow neomorphic fabrics, which formed after a period of leaching and sparry calcite precipitation. Paragenetic relationships show that vuggy and oomouldic pores within the Conecuh embayment and throughout the Northern Gulf region are virtually contemporaneous (Prather 1992a). Extensive leaching of this kind suggests considerable local artesian influxes of fresh to brackish water after evaporite deposition had ceased. The wide band of leached fabrics that parallels the updip limit of the Smackover suggests freshwater entry probably occurred along the Smackover outcrop in western Alabama and where Haynesville alluvial-fan sandstones interfinger with upper Smackover grainstones around the Conecuh Ridge and Conecuh embayment (Figure 10.26a). Leaching trends similar to this are described by Moore and Druckman (1981) from the updip Smackover of Arkansas and Louisiana.

Their marginward position suggests that the downdip limit of leached fabrics is controlled by a change from less stable aragonite oolites updip to more stable calcite oolites downdip. In eastern Mississippi, Alabama, and Florida, however, the trend of leached fabrics is perpendicular to depositional strike. Therefore, the distribution of leached fabrics in the east is more likely related to the downdip position of a zone of undersaturated groundwater (Figure 10.26b). Sparry calcites that line the large vugs in the Smackover of the Conecuh embayment have somewhat depleted $\delta^{18}\text{O}$ signatures and low $\text{Fe}^{++}/\text{Mn}^{++}$ ratios, which suggest precipitation in warm, slightly reduced, fresher subsurface waters. Abrupt changes of formation-water redox conditions or trace-element concentrations outlined by cathodoluminescent zonation patterns indicate these spars probably precipitated at sufficiently shallow burial depths to receive some recharge of oxidized fresher water from the surface after evaporite deposition had ceased.

These isotopically depleted dolostones of the deeply circulating regional fluid mixing stage constitute the signature of the most widespread reservoir rocks in the Smackover. They define areas where deeply circulating meteoric fluids (artesian waters) mixed with marine-phreatic or basinal brines and overprinted sediments from a few metres to hundreds of metres below the Buckner seal. They are confined to grain-supported and boundstone rock types below the Haynesville Formation, suggesting that the fresher water inflows, which mixed with formation brines, were confined to an aquifer lying below the evaporites and fine-grained siliciclastic rocks of the Haynesville Formation. By the time they were circulating they were excluded from the now-tight carbonate mudstones and wackestones of the lower Smackover Formation. Recharge of the regional aquifer probably occurred as phreatic head rose along the Smackover/Haynesville subcrop during basinward tilting. Associated progradation of the overlying Cotton Valley strandline drove basinward migration of a thick continental freshwater lens atop the saltern evaporites.

In a tectonically stable area such as the Gulf Coast, large variations in recharge of regional confined aquifers, like the Smackover, are likely to occur only in response to substantial fluctuations of sea level (Harrison and Summa, 1991). Maximum downdip limit of the regional mixed-water zone and associated dolomite reservoirs is likely, therefore, to have occurred during prominent sea level lowstands, such as those proposed for the Valanginian (Haq et al., 1987). The distribution of dolomite depleted in ^{18}O suggests that the interpreted regional mixed-water zone must have migrated downdip a minimum of 193 km from points of recharge along the Smackover subcrop and the Conecuh embayment (Prather 1992a).

Later precipitation of saddle dolomite in the deeper burial environment has been linked to chemical compaction of dolostones, thermochemical sulphate reduction, hydrocarbon migration, and epigenetic sulphide emplacement (Heydari, 1997). Their depleted $\delta^{18}\text{O}$ values suggest formation temperatures higher than the other Smackover dolomites (Figures 9.45a, 10.28a). Hydrocarbon inclusions suggest that the saddle dolomites are late burial cements that were at least contemporaneous with hydrocarbon migration, which began in the middle Early Cretaceous. In the Smackover, as in the Arab D, evaporites played an early role in the formation of reflux dolomite and then a subsequent role as a focus (aquiclude) for regional flows of deeply circulating groundwaters and basinal waters.

Middle East reservoirs sealed by bedded basinwide evaporites

As well as saltern evaporites sealing and driving alteration processes in intercalated platform carbonates, there a number of reservoirs sealed by thick caps of basinwide salts. Where the traps are stratigraphic, permeability tends to be developed in dolomitised carbonates beneath bedded seals. Such reservoirs tend to be patchy and of lesser quality compared to reservoirs hosted in the downdip areas of the saltern-sealed traps discussed in the previous section. But where the subsalt traps are structural, broadly-drained anticlinal culminations, as in the Miocene successions of the foreland fold belt of the Zagros in Iraq and Iran, the fields are large and many are supergiants. This structural association reflects ability of evaporites to maintain seal integrity under deformation, while the underlying and intercalated dolomites and limestone fracture. This structural association is discussed in more detail later in the chapter, for now our discussion will focus on the effects of syndepositional reflux dolomitisation on reservoir quality below basinwide evaporites.

Eocene and Miocene associations, Middle East

Carbonate platform and sandstone reservoirs beneath Tertiary-age basinwide seals in the Arabian Gulf and the Gulf of Suez have been overprinted to varying degrees by reflux dolomite. The evaporites define two main age-related saline associations: Lower Eocene and Middle Miocene (Figure 10.29). The Eocene evaporites are saltern evaporites precipitated in an intracratonic sag on the continental side of a foreland bulge in front of the rising Zagros chain (Alavi, 2004). Across the Gulf they constitute widespread 10-20m thick anhydrite/gypsum units within the Rus Formation and its equivalents. Salts in the Rus can perhaps also be considered the youngest example of wide-

spread platform evaporites and accumulated immediately prior to the onset of icehouse eustasy (Chapter 5). Miocene basinwide seals in the region are better known and more significant economically as they form caps to the Asmari limestone. They accumulated in the isolated foreland deep in front of the Zagros suture (Alavi, 2004) and make up the Fars/Gachsaran formations in the Northern Arabian Gulf. Their dissolution residues typify outcrops in the Dam Formation of Qatar and Saudi Arabia (Dill et al., 2005). Similar Middle Miocene basinwide evaporites are also highly effective seals to producing intervals in the rift-infilling Ras Maalab Group in the Gulf of Suez (Alsharhan, 2003).

Eocene evaporites (bedded anhydrites) of the Rus Formation seal platform carbonate reservoirs in the northern Arabian Gulf (Iraq and Iran). Reservoir quality tends to be patchy and constitute the upper portions of thicker stacked Mesozoic pay horizons in giant and supergiant fields of the Northern Gulf. In the 45 by 25 km anticline that is the Nahr Uhm supergiant field in Iraq the structural closure for the various pay zones varies with depth and ranges from 200 metres for the Dammam (Eocene) down through the Rus Formation to about 800 metres for the Lower Cretaceous Yamama reservoir. The Cretaceous is the main production focus for many of the huge fields of Iraq and Kuwait. In the western and southern Gulf (Kuwait, Saudi Arabia, Qatar and the Emirates), the Rus Formation outcrops or subcrops and is typically leached of its bedded evaporites (Dill et al., 2003). Once leached of its salts it constitutes an important aquifer capable of producing potable groundwater. Only dissolution residues and collapse horizons remain in outcrop as indicators of the former presence of widespread bedded evaporites in the Rus Formation, along with associated slumps, digitate stromatolites, hollow cauliflower cherts and calcite nodules (pers. obs).

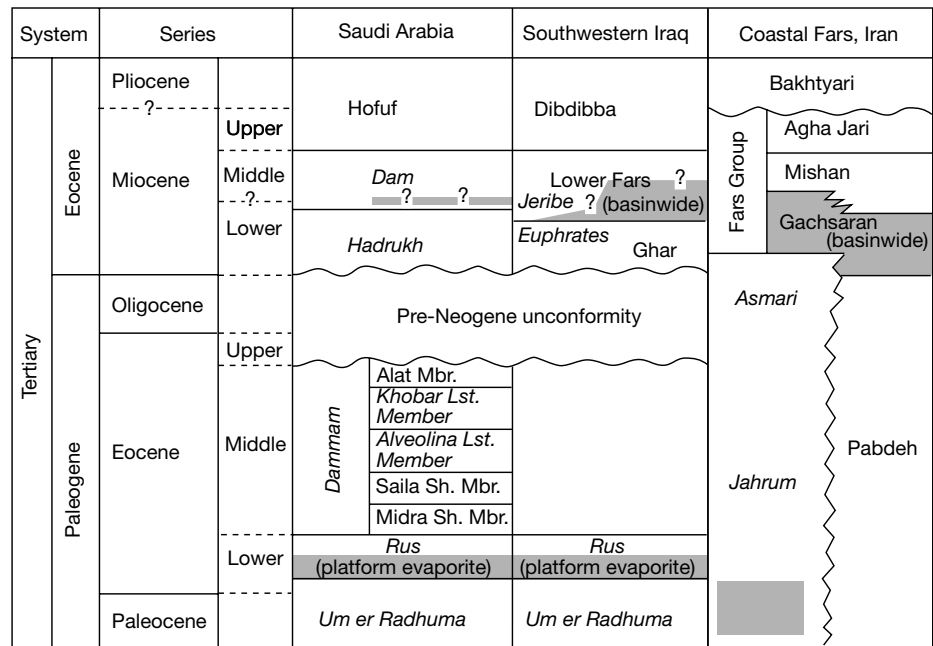

Figure 10.29. Schematic Tertiary Stratigraphy of the Arabian Gulf, with evaporite-entraining successions shaded grey (in part after Tleel, 1973; Sharland et al. 2001, Alavi, 2004).

But the most productive reservoirs in the northern Arabian Gulf are Miocene and are platform or deeper water carbonates (Asmari, Euphrates, Jeribe formations) that are sealed by Middle Miocene bedded salts of the Lower Fars/Gachsaran and equivalents (Figure 10.29). Core analysis of lower Miocene platform carbonates below these seals in Iraq show that open-marine subtidal carbonates have moderate to good porosity (10-35%), but have highly variable permeabilities ranging from less than 1 md to several hundred millidarcies. Restricted tidal flat (evaporitic mudflat) carbonates intercalated in the same sections are tight (Figure 10.30a, 10.31; Sun and Esteban, 1994). In general, the best reservoir quality in the lower Miocene carbonates of the Middle East occurs in: (1) mud-lean skeletal packstones in which leached mouldic and vuggy porosity is well connected (e.g., Euphrates and Jeribe formations of Iraq and Syria), (2) oolitic packstones-grainstones with well-preserved primary intergranular porosity (e.g., local occurrence in the Jeribe Formation of Iraq), (3) coarsely crystalline dolomite (e.g., Euphrates and Jeribe formations of Iraq and Asmari Formation of southwestern Iran); and (4) highly fractured carbonates (e.g., Asmari Formation of southwestern Iran). Dolomitisation in many reservoirs substantially improves reservoir quality, especially in intervals hosting coarsely crystalline dolomites (Figure 10.30b).

Figure 10.30. Poroperm in the Tertiary of the Middle East. A) Permeability versus porosity in Lower Miocene carbonates (replotted from Sun and Esteban, 1994). B) Permeability versus porosity in Kirkuk Field, Iraq, showing the improvement in reservoir quality typical of dolomitised limestone successions (Cretaceous-Miocene).

In the Middle Miocene carbonates of the Gulf of Suez and the Red Sea, the spatial tie of the dolomites to basinwide rift evaporites, and their preferential distribution along the former platform margins, together with their relatively heavy oxygen isotopic values (averaging +4.65‰; Sun and Esteban, 1994), all suggest that the bulk of the dolomite was formed by the lateral migration of evaporitic basinal brines into the shallow platform. The formative hydrology was driven by the rise of brine levels associated with the evaporite filling the basin centre (Sun, 1992; see also “spill and fill” discussion in Chapter 5 and later in this chapter). In contrast, downdip reflux of descending hypersaline brines, generated within platform salterns, were the main cause of extensive dolomitization in the lower Miocene carbonate reservoirs of the Middle East. Differences in the two styles of hydrology can be recognised by mapping isotopic signatures of cements in cores from well to well and documenting the close stratigraphic relationship of reservoir quality to the transition zones between open marine platform carbonates (now dolomitized) and mapping (in seismic) the positions of restricted saltern evaporites or their residues.

Reservoir porosities in many of the evaporite-sealed Tertiary carbonate successions bear little relationship to depositional facies, rather they are strongly influenced by the distribution of anhydrite cements, burial corrosion, dolomite crystal size and fracture intensity. Undolomitised carbonates in the reservoir-

hosting formations typically occur only in local areas: (1) encased units in marls, (2) platform interiors, and (3) areas with active freshwater drainage. This association of undolomitised intervals with basin margins or marine-cemented and exposed shoals is similar to that in the Smackover and San Andres formations.

Dolomite preferentially replaces magnesium-calcite skeletal grains (red algae, benthic foraminifera, and echinoderms) and micritised nonskeletal grains (oids and peloids) throughout most of the dolomitised Miocene carbonate section of the Arabian Gulf and the Gulf of Suez (Sun and Esteban 1994). Micrite matrix, internal muddy sediments, and micritised outer margins of aragonitic skeletons are also extensively replaced by dolomite. The replacement dolomites are subhedral to anhedral, finely crystalline (<10 μm) and show excellent preservation of original depositional fabric (mimetic dolomitization), indicating that the dolomitisation was either syndepositional or relatively early in burial (Warren, 2000a). Less common are coarsely crystalline dolomite cements lining secondary mouldic pores, often after dissolved evaporites. Sucrosic dolomites (40-80 μm, euhedral-subhedral) occur locally in some mixed carbonate-siliciclastic facies.

A particular diagenetic feature of evaporite-associated Miocene dolomite reservoirs of the Middle East is extensive leaching of skeletal aragonite without prominent karst surfaces or predolomite calcite cements (Figure 10.31; Oswald, 1992; Sun, 1992). Mouldic and even vuggy porosity is well developed in carbonate hosts that contained abundant skeletal aragonite, whereas precursors dominated by high-Mg calcite bioclasts, such as red algae, echinoderms, and benthic foraminifera, are commonly mimetically replaced by reflux dolomite, with only minor moulds and other dissolution voids. As such, these nonvuggy units tend to show better-behaved poroperm relationships and more predictable wireline to core responses. Sun (1992) proposes that invading hypersaline brines rather

than fresh waters were the cause of large-scale leaching of skeletal aragonite.

With progressive burial and compressional folding, these Miocene dolomites have experienced repeated episodes of anhydrite cementation, fracturing, and late stage corrosion of pore walls (Sun and Esteban, 1994). Anhydrite cementation is the most widespread porosity-occluding process. In many cases, both primary and mouldic porosities are almost entirely filled by anhydrite cements. Laterally, the distribution of anhydrite cements is highly variable in these Miocene reservoirs, but as a general rule, they are more abundant in relatively coarse, grain-supported carbonates, or those carbonates containing abundant skeletal aragonite, suggesting that original porosity and permeability played a major role in controlling access by later sulphate-bearing fluids. Brine-driven dolomitization and skeletal aragonite dissolution during the early diagenetic stage produces excellent permeability networks. It enabled ongoing active circulation of anhydrite precipitating fluids and, if some permeability remains, even controlled the subsequent ingress of later burial fluids (including oil and gas).

Tectonically-induced fractures are common in the Lower Miocene carbonates of the Middle East, particularly along the Taurus-Zagros belt where these carbonates are intensively folded and fractured. There appear to have been several stages of fracturing. Most of the early formed fractures were occluded

by anhydrite cements, whereas relatively late-formed fractures, which postdate anhydrite cementation, remain open and effective. In places where the carbonate hosts have a relatively low matrix porosity and permeability, such as the Asmari Limestone in southwestern Iran, fracturing plays a vital role in enhancing the reservoir quality (McQuillan, 1985). The mechanism of production in most Asmari reservoirs of southwestern Iranian oil fields is related mainly to open fractures beneath the Fars/Gachsaran seal (Figure 10.57), although variations in matrix porosity (e.g., mouldic or intercrystalline) locally influence production.

According to Sun and Esteban (1994) the last diagenetic event before hydrocarbon emplacement in Miocene carbonates of the Middle East was burial corrosion through which reservoir quality was improved, particularly in the hydrocarbon-producing reservoirs of the Gulf of Suez and Iraq. These late stage corrosive events bear little or no relationship to depositional facies or stratigraphic position. Corrosion preferentially affects anhydrite cements, relatively fine-grained sediments, and matrix materials. Typically, the current reservoir quality of many Miocene carbonates in the Middle East reflects the intensity of such corrosive events. The combination of vugs and chalky microporosity, which dominates effective porosity in the matrix of most producing Miocene reservoirs, was largely produced by late stage corrosion. Other important porosity types, including moulds, intergranular pores, and fractures, were enlarged by

corrosive processes. The distribution of such burial pore types is characterized by a lack of linear or branching passages related genetically to identifiable recharge and discharge points, making these reservoirs difficult but locally prolific producers.

Intensity of late stage corrosion is perhaps tied to levels of sulphuric acid created by the mixing of waters with different H₂S contents, or by oxidation of H₂S in an evaporite-rich hydrocarbon environment (Sun and Esteban, *op. cit.*). In places, organic acids released through source rock maturation may have

Figure 10.31. Stratigraphic cross section of the Lower Miocene succession in the Middle East, centred on Iraq, showing higher order (4th or 5th) platform evaporite cyclicity within a 3rd order depositional sequence, which is made up of a lowstand evaporite of the Dhiban Formation, followed by transgressive and highstand platform carbonates of the Jeribe Formation, followed by lowstand evaporites of the Lower Fars (after Al-Murani, 1986; Sun and Esteban, 1994). Note the high porosity in the open marine carbonate intervals in the Jeribe Formation, while the intercalated restricted marine carbonates and evaporites are tight (see Figure 10.30a).

also contributed to the late stage corrosion. The development of the permeability network and the availability of migration pathways (faults and fractures) regionally connecting acidic subsurface fluids were two key factors controlling the degree to which fine-grained dolomites or anhydrite cements were corroded.

Silurian pinnacle reef fields, Michigan Basin

Since the late 1960s, production from the numerous evaporite-encased Niagaran reefs of the Michigan Basin has been the main local source of oil and gas production for the state of Michigan (Figures 10.32, 10.33; Gill, 1977, 1985, 1994; see Figure 5.52 for detail on seal geology). Productive reef-substrate areas range from around 40 acres (0.16 km²) to 840 acres (3.4 km²). Recoverable reserves in individual pinnacles range from 30,000 to 22 MM BBL of oil equivalent (BOE). The ten largest fields in the Niagaran pinnacle play were found by drilling of the first 25% of the exploration wells. The discovery per wildcat peaked at 1.55 MM BOE after 500 wildcats, and declined stead-

ily thereafter to a level of 0.02 MM BOE per well after 1,900 wildcats, indicating that the play has reached a state of maturity, as does the move to horizontal drilling to improve recovery efficiency. About 25% of the discovered reserves were found in 5% of the fields, indicating a more even reserve distribution pattern than in many other reefal plays, perhaps a reflection of the high efficiency of basinwide evaporites as seals to pinnacle reefs. Consequently, the relative rate of growth of discovered reserves was slower than in other reef plays.

Downdip pinnacle reefs in the Michigan Basin illustrate a major negative to any relatively un-fractured reef play that is sealed by thick basinwide evaporites. That is, the deposition of a thick sequence of salt atop and adjacent to the reef buildup typically leads to high volume flow of dense saturated brines through the underlying porous strata at the culmination of the reef (potential reservoirs). This tends to overdolomitise and extensively plug most of the uppermost porosity with salts. This is clearly seen in the Niagaran trend shown in Figure 10.33a, which shows a band of evaporite-plugged pinnacle reefs down-dip of the main pinnacle reef play. Within the pinnacle reef play the occurrence of oil updip of the gas accumulations is an indication of classic Gussow style migration and segregation (Figure 10.33b).

Why updip reefs remain as reservoirs and the downdip reefs are salt plugged is an interesting quandary. In my opinion it reflects the likely recharge hydrology that effected the basin when it was hydrographically isolated and the A1 and A2 halites were being deposited. As we saw in Chapter 5, the potentiometric surface created by hydrographic isolation creates a marine-fed seepage margin to a drawdown saline giant (Figure 5.32). Toward the basin edge, this head was sufficient to displace any dense reflux brines from the surrounding basinwide brine plume and so allow deeply circulated seawater to rise through the pinnacle reefs and from part of the marine-feed outflow zone. Crest of pinnacle reefs allowing groundwater egress have characteristic seepage carbonate caps (pisolite, tufa, stromatolite and anhydrite haloes) that differentiate them from the surrounding halite plain. Pinnacles further out in the basin did not have sufficient head to prevent the ingress of sulphate-saturated waters and so their porosity was plugged. Reef caps to these salt-plugged reefs lack or have attenuated indicators of seepage outflows. This palaeohydrology also explains why oilfields in pinnacle reefs that acted as marine seeps, such as the Bell River Mills gasfields, not only produce from the reef facies but also produce from the A1 carbonate fringe. Back in the Silurian these units were part of a single flow unit supplying pressurized phreatic seawater to the basin (Figure 10.32). The hydrology that established the active seep reefs can be used as

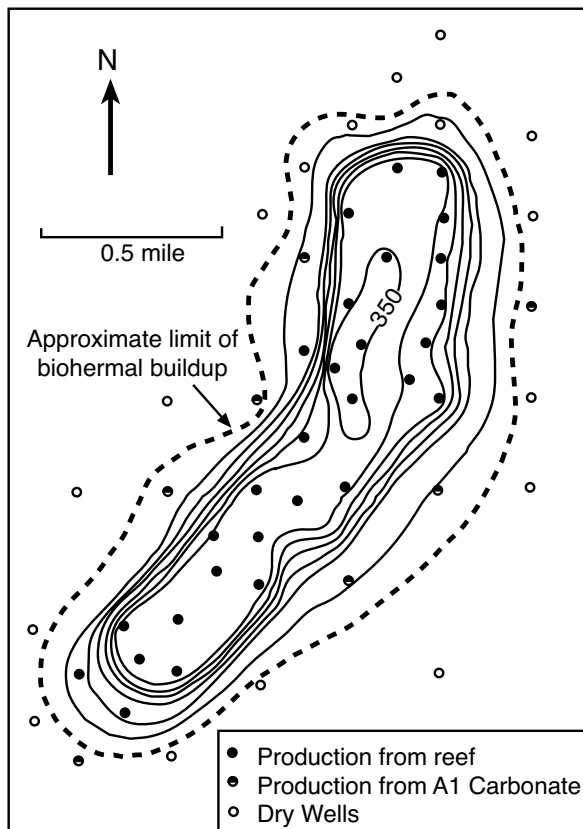

Figure 10.32. Belle River Mills gasfield. Cumulative thickness or isopach of biohermal and organic reef stages, configuration at termination of organic reef stage (after Gill, 1985).

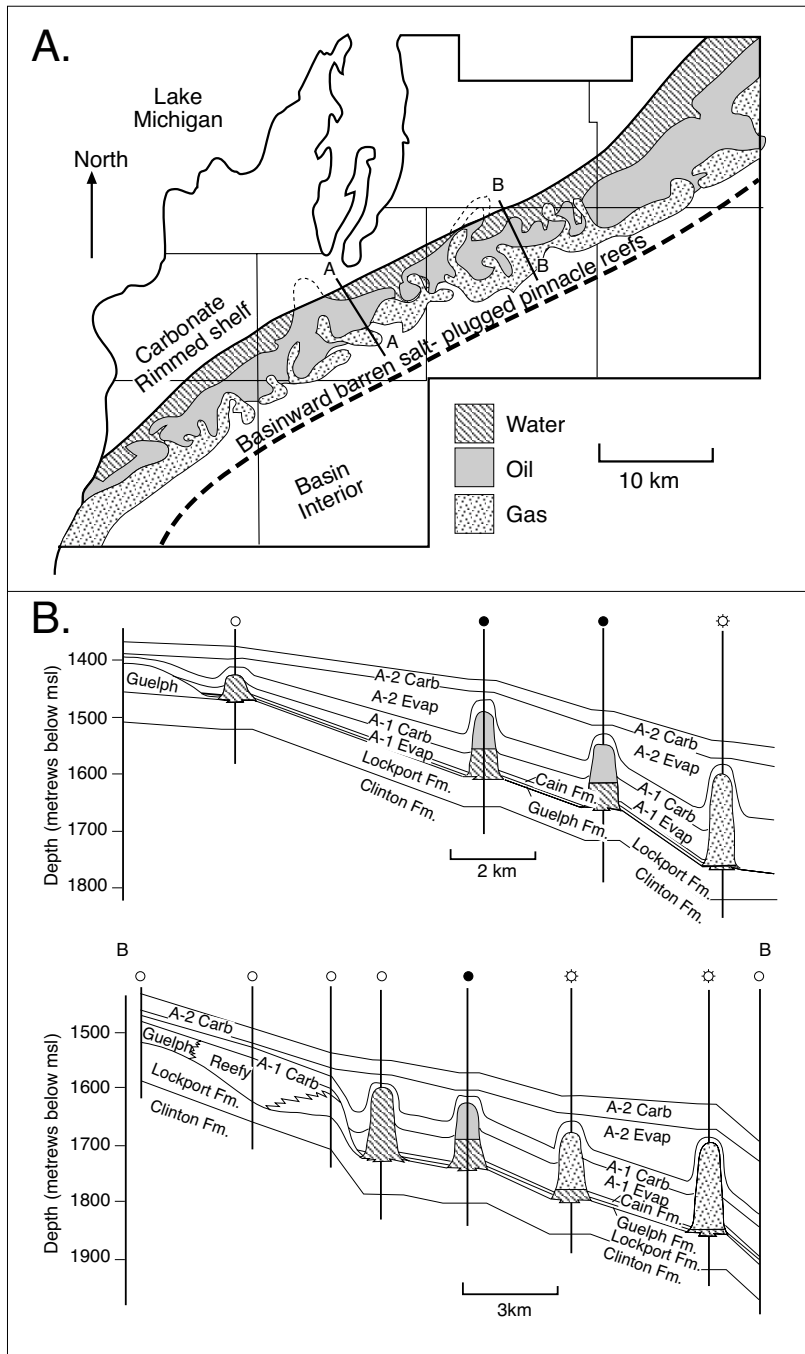

Figure 10.33. Evaporite-sealed Silurian pinnacle reefs in the Northern Michigan Basin. A) Distribution of salt plugged, gas-, oil- and water-bearing reefs. AA' and BB' show the positions of cross sections in Figure 10.25b. B) Cross sections through the pinnacle reef belt showing classical Gussow-migration controlled separation of oil and gas in the reefs. Pinnacles in positions more basinward than shown are not economic due to widespread salt plugging (after Gill, 1985).

an exploration and development tool in such drawdown basins.

Another interesting feature of the Niagaran pinnacle reef play is that many fractures and adjacent pinnacle matrices are overprinted by late stage saddle dolomite and calcite, with ponding of the precipitating fluids driven by circulation of late stage basinal fluids beneath the highly effective evaporite seal (Cercone and Lohmann, 1986). The source of these basinal fluids is not well understood, but is thought to be from the leaching of underlying Ordovician shales.

This argument is supported by the occurrence of fault and fracture-controlled hydrothermal (thermobaric) dolomite reservoirs in Ordovician (sub-Niagaran) marine carbonates in a syncline that defines the oilfields of the nearby Scipio Albion trend (Figure 10.34). Metal sulphides, baryte and coarse sparry anhydrite are coprecipitates from the basinal fluids that formed this set of late-stage coarsely crystalline saddle dolomite. Yoo et al. (2000) argued for an evaporite source to these fluids. Later in this chapter we shall return to this association in a discussion of structurally-focused hydrothermal dolomite overprints and density-driven deep convective circulation cells below the dissolving undersides of highly effective evaporite seals.

Yet again, the presence of a thick sequence of bedded evaporites has exerted a strong influence on reservoir distribution and quality on reservoir distribution and quality well into burial. The Salina salts today acts as highly effective seals to oil and gas accumulations in the

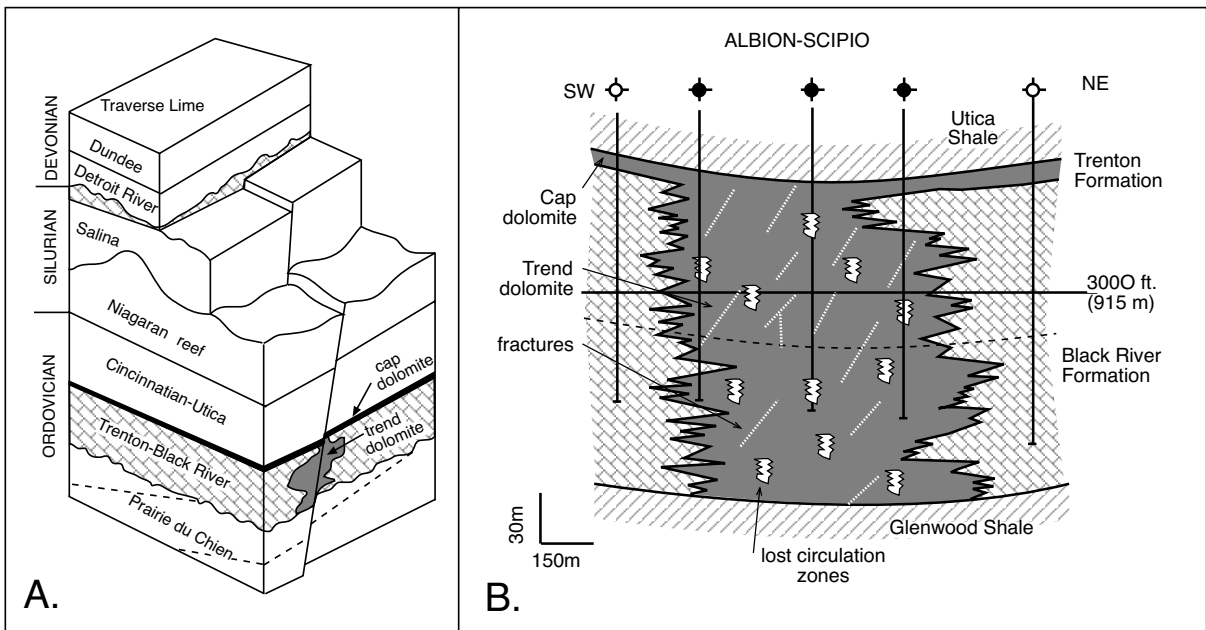

Figure 10.34. Fault-focused late dolomitisation in the Scipio-Albion trend, Michigan (after Hurley and Budros, 1990). A) Structural stratigraphic interpretation of the Albion-Scipio trend. The fault/fracture set that controls dolomitization is pre Devonian. B) Structural cross section of the Scipio-Albion Field. Note that the field is located in a synclinal trend (not usual for a hydrocarbon trap) and there is a rapid lateral transition from a regional nonreservoir limestone into a permeable reservoir dolomite that also hosts late stage anhydrite and other authigenic burial salts. Lost circulation and fracture zones in such fields are common indicators of secondary dolomite-hosted porosity. Note that the seal is a shale not evaporite in this system but the chloride-rich basinal brine responsible for the hydrothermal dolomite has a chemistry strongly influenced by evaporite dissolution deeper in the basin.

pinnacle reefs. During the early drawdown stage the formative hydrology perhaps allowed some pinnacle reefs to remain open, while others further out in the basin were plugged by evaporite cements from brine reflux. Then during later burial the salt bed focused the flow of upwelling basinal waters and the precipitation of later authigenic cements both along its underside and within the salt-sealed pinnacle reefs.

Evaporite-sealed platform and reefs, Devonian, Canada
Early Devonian (pre-Keg River time) in the Alberta Basin of Canada was dominated by multiple-cycle platform evaporite deposits ending with deposition of planar anhydrite sheets of the Chinchaga Formation and shales of the Ashern Formation (Tinker and Kirby, 1991). The lower Keg River/Winnipegosis was deposited as a marine carbonate ramp in shallow waters <75 m deep. Contemporaneous faulting and uplift during Middle Devonian time initiated development of a platform margin composed of stacked, porous (15-25%) packstone and grainstone shoals (Figure 10.35a). Pinnacle and bank growth in on or near the platform edge was contemporaneous with epeiric shelf deposition. Keg River/Winnipegosis deposition ended

with restriction of the basin and subsequent deposition of the basinwide evaporites of the Middle Devonian Muskeg/Prairie Formation (Figure 11.19).

Since the initial discoveries in the mid-1960's, the Keg River/Winnipegosis has produced hydrocarbons from a variety of dolomitic trap types with the largest volumes coming from evaporite-sealed pinnacle reefs. In 1991, Tinker and Kirby listed the following produced volumes; Rainbow/Zama sub-basin (>650 MMBO cum.) and in equivalents in southern Saskatchewan (>2 MMBO cum.); shelf-margin carbonates at Temple Field (>3 MMBO cum.); middle shelf carbonates at Senex (>2 MMBO cum.); inner shelf carbonates in northeastern Montana, southern Saskatchewan, and southern Alberta (>10 MMBO cum.); and inner shelf siliciclastics at Utikima Lake (>75 MMBO cum.). Historically, regions of high production in Middle Devonian carbonates lay to the west and northwest of Calgary, where evaporites acted as the seal for most of the higher volume fields with Keg River/Winnipegosis production (Figure 10.35a). Production in the Rainbow-Zama sub-basin has been declining since the late 1980s. More recent discoveries are smaller and lie along the basin edge, mostly in a region

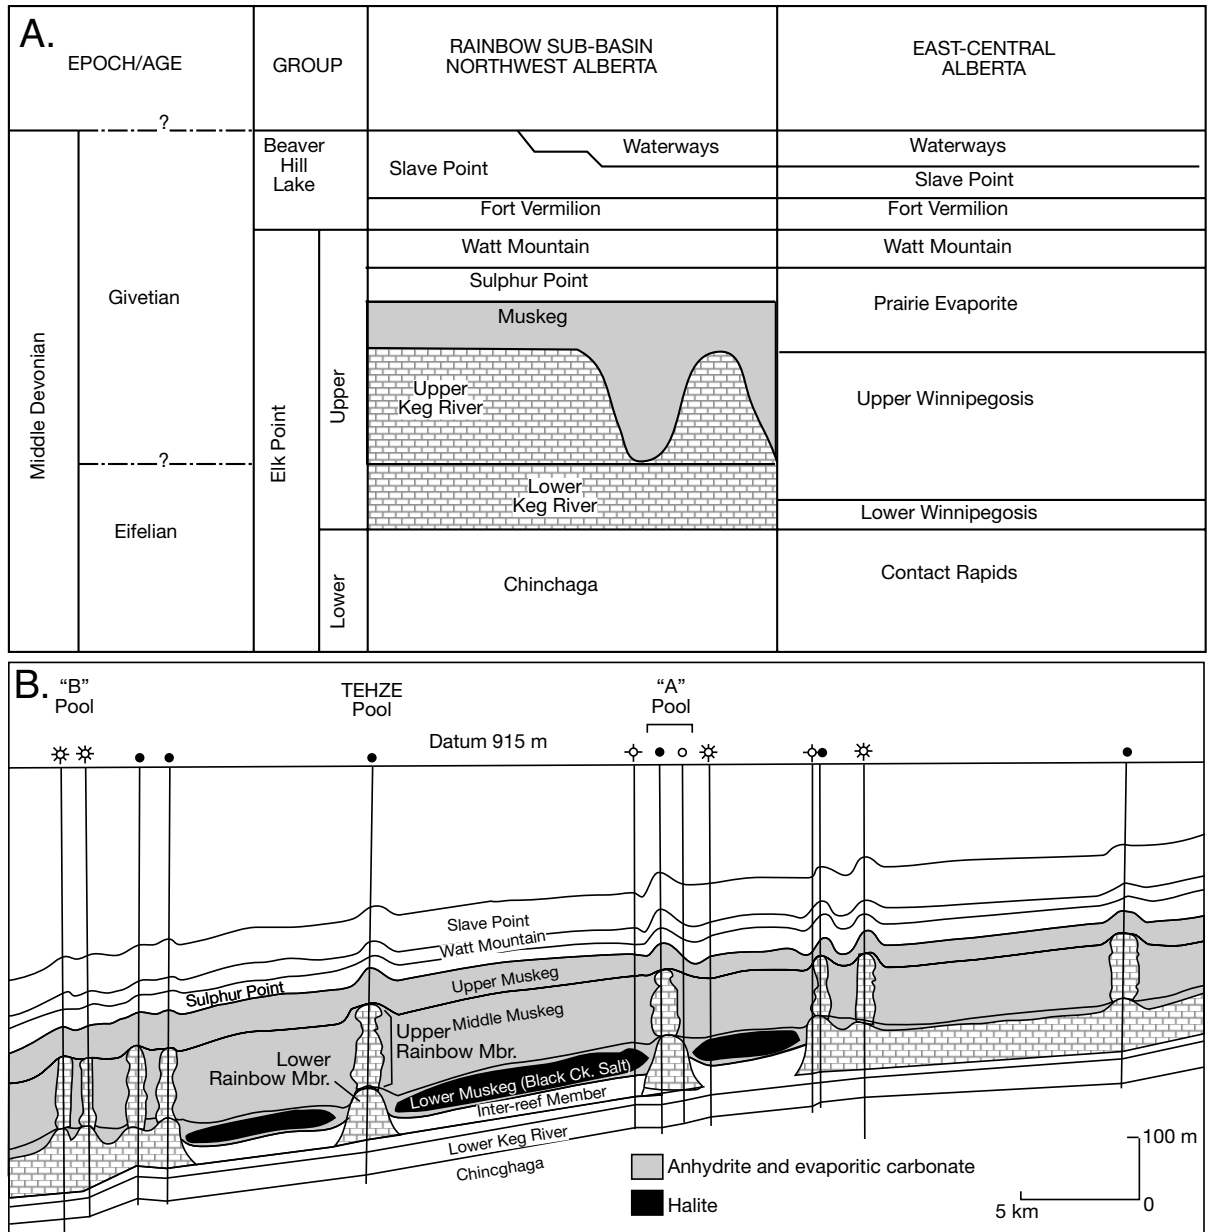

Figure 10.35. Rainbow Basin, Alberta. A) Middle Devonian stratigraphy of the Rainbow Sub-basin and East-Central Alberta (after Chow et al., 1995). B) NE-SW cross section through the mature Rainbow area showing development of carbonate platform in the Upper Keg River and the platform evaporite seal created by the basinwide anhydrite salts of the Muskeg Formation (after Schmidt et al., 1985).

some hundreds of kilometres to the north of the areas of classic production and extending into British Columbia. There the evaporite seal is missing (whether from dissolution or lack of deposition is still contested) and much of the economic porosity is in patchy zones of late stage hydrothermal dolomites, now beneath shale seals.

Today, through enhanced recovery and directional drilling, the Middle Devonian Keg River/Rainbow pools in the mature production area of the Rainbow/Zama sub-basin have produced more than 1.1 billion-barrels of oil, mostly from evaporite-sealed pinnacle reefs and platform dolomites. Historically, the most productive reservoirs have been pinnacle buildups encased by basinwide evaporites of the Muskeg/Prairie formations

(Figure 10.35b; Schmidt et al., 1985; Majid, 1987). Reservoirs in buildups in the upper member of the Keg River Formation consist of floatstone, rudstone and boundstone, with wackestone, packstone, and grainstone matrix. The principal faunal constituents are crinoids, brachiopods, stromatoporoids, corals, and *Stachyodes sp.*, all indicators of open marine sedimentation prior to the onset of evaporite precipitation. Reservoir porosity is a combination of primary intergranular and intragranular and secondary vuggy textures in partially dolomitised intervals. The primary role of the evaporite is as a seal to accumulations in the more permeable carbonates, but evaporite precipitation also drove reflux dolomitization and anhydrite plugging of the reef and platform strata during its precipitation as a saltern seal facies in the basinwide succession.

Prior to the basin's hydrographic isolation the buildups in the upper Keg River member in Alberta were patch reefs or banks, which grew in an open marine epeiric interior seaway fronted by Presqu'île barrier to the west-northwest. Water depth was the main factor controlling the distribution of the more porous intervals of the bank and patch reef facies. The back reef of the main platform became more restricted and anhydrite was precipitated at times of hydrographic isolation prior to the main basinwide event. At times of open marine connection patch reefs were developed in areas of deeper water, whereas banks were formed in shallower areas of an open lagoon. A direct relationship between the thickness of overlying platform anhydrite seal and hydrocarbon occurrences in the platform carbonates of the Keg River Formation was defined by Majid (1987). He concluded that trends beneath the platform evaporite seal can be reliably modelled using depositional fabric and seal thickness. Where the thickness of the anhydrite is more than 10 metres atop areas of patch reefs, it constitutes an adequate seal. In contrast, buildups covered by less than 10 metres of anhydrite constitute regions of higher risk.

Areas of more recent exploration focus in the Keg River and its equivalents are located mostly in British Columbia to the north of the classic areas of Rainbow reef and platform production just described. There, late stage dolomitisation exerts a more significant control over reservoir quality and porosity development does not always follow the depositional plumbing predicted by depositional facies. But effective porosity development still requires what Morrow et al. (2001) termed a "hydrostratigraphic template," first created by a combination of depositional fabric and early reflux dolomitisation. The high-salinity chloride-rich late stage brines driving this burial dolomitisation were largely sourced in regions of dissolving salts (Figure 8.4).

Such a hydrostratigraphic template defines hydrocarbon occurrences in the July Lake gas pool of the Keg River Platform and the Helmet and Peggo gas fields in the Slave Point Formation, all located along the shelf-to-basin transition of the Cordova Embayment in northeast British Columbia. There, burial-stage, coarsely crystalline replacement dolomites and associated saddle dolomite cements and zebra dolomites form a widespread diagenetic facies in the Middle Devonian Presqu'île barrier that extends southwestward from outcrop near Pine Point to the subsurface of the Foothills in northeastern British Columbia. Dissolution and subsequent precipitation of coarsely crystalline burial and saddle dolomites creates hydrocarbon reservoirs with intercrystalline porosity in otherwise tight limestone hosts. The same system hosts sub-salt breccia Mississippi Valley-type Pb-Zn deposits at nearby Pine Point. Porous burial dolomites replacing blocky sparry calcite cements, occur continuously across the sub-Watt Mountain unconformity. They postdate stylolites and earlier replacement dolomites, overlap sulphide mineralization and show regional oxygen isotope signatures that are indicative of deep hot saline basinal fluids escaping via fault and fracture feeds into the adjacent carbonate platform sediments (Figure 8.4; Qing and Mountjoy, 1994).

Recognition of late stage dolomite as a reservoir-former led to a re-examination of core from some of the producing intervals in platform-interior dolomites in the more mature Rainbow sub-basin to the south. Previously, platform carbonate production away from the main pinnacle reef plays had been related to what were considered in the 1970s to be thin pinnacle reefs, biostromes and low relief shoals, all with a depositional control to the reservoir plumbing. But the mechanism and chemistry of porosity retention was never well documented by the explorationists. Subsequent core and thin section studies in the same dolomitized platform intervals established that production was actually tied to later secondary porosity, not relict primary porosity. It was mostly associated with dolomitized subtidal facies at the bases of stacked metre-scale evaporitic depositional cycles (Muir and Dravis, 1995). For example, the Keg River and Muskeg pools on Comet Platform are combination structural-stratigraphic-diagenetic traps with reservoir quality strongly influenced by fracture intensity. Reservoir facies are confined principally to fractured platform-interior beds of restricted subtidal *Amphipora*-peloidal dolopackstones and dolowackestones. They constitute the base of anhydritic 7-12 m thick depositional cycles, which are correlatable across the Comet Platform.

Better quality reservoirs in the platform interior occur at or near the base of each major cycle and result from dissolution

of the platform carbonate, tied to the precipitation of burial dolomite cements. For example, the Keg River pool on the western edge of the Rainbow-Zama sub-basin is locally dominated by spectacular zebra dolomites with vuggy porosity tied to anhydrite dissolution, while Muskeg pool dolomites all exhibit mouldic and vuggy porosities (Muir and Dravis, 1992). Termination of stylolites and fractures into these secondary pore types confirm their burial origin.

Regional tectonic influences on oil pool development in the Comet Platform are indicated by horizontal fractures, vertically-oriented stylolites, and spectacular burial-stage evaporite solution-collapse breccias. Pools are localized over regional fault and fracture trends that affected the carbonates, but did not fracture the evaporite seal, and are related to reactivation of the Great Slave Lake shear zone. Faults and fractures aided burial diagenesis and the creation of late secondary porosity development by focusing the ascent of hot, dolomite-dissolving basement-derived and calcium-rich basal fluids. Seismic data indicate these faults were largely collapse structures generated by salt loss and subsalt breaching in the underlying Cold Lake Salt Formation. Further, some of these faults localized precipitation of massive diagenetic anhydrites (retrograde precipitates) that now provide updip side closure to some pools. This current understanding of reservoir control is a long way from the simple early notions in the 1970s of relict primary porosity in a carbonate biostrome.

Dissolution by hot, basement-derived fluids throughout most of the region is supported by the presence of diagenetic fluorites, megaquartz and polysulphide minerals, helium gas, fluid inclusions, and high carbon dioxide and hydrogen sulphide gases in these hydrocarbon pools. Thus, these platform-interior pools are combination structural-stratigraphic-diagenetic traps with reservoir quality tied to reactivated basement faults and are not directly to depositional porosity in pinnacle reef occurrences. Once reservoir quality in platform cycles was tied to salt solution

Table 10.6. Characteristics of fields in the San Andres Formation of west Texas, which are sealed by bedded salts composed of anhydrite and halite.

induced fractures, rather than to inferred low relief pinnacles, it permitted correlation of larger 7-12 metre-thick composite cycles over distances of several kilometres. This meant reservoirs could be more effectively zoned (Muir and Dravis, 1995). By 1989, daily cumulative oil production rates in platform dolomites were increased from 500 m³/day (1988) to 1400 m³/day as a direct result of this revised understanding of reservoir layering. It also led to improved conformance, sweep, and minimization of oil sandwich loss in these miscible- and gas-flooded pools and to more effective horizontal well design.

Once again, reservoir quality in the Rainbow-Zama sub-basin, and equivalents to the north, is in large part tied to the ongoing diagenetic evolution of the dolomitised host and its strong interaction with evaporite aquicludes, dissolution brines, salt solution induced fracturing and basal fluids. As Warren (2000a) observed, ancient dolomite is never a single-phase mineral. In all areas of Keg River associated production there are at least two styles of dolomite present, an earlier brine reflux dolomite, created when the overlying evaporite was porous and a supplier of dense Mg-rich brines and a later dolomite formed when the evaporite bed was a seal that focused and facilitated convective circulation in sediments beneath.

Figure 10.36. Stratigraphy of the latest Leonardian-Guadalupian units of the Permian Basin, west Texas (after Kerans et al., 1994). Almost all of the fields on the Northwest Shelf and the Central Basin Platform are sealed by bedded mudflats or saltern evaporites.

Reservoir quality tied to bedded seals

Depositional facies preserved in a sealing salt bed atop an oil or gas field can be useful indicators of palaeotopography, energy levels and volumes of syndepositional authigenic cements in the reservoir. Lowermost facies in a bedded evaporite seal can typically be related to the topography of the reservoir’s upper contact at the time the seal was precipitated. This means wireline signatures of the seal can be used to differentiate stratigraphic traps from simple drape traps. Drape traps are created by compactional or structural draping some time after the reservoir and seal were deposited. Wireline signatures through seal facies in this scenario typically show no depositionally-controlled thickness changes or internal depositional differentiation between top seal and lateral seal.

In contrast, repeated evaporitic transgressions over an underfilled carbonate or siliciclastic platform can deposit alternating cyclic carbonates/siliciclastics and evaporites in broad, shallow to ephemeral brine environments. Depositional textures in the sealing evaporites are then controlled by the permanence and depth of the saltern and evaporitic mudflat brines. Top seals to preexisting highs such as shelf margin reefs or shoals,

dune crests or slope carbonate buildups show internal fabrics related to palaeorelief. Such topography-related facies mosaics typify the wireline and core textures in the lower levels of the basinwide evaporites sealing the Silurian pinnacles of the Michigan Basin,. Nodular mosaic anhydrites of supratidal sabkhas dominate evaporitic mudflat seal facies atop the crests of underlying pinnacle reefs, while subaqueous saltern facies, made up of bedded massive/mosaic anhydrite and allochthonous dolomite-anhydrite breccias, typify the lateral seals (Figures 5.51,5.52). Similar textural transitions occur between sabkha and salina seals that make up the top seal to karstified shelf margin reservoirs of the Permian San Andres reservoir of Yates Field, west Texas, as well as other Guadalupian sequences in the Permian Basin of west Texas. Around two thirds of the

reservoirs in Permian rocks of west Texas and New Mexico are sealed by bedded platform evaporites (Figure 10. 36; Table 10.6), most show an intimate relationship between evaporite facies in the seal and reservoir quality beneath (Ward et al., 1986; Warren , 1991; Sarg, 2001).

Yates Field, west Texas

Yates Field, located in the southernmost Central Basin Platform of west Texas, is one of the most prolific reservoirs ever discovered in the United States (4 billion barrels original oil in place). It is shallow (305-460m; 1000-1500ft) and produces mostly from the Upper Permian San Andres Formation, with additional secondary production from stringers in the overlying Grayburg, Queen and Seven Rivers Formations. The field covers approximately 100 km² with more than 1600 wells in the field. The field is now largely depleted of recoverable hydrocarbons.

At the level of the Permian section it sits on the structurally highest point of the Central Basin platform. Structural closure

is dominated by a broad asymmetric domal or anticlinal feature, which appears to be formed by the intersection of two separate tectonic structures that combine to create the horseshoe-shaped high that defines the outline of the field. Yates Field was discovered in 1926, high pressures, supplied by the combined gravity segregation, bottom water and gas cap drives, resulted in unusually high initial production rates and it produced by depletion drive until 1976. As pressure depleted throughout that half century, free gas evolved and migrated rapidly through the natural fracture system to the structural top of the field to form a slowly expanding gas cap drive beneath its evaporite seal. The efficiency of the evaporite seal atop the fractured reservoir system can be seen in an official proration test on the Mid-Kansas Oil and Gas Co. and Transcontinental Oil Co. #30 I. G. Yates "A" well, which in 1929 lists a daily potential production of 204,681 barrels (Hennen and Metcalf, 1929) in a system that is less than 500 m below the land surface.

Yates Field is one of a number of fractured dolomitic reservoirs in San Andres Formation of west Texas with an evaporite top-seal centred on the Seven Rivers Formation (Guadalupian). Systems tracts in the seal facies are characterized by stacked successions of metre-scale, brining upward parasequences deposited across an epeiric platform interior. Depositional facies in the seal in all these fields can be used to infer palaeotopography in the underlying San Andres reservoir and to separate the relative importance of deposition, drape and tilt in controlling the hydrocarbon distribution in carbonates below the seal.

Evaporite deposition during Seven Rivers time in Yates Field occurred in two major settings, sabkha (subaerial mudflat) and salina (subaqueous) in an evaporitic mudflat seal, with their areal separation controlled by the positions of underlying carbonate shoals. Wireline character through areas of subaqueous anhydrite is blocky, indicating 10-30m thick sequences of relatively pure subaqueous evaporite. Wireline signatures in areas of sabkha in the seal facies are richer in dolomite matrix and individual cycles are thinner (≈ 1 m) giving a stacked spikier wireline signature to both the gamma and the neutron-density logs (Figure 10.37; Warren, 1991). Subaqueous signatures dominate in what were the topographic lows, while subaerial evaporites are more common above what were the topographically higher parts of the seaway floor. When seal facies are defined in this way, mapped and related to production statistics across the field, it shows that for cumulative production in the Yates Field unit, as of October 1986, only 85 million barrels of oil had been produced from under the thick salina accumulations, whereas almost 985 million barrels had been produced from the area under the sabkhas. Yet the two styles of anhydrite deposition cover roughly equivalent areas of seal over the field (Figure 10.38; Warren, 1991).

Assuming that the M datum in the Seven Rivers approximates a level depositional surface, then the thick anhydrite in the lower Seven Rivers indicate palaeo-lows, while thin areas define ancient highs (Figure 10.37). Massive anhydrite is found only over the central and western parts of the field. The

Figure 10.37. Yates Field, west Texas. Use of wireline logs to define depositional setting of the seal facies in the Seven River Fm. atop the San Andres Reservoir. Shows how the position of the salinas in the evaporitic mudflat defines the off structure positions (after Warren, 1991) Figure 10.38a shows location of this section.

Figure 10.38. Yates Field, west Texas (after Warren 1991). A) Isopach of the massive anhydrite that typifies much of the base of the Seven Rivers seal to the field, thicknesses were mapped based on core and log signature. Clearly shows the subaqueous evaporites formed in lows that define the palaeotopography and hence quality of the underlying reservoir (see text). B) Geological evolution of Yates Field region. During San Andres time the reservoir (fusulinid grainstone) was a set of karstified carbonate islands. By Seven Rivers time the reservoir was buried but the underlying palaeotopography (and the associated differential compaction) was still sufficiently developed to control the position of the depositional lows (salinas) and highs (sabkhas).

anhydrite thins to zero roughly parallel to the platform margin, and shelfward of the San Andres shelf edge. The isopach map of the massive clean anhydrite (Figure 10.38a) shows closed contours surrounding pod-shaped areas of salina anhydrite (originally gypsum) up to 15 m (50 ft) thick. Two salina areas were generally present in Yates Field during early Seven Rivers time, one on the northern and the other on the southern side of the field. The north and south salina ponds are flanked by smaller pod-shaped thicks and are separated by a line of zero evaporite trending north-northwest through the central part of the field. This linear feature is referred to as the northwest trend. Massive anhydrite is also absent in cores and logs in the northeast corner of the field and forms what appears to be an embayment largely devoid of evaporite at the basal level of the Seven River and so defines the area of production called the “northeast embayment.”

Evaporite facies distribution in the basal part of the Seven Rivers Formation was controlled by palaeotopography, which was in turn controlled by the depositional facies relationships in the underlying San Andres Formation (Figure 10.38b). The San Andres lagoon was an area that was positionally low and one that remained low throughout Queen and Seven Rivers deposition, because of dewatering and mudstone compaction. When sufficiently karstified and fractured to hold producible fluids, the lagoon muds are still poorer quality reservoirs compared to adjacent fusulinid shoals. The lagoonal low was covered by a thick section of massive salina anhydrite that

today provides a lateral seal to the adjacent sabkha-capped reservoirs. Sabkha-crested topographic highs sit atop the more permeable reservoir intervals, which are made up of karstified and fractured San Andres mounds and shoals (Craig, 1988). The platform-edge fusulinid grainstones to packstones that are the main reservoir in Yates Field were cemented, fractured and karstified early. The lack of early burial compaction, compared to adjacent lagoonal mudstones, meant areas atop mounds and shoals remained as highs during early burial.

During lower Seven Rivers time, the then-buried San Andres depositional segregation still controlled the facies mosaic in the evaporite seal. Once this marine-fed evaporite system filled the available accommodation space, subsequent depositional style was controlled by a series of aggrading Stokes surfaces within an aggrading eolian sandflat/mudflat. At times of higher eolian sand flux the mudflat became a deflationary sand flat (Figure 10.38b). Such deflationary sandflats can constitute reservoirs in other parts of the Central Basin Platform, as in North Ward-Estes Field.

North Ward-Estes Field, Texas

North Ward-Estes Field, Ward County Texas, is the largest and most prolific of a chain of producing fields in the Guadalupian Yates Formation, which extends along the western margin of the Central Basin platform for approximately 150 km, with a width of 1.5-6.5 km (Figure 10.39a; Andreason, 1992). Cumulative

oil production within the North Ward-Estes Field from 1929 through 1989 was more than 365 million BBL, with oil-in-place estimated at more than 1 billion BBL. Siliciclastic reservoirs in the middle shelf provide most of the hydrocarbon production within the trend, whereas associated interbedded dolomites contributed patchy minor amounts of economic porosity to this play. Porosity distribution in the various Ward-Estes reservoir layers is best modelled using a depositional model based on a continent-coupled eolian to evaporitic mudflat to shelf setting, with superimposed early evaporite dissolution at the strandzone. Hydrocarbon traps form on gentle structural culminations sealed by updip evaporites. Hydrocarbon maturation and migration from the Delaware basin to the shelf reservoirs occurred during the Cretaceous and early Tertiary (Hills, 1984).

In his comprehensive analysis of the late Guadalupian (Permian) Yates Formation reservoir sands, Andreason (1992) showed that the siliciclastic facies were part of a broad, evaporative mudflat that extended across a wide area of platform behind the Capitan reef. Cyclic sea level fluctuations produced a succession of dolomites, evaporites, and siliciclastics as the evaporative coastal plain oscillated across the Yates shelf. Moving landward,

the environments were; (1) lagoon, (2) intertidal algal flat, (3) beach ridge, (4) siliciclastic sabkha, and (5) sand sheet/playa mud flat/salina/salter (Figure 10.39a). Evaporitic cycles, which formed on the inner shelf and landward, grade upward from massive subaqueous-dominant anhydrites into nodular mudflat anhydrites with increasing volumes of siliciclastic mudstone interbeds (playa mudflats). Carbonate-based depositional cycles consist of basal lagoonal peloid and skeletal dolostones, which grade upward into tidal-flat dolostones, beach-ridge sandstones, and finally into siliciclastic sabkhat.

The characteristic disrupted (haloturbated) textures of the Yates siliciclastics were created by surficial and interstratal halite growth during seasonal flooding and subsequent desiccation in a sabkha environment (Andreason, 1992). A siliciclastic accretionary complex, composed of stacked beach ridges and detrital sabkhas, formed behind a pisolitic strandzone. Local siliciclastic accumulations also occurred over sinks or depressions produced by the dissolution of underlying bedded sulphates. Such dissolution breccias are defined by stacked horizons, made up of sharp clast-to-clast angular rudstones to floatstones with sharp basal contacts with the underlying

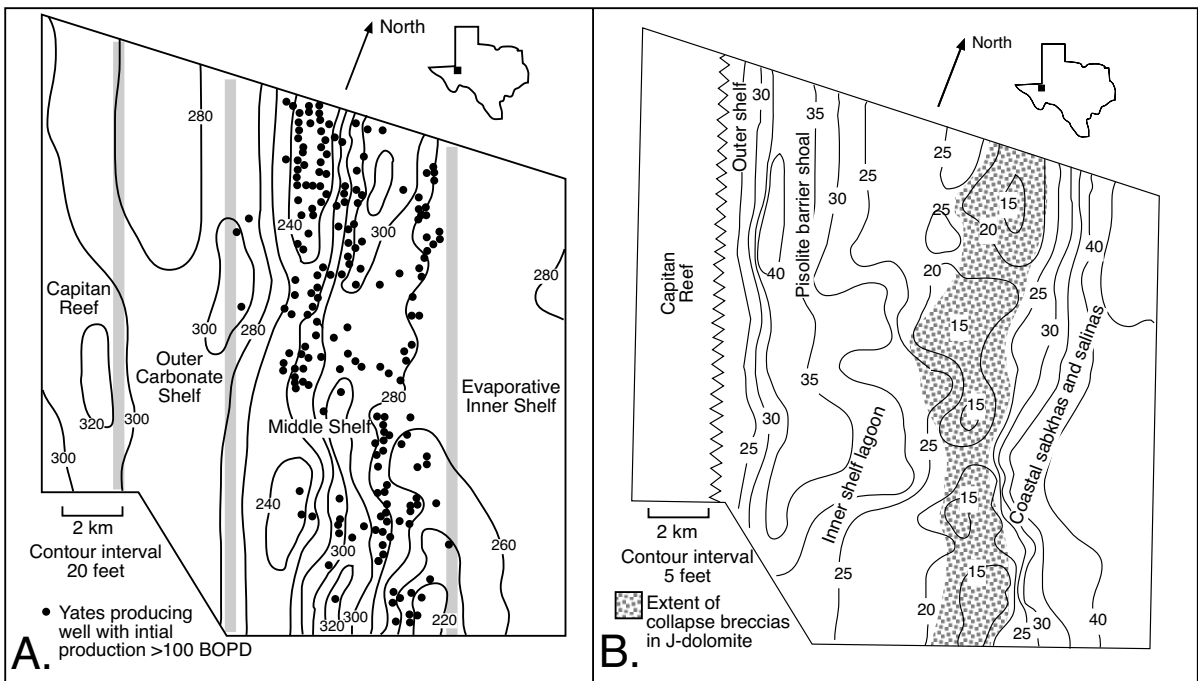

Figure 10.39. Characterisation of Yates Fm., Ward-Estes Field (after Andreason, 1992). A) Total Yates interval isopach showing Yates shelf is divisible into; 1) an outer shelf that includes the Capitan Reef, the backreef flats and the pisolite shelf crest, 2) a middle shelf composed of stacked beach ridges and siliciclastic sabkhas, and 3) evaporitic mudflats made up of extensive flats, salinas and stabilised sand sheets. Hydrocarbons are concentrated in the middle shelf. B) Isopach of the intra-Yates J-Dolomite unit. Shade unit defines the extent of the evaporite collapse breccias that separates inner shelf lagoon from evaporitic mudflat. Depression defined by collapse was filled with greater thicknesses of overlying siliciclastic sand.

crystalgalaminated dolostones and sharp to gradational crackle upper contacts with the overlying subtidal carbonates (peloidal and fossiliferous dolostones). Because of pervasive soft-sediment deformation atop the dissolving mudflat evaporites, these intervals are easily misidentified in core as storm beds or erosive marine transgressive surfaces. Breccia beds correlate

with anhydrite beds (mostly subaqueous) in the inner shelf and with dolomitic mudstones to the west (middle to outer shelf). That dissolution was early is indicated by the excellent correlations between the zone of collapse and a region of differential thickening within the overlying siliciclastics (Figure 10.39b). What is unclear is whether dissolution was driven by a relative sea level rise or fall.

Figure 10.40. Evolution of Yates Shelf (after Andreason, 1992). Early highstand (Stage 1) is characterised by shelf submergence, lagoonal carbonate deposition across the middle shelf and massive evaporites precipitating in embayments and isolated ponds on the inner shelf. As the shelf becomes more emergent during late highstand (stage 2), broad tidal flats extend across the middle shelf and the pisolitic shelf crest becomes re-established. Eolian driven siliciclastics bypass the shelf during lowstand (Stage 3) and deposit within the Delaware Basin. As sealevel rises during the transgressive phase (Stage 4), beach-ridge complexes and siliciclastic sabkhas accrete and prograde in response to a rising water table. This is the phase when most of the siliciclastic Yates reservoirs were deposited.

As we saw in Chapter 2, preservation of evaporites into the early burial realm depends on the maintenance of a narrow range of saline conditions. Dissolution occurs if undersaturated fluids contact the bed at any time during the evaporite's deposition or shallow burial, either from an influx of fresh, meteoric water or from "freshened" seawater. Solution breccias of the lower Yates occur only in the middle shelf and develop preferentially along the seaward extent of the region of massive epeiric saltern sulphates, suggesting dissolution was driven by influxes of normal marine water during relative sealevel rises (Andreason, 1992).

The boundary between the collapse breccias and the massive sulphates marks the position of a concentration boundary on the submerged shelf where evaporative outflow exceeds marine free inflow and gypsum saturation was reached. Andreason argues this concentration boundary was shifted laterally relative to the magnitude of the sea level rise. When located seaward of this concentration boundary and given

sufficient time, evaporites originally present within the now-disturbed siliciclastic facies and the massive sulphate deposits underwent dissolution. Although the shelf position of the collapse breccias strongly suggests dissolution during a relative sea level rise, the possibly of dissolution by meteoric waters during periods of subaerial exposure and sealevel falls cannot be totally excluded.

The Yates Formation is part of the Seven Rivers, Yates, and Tansill trilogy, which in ascending order comprise the shelf-equivalent formations of the upper Guadalupian Capitan reef and represent a complex of lagoonal, coastal and evaporitic platform environments (Figures 5.21a and 10.36). The Yates Formation is unique among upper Guadalupian shelf formations in the Permian Basin in that it marks a period of major siliciclastic shelf deposition, as compared with predominantly carbonate and evaporite deposition of the Seven Rivers and Tansill formations (Figure 10.40; Andreason, 1992). The increased siliciclastic influx onto the shelf, particularly along the western margin of the Central Basin Platform and the northern margin of the Delaware Basin, probably indicates filling of the Midland Basin, which was located to the east. Eolian and wadi-driven siliciclastics, derived from the distant hinterlands to the east and northeast and previously trapped by the shallow Midland pontic sea, The erg migrated across the vast deflationary region of the filled Midland Basin and Central Basin Platform to prograde into the Delaware Basin. Siliciclastics and evaporites had reached the southern portions of the Central Basin platform from the northeast (Midland Basin) by the beginning of the late Guadalupian, as evidenced by the prevalence of these deposits within the upper Queen Formation (Tucker and Chalcraft, 1991).

It was a depositional setting much like the modern coastal zone of eastern Saudi Arabia and southeast Qatar (Figures 2.40, 3.15), but in a coastal strandzone under greenhouse, not icehouse, eustatic control. Throughout the late Guadalupian, the Midland Basin was a site of siliciclastic, anhydrite, and halite deposition within eolian, evaporative mudflat, and playa environments (Ward et al., 1986). In addition, the advancement of a siliciclastic wedge within the upper Seven Rivers Formation from the northeast onto the Central Basin Platform supports the possibility of siliciclastics migrating across the Midland Basin by the close of Seven Rivers deposition. Palaeogeographic reconstructions by Handford (1981) place prevailing winds from the northeast, off the Central Basin Platform. These eolian systems prograded across the Yates Shelf during periods of relative sea level fall and subaerial exposure of the shelf (Figure 10.40).

What is most important in terms of exploration and development models based on this setting is that the thickening and stacking of the better quality reservoir sandstones was controlled by an aggrading marine fed saline water table at the edge of an aggrading pisolitic shoal. Accommodation space for the sands was created by the syndepositional dissolution of a saltern edge along the seaward side of what is now a zone of thick stacked anhydrite beds. The generation of accommodation space for thicker better quality quartzose sands was diagenetically not depositionally controlled. The resulting thickened intervals of higher quality quartzose reservoir sands were then sealed by bedded saltern anhydrites of the Tansill Formation.

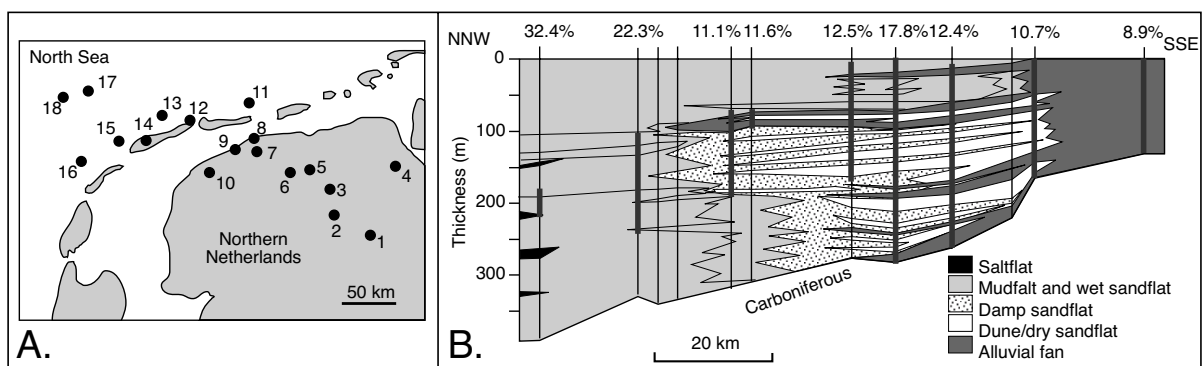

Figure 10.41. Characterisation of Rotliegende Sand reservoirs (after Amthor and Okkerman, 1998). A) Well locations in Northern Netherlands and North Sea. B) Cross section (perpendicular to depositional strike) of the Rotliegende Sand (Slochteren Sandstone) showing the major depositional environments. The average abundance of dolomite and anhydrite (total indicated in percent) increases in a NNE direction from the proximal alluvial fan and dunes/dry sand flat to the distal desert lake (saline pan and mudflat) environments.

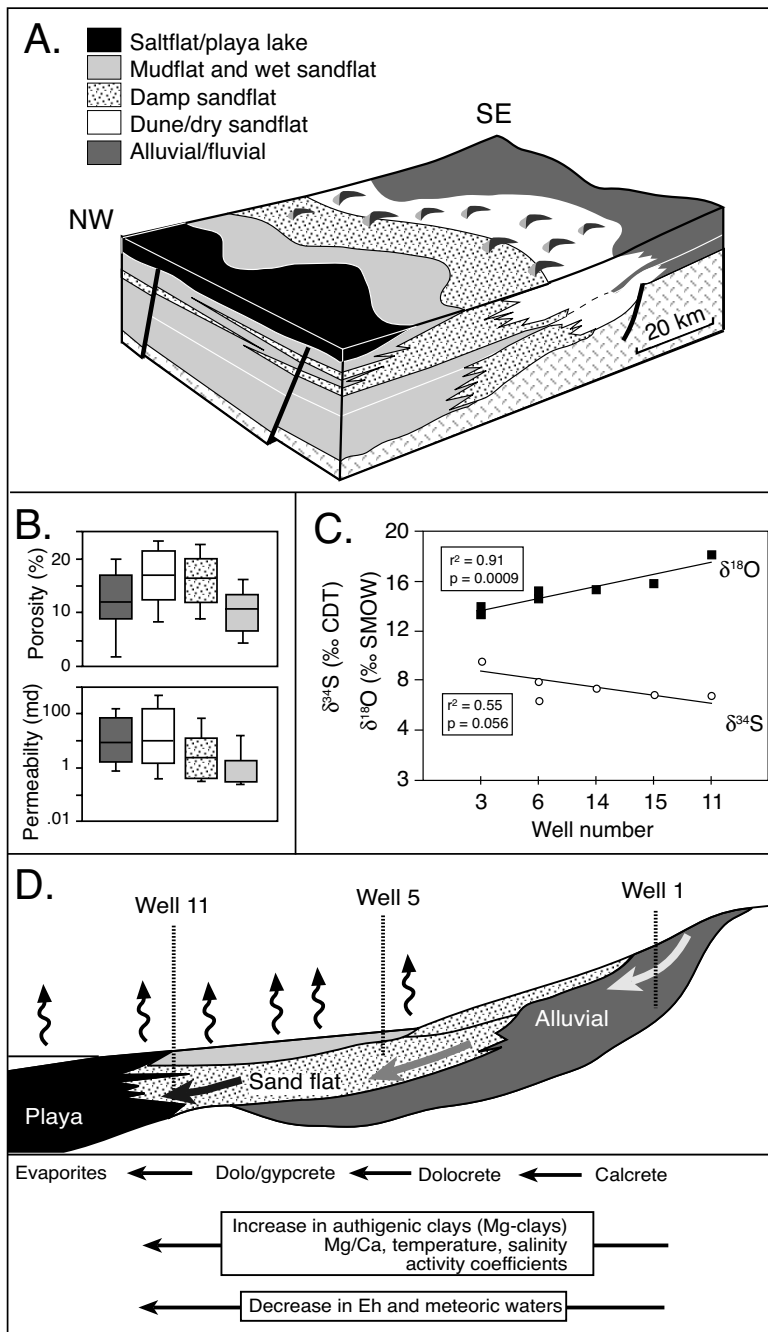

Figure 10.42. Rotliegende of Northern Netherlands (after Amthor and Okkerman, 1998). A) Depositional setting. B) Distribution of porosity and permeability, indicating a relationship between depositional environment, early diagenesis, and reservoir quality. C) $\delta^{34}\text{S}$ and $\delta^{18}\text{O}$ of anhydrite cements relative to geographic well position; oxygen isotopic compositions increase progressively from proximal to distal wells, whereas the sulphur isotopic compositions decrease. Such depletion in $\delta^{34}\text{S}$ and concomitant enrichment in $\delta^{18}\text{O}$ is the result of progressive evaporation in an arid alluvial to marginal desert-sabkha Rotliegende depositional setting. D) Conceptual model of groundwater evolution and its precipitates across an alluvial to sand flat/playa profile with the likely positions of three Rotliegende wells from Figure 10.41a indicated.

Rotliegende sands of Northern Netherlands and North Sea

Rotliegende Formation sandstones in the southern North Sea are important Lower Permian gas reservoirs, with recoverable reserves of $4.25 \times 10^{12} \text{ m}^3$ (150 tcf; Figure 10.41a; Glennie, 1990; Sweet, 1999), they also host much of the onshore gas of the Netherlands and NE Germany including the giant Groningen gas field in the Netherlands. Rotliegende reservoirs in the Netherlands are mostly sandstones and conglomerates deposited in an arid alluvial to marginal desert sand/mudflat and fluvial environments. They are intercalated with shales and evaporites deposited in saline lake/playa settings (Figure 10.41, 10.42a). The northward transport of metamorphic, volcanic, and sedimentary rocks shed from Variscan highlands supplied most of the siliciclastics. In the Netherlands, reservoir quality was significantly affected by early diagenetic processes in a marginal desert/playa lake environment (Figure 10.41b, 10.42a,b; Amthor and Okkerman, 1998).

Further offshore in the southern Zechstein Basin, burial-related products and processes are perhaps more significant and have received more attention than early diagenetic processes as controls on reservoir quality (Figures 7.72, 7.73). According to Amthor and Okkerman (op. cit.) these earlier studies of burial anhydrite cements have largely neglected the effects that early diagenesis can have on reservoir quality and well productivity of Rotliegende sandstones. They argue that much of the precipitation of the main porosity-occluding cements (dolomite, anhydrite, and quartz) occurred early, not late, in the diagenetic history of the Rotliegende reservoirs of the Northern Netherlands and was tied to variations in the syndepositional hydrology. Oxygen isotope values of dolomite cements ($\delta^{18}\text{O}_{\text{SMOW}} = 18.4$ to 23.4 ‰) suggest that meteoric water played a major role throughout the diagenetic history (Figure

10.42c), and that precipitation of the cements occurred at low temperatures (<80° C) characteristic of a desert and shallow burial. The strontium isotopes of dolomite cements ($^{87}\text{Sr}/^{86}\text{Sr} = 0.70935$ to 0.71387) and the sulphur isotopes of anhydrite cements ($\delta^{34}\text{S}_{\text{CDT}} = 6.7$ to 9.7%) are consistent with formation from continental water within a restricted basin and rule out Permian or younger seawater seeps as a source for these cements (Figure 2.23a).

The early diagenetic origin of the cements is also suggested by the fact that the majority of sandstone samples have lost more porosity via cementation than through compaction. Most samples with high amounts of porosity loss via cementation (20%) were affected by early dolomite and anhydrite cements (Figure 10.41b). The relative abundance of dolomite and anhydrite cements can be correlated with depositional environment. Wet depositional environments with water tables close to the surface (interdune and fluvial sandstones) show the highest amount of dolomite and anhydrite cements, whereas dry environments with relatively deep water tables (e.g., dune sandstones) are characterized by low amounts of cements (Figure 10.42d). The precipitation of early diagenetic cements has strongly influenced the present-day porosity patterns in the reservoir, with depositional environments interpreted as depositionally “drier” showing less cements. Early capillary and vadose precipitation of cements significantly altered the porosity patterns in the sandstones and playa mudstones. In effect, the intensity of subsequent cementation in this system largely tracks the palaeohydrology of the depositional setting. A similar set of syndepositional palaeohydrological factors controls subsequent reservoir quality in the Carboniferous eolian sabkha reservoir sands in the anhydritic Juruá Formation in the Solimões Basin (Elias et al., 2004). This is the largest gas sand reservoir in Brazil.

Personalised ramblings on the bedded-evaporite hydrocarbon association

According to Sun and Esteban (1994) the preservation of both primary and secondary porosity in evaporite-associated carbonates is due to varying combinations of the following factors. (1) A relatively arid climate, which means a relatively limited recharge of fresh groundwater, thus minimizing meteoric leaching and calcite cementation. (2) The presence of an extensive cap of impermeable mudflat dolomite and anhydrite. It effectively seals off the underlying permeable carbonate from ongoing early phreatic cementation as it slows or stops surface-groundwater driven flushing by large volumes of meteoric or sulphate-bearing fluids. (3) Early marine cementation and

hypersaline reflux dolomitization, which strengthens the rock framework, thus retarding physical compaction and making it more likely to fracture. (4) The presence of thick evaporites atop carbonates, which tend to form pressurised buffer zones below the salt seal. A thick evaporite retards mechanical compaction in sediments beneath it via the early onset of overpressure, it also prevents an influx of surface-derived cementing waters into the carbonate reservoir.

This listing, and others in the literature like it, do outline some of the reasons for the evaporite-hydrocarbon association, but do not offer predictive tools for explorationists or development geologists. As such they are largely ignored in designing exploration or development programs in evaporite-sealed systems. To create a predictive understanding of reservoir quality beneath evaporite seals is a more difficult task as it requires knowledge of evaporite texture and the ability to construct models of seal-related diagenesis in the carbonates below the seal.

The importance of recognising depositional differences

Our discussion so far has demonstrated that bedded evaporites constitute seals to all of the world’s largest oil and gas accumulations. Without exception, the largest of the various oil and gas fields sealed by bedded evaporites are hosted in partially dolomitized marine platform carbonates. In most giant and supergiant fields the evaporites not only hold back the hydrocarbon column, but also helped create and maintain reservoir quality. The most impressive examples are the various Arab D reservoirs in the Middle East, with slightly smaller but still very significant accumulations in oil pools in San Andres Formation of west Texas. In all these examples the depositional porosity of the reservoir has been altered and sometimes enhanced by brine-related allochem leaching and early reflux-driven dolomitisation. The degree of meteoric overprint at this early burial stage of diagenesis is minor to nonexistent. Syndepositional edge-of-evaporite dissolution from seawater freshening can occur and it led to substantial thickening of high quality groundwater-controlled eolian depopods in the billion barrel North Ward-Estes Field. Deeply circulating regional meteoric influx, mixing with brines of the reflux plume, can also occur in reservoirs below evaporite seals and influence reservoir quality, as in the Smackover Formation reservoirs of the Gulf of Mexico.

In my experience, most variation in subevaporite reservoir quality is the end product of a combination of depositional facies and varying intensities of evaporite plugging, dissolution,

reflux dolomitisation and burial stage cementation. Lateral and vertical variations in all but the latter are indicated by facies variations in the seal itself. Yet, for much of the oil industry, evaporite plugging and reflux dolomitization are associations that geological and geophysical staff do not quantitatively integrate into a reservoir model (other than via loosely controlled geostatistical formulations). The relevance of evaporite at any scale beyond the consideration of its seal integrity is not part of most reservoir studies (The typical question to be asked and answered of the evaporite in a petroleum system is; Is it thick enough? The magic numbers worldwide for answering yes are; greater than 10 metres thick for a clean anhydrite seal, and greater than 5-10 metres thick for halite!). Once the integrity of an evaporite seal or cap to a potential reservoir is established, further study of the seal properties or textures is not considered relevant, other than hoping for, or establishing, its lateral persistence. Rather, subsequent study and measurement focuses on the properties of the reservoir itself.

Attempting to better understand diagenetic intensity in the reservoir using signatures from wireline tools is typically considered too difficult, or the possibility is not even understood. Yet, as any carbonate geologist will testify, diagenesis is what distinguishes properties in a carbonate reservoir from those in a sandstone. Pervasive, but variable, diagenetic intensity is what controls carbonate reservoir quality in every evaporite-sealed petroleum system worldwide. Almost all of the matrix quality in the world's giant and supergiant evaporite-sealed carbonate fields was established during deposition and early burial. This is when surface topography controls intensity of circulation in the diagenetic hydrology (Chapter 2). It can be locally enhanced by later fracture development and perhaps the formation of coarsely crystalline saddle dolomites (typically fed by fractures and faults).

In petroleum systems exemplified by the examples of Yates and North Ward-Estes fields, reservoir quality is predictably tied to the style and position of the early evaporite hydrology and is indicated by evaporite textures in the seal. The same approach is also useful in other reflux-dominated carbonate reservoirs, as in the Arab and Khuff formations in the Middle East.

Much more reliable prediction and modelling (both seismic and reservoir scale) is done by the oil industry in sandstone-shale associations than in carbonate-evaporite systems. Our understanding of reservoir problems in a carbonate reservoir is more often post-mortem than predictive. More reliable maps of anhydrite plugging at the reservoir level and flow unit correlations for waterfloods in carbonates are sorely needed. In

evaporite-sealed systems it requires the integration of field-scale maps of seal facies with maps of reservoir properties in intervals below the seal. This is not currently done by most oil companies. Worldwide the focus of the map is in the reservoir itself and it is almost never related to seal facies.

The first step is the construction of a map of the facies mosaic preserved in the seal, using wireline-based core-calibrated image and conventional logs. At the local scale such a map uses separation of sabkha from salina signatures, at the broader scale it uses wireline based separations of evaporitic mudflat from saltern. Next a field-wide map of reservoir quality is constructed or existing maps of quality can be checked by recalibration to existing core and wireline/image data (in a producing field this data is available at varying degrees of reliability). The field-wide facies mosaic map derived from the seal is then overlain on the fieldwide map of reservoir quality and production data. A match or mismatch of the two outputs tests whether the early burial hydrology and associated palaeotopography has controlled much of the reservoir leaching/dolomitisation and anhydrite plugging.

These maps can then be used to better define untested reservoir zones. In a depositional seal, rather than a drape seal, the better quality reservoir sweetspots are typically beneath mudflat seals. If the evaporite seals across platform cycles are sufficiently thick and possess sufficient impedance contrast, then seismic facies can be constructed over the area of interest and be used to better identify potential sweetspots and other directional drilling targets in the field. This approach of integrating evaporite signatures into maps of reservoir properties is especially useful in carbonates beneath epeiric platform anhydrite beds in systems that have not been substantially overprinted by later stage burial alteration.

But porosity/permeability in an evaporite-sealed system continues to evolve to varying degrees, long after the reservoir has subsided into the mesogenetic realm and early evaporite plugging (via brine reflux) of the subsalt interval has ceased. In some fields the burial overprints are significant and can control reservoir quality, in others they do not. Porosity evolution in the mesogenetic realm is typically driven by focused vertical and lateral flow of ascending basinal brines. Close to their feeders, these waters pervade permeable intervals below the evaporite seal and so overprint the platform carbonate/dolomite to varying degrees, especially atop zones where active faults and fractures cut the reservoir but do not penetrate the evaporite seal. In more diagenetically mature fields, such as the Keg River pools in the western Rainbow-Zama sub-basin, much of the lateral variation

in reservoir quality is tied to burial stage leaching of anhydrite cements, the precipitation of saddle and zebra dolomite, and the formation of coarse, patchy but connected, intercrystalline burial-stage porosity. Now the reservoir altering fluids are fed by ascending brines rising along faults and fractures, these structures are sometimes visible in seismic and this association can be used as an exploration tool. Zones of most intense alteration tend to occur in haloes around the fault or in zones immediately below the evaporite seal and sometimes the drilling target is a narrow zone at the base of a synclinal trough (as in Scipio Albion trend, Michigan Basin). Convincing management to drill a syncline is not an easy task!

In more diagenetically mature portions of a basin, these fault-focused ascending basinal waters can carry high levels of metals and can form MVT deposits via thermochemical sulphate reduction (as in the growth fault-fed accumulations of lead and zinc in the Devonian Platform of the northern edge of the Canning Basin, Australia). In such stratiform MVT deposits the evaporites are typically long gone and all that indicates their former presence are laminar beds of metal sulphides with their coarsely crystalline dolomite gangue.

Even in less diagenetically mature supergiant oil and gas fields, where relict depositional porosity is the dominant control over reservoir quality and reservoir topography can be defined in the wireline signature of the seal, the early stages of overprint from ascending basin fluids will have locally altered reservoir quality, especially in the vicinity of active faults and fractures (as in the Arab D reservoir in the 150 billion barrel-plus Ghawar Field of Saudi Arabia).

The importance of recognising dissolution

Listings of controls of permeability in evaporite-sealed systems, such as that by Sun and Esteban (op. cit.), also underline another problem with many current field-scale geological studies of reservoir quality controls in evaporitic successions. Such studies, even where core is available, have typically not considered the likely presence in many evaporitic platform reservoirs of thin horizons that once were much thicker sequences of bedded evaporite. Yet bedded evaporites are highly soluble both at the surface and in the subsurface (Chapters 1 and 7), their residues are widespread and they can create regional markers easily misidentified in wireline as a correlatable well-to-well flooding surface.

Carbonate reservoirs worldwide are made up of stacks of platform cycles or parasequences, some with and some without

evaporitic capstones. When they were deposited, evaporite capstones in both ramp and platform settings typically mark the tops of zones of shoaling and perhaps cleaning-upward carbonate parasequences. Associated reflux brines were often responsible for formation of stratiform reflux dolomites in the carbonates below, along with variable levels of intergranular anhydrite cement that plug the upper portions of the carbonate cycle. Sometimes the evaporite capstones are absent because they were never deposited, other times the evaporitic capstones to these parasequences have been leached, along with the evaporite plugging cements in the underlying reservoir intervals.

Post-dissolution, all that may be left of a former bedded saltern evaporite is 5-50cm thick stratiform layer of fines, made up of insoluble residues that once were dispersed in the evaporite bed (eolian silts, clays and dolomite rhombs). The overlying succession often shows a characteristic vertical transition of mosaic to crackle breccia or into a zone of syndepositional solution collapse. Leaching of former anhydrite cements from intergranular positions in the carbonates below the residuum layer can create a high permeability interval below the residuum layer. Sometimes beds on either side of the dissolution residue layer may retain nodules of chert, baryte with minor relict anhydrite. The nodules, when present tend to be dispersed as a band on either side of the residuum layer. Using cores and FMI imagery, the associated breccias, sharp bases, crackled and fractured tops, along with slumps into karstic accommodation space created by salt dissolution can be used to define the former positions of these now dissolved parasequence tops.

Unfortunately, many practising geologists in the oil industry are well versed in sequence stratigraphic principles, but not accustomed to thinking and interpreting stratiform surfaces from well to well other than as a depositional interface or perhaps as a marine or subaerial exposure surface. When they see residual horizons in core and an associated clast-to clast breccia they tend to interpret it as either a storm bed or as zones of seafloor disturbance and starved sedimentation "formed at a time immediately prior to the creation of a maximum flooding surface." These layers of dissolution residuals are often clay rich and radiogenic and so show up as spikes on the gamma log through the carbonate platform. If the now dissolved bed was previously associated with an underlying zone of anhydrite cement, then dissolution of this anhydrite can create a zone of high permeability in the interval below the gamma kick.

Without core or image log control, intervals with such high gamma signatures can be easily misidentified as thin shales or mudstones that define flooding surfaces along the muddy base

of the next parasequence cycle. Widespread gamma kicks in a carbonate reservoir can then be miscorrelated well-to-well as depositional surfaces beneath low permeability muddy carbonates at the base of the next shoaling cycle. They are then tied from well to well and used to define regional flooding surfaces. These are in turn used as intrareservoir well-to-well markers to zone up the reservoir into flow units across a field. This misidentification is especially common in correlation studies done in thick carbonate sequences, largely lacking any other markers, and where the team conducting a reservoir zoning study uses a sequence stratigraphic framework for correlation and quality prediction between wells. As discussed in Chapter 5 most sequence stratigraphic and seismic studies currently conducted in carbonate terrains do not deal well with the “comings and goings” of evaporite beds.

Such inappropriate interpretations are not too much of a problem when the reservoir is in the early stages of primary production, or if the field is a single-phase gas field. But they become problematic when the same layer-cake reservoir model is utilised in developing notions of linked flow units via what are considered viable well to well correlations. In the more mature stages of planning of field development it is very important to reconsider any laterally continuous zone in the field, especially if defined by a gamma kick atop or within what is often a dolomitized or high porosity level. It should be redefined for what it is based on its signature in core or a core calibrated image log and not assumed that it is always indicative of some sort of well-to-well marine flooding surface.

Gamma kicks in wirelines taken through anhydritic evaporite platform carbonates do not necessarily indicate depositional shale/micrite. Rather, if it is indicating a solution residuum layer, then depending on how and when it formed and how the overlying section was let down, some of these stratiform residuum horizons may indicate a set of formative processes that have created widespread crosscutting extensional fractures and microfractures in the overburden. In other words, did undersaturated water access the dissolving evaporite from the side, top or base of the former evaporite bed? - as discussed in Chapter 7. Thus gamma kicks associated with an evaporite residuum can be associated with laterally extensive zones of higher fracture permeability above or below the marker. If the creation of the residuum layer was tied to the dissolution of former anhydrite cements in the underlying carbonates then high permeability occurs below the marker. If the formation of the residuum was created by lateral solution loss, then solution induced fracturing can occur across a retreating front in the layer above. In either case there is the distinct possibility

that adjacent high flow units are joined by dissolution induced vertical fractures.

Such a misidentified system becomes more problematic once production induces an oil-water interface rise. Water then penetrates unexpectedly into what were projected to be longterm productive intervals based on depositional assumptions of well-to-well marker or flooding surface correlations. Unrecognised high-permeability vertically-linked zones will drastically reduce sweep efficiencies when production planning of a waterflood continues to evolve based on inappropriate correlations of intra-reservoir permeability. There will be early and unexpected water breakthroughs during the waterflood. Depositional marker-based models do not account for likely vertical fluid transfer via cross fractures that developed at the time of evaporite dissolution. Nor does a sequence-stratigraphic-focused team tend to consider the possibility that likely zones of highly interconnected permeability can be formed by the leaching of former anhydrite or even halite cements in the grainy interval below the now dissolved evaporite unit (e.g. some very high permeability intervals that cut across depositional facies in the carbonate host).

But the reality is that most reservoir models for waterfloods and longterm production must be constructed over large areas of a producing field where closely spaced core to wireline calibrations are not available. The two endmember modes of marker occurrence (dissolution residue versus marine shale) can sometimes be separated using a high resolution conventional wireline tool, such as the MFSL, or better yet an image log. Many residue horizons are systematically associated with a halo of anhydrite or chert nodules on either side of the gamma kick, flooding surfaces typically are not and marine chert nodules, if present, tend to occur within the marker and not above. Clearly, any wireline-based definition of a dissolution surface can be complicated by the development of patchy high density, high resistivity carbonate cements. In this situation wireline separation of the two styles of picks is best done by an interpreter with an understanding of the significance of evaporite cements in the reservoir and who is using a core-calibrated set of wireline and image log signatures, rather than just conventional log shape.

Changing directions of brine flux in an evaporite-sealed system

At the regional scale, brine reflux flushing is most active in the early stages of evaporite deposition, when the evaporite beds retain porosity and permeability and concentrated Mg-rich

brines sink from the overlying free brine pool, through the still permeable bedded evaporite (usually gypsum), and into the underlying sedimentary succession. Elliott and Warren (1989), Saller and Henderson (1998) and Lucia (1999) all point out that the downward cyclic transition from a relatively impervious overdolomitised and salt-plugged platform dolomite (typically with thick intercalated saltern and mudflat seals) into partially dolomitized subtidal platform carbonate reservoirs (with thinner seals) corresponds to a downward decrease in the flux of saturated reflux brines and an increase in dolomite crystal size. This corresponds to a downward decrease in dolomite saturation as the refluxing brines sink deeper and further from the brine source. Thus, the better reflux-enhanced platform reservoirs occur in structures not directly beneath the thicker accumulations of saltern salts, where salt plugging, overdolomitisation and mimetic dolomite dominate. Better potential reservoirs tend to occur more toward the seaward margin of the thickest saltern accumulation where coarser dolomite, partial dolomitization and thinner evaporites are found.

Long term salt plugging, tied to large volumes of saturated brine reflux, means that most hydrocarbon accumulations sealed by basinwide evaporites are typically smaller and less productive fields compared to their platform counterparts (e.g. the relatively small volumes of hydrocarbons in salt-encased Silurian pinnacles of the Michigan Basin and the pinnacles of platform edge of the Rainbow-Zama sub-basin). A lack of widespread potential reservoir in the muddy deepwater setting that immediately predates most basinwide evaporite beds adds to the likelihood of smaller accumulations beneath basinwide salt seals, compared to platform settings. Even so, thick massive basinwide evaporites trap and preserve some of the oldest oil and gas fields in the world (e.g. fields producing from platform carbonate slivers suspended in the Neoproterozoic Ara Salt of Oman).

Most reservoirs associated with bedded basinwide evaporites are in pinnacle reefs where karstification or later subsalt burial corrosion has reinvigorated the reservoir quality. Sun (1995) found porosity distribution in dolomite reservoirs associated with basinwide evaporites typically show no direct relationship to stratigraphic position or depositional trend. His conclusions emphasise the problems of reliable porosity prediction in a syndepositional hydrological system characterized by large autocyclic fluctuations in hydrologic base level (≈ 1 km) over time frames of thousands of years (Chapter 5). It also indicates a lack of differentiation of strandzone versus basin-centre reflux dolomites by most workers, yet both dolomite styles typify basinwide evaporite settings (Warren, 2000b). Unlike

the dolomites associated with platform evaporites, this group of reservoirs cuts across both icehouse and greenhouse periods as basinwide evaporites require tectonics that are independent of sealevel character (Chapter 5).

An evaporite bed can only act as a seal once it has lost its intrinsic permeability. For a gypsum bed converting to anhydrite this happens somewhere in the first 500-1000 m of burial, while for halite it can happen as shallow as a hundred metres below the landsurface. Until then, the permeable evaporite bed facilitates brine reflux, but once tight it only supplies brines to its surrounds via dissolution of its edges and focuses fluid flow along its underside. This transition in rock properties has an interesting effect on diagenesis and explains much of the later stage dolomitisation overprint on early reflux dolomites that are seen in many evaporite-sealed reservoirs (e.g. Canadian pinnacle reef traps and the dolomites of the Arab cycles in Saudi Arabia). As the evaporites were accumulating they flushed the underlying carbonates with dense sinking Mg-rich brines. Once buried and tight, the evaporite seal then prevents the free vertical escape of hot rising brines, which pond in carbonates immediately below the slowly dissolving underside of the evaporite seal. The resulting chemical interface drives salting out of hydrocarbons, creates of burial porosity, and drives the precipitation of authigenic or burial cements, including coarse sparry dolomite. It means most dolomitic reservoirs below an evaporite seal retain evidence of diagenesis first driven by descending reflux brines, which were created as the evaporite seal precipitated. Then later the same subsalt carbonate gathers a new diagenetic signature (of varying intensity) via the seal-focused flushing of hot ascending basinal brines moving along active subseal fractures.

Halokinetic salt traps

In many parts of the world, such as offshore Brazil, offshore west Africa, the North Sea and the Gulf of Mexico, a significant part of the association of evaporites with hydrocarbons can be tied to salt's ability to flow, and by its flow generate large and numerous structural and stratigraphic traps. The emplacement of broad sheets of salt against more porous sediment greatly improves the efficiency of hydrocarbon drainage, both in terms of area drained and in tightness of the reservoir seal (Demaison and Huizinga, 1991; Hindle, 1997).

We saw in Chapter 6 how advances in 3D depth migration and computing power, still occurring today, have revolutionized subsalt and suprasalt hydrocarbon exploration. Only a decade

Figure 10.43. Regional model of the development of outboard shelf/ramp margin buildups (structural control to shelf margin) and the “inboard” pinnacle reefs growing in seafloor shoals created by salt pillows in the Marquez Platform, East Texas Basin in Upper Cotton Valley to Lower Bossier time (after Montgomery et al., 1999a).

or so ago, most seismic reflection information in halokinetic provinces was acquired as 2D data; today, most seismic data is acquired as 3D data volumes. The 3D cube provides a dense grid of subsurface information, which can be used to more accurately map salt body contacts and shapes. Older vintage seismic used mathematical models for conventional migration and processing that assumed that the acoustic properties of subsurface sediments did not make abrupt lateral variations. This assumption obviously breaks down near salt structures; a solution required cheap computing power, more sophisticated depth migration techniques and denser data grids. Positioning of contacts in older vintage data can sometimes be improved using more recent processing algorithms and greater computing power, offering a cheaper but less accurate alternative to reshooting a grid.

The notion that salt flow was a horizontal as well as a vertical process was increasingly accepted by the late 1980s. It opened up a whole new set of subsalt or more correctly suballochthon plays in the deep waters of the slope and rise in the circum Atlantic salt basins and similar terranes elsewhere in the world. At the same time drilling technology was improving rapidly, along with geosteering capabilities and broader MWD logging tool suites. Each year wells were being spudded in progressively deeper water. For example, ultradeepwater exploration in Gulf of Mexico, in the decade through to the early millennium, has found more than 3-4 billion BOE in nine major discoveries, in a hydrocarbon exploration province previously considered mature (Enger and Logan., 2001).

But before we discuss the sub-allochthon traps we will look at the suprasalt trap, which was the classic exploration association in halokinetic regions prior to the 1980s. Historic limitations in seismic resolution meant that examples of suprasalt-related oil and gas traps were done in the context of subvertical thumb-like appendages of salt fed by a direct connection to a mother salt bed below. Interpretations of the many producing structures in the onshore and shelf waters were biased toward this older notion of strongly vertical salt flows with salt pillows as the precursor to subvertical diapir stems. We now know that many nonpiercing pillow structures can be compressional features created during inversion or foot of slope gravity gliding (Figure 6.34). Other pillows do form in response to depositional loading as a flow stage preceding the diapiric stage (Figure 6.15). This is the classic model of Trusheim (1960) and based on his extensive work in the Zechstein salt structures of northern Germany. More recent work, even in this classic area, shows thumb-like geometries and associated assumptions of a connection to a more deeply buried mother salt bed are not necessarily correct (Mohr et al., 2004). Isolated rising blebs cut off from the source layer are more likely in the mature portions of many salt basins undergoing compression and inversion. This notion perhaps offers some possibilities for future sub-salt flange sealing plays even in very mature regions of onshore and shelf exploration in the Gulf of Mexico and onshore Europe. But, such traps are likely to be small and discontinuous. Currently the possibility of drilling giant structures in the deep waters of the Gulf of Mexico and other circum Atlantic salt basins are more appealing to the exploration economics of large and mid-sized oil companies.

Supradiapiric traps

Oil and gas reservoirs atop salt structures are as varied as the shapes and timings of the salt structures that caused them. Salt buoyancy means areas above shallow actively flowing salt structures are topographic highs, while the areas between are topographic lows (Table 6.3; Figure 6.51). Fluvio-deltaic, coastal, and submarine slope deposits are usually sand poor over the salt crest (Figure 6.50). Most of the coarser-grained sediments in either setting is deposited in troughs as various types of channel fill and beach deposit, especially in landscape depressions atop zones of active salt withdrawal. In continental settings the pinchout of the high-porosity sand occurs along the flanks of a salt structure, usually well down-dip from the crest. Occasionally, reservoirs can form in the muddy crestal sediments in a continental setting due to diagenesis associated with subaerial exposure and/or unconformities. In arid coastal areas the crest could have been covered by evaporitic mudflats as environments tied to the development of early dolomite in pelleted mudstones with the associated formation of good intercrystalline porosity (Figure 6.56).

In nonpiercement structures in shelf settings the high-porosity sediments tend to form atop or immediately adjacent to a suprasalt crestal shoal (Figures 6.57). Boundstones, skeletal and oolitic grainstones, and well-winnowed siliciclastics are found on such highs. For example, studies by Mancini and Benson (1980) and Ahr and Palko (1981) of the Jurassic Smackover Formation reservoirs in southwest Alabama and Louisiana show that reservoirs often occur in oolitic-pisolitic grainstones located over salt pillow crests, while Montgomery et al. (1999a, b) describe hydrocarbon accumulations in numerous inboard Jurassic (Cotton Valley - Bossier) reefs atop salt pillows and diapirs in the East Texas Basin (Figure 10.43). Similar Jurassic stromatolite and coral stromatoporoid reefs are found in the Smackover atop other salt pillows, such as the Walker Creek Field, Arkansas, in the Hico Knowles Field, Louisiana (Baria et al., 1982), and Hatters Pond in southwest Alabama. There the Smackover buildups are typically 3 - 40 m (10 - 130 ft) thick, commonly elongate, and several square kilometres in plan.

Reef rubble zones throughout the Smackover trend tend to have reservoir-quality porosity, but reef boundstones are economic only when extensively leached, dolomitized, and fractured. Such alteration can create commercial production from reef crests with mean porosities of 15% and permeabilities of 20 md. Hatters Pond Field is typical of a field where the reef crest is tight and depositional facies crosscut the reservoir trend. The distribution of the reef was controlled by the position of the Jurassic high above a growing autochthonous salt pillow, while the trap was created during Cretaceous faulting associated with the structure's diapiric stage (Worrall and Warren, 1986). The level of the reservoir dolomite lies well below the reef crest and above a dolomite unit characterised by post-hydrocarbon saddle dolomite. As in bedded evaporites, the initial porosity controls in carbonate reservoirs atop salt pillows and diapirs are often depositional, but are usually complicated by closures and alteration haloes related to fault welds and subsequent fluid flow.

Siliciclastic examples of closure forming high capacity suprasalt reservoirs by sand-shale juxtaposition across clay-smeared extensional faults can be seen atop salt structure crests in the West Bay Field in Louisiana and the Heidelberg Field in Mississippi (Halbouty, 1979). Bay Marchand - Caillou Island Field is a classic example of this style of fault-controlled suprasalt sand reservoir above the crest of salt structure (Figures 8.23a, 10.44). The three diapirs that constitute the field are passive diapirs atop a salt wall feed. Under the new paradigms of flow that have been developed since this structure was documented by Frey and Grimes (1970), it can now be seen to be the remnant of what was an active salt feeder systems with the current fault weld once acting as a salt wall

Figure 10.44. Structure contours (in metres) on the productive Upper Miocene sand in the vicinity of the Bay Marchand - Timbalier Bay - Caillou Island diapirs, coastal Louisiana. Diapirs merge at depth into a salt wall and occur along a main extensional fault linking all three domes, each with its own association of radial faults (after Frey and Grimes, 1970).

feeding diapiric allochthons higher in the section. Most of the extension driving the faulting was a response to gravity gliding and salt deflation and not the active intrusion visualised in the original interpretation. The faults show radial, peripheral, or tangential patterns relative to the salt stock. Elsewhere in the Gulf of Mexico similar faults have downfaulted, uplifted, or overthrust sands against impervious shales and multiple stacked reservoirs are stacked up against the fault (e.g. Bryan Salt Mound, Brazoria County, Texas).

Many of the numerous radial faults drawn in older interpretations of suprasalt traps (pre-1990), were published prior to the industry's recognition of salt's intrinsic lack of strength under tension. These interpretations tended to visualise faulting (mostly inferred rather than intersected) as a response to buoyancy and active salt intrusion. This is understandable as in most cases much of the salt that fed into an allochthon has long since dissolved or moved on to higher levels in the stratigraphy, via what are now deflated salt welds. In more recent interpretations of the same structures the faults are seen to be a response to salt withdrawal and to downbuilding in the adjacent sediments. High resolution seismic has shown that many of the inferred radial faults of older interpretations do not exist. Such faults were inferred in order to explain discontinuities between sands in adjacent areas. In reality, many of these discontinuities, are more often a response to unconformities and depositional pinchouts rather than fault-outs, especially in flank traps.

For example, a reinterpretation of the Cote Blanche Field in Louisiana in the mid 1990s, based on newly acquired 3D seismic reduced the number of radial faults in the crest of the field to nine, compared to more than thirty in mid 1970s vintage 2D interpretations. But radial faults do exist about salt structures and are largely a response to salt deflation during the passive stage of diapirism or are a response to later basin inversion and diapir squeezing. In halokinetic extensional terranes that have been subject to later compression, such as parts of the North Sea, offshore UK and Norway, many of the earlier radial faults are reactivated and have evolved into inversion structures (Figure 6.42).

Syndepositional suprasalt traps occur in the sand-rich edges to withdrawal synclines, along with associated pinchouts onto the diapir crest (Figure 10.45a). An example of this type of reservoir is the West Saratoga Field, Hardin County, Texas. There, multiple Yegua sand reservoirs shale out as they pass into the Saratoga Salt Dome (Galloway et al., 1983). The secondary peripheral sink continued to subside as the diapir grew (downbuilding), resulting in steep dips in the sand units as they shale out into the diapir stem (Figure 10.45a) Subsequent loss of salt supply and cap rock formation may cause loss of salt volume and local collapse around the salt stem (Figure 10.45b). Steeply dipping suprasalt reservoirs are characterized by stacked thick oil columns, which may approach 300 m (1,000 ft) where they pile one atop the other alongside the salt or a clay-smear

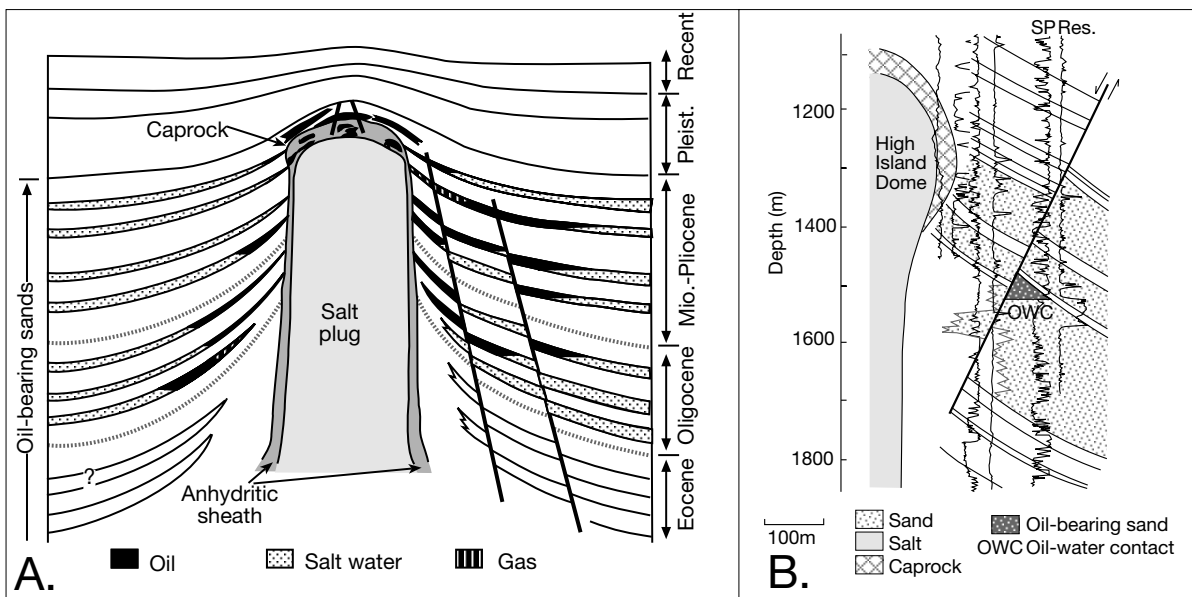

Figure 10.45. Reservoir sands in the Gulf of Mexico A) Stacking of Tertiary-age peripheral reservoir sands creates some of the most productive acreage in the world (after Halbouty, 1979). B) Cross section of the south flank of the High Island Dome, Chambers County, Texas, where the trap is interpreted as due to peripheral faulting juxtaposing a reservoir sand to a shale seal across the fault (after Galloway et al., 1983).

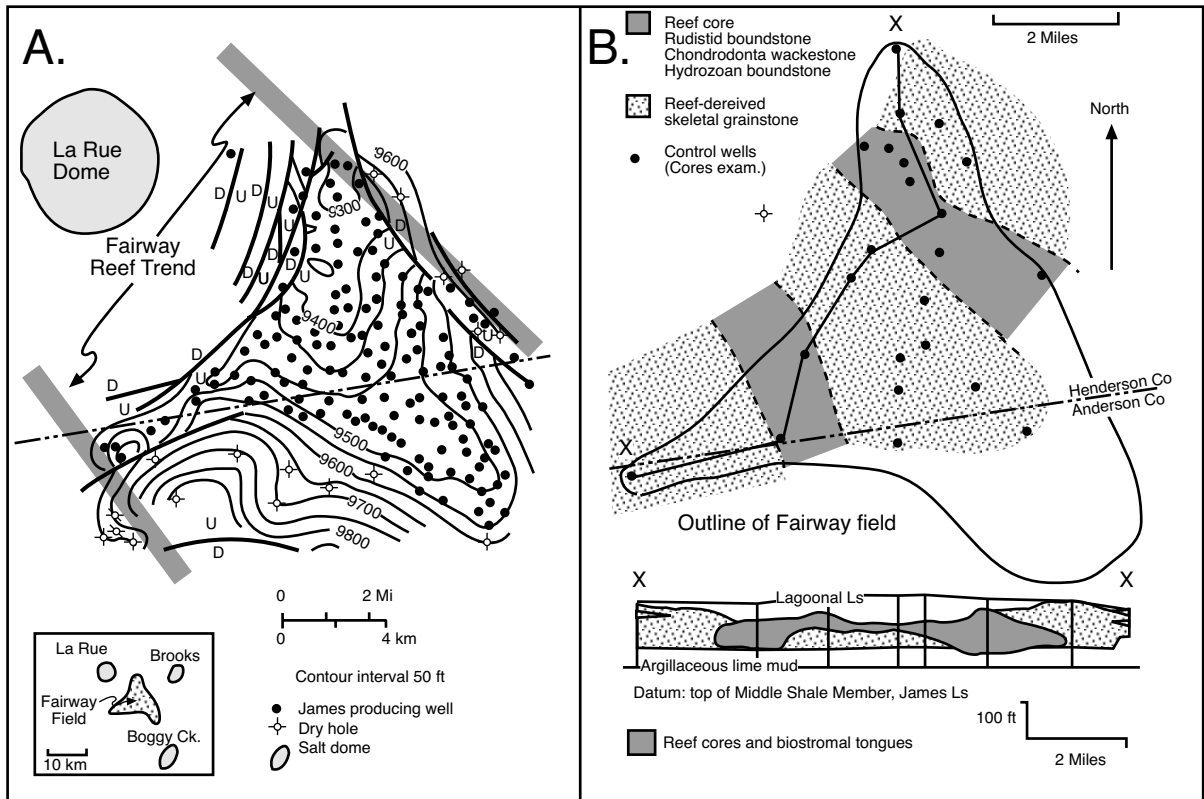

Figure 10.46. Fairway Field, East Texas Basin (after Achauer, 1985). A) Structure map on top of Cretaceous James Limestone Fairway Field, Henderson and Anderson Counties, Texas. The trap is a fault bounded southeast-plunging nose crossed by the northwest trending James Reef Complex. Inset shows Fairway Field formed atop a turtle structure between three salt domes. B) Facies map and interpreted depositional setting of the James Limestone. The main reef core lies in the northwestern part of the field, while satellite reefs to the southeast and southwest are composed of corals, stromatoporoids, algae, and rudists. Carbonates sands and gravels were deposited in the southern part of the field; while elsewhere, muddy lagoonal sands are the dominant lithology.

fault weld. Efficient gravity segregation aided by water influx results in high recovery efficiencies.

Grainstone shoals and reefs may rim the diapir or allochthon crest in carbonate shelf settings. With ongoing subsidence, these units tend to aggrade into a porous rim around the salt stem. A good example of this style of grainstone trap is the West Purt Field in the East Texas Basin, where the reservoir (Rodessa Limestone, Lower Cretaceous), is a fractured mollusc peloid grainstone and rudstone unit abutting the northwest side of the Brushy Creek Diapir (Lomando et al., 1984). The same style of carbonate facies, growing around diapirs and salt welds, now outcrops as the various carbonate lentils associated with the La Popa weld in Mexico (Figure 6.59).

Pulsing salt emplacement, with numerous switches from active to passive, means that any sediment deposited above a passive allochthon or diapir crest is temporary. Whatever the

depositional setting atop the crest, it is shed periodically into the structure's flanks. The resulting salt ablation unconformities can cut into flanking coarser grained deposits, which may then be sealed by subsequent finer-grained deposition or by the encroachment of allochthonous salt (Figure 6.62). The resulting unconformities and truncational traps can be located some distance from the diapir stem. The dip of such unconformity traps is as steep as the dip of the adjacent shaled-out sands. Unconformity traps have thick oil columns and can stack, but show a limited lateral extent away from the salt stem. A good example occurs along the north side of Nash Dome in Texas, where steeply dipping Frio sands (Oligocene) are truncated by multiple dome-flank unconformities.

Stacked flank traps dominate below the crestal level of many producing salt structures in the onshore Gulf of Mexico, reflecting sedimentation about a salt system during the passive stage of its growth. The crest of the structure maintained

its position in earth space while the flanks subsided so that most flank traps are of two interrelated types (Figure 10.45a; Halbouty, 1979): a) Traps created by sedimentation and erosion contemporaneous with salt movement; b) Traps created by the relative upward movement of the salt (downbuilding). Stacked flank and unconformity traps have yielded greater volumes of hydrocarbons per acre than any other type of trap in the Gulf of Mexico (Halbouty, 1979).

The diapir stage is also the time when turtle structure anticlines form in the salt-withdrawal basins between diapirs (Figure 6.17). The region above a turtle is often a topographic high where high-energy shelf sands and reefs accumulate atop an anticlinal drape, creating an excellent trap for the subsequent accumulation of hydrocarbons. A good example is the giant Fairway Field in Lower Cretaceous James Reef Limestones in Henderson and Anderson counties, east Texas (Terriere, 1976, Achauer, 1985). The reservoir is a rudist-reef complex above a shoaling turtle structure and is situated on a saddle between the salt-withdrawal areas of Boggy Creek, Brushy Creek, and La Rue Domes (Figure 10.46).

The growth of a turtle structure between the La Rue, Brooks and Boggy Creek diapirs converted what was a muddy area of open shelf limestones into a shoal area of rudist reefs and grainstone shoals. Postdepositional faulting truncated the northwestern and northeastern margins of the trap, which is now a southeast-plunging nose (Figure 10.46a). Reservoir porosity is largely secondary and is better quality in the meteorically leached portions of mechanically deposited rudist grainstone belts rather than in the reef proper (Figure 10.46b). Secondary porosity tied to halokinetic activity after the reef growth stopped is also the case in many other rudist grainstone buildups atop or adjacent to salt structures in the Gulf of Mexico and the Middle East (e.g. Mishrif Formation

in Umm al Dalk Field, UAE). The main control on reservoir quality in these Cretaceous oil and gas fields is karstification and exposure, driven by periodic seafloor shoaling near or atop the underlying salt structure. Pervasively dolomitised Albian oolite pisolite sands also form extensive reservoirs atop turtle structures in the offshore of Angola (Eichenseer et al., 1999).

Chalk reservoirs above salt structures, such as Danian chalks in Ekofisk, Machar and Medan fields in the North Sea, often had the crestal reservoir properties enhanced by the movement of subadjacent salt during basin inversion (Figure 10.47). Tension was created in the chalk above the growing salt structure and this led to gravitationally-induced microfracturing (D'Heur, 1990a). Oil migrated up these fractures in the chalk and, when the oil column in the fracture system was 50 to 100 m tall, the buoyancy force was sufficient to overcome the high entry pressures inherent in narrow pore throats. Oil was then stored in the matrix as well as in the various fractures. Hardman and

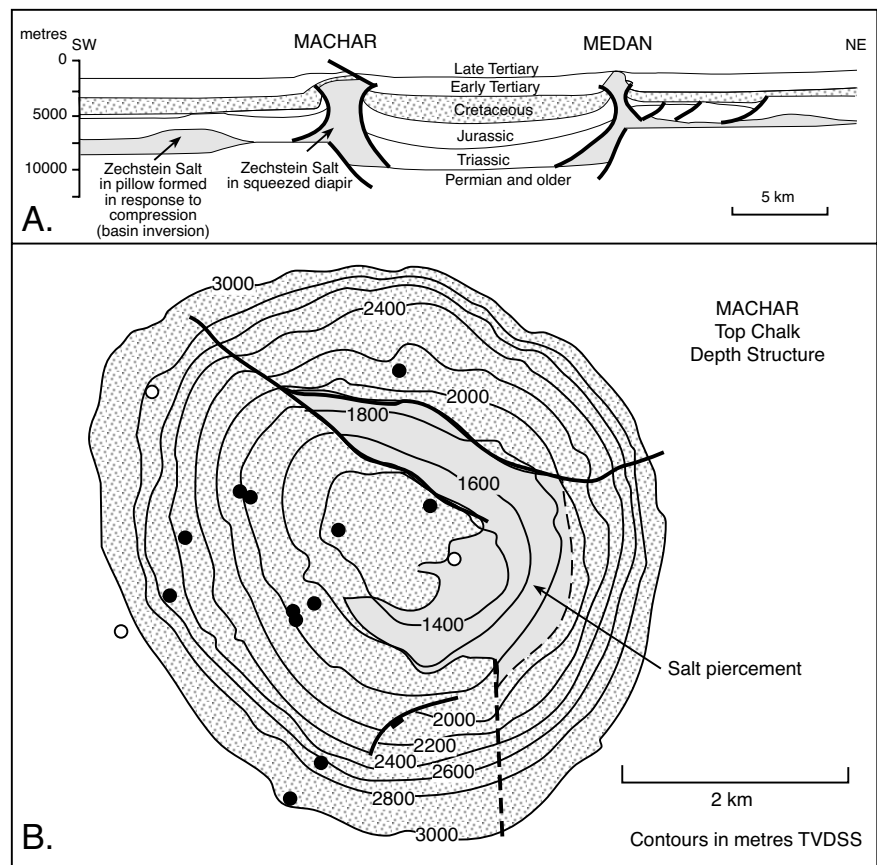

Figure 10.47. Machar Field, UK sector North Sea. A) Interpretive cross section showing position of field and a geometry that is a response to compression of a formerly extensional salt structure. B) Contoured top of chalk in metres TVDSS showing zone of piercement of Zechstein salt (after Foster and Rattey, 1993).

Kennedy (1980) postulated that this process explains why high-relief features in the North Sea chalk/salt structures have better oil saturations and why low-relief traps can have water-wet matrix porosity. Early entry of oil into matrix pores and the associated overpressures then retarded the normal sequence of chalk lithification with burial by inhibiting chemical diagenesis and reducing overburden pressure on the matrix grains (D'Heur, 1990a, b). These processes were most effective in reservoirs above the centre of the salt structure and with time migrated out into the flank reservoir; hence the reduction of porosity and increase in water saturation radially and the concave-upward oil water contact at West Ekofisk.

In a recent study of fracture distribution in chalks reservoirs from a number of rejuvenated diapir fields in the North Sea, including Machar, Davison et al., 2000b found that almost all (>99%) faults and fractures observed are extensional, and form at high angles (>70°) to bedding. Fracturing in the chalks is a response to the rejuvenation of salt flow as the North Basin underwent mild inversion in response to the Alpine Orogeny. The greatest amount of interconnected fracturing and brecciation (natural rubble zones) in the chalk is in wells at or near the crests of the diapirs (Figure 6.47a). The fractures are commonly open, indicating that deformation has continued until the present day, and/or cementation has been inhibited owing to the presence of hydrocarbons, which began to accumulate in the fractures after chalk deposition. Close to the diapir contact (<50 m), the fractures in the chalk are cemented with calcite or anhydrite, which is interpreted to be due to increased fluid flow concentrated along the diapir contact.

This plume of rising saline fluids rising along the dissolving diapir has created a celestite halo in the cap of Machar Field. The fracture intensity within the chalk does not vary consistently from base to top at any one position on the diapir. Reservoir productivity in the chalk is significantly enhanced by fracture permeability over the crest of the diapir structure, where intrinsic permeability in the chalk is insufficient to sustain economic flow rates. However, the chalk is absent on parts of the crest due to non-deposition or downslope sliding (Figure 6.47b; Davison et al., 2000a). These are areas where salt sometimes made it to the Cretaceous seafloor as small allochthon wings off the main salt trend stem. Stylolite and dissolution residue seams, which are parallel to bedding, can slow vertical flow rates in the chalk (Davison et al. 2000b). They are made of clays and other insolubles and show very low permeabilities on the order of nannodarcies.

Understanding the fault and fracture network in Machar chalk as a response to diapir squeezing and the rise of the diapir crest created a new fracture and fault model. Using this knowledge in the field development plan, along with greatly improved seismic imaging, controlled acidising of the chalk, and steered MWD drilling technology, converted Machar from a field that appeared subeconomic in the early appraisals of the late 1980s with test wells returning at best 8,000 bopd to the current producing field with acidised intervals in fractured zones capable of reliably producing at rates of up to 30,000 bopd.

Even as a diapir crest becomes buried and caprock formation comes to dominate, potential reservoirs can still be created. Caprocks host hydrocarbons in many Gulf of Mexico domes show porosities as high as 40%, with porosity types ranging from pinpoint to vuggy to cavernous. Caprock reservoirs in the Gulf of Mexico onshore are shallow and so were attractive targets in the early heyday of drilling in Texas. Many of the famous early Texas reservoirs were in caprocks; examples include Spindletop (the most famous), Sour Lake, and Humble. Caprock reservoirs tend to be made up of relatively small, but numerous, pools. Today, most onshore diapir crests have been drilled and offshore the small size of possible caprock pools means they are not primary targets in most exploration programmes.

Traps can occur below a salt wing (remnant allochthon) or an overhang in a squeezed salt structure with a shape like an inverted teardrop. Prolific production comes from beneath the overhang of Barber Hill Dome in Chambers County, Texas; High Island Dome in Galveston County, Texas; Batson Dome in Hardin County, Texas; and the Weinhausen-Eicklingen salt dome in the Zechstein Basin of northwest Germany (Figure 10.48). Sands below the Barber Hill overhang in east Texas have produced more than 100 million barrels of oil (Halbouty, 1979). All these traps are onshore and were interpreted under the classic styles of Trusheim's pillow to diapir model using the notion that salt was capable of sill-like intrusion at depth. Today they would be interpreted as remnant allochthons created by passive diapirism or allochthons created by reactivated flow due to salt squeezing.

Allochthon plays in the deepwater realm

Throughout the last three decades the deeper offshore province of Gulf of Mexico has been a focus for the development of improved deepwater drilling and seismic technology as deepwater exploration expands into a deepwater realm where much trap structuration is a response to salt flow. Accordingly, as much

Figure 10.48. Cross section through traps below flank overhangs of the Weinhausen-Eicklingen salt dome, Hanover Basin, northern Germany (after Lotze, 1957). The current geometry also suggests that the structure also underwent compression in the Alpine orogeny.

of the published exploration paradigm for salt allochthon plays comes from the Gulf of Mexico and the examples and models cited in this section largely come from there. However, similar paradigms of allochthon development are being used to drive

two largest deepwater fields found to date are Mars (750 mmbbl oil equivalent) and Thunder Horse (1,000 mmbbl oil equivalent and possibly as high as 3,000 mmbbl). Thunder Horse was not discovered until 1999, a quarter century after the 1975 discovery

exploration in other circum Atlantic basins. As yet this work is not as extensively documented as the Gulf of Mexico, but is a rapidly expanding dataset (see Figures 6.18, 6.37, 6.38).

Since 1975 over 21.2 billion barrels of oil equivalent have been discovered in the deepwater Gulf of Mexico, while some 9.2 tcf of gas and 2,200 mmbbl were produced between 1979 and the end of 2002. Deepening water depths of the various discoveries reflect this time-related technological development (Figure 10.49a; Table 10.7). There were 232 commercial fields discovered in the Gulf during the period from 1975 to the end of 2003 (Cossey, 2004). The current mean size of these discoveries is 94.3 mmbbl oil equivalent. The

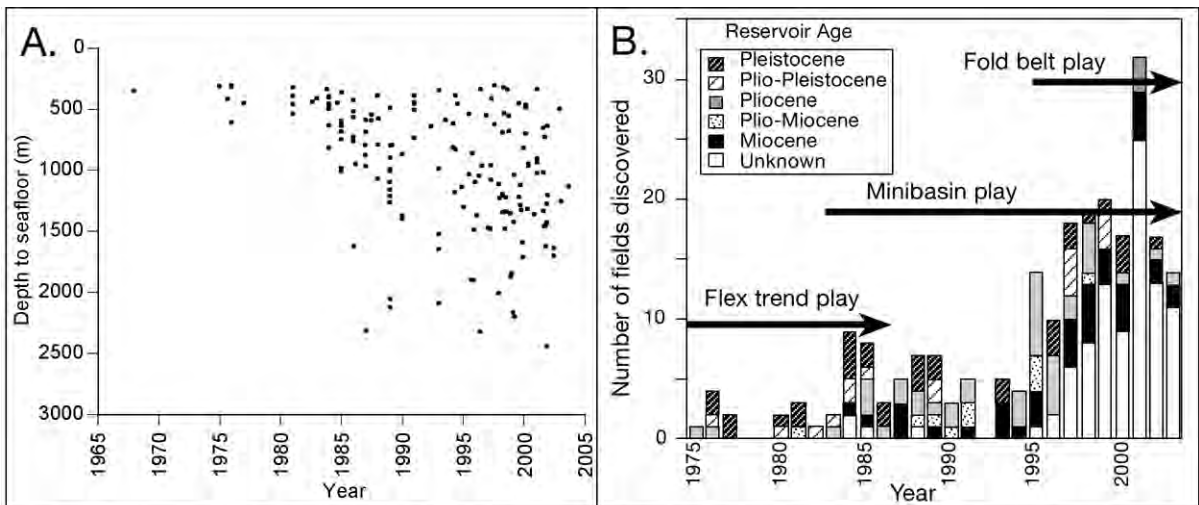

Figure 10.49. Deep water exploration in the Gulf of Mexico. A) Water depth to seafloor for deepwater discoveries in the period 1965-2003 (replotted from Appendix 1, a data table in Richardson et al., 2004). Plot clearly shows the technology-driven expansion of the oil industry into greater drilling depths in this salt allochthon province - see also Table 10.7. B) The number of discoveries for the years 1975-2003, showing reservoir age and dominant play type. It also shows the large increase in discoveries from 1995 onward after the passing of the Royalty Relief Act removed some government tax restrictions to deepwater exploration. There were no discoveries in 1978, 1979 or 1992 (after Richardson et al., 2004; Cossey, 2004).

of Cognac, the first deepwater field (Table 10.7). Initial well flow rates in the deepwater province did not exceed 10,000 bbl/day until 1995, some 20 years after the discovery of Cognac. Three years later, individual well rates at Ram-Powell and Troika had exceeded 20,000 bbl/day.

Several early subsalt wells were accidental subsalt penetrations where operators were drilling to test anomalous seismic reflectors and found salt where they expected hydrocarbons. The first subsalt well drilled in the Gulf of Mexico Outer Continental Shelf was Placid Oil Company's Ship Shoal 366 well in 1983. This well encountered three separate salt intervals, but only 90 metres of subsalt sediment were penetrated. Over the next several years, sporadic subsalt drilling continued. One of the more interesting early subsalt wells was Diamond Shamrock's 1986 well, South Marsh Island 200, which encountered a reservoir-quality sand with a massive 245m net thickness. The potential for worldclass reservoir sands beneath salt allochthons became apparent with this well, but the absence of reliable subsalt targeting from existing seismic technology limited drilling activity.

Porosity and permeability in what are producing deepwater sands in these subsalt fields can be impressive, even though deposition has occurred on deepwater bottoms, situated well out on the continental slope and rise, sometimes in regions that were more than 100 km from their contemporary shorelines. Sands in the Auger Field (Garden Banks 426) retain porosities of 26% and permeabilities up to 350 md. Pliocene and Pleistocene turbidite sands in Green Canyon 205 Field have reported porosities ranging from 28 to 32% with permeabilities between 400 md and 3 darcies. Connectivity in these deepwater sheet sands and amalgamated sheet and channel sands is high for deepwater turbidite reservoirs worldwide and recovery efficiencies are in the 40-60% range (Cossey, 2004). The high production potential of ultra-deepwater reservoirs in the Gulf of Mexico deepwater was documented by production results in Troika and Mars fields where flow rates from turbidite sands are as high as 31,000 and 50,000 barrels of oil per day per well, respectively, far surpassing the previous Gulf of Mexico single well record of 12,000 barrels of oil per day at Auger. This compares to 500-1,000 b/d from a good well on the shelf in the Gulf of Mexico. Although these fields do not compare in size (storage) to the Middle East, they generate Middle

Eastern rates of production. The surprising discovery in 1994 of how productive these reservoirs were in tests at Shell Oil's Auger platform entirely changed the company's cost structure for this deepwater play.

Regional plays in the Gulf of Mexico

Regionally, there are three subsalt-associated allochthon trends in the deepwater Gulf of Mexico (Figure 10.49b, 10.50a): i) Flex trend, ii) Minibasin, and iii) Fold belt (Cossey, 2004). The term subsalt is used by explorers to describe plays obscured by a salt canopy. The flex trend describes the shallowest region of the three (in terms of water depth) and it covers a geographic area encompassing the outermost shelf and uppermost slope. Geologically it constitutes the halokinetic zone in front of the Plio-Pleistocene Roho, and is an area where there is no wide-spread salt canopy. It can be further divided into a "toe thrust"

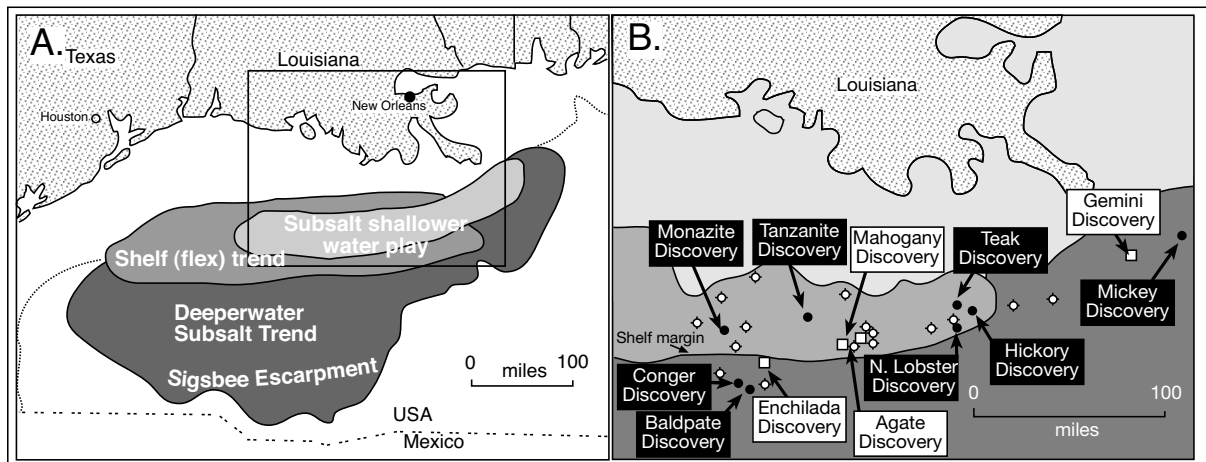

Figure 10.50. Allochthon-related discoveries in the Gulf of Mexico. A) Distribution of shelf and deep water salt plays in the Northern Gulf of Mexico. (in part after Cossey, 2004). B) Selected early discoveries, until the mid 1990s, in the updip slope and rise minibasin province in the eastern Gulf of Mexico (not in as deep water as most of today's targets).

belt and a “primary basin” belt (Figures 6.30; 10.51a; Shinol, 2000 as reported in Shirley, 2000). Large volumes of salt have been lost in this region via allochthon evacuation, dissolution and weld creation. In terms of salt allochthon evolution much of the Flex trend and the Primary Basin region has evolved well past the canopy stage and the area is now a relict thrust fold belt (Figure 10.51b). The minibasin play, as the name implies, encompasses sand deposition associated with the development salt depopods and minibasins (Figure 6.25). It is typically located in somewhat deeper water than the exploitation began in 1983 with the discovery of Bullwinkle. The fold belt trend is located beneath and downdip of the canopy belt and encompasses reservoirs developed by compressional folding at the downslope end of a developing allochthon belt. It constitutes the deepest water region of current areas of exploration activity in the Gulf of Mexico (Figures 6.34; 10.51).

Flex trend exploration began in the early 1970s with the discovery of Cognac Field located just beyond the present-day shelf edge where there is a “flex” in the sea floor profile (Cossey, 2004). Some of the larger flex discoveries were Lena, Zinc, Pompano and Green Canyon 18. Most discoveries in the Flex Trend are fields with small reserves, characterised by discontinuous sands with producing wells showing fairly low flow rates. Exploration wells in this trend generally targeted “bright spots” on 2-D seismic. Gemini, for example, showed up as a very strong event on the seismic. Texaco was so confident of its Gemini prospect that based on a very strong event on the seismic they stopped drilling and set casing just before entering the pay zones. In fact, this hydrocarbon-indicating anomaly could be seen on non-processed, mid-1980s vintage 2D seismic.

Exploration for minibasin plays typically targets the flanks of intraslope basins where reservoir sands pinch out and form combination structural/stratigraphic traps, or it targets zones of drape over turtle structures. Many minibasins plays are sealed and obscured by allochthonous salt, which can fuse into a salt canopy. Some of the larger mini-basin fields discovered to date are Auger, Mars, Diana, Genesis, Troika and Europa. Ram-Powell was discovered in 1985 and is a very large, stratigraphic trap developed in a more unrestricted mini-basin. Larger minibasins typically have turtle structures developed in their centres. The first mini-basin fields brought on-line (Bullwinkle in 1989, Auger in 1994) produced at much higher than expected rates, had better than expected aquifer support and needed fewer wells to develop them. Much of the early production from these minibasin fields ended up being facilities constrained.

Suballochthon exploration for minibasin traps in the deepwater offshore Gulf of Mexico was first successful south of New Orleans in the region known as the “Isolated Salt Tablets” province or Florida slope. It is located in the easternmost Mississippi Canyon area in waters 1,000 to 2,000 metres deep (Figure 10.51a; Shirley, 2000; Hall, 2002). Productive reservoirs are Pliocene to Miocene unconfined turbidites occurring some 3,000-4,500 metre seafloor. These are usually sealed beneath allochthonous salt and are considered combination structural/stratigraphic traps. Exxon made the first deepwater subsalt discovery of oil and gas in this region with its Mississippi Canyon 211 well. This prospect, nicknamed “Mickey” because of the resemblance of three allochthon sheets in plan view to the head and ears of “Mickey Mouse” has hydrocarbons

below salt canopy and lies beneath 1310 m (4,300 ft) of water (Figure 10.50b). Reserve estimates for “Mickey” range between 50 to 150 million barrels of oil equivalent, but the discovery was deemed subeconomic and has yet to be put on production. The “Mickey” discovery indicated the prospectivity of subsalt plays in this region and focused exploration efforts into sub-allochthons, both on the shelf and in deeper water.

As drilling technology and subsalt imaging improved throughout the later 80s and into the 90s, subsalt exploration moved into progressively deeper water. Drilling now could reliably reach larger potential suballochthon minibasin structures, including turtles located further out in the Gulf (Richardson et al., 2004). Minibasin fields currently contain the largest economic resource base in the deepwater Gulf. The subsalt “Mahogany” Field, operated by Phillips Petroleum, is a minibasin play that was discovered in 1993 by the Ship Shoal 349 well in the Mission Canyon region. This field, which began production in December 1996, was the first commercial subsalt oil development in the Gulf of Mexico. In 1994, Shell Offshore, Pennzoil, and Amerada Hess announced another significant minibasin discovery in Garden Banks 128 well, nicknamed “Enchilada” (as in the idiomatic “it’s the big enchilada”). Enchilada has combined reserves estimated at 400 bcf of gas and 25 million bbl of oil/condensate (DeLuca, 1999), and was brought online in July of 1998. In 1996 nine subsalt wells were drilled and three were discoveries. The largest discovery (Anadarko and Chevron) was “Gemini” in Mississippi Canyon Block 292 with estimated reserves of 250-300 Bcf of gas and 3-4 million bbl of condensate (DeLuca, 1999). It currently produces from a single reservoir using a subsea system.

Gemini was the first deepwater subsalt production in the Gulf of Mexico - and showed explorers the potential for prolific production from the deeper water portion of the subsalt play.

In June 1999 one of the Gemini wells tested around 76 million cubic feet of gas and 1,370 barrels of condensate a day. Agate Field in Ship Shoal 361 was discovered in 1996 by Anadarko and Phillips and is now producing through a tieback into the neighbouring Mahogany platform. Anadarko, along with partner BHP, also announced a second subsalt discovery in 1996 in Vermilion 375, called Monazite. The discovery well revealed multiple pay zones, but because of problems during testing, the hole was plugged and abandoned. Amerada Hess and Oryx made a major discovery in late 1997 in their Penn State prospect in Garden Banks 216, the field came on stream in 1999 through a tieback to the Baldpate production facilities.

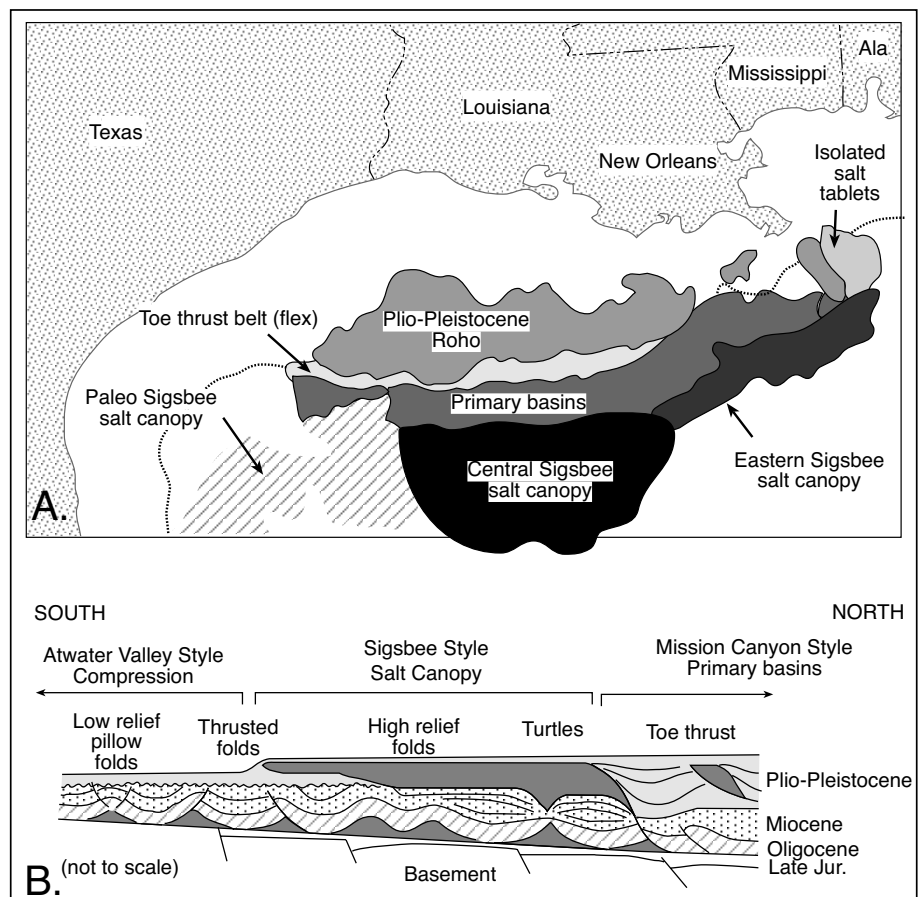

Figure 10.51. Distribution of the various salt fairways in the Northern Gulf of Mexico. Also shows an idealised south to north cross section illustrating typical subsalt and suprasalt structures where the position of the salt defines major play types. Note that the low relief pillow folds in the south are autochthonous and probably define the original southern extent of thick Jurassic salt in the basin.

In July of 1998, Anadarko announced a subsalt discovery at the Tanzanite prospect in 95 m (314 ft) of water in Eugene Island 346 with reserves estimated at 140 million BOE. Later in 1998, Anadarko also announced the discovery of their Hickory prospect in Grand Isle 116 in 97 m (320 ft) of water. The discovery well, drilled to a total depth of 6580 m (21,600 ft), penetrated approximately 2400 m (8,000 feet) of salt before passing into the reservoir, via one of the thickest sections of salt ever drilled in the Gulf of Mexico. Reserves are estimated at 40 million BOE (DeLuca, 1999).

Thunder Horse Field (formerly known as Crazy Horse Field) in Mississippi Canyon Blocks 776, 777 and 778 is a substantial minibasin discovery with a turtle style of reservoir development. It is located in the Boarshead Basin, 200 km south-east of New Orleans and is the largest deep water discovery made to date in the Gulf of Mexico (Enger and Logan, 2001). It has estimated reserves of greater than a billion barrels of oil equivalent in early and middle Miocene sands at about 7,000 - 8500 m (23,000-28,000 feet) depth. BP-Amoco has said reservoir characteristics are excellent and compared Thunder Horse favourably to Magnus Field in the UK North Sea, where wells flowed at rates exceeding 20,000 bbl/day at peak. Thunder Horse shows that deepwater subsalt sands can be highly productive, even at depths well below 7500 m. It is one-and-one-half to twice the size of the next biggest structures in the region (Enger and Logan, 2001) and is one of three large discoveries on turtle structures. The other two are Pluto (aka BS and T; Mississippi Canyon 718) and Mensa (Mississippi Canyon 731). Both the Thunder Horse and Pluto discoveries are partially covered by shallow salt canopies.

Methods of most effectively exploring for minibasin plays are still emerging, especially if a turtle is obscured by a salt canopy (Shirley, 2000). Deeper turtle structures are difficult to image on 3D seismic data, especially beneath thick salt canopies and there are no diagnostic hydrocarbon-indicating amplitudes (bright spots) related to this play, so structures rather than accumulations are targeted. Geologically, turtle structures can be complicated as these structures were synclines at the time they were receiving sediments (Figure 6.17). Then the structure inverted due to ongoing salt withdrawal. That in itself implies there is a complex relationship between timing of trap formation, hydrocarbon charge and migration. The key uncertainty with turtle structures in this style of play is whether a trap was in place during the hydrocarbon migration phase. Also, there can be crestal faulting on these structures that can degrade the top seal of the traps, but the size of the potential discoveries makes the risk worthwhile.

Petroleum systems in the fold belt feature underlying high relief salt cored folds (mostly to the west) and thrust folds to the east in what Hall (2002) calls the Atwater Valley style structural province. Lower and middle Miocene turbidite reservoirs extend across the crests of folds, which typically formed during foot of slope compression in the mid-Miocene to Early Pliocene (Figure 6.34). Three major fold belt trends are currently considered prospective: the Mississippi Fan, the Perdido and the Port Isabel fold belt, all are located in deeper water downdip of the salt canopy/minibasin trend. The Fold Belt play began to be exploited in 1995 with BP-Amoco's discovery of Neptune in Atwater Valley 575 in the Mississippi Fan fold belt. Soon thereafter BP discovered Atlantis and Mad Dog (Hall, 2002). K2/Timon was found just north of the earlier discoveries, and more recently Texaco discovered the Champlain Field in the middle of Atwater Valley, extending the play further east.

To date, there have been five separate discoveries in this Mississippi Fan belt, although four have been centred in the fold belt of the western part in a small area of the southeast Green Canyon area. All are near the edge of the Sigsbee Escarpment and within 50 km of each other in water depths ranging from 1,200 to 3000 metres (4,000 to 6,500 ft). Target reservoirs are found in the 5,000 to 8,000 m (17,000 to 26,000 ft) depth range, and the structures can be prolific with greater than 300 million barrels of oil equivalent. Mad Dog is currently the most prolific of the fold belt discoveries, with reserve estimates ranging from 400 to 800 million barrels of oil equivalent from about 100 m of net hydrocarbon pay in a large, high relief fold under the edge of the Sigsbee Escarpment. Atlantis, however, is now vying with Mad Dog in terms of size. The first appraisal well at Atlantis added significant additional sand section, bringing the total net pay to 150 m (500 ft).

Current seismic quality in this part of the fold-belt province is good to fair, but companies are exploring very high relief features, which are difficult to miss. For example, Mad Dog is a 3,000 m relief feature. Even though imaging is not the best quality, it's hard to overlook a 3,000-metre-tall structure in the subsurface. Plays in the area known as the Eastern Sigsbee Escarpment do not involve the search for the subtle trap! The province's western portion is relatively well drilled now, so the play's future lies in taking the charge risk and moving east to determine how far the play will extend (Shirley, 2000). In contrast, the Perdido Fold Belt Play is under explored. The play is similar to the Mississippi Fan Fold Belt Play in that it consists of very large compressional fold belt structures. Like the Mississippi Fan Fold Belt Play, the compressional folds

extend a considerable distance landward beneath the Sigsbee Salt Canopy. However, the plays differ in the age of the structures and the targeted reservoir.

So, exploration drilling in the deepwater Gulf of Mexico in 2002 and 2003 has found over 2 billion BOE (Richardson et al., 2004). Today (late 2004) the traditional deepwater mini-basin plays are still providing many successful exploration opportunities (e.g. the Thunder Horse and North Thunder Horse discoveries in southern Mississippi Canyon), but recent discoveries in new fold belt deepwater plays continue to expand the exploration potential of the deepwater Gulf of Mexico. Some 99% of total production in the deepwater Gulf of Mexico is from Neogene reservoirs (Pleistocene, Pliocene, and Miocene; Figure 10.49a); however, several recently announced deepwater discoveries encountered large potential reservoirs in sands of Paleogene age (Oligocene, Eocene, and Paleocene). This older portion of the geologic section has been very lightly tested and the discovery of reservoirs of this geologic age may open wide areas of the fold belt in the Gulf of Mexico to further drilling.

How suprasalt becomes subsalt

Salt-withdrawal minibasins are characterized by Karlo and Shoup (2000) as either; (1) shelf-loaded, or (2) slope-loaded (Figure 10.52). Salt withdrawal minibasins on the shelf, which mostly host fluvio-deltaic reservoirs of the northern Gulf of Mexico, are rooted in autochthonous salt at depths of 12,000-14,000 m (40-45,000 ft). They typically show continuous subsidence in a seaward-migrating belt of sediment loading from the Cretaceous onward, with some basins beginning to fill with sediment even earlier in the Jurassic. The basins are aligned in sub parallel linear trends with salt domes intermittently dispersed along the bounding faults. Updip they tend to be simple minibasins while their downdip extent is defined by stepped counter-regional fault basins, often with a secondary turtle structure on the 'step,' along with some local Roho development (Figure 6.30; Karlo

and Shoup, 2000). Associated salt masses grade from simple diapirs updip into larger volume, overhung salt domes and successively into salt wings and allochthons downdip. Block 330 is one such system (Figure 6.58).

Plio-Pleistocene Roho systems are shelf-loaded features (Figures 10.53) with updip zones of extension marked by a series of nested highly listric faults, which display a characteristic horseshoe geometry in map view (Figures 6.30, 10.53b; Karlo and Shoup, 2000). Deltaic sands and shales tend to be stacked in lower parts of the seafloor in a feedback between depositional loading of the rotated wedges associated with these growth faults. The central portion of the same depositional system is typically manifest as a complicated zone of remnant salt, perched diapirs, salt-floored faults, and strike-slip faults. Basinward of this region is the compressional toe, which consists of a melange of salt and deformed sediment. All faults sole into the evacuated remnant of the original salt tablet, which typically overlies a salt-withdrawal minibasin. In map view, the overall geometry of the salt-based detachment system is constrained by the geometry of the salt tablet upon which it is forming.

Slope-loaded minibasins (turbidite reservoirs) are similar to shelf minibasins in terms of sand distributions, but involve much more salt than the shelf systems (Figure 10.52). The slope withdrawal basins are flanked by salt walls with little fault rim development. Formation began with ponding of turbidites trig-

Figure 10.52. Model of reservoir styles showing distribution of subsalt traps in both shelf and deepwater minibasin (primary basin) settings (after Karlo and Shoup, 2000).

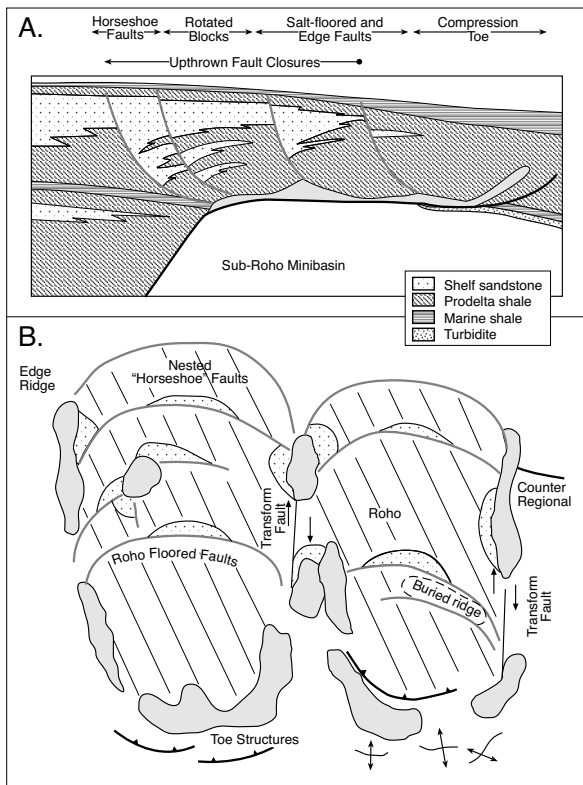

Figure 10.53. Model of reservoir styles showing distribution of Roho (suprasalt) traps in both shelf and deepwater minibasin (primary basin) settings (after Karlo and Shoup, 2000).

gering loading and the creation of diapirs. Because of the great thicknesses of autochthonous salt involved, turbidite ponding is more or less continuous, so long as there is salt withdrawing from the basin. Should the depocentre shift during the diapiric phase, a salt wing forms during the hiatus and overflows the basin resulting in the formation of a salt canopy. Once the allochthonous salt has been evacuated, subsequent turbidite deposition bypasses the basin.

Intrasalt halokinetic plays

Not as yet in full production, but still worthy of consideration, is the intrasalt halokinetic play exemplified by cherty overpressured stringer reservoirs encased in the Precambrian Ara Salt Formation of the Ara Group in Oman. These intrasalt targets of Athel Formation silicilyte represent one of the more complex deep oil exploration plays in onshore Oman and constitute a significant part of Petroleum Development Oman's undrilled prospect portfolio (Reinhardt, 1999; Peters et al., 2003). During the late 1970s to early 80s Petroleum Development Oman (PDO) drilled several significant oil and

gas shows in intrasalt objectives within the Neoproterozoic Ara Salt of the South Oman Salt Basin (Figure 10.54). These potential reservoirs were in porous (15-25%), overpressured siliceous microlaminated sediments that were stratigraphically trapped and encased in halokinetic salt at depths of 3 to 4 km. Based on these intersections, the size of potential intrasalt pools was thought to be large, with individual slabs or slivers of possibly oil-saturated silicilyte seen in seismic to be up to 2x6 km across and more than 300 metres thick.

In 1989 and 1995, respectively, Al Noor and Al Shomou were drilled as two sliver prospects in the Athel Formation (silicilyte). The first two wells in the Al Noor Field encountered over 300 m of pay within low permeability fractured intervals that well tests showed had levels of 8 to 9 md per metre. Reserves of $15.0 \times 10^6 \text{ m}^3$ oil were calculated from these early intersections with an expectation of oil-in-place in the fields of up to 2 billion barrels (Wong et al., 2000). Oil recovered from the wells was attractive, although it was largely hosted in an unusual reservoir of microlaminated organic-rich chert (silicilyte is a general term for a fine-grained silica rock). The oil is light (48° API) with a viscosity of 0.3 to 0.36 mPas^{-1} and a bubble point of 277 bar. The initial solution gas-oil-ratio was 400 to $550 \text{ m}^3/\text{m}^3$, with H_2S levels of 1.5 mol% and CO_2 levels of 3 mol%. It was recovered from wells with early flow rates of up to 8,800 bbls/day. Average well flow rates varied between 40 to $110 \text{ m}^3/\text{day}$ prior to reservoir stimulation, post-stimulation figures have not been released. The silicilyte slivers define a play type worth pursuing, but a number of dry holes drilled after the initial successful wells defined inherent complexities with respect to reservoir quality prediction, hydrocarbon charge, production behaviour, and seismic imaging. Inherently high variability in the silicilyte permeability both vertically and laterally means successful future exploitation must involve targeted directional drilling and reservoir stimulation.

Varying thicknesses created by deep salt pillows atop potential reservoir slivers, and the occurrence of reservoir slivers near the base of the thick halokinetic salt unit, has hampered reliable seismic positioning of these deep (>3000 m) intrasalt reservoir objectives. Likewise, pressure transient tests in the intersected reservoir indicate an effective reservoir permeability that is one-tenth of that measured using cleaned core plugs (O'Dell, 1998). The difference in well and plug determinations is likely caused by a combination of pressure-sealed fractures and the pervasive plugging effect of bitumen in the reservoir (bitumens are removed in standard plug preparation) Uncertainty in these and many other aspects of silicilyte understanding meant that until very recently the Athel Silicilyte was not pursued as a high

value target within the PDO exploration portfolio. Improvements in seismic processing, targeted hydrofracturing, and geosteering technology, means it is possible to now pursue salt-encased permeable slivers as difficult but viable exploration targets.

Recently, wells in the two known silicilyte fields were the successful subject of what was perhaps one of the largest fracture jobs in the region to date. PDO also instigated a number of detailed sedimentological and engineering studies to better understand what characterises reservoir versus non-reservoir associations in the silicilyte slivers. This work is also of broader geological interest as the Ara Group is one of the few sequences in the world where ongoing deposition straddles the Precambrian-Cambrian boundary (Al-Husseini et al., 2003). This broader more academic work established a regional geological framework for silicilytes, carbonates and platform sulphate evaporites of the Ara Group and better defined the stratigraphy of the South Oman Salt Basin. Silicilyte slivers of the Athel Formation currently occupy a more central subsalt basinal position encased in basin-centre halokinetic halite and so are not easily correlated to the carbonates of the platform margin.

The Neoproterozoic/Early Palaeozoic Ara-Group is the terminal subdivision of the Huqf-Supergroup of Oman. Deposition of the Huqf spanned several tens of millions of years during the Vendian Neoproterozoic and early Cambrian. The Ara Group in the South Oman Salt Basin is made up of five to six 3rd-order carbonate-evaporite cycles (Figure 10.55; Schröder et al., 2000a, b, 2003, 2005; Gorin et al., 1982). Wherever the salt seal is breached, the Neoproterozoic organic-rich evaporitic sediments of the Huqf Supergroup have sourced most of the oil and gas stored in halokinetically structured suprasalt Phanerozoic reservoir sands and there is a concentration of large fields along the dissolution edge of the salt (Figure 10.5b; Terken et al., 2001). Oil generation from this ancient source rock began in the middle of the Cretaceous.

Depositional cycles in the Ara Group tend to be lithologically symmetric, with thick dolomitised carbonate platforms sandwiched between anhydrite, halite, and some thin intervals of potash salts (Figure 10.55). The sedimentology constitutes what is a typical marine-fed continental sag succession fill. In each cycle the carbonate is interpreted as representing the initial flooding of the basin platform, with the subsequent progradation of a carbonate ramp system prior to a basinwide episode of evaporite fill. Today all the sulphate is platform anhydrite, but it retains pseudomorphs after selenitic gypsum, showing it was originally deposited as a gypsum saltern (Schröder et al.,

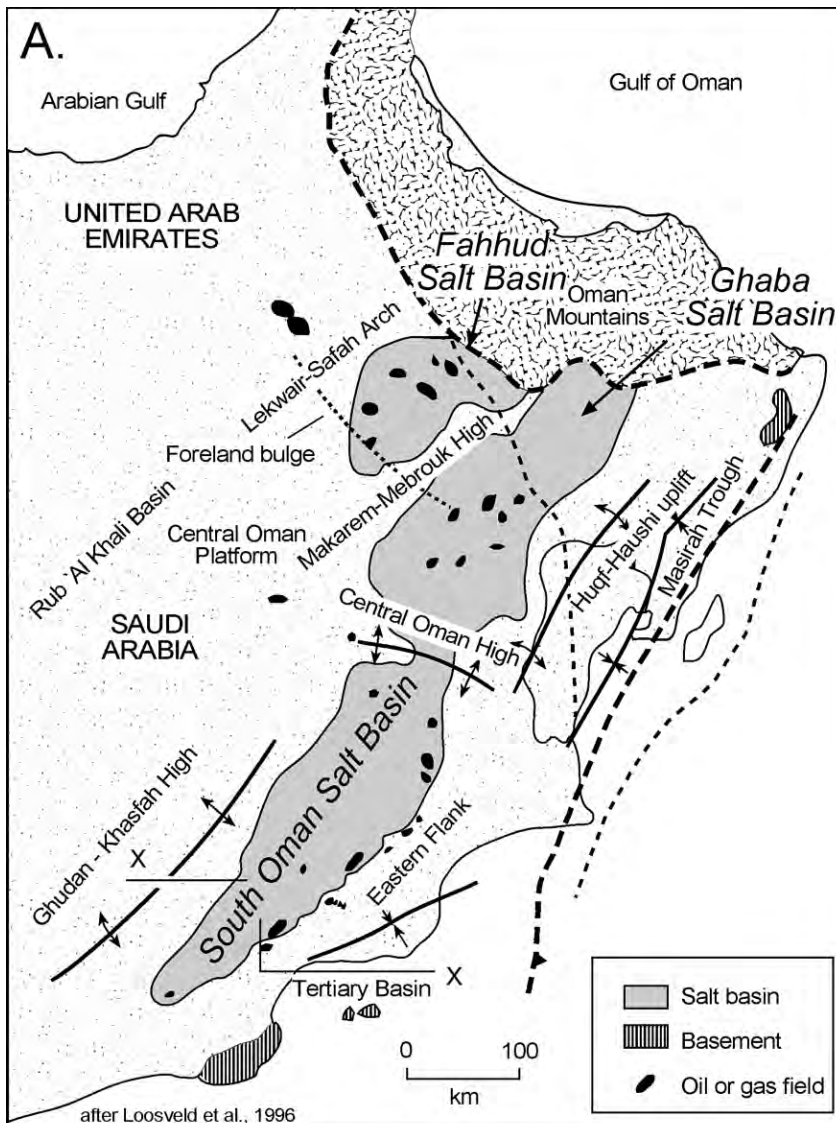

2003). Well-preserved sedimentary structures (e.g. palmate gypsum morphologies and desiccation cracks) suggest a shallow (<5 m deep) subaqueous environment for the various carbonate-sulphate platform cycles. Sabkha deposits represent only a minor fraction of the total platform evaporite volume. Following times of basinwide saltern sulphate accumulation, brine depths shallowed further and thick beds of basin centre halite precipitated, along with thin beds containing potash salts. Evaporite geochemistry indicates a marine source with some minor contributions from continental and/or hydrothermal waters (Schröder et al., 2003).

Much of the halite in the Ara Group was subsequently recrystallised during halokinesis. Most of the deformation evident in the Ara Group is taken up in intervals of flowing salt rather than by internal deformation and folding of the platform carbonates and sulphates. Halokinetic salt also encases the silicilyte slivers or blocks in the more central portions of the South Oman Salt Basin and is why it is difficult to place the various slivers into a depositional reconstruction of the basin. Are these laminated organic-rich cherty slivers still near their original somewhat deeper water depositional position in the basin palaeogeography, or have they slide tens of kilometres or more into the basin via salt-lubricated gravity gliding and raft tectonics? The latter scenario would create a more complex jumble of slithers with porosity distributions largely unrelated to current block orientations.

Internally, the various carbonate and sulphate facies of the undeformed platform blocks are simple to interpret. Energy related facies developed in different water depths in an into-the-basin deepening ramp system, within what was an intracratonic rift or sag. Salt layers in the Ara Group are roughly equivalent to the Hormuz Formation to the north (Schröder 2003; Sharland et al., 2001). Finely laminated organic-rich dolomites and some thrombolite buildups of the carbonate platform facies occupied an outer to middle ramp setting, typified by lower energies and outcrop out the margins of the basin. Further out in the current basin they are overlain by shallow water platform mudstones, packstones, and evaporites (Figure 10.55).

Several factors are listed by Schröder et al. (2000b, 2003) as explaining the porosity dichotomy between Neoproterozoic platform carbonates and basin centre silicilytes:

- Downward circulation of saline brines caused mimetic dolomitisation and deterioration of reservoir characteristics in underlying platform carbonates. Any lithofacies close to overlying evaporites also suffered from evaporite cementa-

tion - i.e. shallow water carbonates at the top of stringers, as well as thin stringers.

- Early maturation of organic matter flushed the pore networks in the deeper water siliceous organic-rich laminites (silicilytes) with hydrocarbons that then prevented subsequent cementation by later carbonate and evaporite cements.
- Early reflux brines tended to flush the larger connected pores of the shallower and higher energy grainier carbonate units (e.g. thrombolite shoals) and so they were more easily filled with evaporite cements than the smaller hydrocarbon-rich pore networks of the basin centre silicilyte laminites.

Porosity evolution in the laminites contrasts with that of thrombolite buildups and shallow water packstones where high porosities have been almost completely plugged by dolomite and evaporite cements, so typical of a depositional association with a basinwide evaporite unit. Thus production in Al Noor and Al Shomou fields comes from salt-encased organic rich blocks of chert of the Athel Silicilyte, not from platform dolomite sulphate successions, which are typically too tight and too evaporite-cemented to produce.

The Athel Silicilyte is part of the Athel Formation in the Vendian to

Figure 10.54. Salt Basins of Oman. A) Map view of three main salt basins. Palaeozoic strata are the main oil and gas producers, not Neoproterozoic platform carbonates or Athel Fm. silicilyte slivers, which occur more toward the centre of the South Oman Salt Basin. B) Cross section through the South Oman Salt Basin, schematically showing position of laminites and slivers in the Ara Salt (after Loosveld et al., 1996 and Schröder et al., 2000a, b).

Early Cambrian Huqf Supergroup. It is a unique source and reservoir rock in the South Oman Salt Basin and is not equivalent in depositional style to the platform setting of the various carbonate-sulphate stringers and blocks (Peters et al., 2003). According to Sharland et al., (2001) silicilyte forms km-scale stratiform blocks encased in a thick halokinetic halite, which also separates the A2 and A3 carbonate stringers. Within slivers the Athel Fm. silicilyte is typically made up of metre-scale interlayers of finely microlaminated, porous silicilyte alternating with non-porous silica-cemented silicilyte. The latter act as vertical baffles to flow within the reservoir. In the absence of outcrop analogues, borehole-imaging logs are extensively used to delineate and to correlate reservoir units. FMI shows that more than 70% of the lithofacies in the Athel Fm. are constituted of beds thinner than 1 metre. Cemented fractures (some with fibrous halite fills) are locally common, typically reducing the horizontal connectivity. The rock matrix consists up to 80% of microcrystalline quartz with high amounts of intercrystalline microporosity (up to 30%). The very small modal crystal size of 2-3 micron and widespread bitumens in the silicilyte pore throats result in microdarcy levels of reservoir permeability (Amthor et al., 1998; Peters et al., 2003). The present-day thicker (distal) silicilyte sections in the basin tend to have a higher average porosity than thinner (proximal) sections toward the platform.

The silicilyte play is an unusual basinal evaporite association, characterized by light and sour oil, hard overpressures and a high-porosity, low-permeability silica matrix (0.2-0.3 md) constituting a fine-grained microlaminated chert that is consistently rich in organic matter (Wong et al., 2000; Amthor et al., 1998; Amthor and Frewin, 1999). Encasing halite has prevented hydrocarbon expulsion from the

silicilyte, explaining inherently high formation pressures ≈ 19.8 kPa/m and high present-day oil saturations $\approx 65-90\%$. The absence of oil expulsion is evident from Rock Eval data, which are characterized by high production indices. A good correlation between S_1 and the generative potential S_1+S_2 suggests that hydrocarbons were indeed generated in situ and did not result from migration of hydrocarbons generated at deeper horizons. This also fits with the typical tight character of source rocks in style 1a basinwide evaporite settings (Chapter 9). As a source rock the Athel Formation silicilyte is also unique (Terken et al., 2001). Finely disseminated kerogen occupies up to 10% of the rock volume, with a third of the organic matter concentrated in stylolites. Source rock extracts reflect the Infracambrian age of the formation, namely; light $\delta^{13}C_{PDB}$ of -37 to -35‰, a strong predominance of C29 over C28 steranes, and high 24-isopropyl/n-propyl cholestane ratios. The kinetic behavior of the Athel is similar to that of the Miocene Monterey Forma-

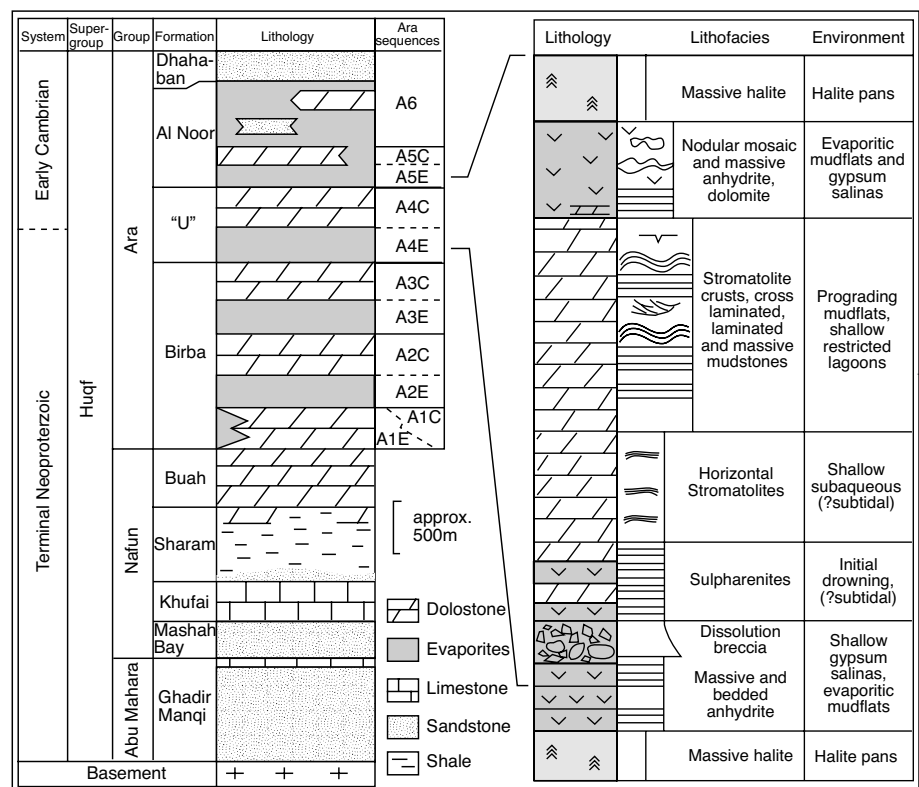

Figure 10.55. Stratigraphy of the Neoproterozoic-Early Cambrian Huqf Super group and a typical platform cycle (A4) in the Neoproterozoic Ara Formation of the South Oman Salt Basin (after Schröder et al., 2000a, b; 2003, 2005). Further out in the now chaotic central parts of the basin, some consider the Athel Silicilyte was originally deposited as a time-equivalent to the A4 carbonate, others argue it once lay immediately atop the unconformity capping the A3 carbonate (more likely). It can even be argued that in the original basin centre stratigraphy, prior to halokinesis, there was more than one level of mesohaline silicilyte deposition. This quandary could perhaps be resolved by more detailed determinations of basinwide versus platform evaporite signatures using wirelines and cores from across the basin).

tion, which, like the Athel, generates oil at low temperatures. Thin microfractures control production and much of the oil in fractures in this silicilyte reservoir is probably self-sourced from the adjacent matrix.

Based on the hydrology of Phanerozoic evaporite basin drawdown, I would argue that the time of Athel Silicilyte deposition probably corresponded to a hiatus in the accumulation of the platform carbonates. The palaeogeographic setting at the time of silicilyte deposition was that of a relatively-shallow restricted marine-fed sag basin. Silicilyte probably accumulated in the somewhat deeper density stratified (meromictic) portions of this rift or intracratonic sag basin immediately prior to the onset of a basinwide episode halite deposition in the central parts of the basin. At that time the basin was bound by exposed and hydrographically isolated carbonate-sulphate platforms along the basin edge. Waters in the basin centre at that time were probably mesohaline and density stratified, with the lower deeper parts of the brine column periodically if not perennially anaerobic (see Chapter 9 - basinwide mesohaline source rocks - style 1a). The silica matrix is considered to have been biochemically (bacterially) precipitated as primary microcrystalline quartz precipitates at ambient surface temperatures (Amthor and Frewin, 1999).

Inflow was via a hydrographically restricted entrance that with cutoff evolved into a marine seepage feed to a halite drawdown basin. Silica levels in Neoproterozoic seawater that were much higher than the biologically-limited silica chemistries of Phanerozoic seawater. Bottom stratification resulted in the preservation of substantial amounts of organic matter in the silicilyte and the formation of hydrocarbon source rocks of exceptional quality and thickness (SPI = 28-65 ton HC/m²; Amthor et al., *op. cit.*). The highest rates of silica accumulation are likely to have been in the distal parts of what were silicilyte half-graben depressions located well away from the source of clastic and carbonate input, much like the diatomites that typify Quaternary chert phases in the African and Turkish subaqueous lacustrine settings (Chapter 4).

Thick organic-rich basinal laminites are not uncommon in many marine-fed Proterozoic basins without an evaporite fill (e.g. oil and gas shales of the Velkerri Fm. of Central Australia; Warren et al., 1998). What makes the slivers in the Ara salt so economically interesting is that their organic maturation took place encased in halite. The liquid fraction could not leak away, so the matrix permeability did not degrade to levels where it was subeconomic, unlike the Mesoproterozoic oil shales of northern Australia and many other Proterozoic oil shales.

Subsalt reservoirs in compressional provinces

There are more than a dozen world-scale fold and thrust belts that have at some time slipped atop a layer of evaporites (Figure 6.33; Davis and Engelder, 1987). Such movement in a zone of horizontal compression often results in “thin-skinned” or gravity-driven tectonics and the deposition of sediments atop salt-cored growth folds. Deformation in the overlying rocks produces seafloor or landscape topography and syndepositional inhomogeneity in overburden porosity and thickness, as well as stress instability in the salt bed. Both processes can initiate diapirism and allochthon breakout in a compressional terrain. Even when there is no development of piercement from salt-cored anticlines, folds show considerable anticlinal thickening in the salt layer, and associated synclinal thinning, as in the Jura and the SE Zagros. Any diapirism typically follows fault planes or tensional shears in the overburden (Figure 6.46b, c).

Overburden deformation styles tend to have geometries that are controlled by the regional state of stress, and that geometry is frequently inherited by the salt structures. The close correspondence between the elongate salt structures of the North Sea and northern Germany to regional tectonic fabric clearly demonstrate this relationship (Figure 6.42). Perhaps the best-studied hydrocarbon province controlled by salt-influenced folding and thrusting is in the Zagros Mountain region of the Arabian Gulf. In terms of hydrocarbon volumes it is certainly the most prolific fold belt in the world and holds as much as a third of the total reserves of the Middle East. Beydoun et al. (1992) estimated that there is more than 200 billion barrels of recoverable hydrocarbon in the Zagros foreland basin.

Zagros Fold belt, Iran

Oil accumulations in anticlines of the Zagros Basin are the result of a Late Tertiary foreland basin foldbelt growing at the outer edge of the vast hydrocarbon-rich Palaeozoic-Mesozoic passive margin shelf of the Arabian plate (Beydoun et al., 1992; Versfeld, 2001). This foreland succession shares many of the same source rocks and salt seals as the relatively undeformed petroleum system of the Arabian Plate to the south. The compressionally driven folding and thrusting began in the Eocene and continues today, still driven by the collision of the Arabian and Iranian plates. Miocene uplift of the growing alpine belt and subsidence of the adjacent foreland created a hydrographically isolated subsealevel depression in an arid climate (Figure 5.27). The Fars/Gachsaran basinwide evaporite precipitated and today seals many of the giant and supergiant fields in the region.

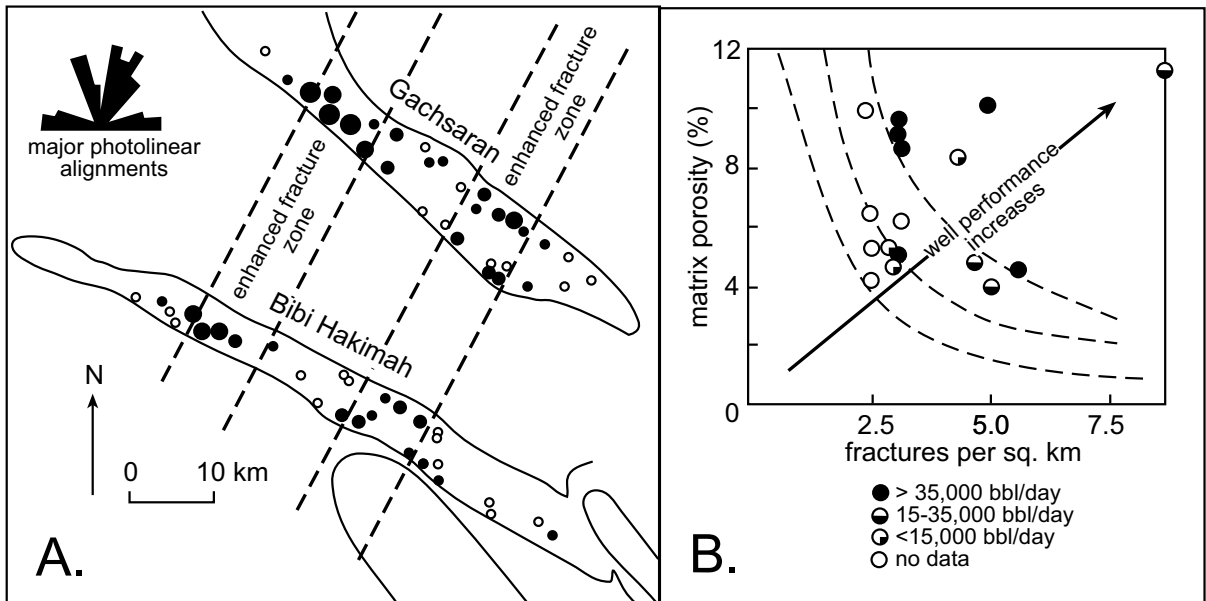

Figure 10.57. Gachsaran and Bibi Hakimeh fields, Iran (after McQuillan, 1985). A) Formline map; areas of solid circles are proportional to maximum allowed production rates. Open circles are non-commercial or nonproducing wells. High production wells lie in zones of enhanced fracturing induced by deformation controlled by basement features. B) Well production rates in Bibi Hakimeh Field as a function of matrix porosity and fracture density.

situated below Asmari production levels in the same wells in the same fold structures (multiple or stacked columns).

In its main producing area the Asmari Fm. is predominantly a shallow-water non-reefal micritic platform limestone containing minor dolomite. Matrix porosity and permeability are low (typical porosities of up to 15% and matrix permeabilities of up to a few millidarcies). The unit owes its excellent reservoir qualities to extensive brittle fracturing induced by Neogene compression (Figure 10.57). Wells intersecting fractured intervals of Asmari Limestone have tested at rates of up to 19,080 m³/day (120,000 bbl/day) and have sustained production rates of 12,700 m³/day (80,000 bbl/day), with estimated averages for wells producing from the fractured Asmari in various fields ranging from 3,180 to 3,975 m³/day (20,000 to 25,000 bbl/day). Where wells fail to penetrate fracture intervals in the Asmari in the same fields they are essentially nonproductive (Figure 10.57; Beydoun et al., 1992).

Second, the continent-to-continent approach prior to final collision and suturing created a subsealevel soft suture belt that in the Miocene hydrographically isolated the basin from the ocean and so deposited the Lower Fars or Gachsaran Formation as a marine-fed basinwide evaporite seal to the growing folds (Figure 5.27; Kashfi, 1983, 1985). The presence of this impermeable unit, with its anhydrite base and halite top, is

critical in sealing reservoirs in the Asmari Limestone and its equivalents and in maintaining seal integrity atop growing whaleback anticlines as underlying carbonates fractured and faulted. Erosion or nondeposition of the Lower Fars seal on growing folds to the northwest and southeast of the main producing Asmari folds in Iran and in parts of Iraq has destroyed the trapping potential of many otherwise suitable whaleback growth folds. And third, in the SE portion of the Zagros Belt, continent-to-continent collision acted as a huge bellows to the underlying Hormuz salt which by flowing up toward the surface further exaggerated the structural closure of many existing nearsurface folds and also reactivated older Jurassic structures further out in the Gulf.

Although the presence of an evaporitic seal overlying a reservoir is always good news for sealing hydrocarbons, a thick underlying salt unit deformed into salt structures that breakout onto the surface is not always so useful in terms of accumulating large quantities of hydrocarbons in large broadly draining structures. Along-strike changes in the tectonic style of the Zagros Mountains demonstrate this point. The NW part of the Zagros fold belt is the most prolific hydrocarbon area and is characterized by a thick and relatively deep section of fractured Asmari. It has been gently folded into whaleback anticlines and sealed beneath laterally continuous Gachsaran/Fars evaporites (Ala, 1982; McQuillan, 1985). There is no halokinetic surfacing of

Hormuz Salt in the Dezful area to break up the continuity of these broad anticlines. Oil fields in this part of the outer Zagros fold belt were relatively easy to define back in the 1920s by a combination of seeps and surface mapping and with development wells stepping out along anticlinal axes.

But salt cored folds in the region of the Zagros fold belt in southeast Iran are characterized by namakiers sourced in the underlying Hormuz Salt (Figure 6.45). Most of the fields in this region are relatively small and gas prone (Ala, 1982; Versfeld 2001). There the Asmari is thinner and often outcrops as erosionally-breached salt-cored anticlines. In addition the Fars Gachsaran is less evaporitic and more carbonate rich (Gill and Ala, 1972). The style of deformation in this area is uplift with salt-cored transtensional shear faults and greater vertical components to the fault breaches compared to areas to the west. This greater intensity and verticality perhaps relates to withdrawal of thick successions of Hormuz salt into adjacent salt diapirs and glaciers. During ongoing periods of vertical

uplift and diapir induced breaching many hydrocarbons either escaped through fractures in the exposed Asmari and its less evaporite-rich cap or underwent secondary migration, possibly becoming trapped on the western side of the Oman Mountains (Kashfi, 1983). Gravity-driven shear faults developed in association with salt intrusions and a poor development of an evaporite seal, probably facilitated the migration and escape of hydrocarbons.

The presence of a thicker Hormuz section in this part of the Arabian Gulf may well have prevented the transferral of the fracture system from the basement into the Asmari, the same fracture system that McQuillan (1985) uses in explaining the prolific production of the giant fields in the thrust belts further to the Northwest. Offshore from the Southern Zagros some large structural accumulations in the Tertiary strata may still remain to be discovered, but future onshore exploration will probably be for smaller stratigraphic or combination traps situated about and sealed by halokinetic structures.

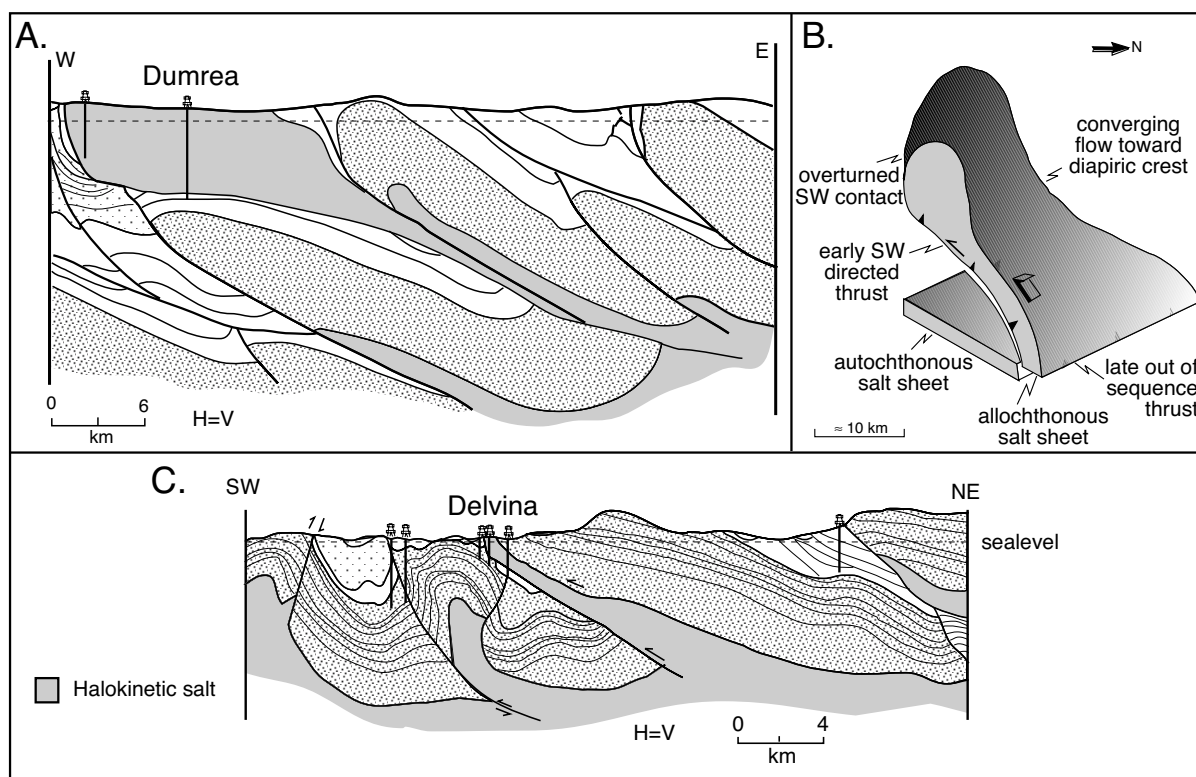

Figure 10.58. Giant fields in the Albanides, Ionian Basin. A) West-east-trending cross section through the Dumrea evaporite body showing the structure of Dumrea Field. B) Three-dimensional block diagram of the Dumrea diapir. C) Cross section of the Delvina gas condensate field trapped below a thrustured Triassic evaporite sheet (after Velaj et al., 1999; Velaj, 2001).

Figure 10.59. Cross section through the Moreni-Gura Ocniței oilfield, the largest field in the Carpathian foredeep. Productive sandstones are Pliocene in age. Structure is a sheared anticline where lower Miocene salt (grey) has lubricated the thrust and now forms a lateral seal to multiple reservoir sands. Also note the greater concentration of oil on the right side of the thrust, which is the downthrown side of the principal fault (after Paraschiv and Olteanu, 1970).

Alpine fold belt in Albania and Romania

Giant salt-sealed highly deformed salt structures characterise onshore oil fields in the compressional Alpine fold and thrust belt of the Ionian basin in Albania. The Triassic evaporites form a regional detachment layer (e.g. Figure 7.24c), but are also cut by thrust ramps that carry evaporites to the surface in their hanging walls (Figure 10.58; Velaj et al., 1999). Contraction of the Ionian zone reached a peak in the late Oligocene–Miocene Alpine Orogeny during an intense episode of overthrusting and major folding. The oil and gas fields in the region produce mainly from fractured Cretaceous–Eocene carbonates (e.g., Balshi-Hekal, Visoka, Gorisht-Koculi, Cakrani, Amonica, Finiq-Krane, and Delvina fields). Where a detachment is located at the top of the evaporite section, salts are dragged up in the footwall along thrusts. Faults develop both at the base and the top of the evaporite. Simple shear deformation along the thrusts causes greater than 80% thinning of the evaporite, so that thinned salt sheets of only 40–200 m thickness are now preserved in regions where the original evaporite thickness was in excess of 2000 m. Where thrust ramps cut through the evaporite and cause repetition of the complete evaporite layer, salt is remobilised into salt-filled compressional anticlines or it escapes at the surface to produce smeared-out allochthonous extrusions capable of sealing large volumes of hydrocarbons.

The most spectacular example of this is the Dumrea structure, where the mobilised evaporites have a complex shape that evolved from an overthrust allochthonous sheet, which today subcrops at the modern landsurface (Figure 10.58a). The Dumrea salt allochthon is up to 5.6 km thick, as proved by drilling, and has been displaced laterally by up to 25 km. It has the effective geometry of a giant sheath fold (Figure 10.58b). Untested traps still exist below the allochthonous evaporites and good quality non-biodegraded hydrocarbons are possible at depth, as was the case in the Delvina Field in southern Albania (Figure 10.58c). Shallower oil fields in the Albanides, not sealed by evaporites, typically contain very heavy oil due to ongoing bacterial degradation (e.g., Balshi-Hekali and Patos-Marinza fields).

The nearby Romanian section of the Carpathians Mountains of eastern Europe is another collisional thrust-fold Alpine belt where hydrocarbon accumulation is intimately related to the presence of smeared basinwide evaporites, in this case of Lower Miocene age (Figure 10.59; Paraschiv and Olteanu, 1970). Most of the reservoirs are Pliocene lacustrine sands, interbedded with fine-grained marls. The latter may well have been both source and seal. Suitable Pliocene sands with sufficient thicknesses and favourable reservoir facies only occur in the Ploiesti area at the convexity of the Carpathian Bend. Like the Zagros Mountains and the Albanides this hydrocarbon province is another halokinetic province where the original basinwide evaporites have been squeezed into a compressive layer during large scale thrust movement. Where thrust ramps toward the present surface the Miocene salt defines stocks, sills, dyke-like masses and other irregular shapes, whose original injection pathways were perhaps controlled by pre-existing diapirs, faults, folds and fault/fold intersections.

Rocky Mountain fold belt, USA

Deformed basinwide salt also plays a role in sealing the Nugget Sandstone reservoir in the Painter and East Painter fields of the Rocky Mountain thrust belt in the USA and the much more gently deformed sequence of Leadville Formation carbonates in the Lisbon Field, Utah. The Mississippian Leadville Limestone reservoir in Lisbon Field in the northern Paradox Basin, Utah, lies below a thick section of halokinetic Paradox salt and has produced some 50 mmbbl and 760 bcfg since its discovery in 1959 (Figure 10.60a). The trap is an elongate, asymmetrical,

northwest-trending salt-cored anticline with nearly 600 m of structural closure (Figure 10.60b; Miller 1985). The field is bound on its northeast flank by a major, basement-involved normal fault with nearly 760 m of displacement. A number of smaller northeast-trending normal faults dissect the reservoir into segments with fractured sweetspots located close to these secondary faults (Miller 1985). The Leadville Limestone was deposited as an open-marine, carbonate-shelf system with local crinoid banks, mud mounds and peloid/oolitic shoals. Two dolomite types characterise the Leadville reservoir, a tight stratiform micritic mimetic dolomite and a later coarser saddle dolomite. Solution-enlarged fractures and breccias are also common in the reservoir interval. The dichotomy in dolomite type and the association of the saddle dolomite with faults and fractures is similar to the evaporite-focused occurrences seen in Ghawar Field. But in the case of Lisbon Field the evaporite seal has gone one stage further. It has maintained its seal integrity even when the salt first underwent extension in the Palaeozoic and then compression during the Laramide orogeny. The oil in the structure is thought to be sourced from the overlying and now fractured Gothic Shale member in the Paradox Salt.

More highly deformed salt in the Painter and East Painter fields maintains its seal integrity atop the deformed and fractured reservoir intervals in the giant Painter and East Painter fields. The same salt also acts as the isolating décollement surface to the overlying overthrust plane (Figure 10.61a). The Painter reservoir structure consists of a rounded asymmetric fold in the Jurassic Nugget Sandstone reservoir (eolian) sealed by the Gyp-

sum Spring Member of the Twin Creek Limestone and the overlying salt. Significant thickening was accommodated in the underlying ductile Ankareh shales and the Thaynes limestones, which comprise the core of the structure (Figure 10.61b; Mitra, 2002). The forelimb of the structure is steep to overturned. A series of small-scale imbricates cut through this limb, but the displacement on these faults is relatively small and does not control the geometry and structural relief of the structure. The tightness of the structure also results in the formation of one or more out-of-syncline thrusts on the forelimb, which terminate upward within the salt unit and downward within the Twin Creek limestones. These out-of-syncline thrusts were folded during the later stages of deformation.

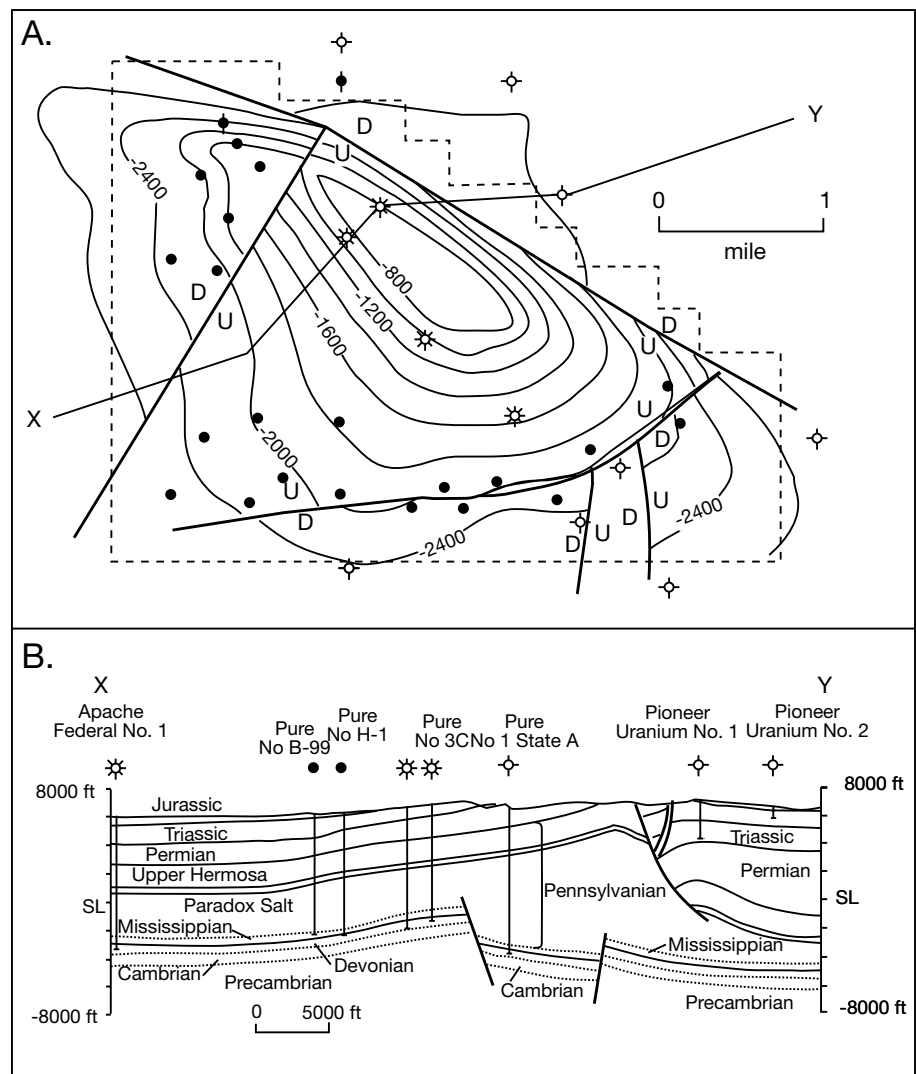

Figure 10.60. Lisbon Field, Utah. A) Depth to top of the Leadville Formation (Contours in feet subsealevel). B) Regional cross section X-Y across the field showing its position beneath the seal of halokinetic Paradox Salt (after Miller 1985).

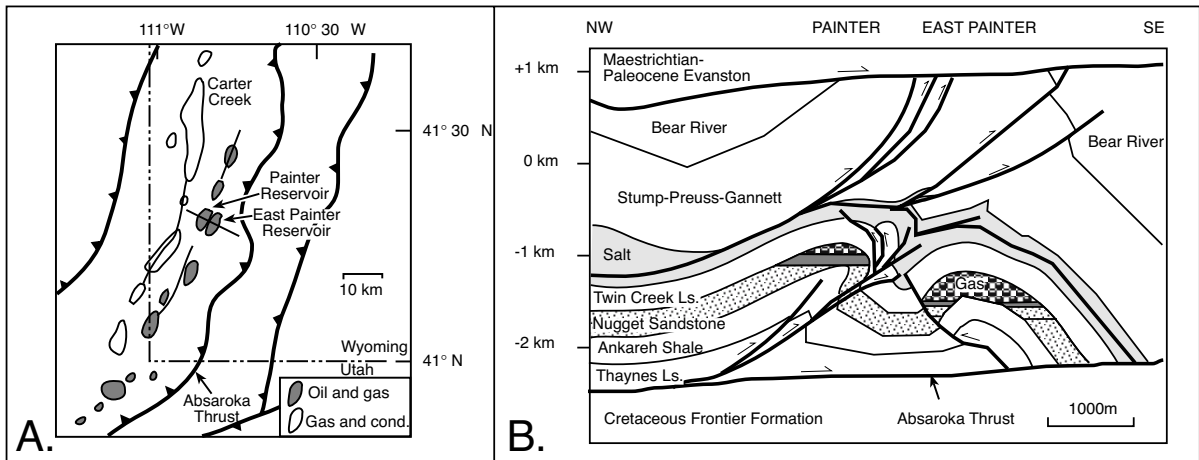

Figure 10.61. A) Geologic map of the Idaho-Wyoming-Utah fold and thrust belt showing some of the major oil- and gas-producing structures in the Absaroka thrust sheet. B) Interpretive cross section through the Painter reservoir and East Painter reservoir structures. (after Mitra, 2002).

The East Painter reservoir structure is a west-vergent detachment fold, formed above the hanging-wall cutoff of the Mesozoic units atop the Cretaceous detachment (Figure 10.61b). The steep frontlimb of this structure is also cut through by a west-vergent thrust. The convergence of the two opposite-vergent structures results in significant disharmonic folding within the Twin Creek limestones and the overlying salt. Interestingly, the hydrocarbons stored in the Nugget Formation sands were sourced in stratigraphically younger but now underlying Cretaceous mudstones (Lamb, 1980).

Evaporite Solution

Collapse-related traps can form early within the depositional setting, or much later during catbaric salt removal. A dissolving subsurface salt unit creates zones of differential collapse, which can induce economic levels of fracturing in the overburden. Where the effects of a shallow dissolution edge reach the landsurface it creates a depression, which focuses deposition of sand, mud or even reefal buildups around its rim (Figure 7.7a; subsidence trough). If it does not reach the surface it still affects brittle overburden as it creates fractures that increase permeability. Either style of dissolution creates anomalous fluid movements, diagenetic haloes, and reservoir modification that can form a structural anomaly at the seismic scale. Salt dissolution breccias that define the position of former salt units or intervals of former salt cements can contribute to the permeability of the fractured overburden interval.

An association between salt collapse, fracturing and oil production is proven in the oil and gas fields of southeast Saskatchewan, southeastern Montana and southwestern North Dakota (Smith and Pullen, 1967; Swenson 1967). Examples include reservoirs in Upper Devonian carbonates of the Hummingbird Field (Birdbear Formation), and the Dolphin, Fryburg, Kisbey, Flat Lake, Medoria-Scoria, Outlook, Star Valley, Tatagwa, Tule Creek, Walpole and West Hope fields. In their study of reservoir porosity in Devonian reef and bank carbonates of western Canada Beales and Oldershaw (1969) make the observation that, “much of the so-called primary porosity in reef reservoirs may be evaporite solution porosity.” Salt collapse depressions in the landscape also focused deposition of Cretaceous reservoir sands in the Mannville Formation in Westhazel Field. Subsurface salt bed leaching and collapse has also contributed to porosity distribution in various North Sea fields (Jenyon and Taylor, 1983; Lohmann, 1979) and to the fracture-focused creation of porosity in hydrothermal dolomites in the platform carbonates of the Rainbow/Zama Basin.

The various salt collapse reservoirs in Devonian carbonates of Canada are typified by fractures and solution-enlarged vuggy to karstic pore systems in what are otherwise dense carbonates. These reservoirs have porosities exceeding 20-30% and permeabilities in the range of darcies. The fields are small but their location makes them economic. Hummingbird Pool has produced more than 3 million barrels and Kisbey more than 1.6 million barrels. The Hummingbird oil pool was discovered in September 1966 on the northwest flank of the Williston Basin by drilling a semi-circular collapse-fill structure covering 2.6 km², thought to be a pinnacle reef prior to drilling (see

Figure 7.5 for location of Hummingbird Trough). Oil in the Hummingbird structure is produced from fractured 15 m-thick algal and bioclastic limestones of the Mississippian Charles Formation and 17m-thick vuggy dolomites of the Devonian Birdbear Limestone. The structure was created by local solution collapse followed by complete regional dissolution during multiple episodes of Prairie Evaporite solution loss during the Late Devonian and Early Mississippian.

Synthesis of the various styles of dissolution induced traps in the Alberta Basin of Canada and the Williston Basin in the USA shows the dissolution process is broad ranging, variable in terms of timing and tied to the dissolving edge of the Prairie Evaporite (Figure 7.5) Compactional drapes can create a rollover anticline that is closed over the dissolved edge of a residual salt body (Figure 10.62a; Anderson et al., 1988; Anderson and Knapp, 1993, Parker 1967). Local solution or collapse can form a sediment-filled sink that transforms to an inverted thick with the ongoing solution of the surrounding salt (Figure 10.62b; a “pseudo-reef” - Anderson and Hunt, 1964). Or subsidence can form a focused sand infill within a solution-induced depression on the land surface (Figures 7.7, 10.62c); or it can form as a remnant of a formerly widespread sand unit that was ultimately preserved only in sediment-filled depressions within the salt bed (Figure 10.62d). Seismic is very useful in defining the

lateral and vertical extent of many collapse anomalies and, if properly acquired and processed, can be used to define internal stratigraphy and reservoir development. Salt collapse structures can lead to focused oil entrapment in fractures in what otherwise may be a “tight” overburden lithology (Figure 7.8). A breach in a dissolving salt bed can also create structural and stratigraphic closure in the overburden. This is especially so if the collapse anomaly occurs “on-salt”, i.e. within a breach surrounded by, or adjacent to, the dissolving salt edge.

Ongoing fluid throughflow prior to oil emplacement in intervals above a dissolved salt bed or collapse chimney may have become pervasively cemented and thus rendered impermeable. Even so, the interval may then provide a seal for fractured and leached reservoirs still being created along the downdip side of the adjacent collapse basin. Collapse structures in the carbonate overburden may be multistage structures located “off-salt”, i.e. in areas where all salt has been removed, as in the classic “Hummingbird” oil trap. Hummingbird drape was created by sequential collapse and its pinnacle-like appearance in seismic gave it the name “pseudo-reef” in early exploration programmes in the Alberta Basin (Figure 10.62b). When dissolution is early, sediments often thicken above the areas of dissolution and thin in the areas over the remaining salt outlier. These overlying sediments can develop the same types of porosity patterns that

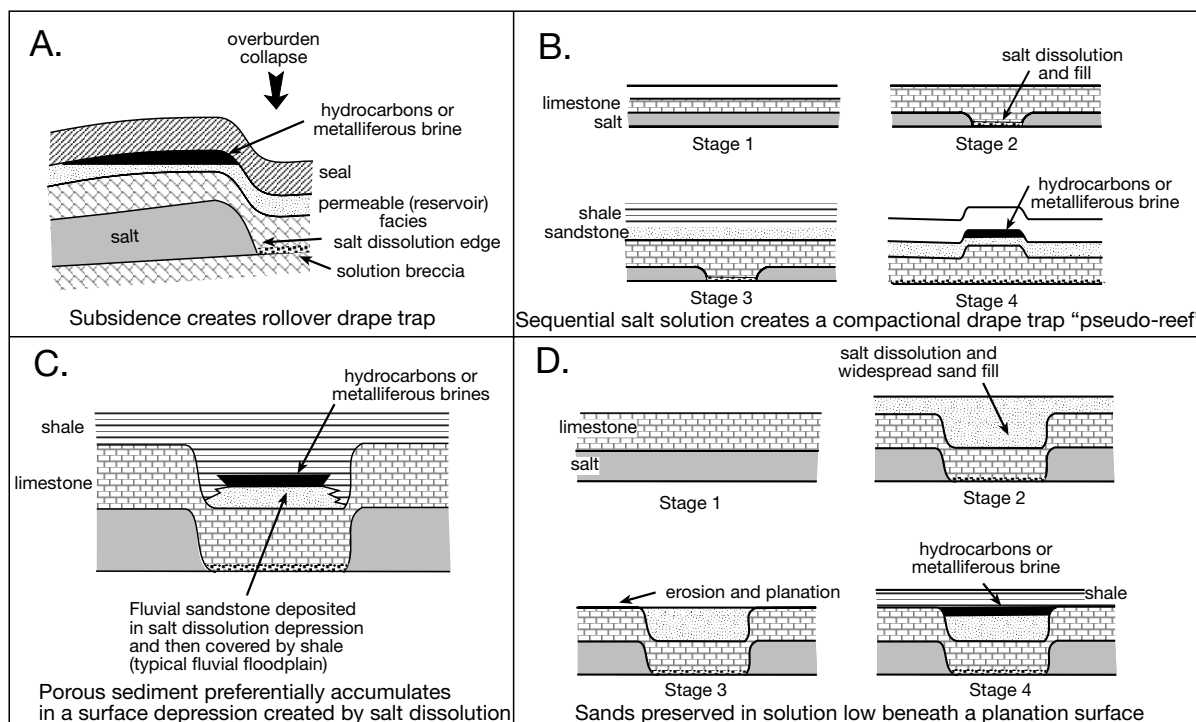

Figure 10.62. Styles of structural and diagenetic trap created by localised salt solution (in part after Anderson et al., 1988).

form above salt ridges. Sometimes the salt dissolves in stages and so creates sequential thickened beds up section as the locus of salt dissolution shifts. In Figure 10.62b, two areas of sediment thickening are created by salt dissolution; the first forms in stage 2, the second in stage 4. This and later differential compaction and drape can create reservoirs above salt remnants (high in stage 2) or by later differential compaction (stages 3 and 4). Other solution traps may be “on-salt,” the result of compactional drape over a single stage fill of a salt solution trough such as at Kisbey Field (Figure 10.62c, d).

Collapse has also created reservoirs in quartz sands such as Berry Field and the Westhazel pool in Lower Cretaceous fluvial sandstones of Alberta. These reservoirs were created by depositional focusing of fluvial sands at the migrating edge of the dissolving subsurface salt of the Prairie Evaporite (Hopkins, 1987). Compared with most stratigraphic traps in Cretaceous sands in the region, the Berry Field is unusual in its occurrence on the flank of a local structural high within a larger regional structural depression. This unusual synclinal setting for the reservoir is a direct indication of its origin as a fluvial system within a landscape position controlled by salt solution.

The Westhazel General Petroleum Pool of west-central Saskatchewan, Canada, produces from the GP member of the Lower Cretaceous Mannville Group and is an excellent example of reservoir stacking in a salt dissolution trough (Figure 10.63; Anderson and Cederwall, 1993). The reservoir facies consists of fine- to medium-grained quartzose sandstones. The lateral

uniformity and coarsening upward appearance of this unit and the uniform thickness of the underlying and overlying shales indicates that the General Petroleum Member was deposited in a relatively shallow, marine environment. The pool was discovered in 1971 and produced in excess of 60,000 m³ (380,000 barrels) of heavy oil from the marine sandstones of the General Petroleum (GP) Member.

This reservoir is structurally closed across the updip, eastern dissolutional edge of the underlying Middle Devonian rock salt of the Leofnard Member of the Prairie Evaporite. The leaching of these salts occurred in post-Mannville time in the Westhazel area and caused the regional southwest dip of the General Petroleum member to be locally reversed (Figure 7.5). The thin, 10 m-thick reservoir facies at Westhazel does not exhibit a diagnostic signature on either seismic or gravity data. Rather, it is the updip edge of the salt, across which the reservoir is closed, that can be mapped using geophysical techniques.

On seismic data, the dissolutional edge of the Prairie salt is characterized by: (1) a subtle decrease in the amplitude and lateral coherency of the underlying Winnipegosis event; (2) a gradual thinning of key encompassing Palaeozoic intervals; (3) dip reversal along the Beaverhill Lake (Late Devonian) event; (4) dip reversal along the Mannville (Lower Cretaceous) event; and (5) time-structural “push down” of Lower Cretaceous and underlying reflections in areas of recent salt dissolution (salt is characterised by fast seismic velocities). On the gravity profile, the edge of the salt is manifested as a 1.5 mGal anomaly. The

Figure 10.63. Schematic section illustrating the eastern dissolutional edge of the Prairie Formation. The Westhazel study area straddles T50 and T51 in R23W3M - see Figure 7.5 for location (after Anderson and Cederwall, 1993).

Figure 10.64. Type log for the Wolf Springs Field area. The Botts, White, and Horton members of the upper Amsden are readily discernible as resistive kicks. The White and Horton members correspond to the zones of solution-collapse breccias. The Botts member is a shaly dolomite breccia. The lithologies shown in the Amsden and Piper formations represent compilations assembled from cores in the area (after Luebking et al., 2001).

interpretation of both geophysical data sets is consistent with available geologic control. For more detailed information on salt solution traps the interested reader is referred to an excellent summary paper by Anderson and Knapp (1993).

Occasionally, the solution breccia created by the dissolution of salt can itself act as the reservoir rather than just fracturing and structuring the overburden. This is the case with Wolf Springs Field (north and south pools) and South Wolf Springs Field, located in Yellowstone County, Montana (Luebking et al., 2001). The Wolf Springs fields are unconformity-related combination structural and stratigraphic traps (Luebking et al., 2001). The fields are located on a structural closure on the Custer anticline, where porosity and permeability development exhibits a northeast-southwest orientation perpendicular to structural strike of the anticline. The solution-collapse breccias pinch out laterally into either dense dolomites or anhydrite-plugged collapse breccias. The overlying shaly dolomite breccia of the Botts Member, located just below the Piper unconformity, and the Jurassic Piper Limestone together provide the top seal.

The Wolf Springs and South Wolf Springs fields were discovered in 1955 and 1957, respectively, and have produced more than 5.7 million barrels of oil from the Pennsylvanian Amsden Formation. Amsden reservoir rocks in the area are fractured and

brecciated cherts and dolomites that occur in several laterally persistent and mappable zones (Figure 10.64). The Amsden was deposited in a peritidal to sabkha setting, where evaporite minerals, mainly anhydrite, were once common. These evaporites were partly replaced by silica (chalcedony and chert) soon after deposition. Later dissolution of the remaining evaporites not long after the silicification event, or during the preMiddle Jurassic unconformity, produced the solution-collapse chert breccias that now serve as the best reservoir facies in the field. Subtle variations in the diagenetic history of these breccias are a major factor in shaping reservoir quality.

Interestingly, not all hydrocarbon-reservoirs in salt entraining basins typified by stratiform breccias in carbonate platforms are related to earth-bound dissolution processes. The Cantarell oil field in the Campeche Platform of Mexico, with a current daily production of 1.3 million barrels of oil, is probably the most voluminous oil-producing unit with fracturing related to a bolide impact event. The K-T breccia reservoir itself, its ejecta horizon and its sealing muds are related to the same bolide event that wiped out the dinosaurs (Grajales-Nishimura et al., 2001).

Chapter 11: Evaporites as exploited mineral resources

A history of salt usage

Sodium chloride (halite), the most common industrial evaporite salt, is used in some form by virtually every person in the world. There are more than 14,000 reported usages of halite and more than 30 references to salt in the Bible. Halite, along with other salts, has long played a very important role in human affairs. Some 3,200 years ago Bronze-Age Celtic miners were extracting salt near Hallstatt in Austria, from a network of several kilometres of galleries up to 300 metres below the surface. Seventeen hundred years later some ten pages deal with salt in the "De Re Metallica" by Georgius Agricola (Georg Bauer), both mining it and producing it from seawater. Published in 1556, his was the first book on mining to be based on field research and observation. Until the 19th Century and the advent of refrigeration, salt's main uses were as a preservative and as a much sought after additive to flavour foodstuffs (Kurlansky, 2002). Without salt, the human metabolism cannot function. Even today, most people think of salt in terms of sprinkling it on their food, or in colder climates they may also think in terms of road de-icing. These are in fact lesser modern usages of halite; its main use is as a feedstock in the chemical industry.

The human body's need for salt gave it military significance; the earliest recorded war over access to a supply of salt was over a salt lake in China in 3000 BC. The words, 'war' and 'peace' originate from the words for salt and bread in ancient Hebrew and Arabic. In the American Civil War the salt production facilities in Saltville, Va., Virginia's Kanawha Valley and Avery Island, Louisiana, were early targets of the Union Army. The North fought for 36 hours to capture Saltville, Va., where the salt works were considered crucial to the Rebel army - so crucial that Confederate President Jefferson Davis offered to waive military service to anyone willing to tend coastal salt kettles to supply the South's war effort. In addition to dietary salt, the Confederacy needed this precious mineral to treat wounds, tan leather, dye cloth for uniforms and to preserve meat and other foodstuffs. Thousands of Napoleon's troops died during his retreat from Moscow, because for lack of salt their wounds would not heal.

Early hominids lived on the edge of the saline Lake Olduvai (Hay and Kyser, 2001) and salt was part of their diet. In ancient Greece it was so valuable that the slave trade involved an exchange of salt for a slave and gave rise to the expression, "not worth his salt." Some 4,700 years ago the Peng-Tzao-Kan-Mu was published in China. It is probably the earliest known treatise on pharmacology, with detailed discussions

of the palliative and curative powers of more than 40 kinds of salts, including descriptions of two methods of recovering usable salts from brine. In 2200 BC the Chinese emperor Hsia Yua declared that Shandong Province must supply the Imperial Court with salt. An ancient Chinese philosopher once called salt "the sweetest thing on earth."

In Europe, the first recorded industrial production of pan salt took place in Italy some 2500 years ago when Ancus Martius, one of the early Roman kings, began letting sea water into an enclosed basin, then allowing the sun to evaporate the water to create a salt residue. The importance that Rome attached to the salt works and port at Ostia was such that the main highway along which the salt was carried to Rome was called the Via Salaria. Like Venice after it, the city of Rome based much of its early commerce on trading salt. Special salt rations paid to early Roman soldiers were known as "salarium argentum", the forerunner of the English word "salary." With a near monopoly on supply to Rome, the traders in the port of Ostia raised the salt price so high that the state was forced to take over the industry in 506 BC.

When Julius Caesar landed in Britain in 55 BC, he brought his salinators with him, but found that even the backward Britons were extracting salt by pouring brine on to hot stones. The Romans, however, used iron pans in which they boiled the brine, and Caesar established a brine-based salt works in Cheshire and subsequently in other localities. The towns in Britain where salt was made can be distinguished to this day by the termination "wich", an Anglo-Saxon descriptor for a place where salt was made and includes towns like Greenwich, Ipswich, Droitwich, Northwich and Middlewich. Merchants in 12th-Century Timbuktu in Africa, the gateway to the Sahara Desert and the seat of renowned scholars, valued salt as highly as books or gold. In Tibet, Marco Polo noted that tiny cakes of salt, manufactured from salt lakes in the high plains of Tibet were pressed with images of the Grand Khan and used as coins. Salt is still carried by camel trains and still used as money among the some of the nomadic tribes of the Sahara and Ethiopia's Danakil Plains. The ancient Maya made salt at Salinas de los Nueve Cerros, Guatemala, an area where natural salt springs flowed into a river gully, giving easy trading access to downstream customers. This site was the only large-scale source of salt for the interior Lowland Maya. Maya technology included solar evaporation and firing of brine from salt springs in special large ceramic bowls that are the largest receptacles ever found in any Maya sites.

Type	Mineralogy	Source	Uses
Ammonium Chloride	NH ₄ Cl	Brine Processing	Fertiliser, industrial additive
Ammonium sulphate	(NH ₄) ₂ SO ₄	Brine Processing	Fertiliser
Borate	B ₂ O ₃	Borax (tincal), Boracite, Colemanite, Hydroboracite, Kernite, Ulexite	Glass, ceramics, fibreglass, textile manufacture, agricultural chemicals, pharmaceuticals, flux cleansing agent, water softener, preservative and fire retardant
Bromine (sodium bromide)	Br ₂ , NaBr	Brine Processing	Additive
Calcium sulphate	CaSO ₄	Gypsum, secondary after anhydrite	Construction industry, plaster, cement retardant, soil enhancer
Iodine	I ₂	Brine Processing	Animal feed supplements, catalysts, inks and colorants, pharmaceutical, photographic equipment, sanitary and industrial disinfectant, and stabilisers
Lithium	Li	Brine Processing, hectorite in some saline clays	Production of ceramics, glass, and primary aluminium, battery technology, pharmaceutical
Magnesium carbonate, Magnesium oxide, Magnesium sulphate	MgCO ₃ , MgO, MgSO ₄	Brine Processing, magnesite, electrolytic processing	Majority used for refractories. A constituent in aluminium-base alloys, used for packaging, transportation, and other applications. Remainder is consumed in agricultural, chemical, construction, environmental, and industrial applications
Potash	KCl, KNO ₃ , K ₂ SO ₄	Sylvite, sylvinitite, brine processing	Fertiliser, chemical industry
Sodium carbonate	Na ₂ CO ₃	Trona, solvay process, brine processing	Glass manufacture, chemicals, soap and detergents, pulp and paper manufacture, water treatment, and flue gas desulphurisation
Sodium chloride	NaCl	Halite, brine processing	Food processing, chemical and industrial products, chloralkali industry, swimming pool additive, stockfeed additives
Sodium sulphate	Na ₂ SO ₄	Mirabilite, thenardite, glauberite, brine processing	Detergent powder, glass, pulp and paper
Strontium	Sr	Celestite, strontianite	Television faceglass (decreasing use), ceramic magnets, colouring agent in pyrotechnics and signals
Sulphur	S ₂	Biogenic sulphur, Frasch process	Agricultural chemicals, chemicals manufacture, metal mining, and petroleum refining

Table 11.1. Evaporite salts as a mineral resource.

Salt's economic value meant it was taxed by governments from the ancient Chinese and Romans to late medieval Europe. In 2200 BC the Chinese Emperor Hsia Yu levied a salt tax as one of the world's first documented taxes. Mary Queen of Scots was perhaps the first European head of state to have the idea of making salt a source of governmental revenue. She granted a patent to an Italian to make salt in Scotland and then placed a heavy tax on it, which she appropriated to herself. Elizabeth, Queen of England, and Mary's lifelong "dear sister" and eventual executioner, thought this an excellent idea and likewise taxed English salt making. Salt tax was a source of great resentment to everyone, English and Scots alike, and smuggling grew to alarming proportions. In 1785, the Earl of Dundonald wrote that every year in England, 10,000 people were arrested for salt smuggling. During Queen Anne's reign, the salt tax rose to £30 a ton, an enormous amount of money in those days. The whole of England arose in rioting protest, with the result that the salt tax was finally abolished.

In Burgundy, salt was taxed at more than 100% as it came from the salt-works. This tax was extended to the whole of France when Burgundy was absorbed and the notorious salt tax "la gabelle" became a necessary input to the government's finances. Cardinal Richelieu said that salt was as vital to France as American silver was to Spain. The repeal of the salt tax was a major goal of the revolutionaries of 1789, but Napoléon restored the salt tax to pay for his foreign wars as soon as he became Emperor and it continued until 1945 to feed French government coffers. It is said that income from a salt pan in southern Spain largely financed Columbus' voyages. The Erie Canal, an engineering marvel that connected the Great Lakes to New York's Hudson River in 1825, was called "the ditch that salt built" as salt taxes paid for half of the cost of construction. The "Great Hedge of India," the mid-18th century colonial equivalent of the Great Wall of China, stretched 3,700 km from the western border of Punjab down to the Bay of Bengal. It was manned by 12,000 men and planted by the British to minimise

salt smuggling into Bengal and enforce the collection of the Indian salt tax. As late as the 1940s the people of India under the leadership of Mahatma Gandhi protested British taxes on salt supply. In 1930 he led a 200-mile march to the Arabian Ocean to symbolically collect untaxed salt for India's poor.

Salt, because of its value in the ancient world, still has religious significance. Ancient Greek worshippers consecrated salt in their rituals. Jewish temple offerings included salt; on the Sabbath, Jews still dip their bread in salt as a remembrance of those sacrifices. Covenants in both the Old and New Testaments were often sealed with salt, explaining the origin of the word "salvation." In the Catholic Church, salt was or is used in a variety of purifying rituals. Jesus called his disciples "the Salt of the Earth", a statement that was commemorated by the Catholic church until Vatican II, by placing a small taste of salt on a baby's lip at his or her baptism. In Leonardo Da Vinci's famous painting, "The Last Supper," Judas Escariot has just spilled a bowl of salt - a portent of evil and bad luck. In Buddhist tradition, salt repels evil spirits. That's why in many Asian cultures it's customary to throw salt over your shoulder before entering your house after a funeral: it scares off any evil spirits that may be clinging to your back. In 1933, the Dalai Lama was buried sitting up in a bed of salt. Shinto religion also uses salt to purify an area. Before sumo wrestlers enter the ring for a match - which is actually an elaborate Shinto rite - a handful of salt is thrown into the centre to drive off malevolent spirits. In the American Southwest, the Pueblo worship the Salt Mother. Other native American tribes had significant restrictions on who was permitted to eat salt. Hopi legend holds that the angry Warrior Twins punished mankind by placing valuable salt deposits far from civilization, requiring hard work and bravery to harvest the precious mineral.

Today, halite is a cheaply produced commodity extracted either from mines or salt pans. In the production of table salt, processing, packaging and marketing are the major costs. An exception to the low sale price of modern salt is "Fleur de Sel de Geurande" a delicate gourmet form of white seasalt that is still hand-produced on the fens along the coast of Brittany. It costs \approx US\$40/kg and is produced by "paludiers" only on suitable summer days when halite rafts can be raked from the brine surface of specially maintained coastal salt pans, which are floored with grey clay. According to the local legend it only forms when the wind blows from the east (from the sea). It and the cheaper grey salt (sel gris), which is scraped from the pan floors and also prized by gourmands, has been produced this way since Pre-Roman times. Impurities like this clay are called grey spot or black spot in highly efficient mechanised

production plants elsewhere in the world and are considered undesirable in the end product. It says something about French marketing skills, and perhaps the gullibility of middle-class gourmands with too much money and time on their hands, that each year the gourmet industry successfully markets dirt-polluted salt for top prices.

Salts other than halite have a diversity of usage (Table 11.1). Potash salts are used mostly as agricultural fertiliser, while the sodium salts, halite-trona-glauberite, are major feedstocks in the formation of a wide range of industrial chemicals. Gypsum is used in plaster and cement manufacture throughout the world. This chapter first focuses on the potash salts and then on the other industrial salts and the products of alteration associated with evaporite salts, such as sulphur and zeolites; emphasis is on depositional and diagenetic modes of formation. Halite and gypsum (anhydrite), the two most commonplace salts, are not considered in the same detail as the other salts in this chapter as their deposition and diagenesis was discussed in earlier chapters.

Annual production figures and tables for the various salts in this chapter were compiled from the raw data sheets in various pdf-format documents held on the US Geological Survey web site <<http://minerals.er.usgs.gov/minerals/pubs/commodity/>>. In addition to the cited references, other very useful sources used extensively in the compilation of this chapter were the excellent books on industrial minerals by LeFond (1983), Harben and Bates (1990), Garrett (1995, 1998, 2004) and Harben and Kuzvart (1996).

Potash salts

Natural potash evaporites are part of the bittern series precipitated at the surface or in the shallow subsurface at the higher concentration end of the evaporation series. Today the deposition of thick beds of potash minerals at the earth's surface is a relatively rare occurrence. The extremely high solubility of potash means it can only accumulate in highly restricted, some would say highly continental, settings (Cendon et al., 2003). Where it does occur as beds in the modern playas of Qaidam in China and in the Danakil Depression of Africa, carnallite, not sylvite, is the precipitated salt. This has led some to postulate that carnallite is the primary marine potash phase, while sylvite is a secondary diagenetic mineral formed by incongruent dissolution of carnallite. Others have argued that ancient sylvite was sometimes a primary precipitate deposited by the cooling of highly saline surface or nearsurface brines

Mineral	Composition	K ₂ O %	Comments
<i>Chlorides</i>			
Sylvite	KCl	63.2	Principal ore mineral
Carnallite	MgCl ₂ ·KCl·6H ₂ O	16.9	Ore mineral and contaminant
Kainite	4MgSO ₄ ·4KCl·11H ₂ O	19.3	Important ore mineral
<i>Sulphates</i>			
Polyhalite	2CaSO ₄ ·MgSO ₄ ·K ₂ SO ₄ ·2H ₂ O	15.6	Ore contaminant
Langbeinite	2MgSO ₄ ·K ₂ SO ₄	22.7	Important ore mineral
Leonite	MgSO ₄ ·K ₂ SO ₄ ·4H ₂ O	25.7	Ore contaminant
Schoenite (picromerite)	MgSO ₄ ·K ₂ SO ₄ ·6H ₂ O	23.4	Accessory
Glaserite (aphthitalite)	K ₂ SO ₄ ·(Na,K)SO ₄	42.5	Accessory
Syngenite	CaSO ₄ ·K ₂ SO ₄ ·H ₂ O	28.7	Accessory
<i>Associated minerals</i>			
Halite	NaCl	0	Principal ore contaminant
Anhydrite	CaSO ₄	0	Common ore contaminant
Bischofite	2MgCl ₂ ·12H ₂ O	0	Accessory contaminant
Bloedite (astrakanite)	Na ₂ SO ₄ ·MgSO ₄ ·2H ₂ O	0	Accessory
Loewite	2MgSO ₄ ·2Na ₂ SO ₄ ·5H ₂ O	0	Accessory
Vanthoffite	MgSO ₄ ·3Na ₂ SO ₄	0	Accessory
Kieserite	MgSO ₄ ·H ₂ O	0	Common ore contaminant
Hexahydrite	MgSO ₄ ·6H ₂ O	0	Accessory
Epsomite	MgSO ₄ ·7H ₂ O	0	Accessory
<i>Ores</i>			
Sylvinitite	KCl+NaCl	10-35	Canada, USA, Russia, Brazil, Congo, Thailand
Hartsalz	KCl + NaCl + CaSO ₄ + (MgSO ₄ ·H ₂ O)	10-20	Germany
Carnallitite	MgCl ₂ ·KCl·6H ₂ O + NaCl	10-16	Germany, Spain, Thailand
Langbeinitite	2MgSO ₄ ·K ₂ SO ₄ + NaCl	7-12	USA, Russia
Mischsalz	Hartsalz + Carnallite	8-20	Germany
Kainitite	4MgSO ₄ ·4KCl·11H ₂ O+NaCl	13-18	Italy

Table 11.2. Potassium salts.

or from seawater with ionic proportions different to those of today (Figure 2.30).

Phanerozoic potash salts comprise two distinct groups: MgSO₄-rich and MgSO₄-poor. Potash salts have not been recovered from Precambrian sediments other than in minor amounts in the Neoproterozoic Ara Salt of Oman. Potash deposits rich in MgSO₄ are composed of some combination of gypsum, anhydrite, polyhalite, kieserite, kainite carnallite and bischofite. Potash deposits free of, or poor in, MgSO₄ are dominated by some combination of halite, carnallite, and sylvite. This latter group constitutes a majority of exploited Phanerozoic potash. The hydrogeochemical significance of the two groups was

discussed in Chapter 2; this chapter emphasises the geology of potash salts.

Potash is the generic term for a variety of ore-bearing minerals, ores and refined products, all containing the element potassium in water-soluble form (Table 11.2). It was originally used to describe the mixture of potassium carbonate and potassium hydroxide crystals, which were recovered in heated iron “pots” from boiling the washings of wood (or other plant) “ashes,” both the recovered potash salts were caustic. Lye meant sodium hydroxide and potash lye was potassium hydroxide, a higher grade product that was used in the manufacture of higher-grade softer or facial grade soaps.

Since the 1950s the terms potash or potash salts have been used commercially as general descriptions of potassium chloride (KCl or muriate of potash), potassium sulphate (K₂SO₄ or sulphate of potash), potassium-magnesium sulphate (K₂SO₄ MgSO₄ or sulphate of potash magnesia), potassium nitrate (KNO₃ or saltpetre), or mixed sodium-potassium nitrate (NaNO₃ +KNO₃ or Chilean saltpetre). The most common naturally occurring potash minerals are carnallite and sylvite, with sylvite the most economically important. Other common potassium-entraining evaporite ores include: kainite, kieserite, langbeinite, leonite and polyhalite (Table 11.2).

In 2004 there were 14 potash producing countries, including small volumes from the Ukraine and Chile. The North Americas produce 36% of the world’s total potash production, eastern Europe and Russia some 30%, western Europe 19%, and the

Figure 11.1. World potash production in thousand metric tons^{11.1} of K₂O equivalent - (compiled from USGS on-line data tables downloaded from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005).

Dead Sea 11% (Figure 11.1). Of total world production, just ten companies control 90%, and the five largest companies control more than 75%. Canada, the world's largest producer holds more than 35% of the world's potash reserves, and recovers potash by conventional underground mining of bedded sylvinite deposits. Production is centred on the Devonian Elk Point Basin in Saskatchewan, with lesser production in the Maritime Provinces and Quebec. Devonian potash is also mined in the Pripyat depression of Belarus. Permian potash is mined from the northern margin of the Delaware Basin in New Mexico, USA; from the Zechstein of Europe (Germany, UK and the Netherlands); and from the Upper Kama Basin in the Russian Federation in the Solikamsk region west of the Urals. Oligocene potash is extracted from the Rhine graben in France, while Miocene potash is mined in the Stebnik area in the western Ukraine. In Spain, in the northern part of the Ebro Basin near the border with France, potash is produced from Eocene-Oligocene lake sediments. In Utah, potash is solution mined from Tertiary playa deposits and recovered from the brine by solar evaporation and flotation. Israel uses similar solar technology to produce large volumes of potash from lake brines created naturally from recycled marine Miocene evaporites and connate waters buried beneath the

floor of the Dead Sea. In California, potash and coproducts, borax pentahydrate, soda ash and saltcake, are recovered from various subsurface playa brines using mechanical evaporation. Sylvite is also a byproduct of nitrate processing in the Atacama Desert of Chile, South America.

The fertiliser industry uses more than 90-95% of produced potash, and the chemical industry uses the remainder in the manufacture of soaps and detergents, glass, ceramics, synthetic rubber and numerous industrial chemicals. About 70% of the potash is produced as potassium chloride and sylvite is the preferred ore mineral in most mines. Potassium sulphate and potassium magnesium sulphate, required by certain crops and soils, comprise about 25% of potash production. Retailers typically sell potash, or potash blended with other fertilisers, in dry or liquid form. Potash is a source of soluble potassium, which is one of the three primary plant nutrients; the others are fixed and soluble phosphorus and nitrogen. Mankind's use of these three nutrients, in commercial forms, started the "Green Revolution" in agriculture.

Other uses of the various potash salts include KCl as a mud additive to stabilise reactive clays in oil well drilling. It is also used in aluminium recycling, in various steel heat-treating processes, metal electroplating, snow and ice melting, and water softening. Potassium chloride is used by the chlor-alkali industry to produce potassium hydroxide. The alkali potassium hydroxide

^{11.1} 1 metric ton (tonne) = 1,000 kilograms = 2,204.6 pounds
1 metric ton (tonne) = 0.9842 ton (imperial)

is used for industrial water treatment and is the precursor of; potassium carbonate, several forms of potassium phosphate, many other potassic chemicals, and is the main ingredient in soap manufacture. The alkaline salt potassium carbonate is used with strontium and barium carbonate in the faceglass for televisions and computer monitors (used as radiation screen, but is a decreasing use with advent of digital flatscreens), alkaline batteries, food products, pharmaceutical preparations, photography, some fire extinguishers, animal feed supplements, and as a catalyst for synthetic rubber manufacture. Generally, the nonagricultural uses account for no more than 5-10% of annual world consumption.

Although it is today a low cost commodity, the importance of potash to world agricultural economy means it is worthwhile gaining a detailed understanding of how potash salts accumulate in a variety of depositional and diagenetic settings. First, we shall look at some Quaternary deposits and then at some ancient counterparts.

Quaternary potash

Natural modern potash accumulations are rare: there are only two well documented examples of substantial Quaternary potash accumulations, namely, the Qaidam Basin in China and the Danakil Depression in Ethiopia. Other examples where carnallite or sylvite are forming today are either minor efflorescences and thin crusts in continental lakes, playas and soils, or are artificial products, either precipitated by enhanced solar pond evaporation of seawater, as in Lake McLeod in Australia, or by evaporation of lake and pore waters pumped into surface pans as in the Dead Sea in the Middle East. Sylvite occurs naturally as a widespread pedogenic salt along with nitrates in the hyperarid regions of the Atacama Desert in Chile.

Playas of the Qaidam Basin

The high plateau region of northern Qinghai-Xizang in west central China north of Tibet contains large endorheic lake basins with thick fills of Mesozoic and Cenozoic nonmarine sediments (Figure 11.2). The modern at-surface playas and salt lakes are subject to intense evaporation and are characterised by hypersaline brines and in some by accumulations of potash and borate evaporites. Lake Dabuxum is of special geological interest as it is one of the few localities in the world where significant quantities of potash salts are precipitating today (Yang et al., 1995; Vengosh et al., 1995; Casas et al., 1992).

The Qaidam Basin is a large intermontane sedimentary and structural basin at the northern margin of the Qinghai-Tibet

Plateau. With an area of 120,000 km², it has an extent that approaches that of some of the moderate to small ancient continental "saline giants," but the active-salt accumulating salt lakes are a much smaller proportion of the basin and only occupy its lower parts (Figures 5.5, 11.2). The Plateau encompasses a large, tectonically active plain, bound by mountains, filled with clastic and evaporite sediments and is totally isolated from the ocean (Figure 11.2). The Kunlun Mountains bound the basin to the south, the Altun mountains to the west and the Qilian Mountains (that reach 5,000 m above sea level) bind the northern portion of the basin. The basin centre has an average elevation of 2,800m and contains numerous shallow to ephemeral saline lakes and dry saline pans.

The Qarhan playa or salt plain, with an area of some 6,000 km², is the largest saltflat in the Qaidam Basin and is underlain by bedded halite (Figure 11.3). It is a broad flat plain floored by a layered halite pan crust with a permanent groundwater brine lens located 0 to 1.3m below the surface. The surface crust consists of a chaotic mixture of fine-grained halite crystals and mud, with a rugged, pitted upper surface (Schubel and Lowenstein, 1997). Vadose diagenetic features, such as dissolution pits, cavities and pendant cements, form where the salt crust lies above the water table. Interbedded salts and siliciclastic sediments underlie the crust to reach thicknesses of up to 75m, and over the last 50,000 years have formed the potash-hosting Qarhan Salt plain or playa (Kezao and Bowler, 1985). Patchy carnallite, hosted in bedded halite, occurs in karst cavities in the upper 13m of the Qarhan playa sequence (Figure 11.3).

The compositions of fluid inclusions in primary (chevron) halite in the various Qahan salt crusts represent preserved lake brines and indicate relatively wet conditions throughout most of the Late Pleistocene (Yang et al., 1995). Oxygen isotope signatures of the inclusions record episodic freshening and concentration during the formation of the various salt units interlayered with lacustrine muds. Desiccation, sufficient to allow halite beds to accumulate, occurred a number of times in the Late Quaternary: 1) in a short-lived event \approx 50,000 ka, 2) from about 17 - 8,000 ka, and 3) from about 2,000 ka till now (Figure 11.3). Modern halite crusts in Qahan playa contain the most concentrated brine inclusions, suggesting that today may be the most desiccated period recorded over the last 50,000 years. Measurements of inclusions in early diagenetic halite that formed from shallow groundwater brines (clear halite spar between chevrons), confirm the climatic record derived from primary (chevron) halite. The occurrence of carnallite-saturated brines in fluid inclusions in the diagenetic halite in the top 13 m of Qahan playa sediments also imply a diagenetic, not depositional origin

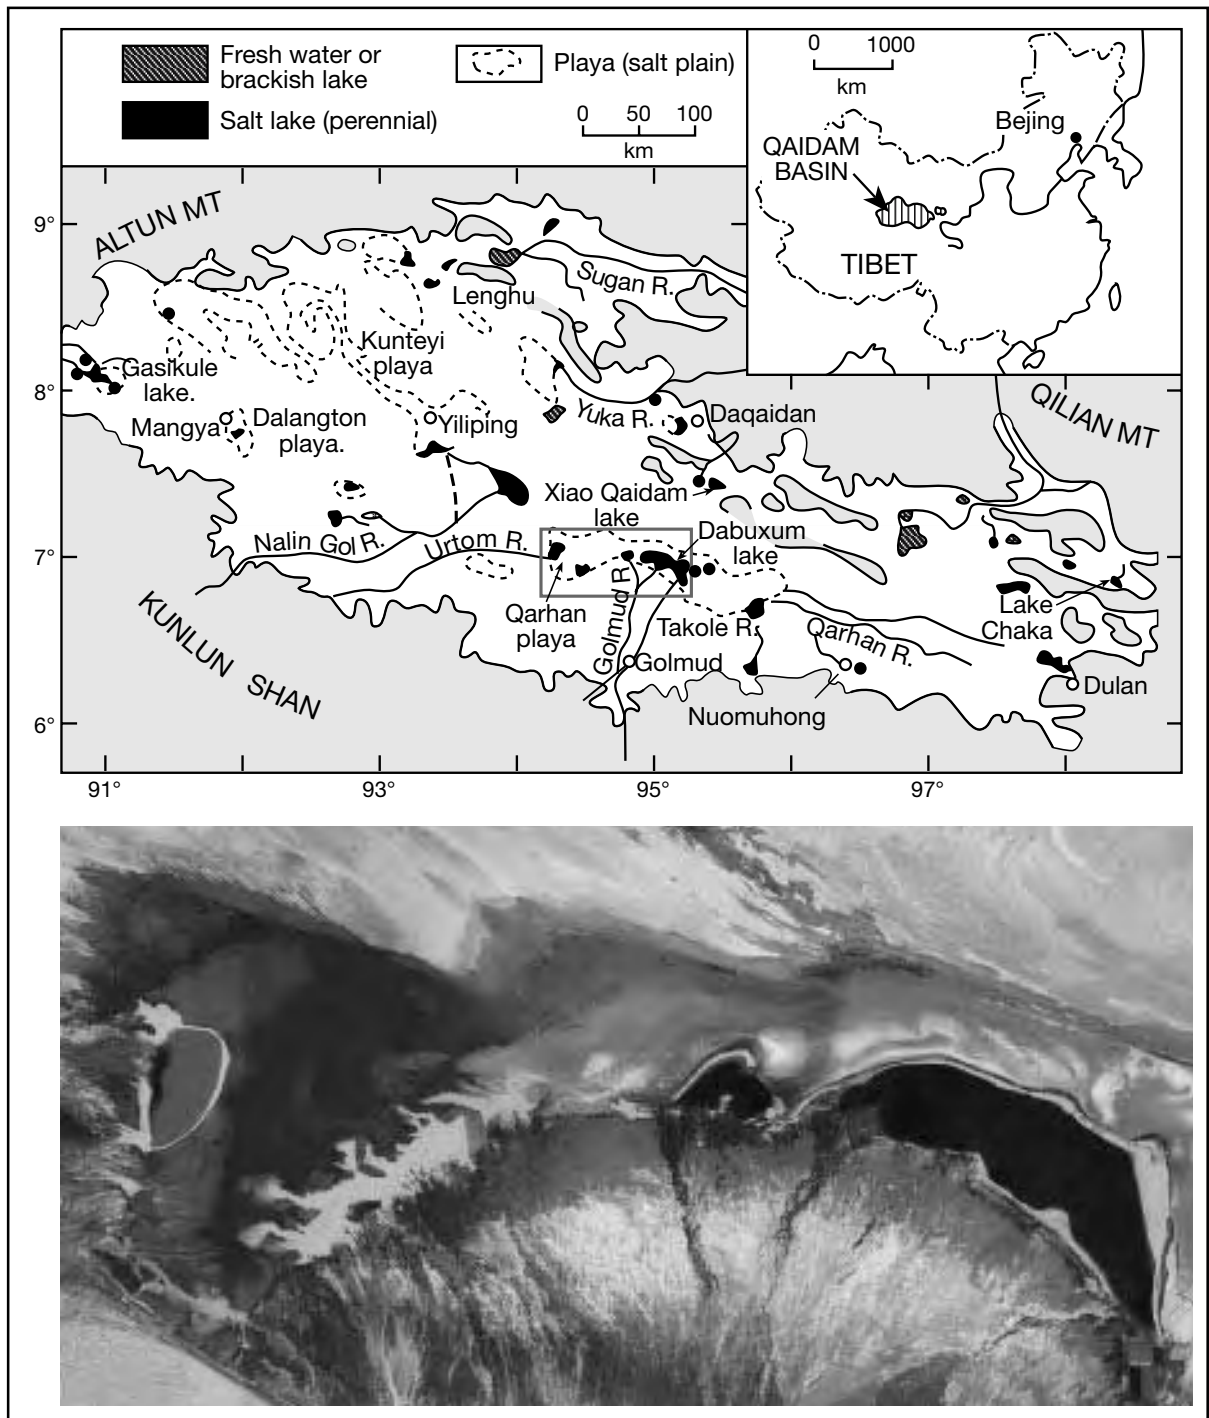

Figure 11.2. Location of salt lakes, freshwater lakes and playas in the Qaidam Basin, China. The Landsat image shows the Golmud fan delta feeding into Lake Dabuxum and the adjacent Qahan playa salt flat, the lake on the eastern side edge of the Qahan playa salt flat is Xiao Lake. B) Strandline geology of the northern shore of Lake Dabuxum showing position of coring traverse as shown as inset in C. C) Cross section showing how the process of brine cooling forms carnallite cement in the karstic voids in shallow subsurface halite crusts and creates karst-filling cement textures (after Casas et al., 1992).

of carnallites that locally accumulated in the same voids as the more widespread microkarst halite cements.

Today the salt plain of the Qahan playa encloses 10 shallow perennial saline lakes and is fed mostly from the Kunlun Mountains (Kunlun Shan). The largest lake on the Qarhan Salt Plain is Dabuxum Lake; an area where carnallite has recently accumulated along the strandline (Figure 11.2; Casas et al., 1992; Casas, 1992). The greatest volume of water entering the lake comes from the Golmud River (Figures 11.2, 11.3a).

Cold springs, emerging from a linear karst zone some 10 km to the north of the strandline, also supply solutes to the lake. Thus, evaporation of a mixture of river water and spring water creates the carnallite-saturated brines of the Dabuxum Lake system (Lowenstein et al. 1989).

Surface sediments of Dabuxum Lake are zoned (Figure 11.3a, b). The southern part of the lake, closest to the Golmud River delta, is underlain by fine-grained siliciclastic sediments that pass lakeward into a centimetre-thick aragonite crusts, which

floor much of the water-covered area of the lake. A small island in the centre of Dabuxum Lake is made up of mud and silt laminae coated by microcrystalline aragonite and mud chip breccias cemented with aragonite. Stacked halite pan crusts define most of the subaerial Qahan playa saltflats to the north of the perennial lake.

Surface efflorescent crusts of halite and carnallite accumulated along the edges of Dabuxum Lake from 1987-1989 with carnallite reaching thicknesses of up to 0.3 m along a strandline zone approximately 1 km wide. The water-covered lake area at that time was approximately 250 km² and waters were less than 1m deep (Casas et al., 1992). The carnallite crust was brine-saturated, poorly cemented and had a mushy consistency. It was dominated by equigranular, anhedral carnallite crystals up to 5 mm in diameter. Thin sub-centimetre layers of very fine grained (submillimetre) carnallite and siliciclastic mud occurred within the carnallite mush. Individual carnallite crystals in the mush were often linked with textures identical to rafts or films of fine-grained carnallite, which could be seen floating on the surface of the very shallow brines near the lakeshore. Rafts were being blown onto the strandline or left behind on the lake floor as the drying brine sheets retreated from the northern strandzone of the lake. Strandline carnallites underwent extensive syndeositional diagenetic modification depending on daily temperature and weather conditions. In a single two-week period, dominated by fine sunny weather with daily temperatures up to 35°C, carnallite precipitated in the afternoon as rafts, or as centimetre-size, needle shaped skeletal crystals, or as efflorescent puffs of submillimetre crystals on evaporitic mudflats wherever the brine level was below the surface.

Light rains and strong southwest winds are common in the summer in Qaidam Basin. During such storms Dabuxum lake waters are blown over the halite-encrusted north shore and pond as thin brine sheets (Figure 11.3b). For example, vigorous winds on 6 and 10 August 1988 shifted the northern lakeshore several hundred metres north (Casas et al., 1992). These overlapping open lake waters were at or slightly below halite saturation and considerably below carnallite saturation. The carnallite strand zone was modified and partly dissolved after being covered by these waters but was re-established during subsequent warm days. In a subsequent large flood, during July to September 1990, the Dabuxum Lake area expanded from 250 km² to 800 km², while the associated freshening of the expanded lake completely dissolved the carnallite crust. Clearly, surface carnallite along the north

shore of Lake Dabuxum is an ephemeral strandzone sediment with little or no preservation potential.

However, carnallite has been widely precipitated and preserved in the upper 13 m of the 45m thick interbedded clay-halite succession that underlies the modern Lake Dabuxum strandline (Figure 11.3c). These subsurface carnallites are diagenetic void-filling cements and displacive crystals, which indicate a carnallite distribution with a strong temperature control. As dense carnallite-saturated lake brines sank into the underlying sediment they cooled and so precipitated carnallite in preexisting karst holes and pits in the halite bed (Figure 11.3c; Casas et al., 1992). The voids in the halite were created by earlier lowerings of the water table, alternating with times of freshening of the lake waters, with both events occurring numerous times prior to the accumulation of the present salt crust. This style of secondary nearsurface carnallite as early cements in the active phreatic zone is texturally analogous to much of the secondary carnallite and sylvite karst-fill fabric seen in ancient potash deposits in Thailand, Canada and the USA.

Danakil Depression, Ethiopia

The Danakil Depression (aka Dallol Depression) of Eritrea is an area of intense hydrothermal activity related to rift magmatism and deep brine cycling, located in the axial zone of the Afar rift near the confluence of the East African, Red Sea and Carlsberg rifts (Holwerda and Hutchison, 1968; Hutchinson and Engels, 1970; Hardie, 1990). The depression is the northern part of the Afar depression and runs parallel to the Red Sea coast but is some 50 to 80 km inland and separated from the sea by the Danakil Mountains. It is 185 km long, 65 km wide, with a floor 116 metres below sea level in the deepest part of the depression. A shallow volcano-tectonic barrier behind Mersa Fatma prevents hydrographic recharge or even seawater seepage into the current depression from waters of Howakil Bay, which is some 50-60 km WNW of Ito Aichil on the Red Sea coast. In terms of daily temperature the floor of the Danakil is one of the hottest places on earth; year round the daily temperature is above 34°C and in summer every day tops 40°C, with some days topping 50°C.

A halite-floored elongate saltpan covers the deepest part of the Danakil Depression over an area some 40 km long and 10 km wide, (Figure 11.4). The pan's position is asymmetric; it lies near the depression's western edge, some 5km from the foot of the escarpment to the Balakia Mountains, but some 50 km from the eastern margin of the depression. Pleistocene halite beds, exposed by uplift, deflation and water table lowering,

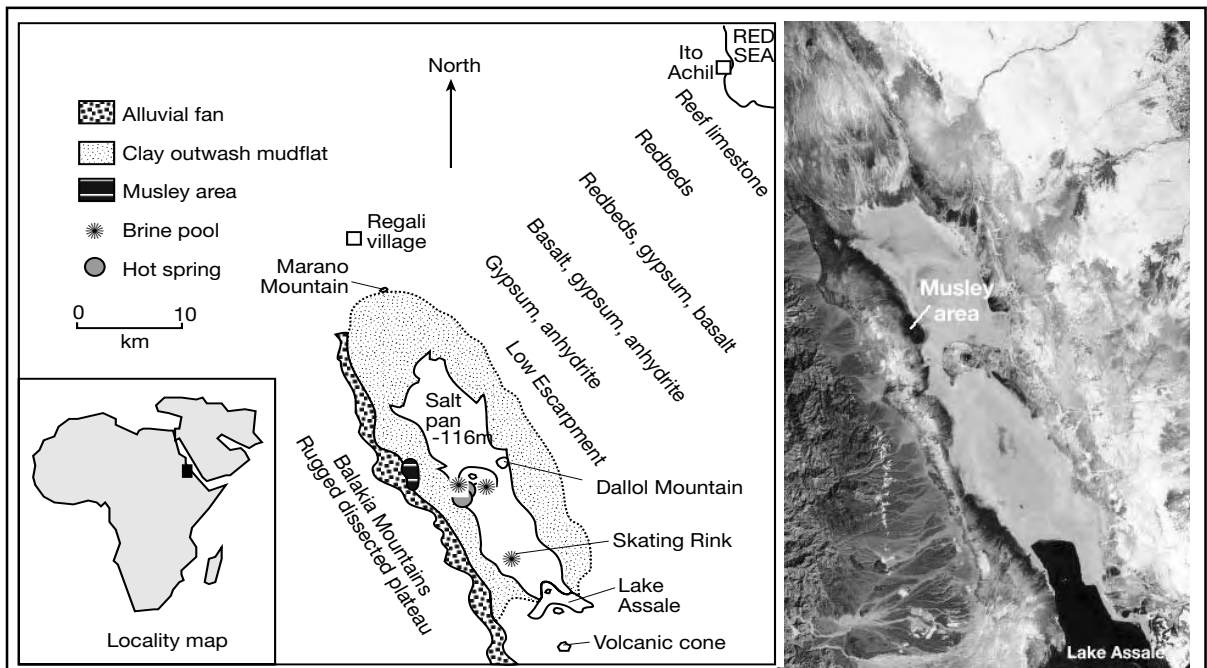

Figure 11.4. Location and geological features of the saline pan located in the northern half of the Danakil Depression, Eritrea (geological map after Holwerda and Hutchison, 1968; Landsat image courtesy of NASA).

outcrop about the salt crusted parts of the northern Danakil, and form low flat-topped plateaus or mesas on the plain, which are heavily dissected and eroded by occasional storm runoff and rainfall. More than 970 metres of halite-dominated Quaternary evaporites have accumulated beneath the present salt pan of the Northern Danakil, along with interbeds of gypsum, anhydrite and shale (Holwerda and Hutchison, 1968; Augustithis, 1980). Similar bedded evaporites probably underlie the entire Danakil depression, but lava flows and alluvium obscure much of the southern part of the depression beyond Lake Assale (Figure 11.4).

In the Musley area the km-thick subcropping Quaternary halite fill contains one and perhaps two dipping potash beds (Figure 11.4). The upper potash bed lies at a depth of 38-190 metres and has been cored in a number of wells, while the lower bed is at a depth of 596m near the western end and it has been interpreted only from gamma logs. Both units dip to the east and the deepest they were encountered by the drill was at 683 and 930 m, respectively.

The upper potash interval in the Musley area is between 15 and 40 metres thick; it consists of a basal member rich in fine-grained laminated kainite (4-14m thick), an intermediate carnallite member (3-25 m thick), and an uppermost stratiform sylvinite member (0-10 m thick) with lenses of carnallite, kieserite,

kainite or polyhalite. It is overlain by and eroded and etched with a 4-15 m-thick halite unit. Finely laminated and layered textures show that kainite and carnallite members are primary or syndepositional precipitates.

Core through the sylvinite member has three types of barren zone within it: a) the entire sylvinite bed is replaced by a relatively pure stratiform halite with dispersed nodules of anhydrite, b) zones up to 23 m across of pure crystalline halite within the sylvinite bed and c) linear potash depleted zones defined by coarsely crystalline halite. Bedding plane spacing and layering in the halite in styles a and b are similar to that in the adjacent sylvite bed. Contact with throughflushing freshened waters probably created most of the barren zones in the sylvinite. Fluid crossflow may also have formed the sylvite of the upper member via selective surface or nearsurface leaching of $MgCl_2$ from its carnallite precursor (Holwerda and Hutchison, 1968). Due to its secondary origin, the proportion of sylvite in the sylvinite member decreases as the proportion of carnallite increases, along with kieserite, polyhalite and kainite.

Beneath the sylvinite member, the carnallite member contains a varied suite of non-commercial potash minerals that in addition to carnallite include, kieserite, kainite (up to 10% by volume) and polyhalite, along with minor amounts of sylvite. Minor anhydrite is common, while bischofite and rinneite may

occur locally, along with rust-red iron staining. Sylvite is more abundant near the top of the carnallite member and its proportion decreases downward, perhaps reflecting its groundwater origin. Kainite is the reverse. The sylvinite member and the carnallite member also show an inverse thickness relationship. Bedding in the carnallite member is commonly contorted with folded and brecciated horizons interpreted as slumps. The base of the carnallite member is defined as the level where carnallite forms isolated patches in the kainite before disappearing entirely.

The kainite member is composed of nearly pure, fine-grained, dense, relatively hard, amber-coloured kainite with $\approx 25\%$ admixed halite. Texture and colour are characteristic of the unit, but even more so are the distinct “ruler-straight” bedding planes in the kainite, a striking contrast to the wavy, contorted and irregular bedding planes of the carnallite and sylvinite members. The preponderance of MgSO_4 salts in these Pleistocene evaporites means they most likely formed by the evaporation of seep-supplied seawater.

This is in marked contrast to the present hydrology of the Danakil Depression (Hardie, 1990). Today hot springs, rich in basinal CaCl_2 , supply and maintain the active brine pools and lakes of the Depression. Lake Giulietti (Lake Afrerá), with an area of 70 km^2 and a floor some 120m below sea level, is located within the active volcanic field of the southern Danakil. Both the inflowing hot springs ($40 - 50^\circ\text{C}$) and the brines of the lake itself are rich in CaCl_2 and poor in MgSO_4 . Extensive concentration of these lake waters will eventually lead to deposition of an MgSO_4 -poor series of salts dominated by sylvite, carnallite, halite and CaCl_2 salts. This will be in marked contrast to the thick underlying MgSO_4 -rich Pleistocene evaporites of the Musley area. It seems that seawater was much more important as a brine source in the Pleistocene than today.

Interaction between hot basinal groundwaters and volcanic bedrock is the likely explanation of the present inflow chemistry. Dissolution of the earlier highly soluble potash evaporites in preference to the less

soluble Mg-salts also plays a part. Many hot brine springs in the geothermally active area in around the Danakil salt pan are rich in FeCl_2 , sulphur and manganese, clearly indicating a hydrothermal interaction of saline groundwaters with volcanics and giving a bright red-orange colour to many of the mineral assemblages precipitating in and about active springs.

Inland chotts and coastal sabkhas in North Africa

Chott el Djerid in southern Tunisia is an endorheic playa where ephemeral carnallite crusts accumulate as efflorescences and intercrystalline cements in the uppermost parts of the central portions of the saline pan facies (Figure 11.5; Bryant et al., 1994a, b). The chott has an area of approximately $5,360 \text{ km}^2$ in a drainage basin with an area of $10,500 \text{ km}^2$. Mean annual rainfall for the area is 80–140 mm, the mean annual temperature is 21°C and evaporation, which is highest between May and September, has a mean annual value of 1500 mm.

Chott el Djerid is the largest in a zone of chotts formed where a series of regional aquifers emerge to create a region of discharge playas along the northeast extremity of the Bas Saharan Artesian Basin (Figure 11.6a). The basin covers most of the Algerian and Tunisian Sahara, extends into Morocco and Libya

Figure 11.5. Chott el Djerid, Tunisia, showing the extensive saline mudflat that characterises the lowermost part of this inland depression. A surface geology map of the saline mudflat in northeastern portion of this region is given in Figure 11.6c. (Landsat image courtesy of NASA).

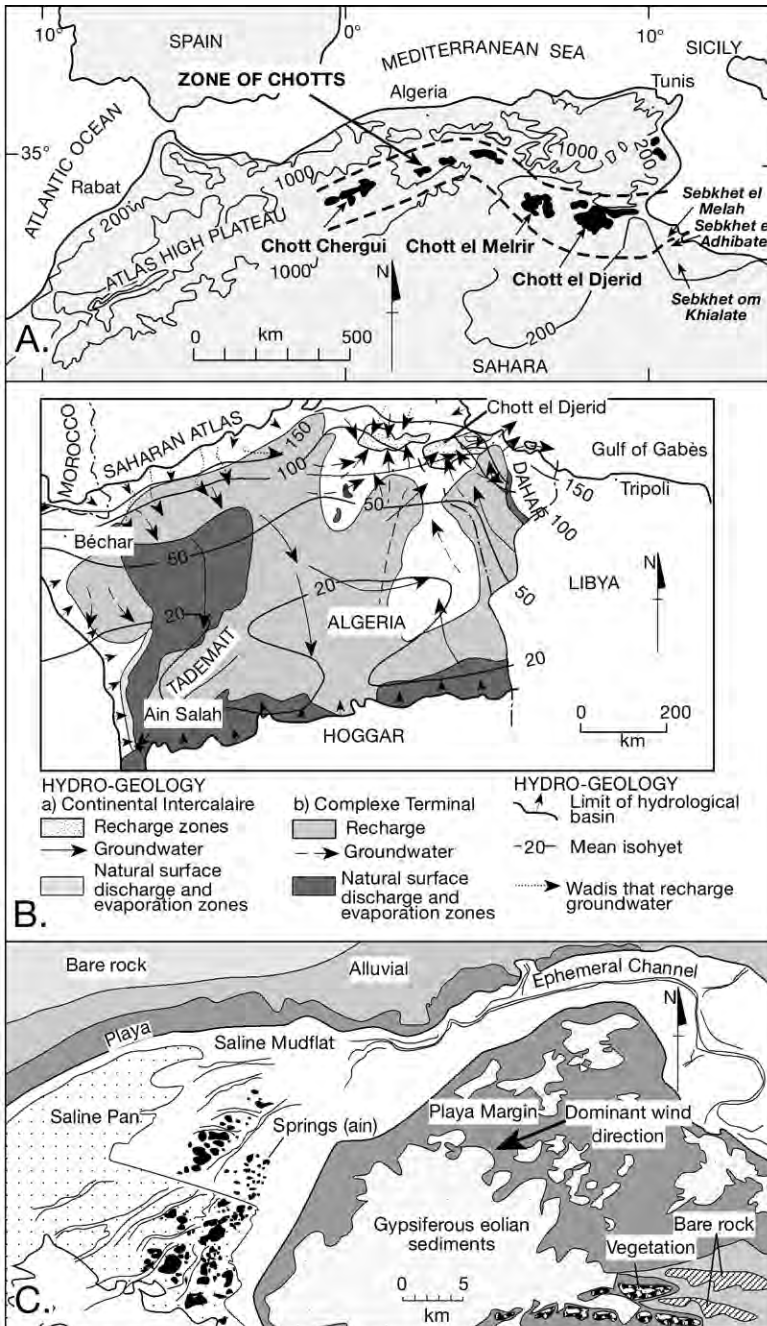

Figure 11.6. Chott el Djerid. A) Locality showing Zone of Chotts as regional groundwater outflow zone. B) Regional hydrology. C) Facies in northeastern corner of Chott el Djerid (after Bryant et al., 1994a).

and encloses the whole of the Grand Erg Oriental. The zone of chotts defines the major discharge area of the “Complexe Terminal” aquifer system, which is made up of permeable Turonian dolomites and Upper Cenomanian limestones and intercalated evaporites, along with some Mio-Pliocene sands

and conglomerates (Figure 11.6b). Discharging continental groundwaters seep into the chotts beneath the edges of thin Quaternary clay aquitards that also form the bottoms to the playas. The same clay bed facilitates temporary ponding of waters supplied by winter floods onto the central playa facies. All the chotts in the “Complexe Terminal” occupy the lowest areas on the north African interior; Chott el Melhir in Algeria is 40 m below sea level, Jar-d and Gharsah lakes in Chott el Djerid are 16 m and 21 m below sea level, respectively. Like the interior basins along the southern edge of the Great Artesian Basin of Australia, the chotts are deflationary rather than accretionary depressions and have lost something like 15-20m of late Quaternary fill via eolian deflation (Blum et al., 1998).

The lowest and more central part of Chott el Djerid is a halite pan covered with an ephemeral halite crust. It is surrounded by gypsum mudflats that in turn passes marginward into a broad evaporitic mudflat and dry sandflat. Much of the mudflat surface is covered by gypsum petees and adhesion ripples (Figure 11.6c). Parts of the sandflat are transitional into aeolian-overprinted sediments with characteristic wind-blown sand streaks, wind-rippled sand sheets mounds and shadow dunes, all of which are cross cut by wadi channels that feed surface water into the central depression during times of flood (see Chapter 3 for more detail on this ephemeral-stream-dune-saline lake association). To the north, beyond the sands flats are the low-relief alluvial fans of the Atlas foothills (Figure 11.5). To the south of Chott el Djerid is the transition into the Saharan erg, the outer edges of which are characterized by low-relief, isolated sand mounds that mostly lack well-defined slip faces and are separated by interdunal sabkhas.

A flood occurred in the northeast portion of Chott el Djerid in January 1990 after an intense storm period when more than

120 mm of rain fell (Figure 11.7) Its aftermath showed that Chott el Djerid undergoes four evolutionary stages as it desiccates to salinities where small volumes of potash salts precipitated as thin efflorescent crusts and pore cements in uppermost parts of the saline mudflat (Bryant et al., 1994a): (1) initial flooding, (2) evaporative concentration of lake waters, (3) the movement of concentrated thin brine sheets over the playa surface as a result of wind action, and (4) total desiccation of the lake by September 1990, some nine months after the initial flood.

Figure 11.7. Rainfall and lake areas recorded on the Chott el Djerid from 1987 to 1990. (after Bryant, 1999).

Surface waters and seeps in the chott have a consistent $\text{Ca-SO}_4\text{-Cl}$ rich and $\text{HCO}_3\text{-CO}_3$ poor chemistry, reflecting the recycling of older (Pleistocene - Cretaceous) evaporites within the catchment area. As the lake desiccates and shrinks, these waters concentrate to produce an Na-Mg-K-Cl-SO_4 continental brine with ionic proportions similar to those of modern seawater (Table 11.3), but the brine source is continental not marine, although the contribution from marine aerosols has not been quantified. During desiccation, saturation of surface water was reached first with respect to gypsum and then with halite and ultimately with potash minerals. The total brine volume in the chott is $\approx 5 \times 10^9 \text{ m}^3$ and average subsurface salinity $\approx 330 \text{ ‰}$. Brines tend to be more potash rich on the western side of the playa and more sulphate rich on the eastern side (Kbir-Arigoib et al., 2001). After complete desiccation, the main mineral phases in the crystal mush on the floor of the many saline pans across the surface of the chott are gypsum and halite. The ephemeral carnallite is present mostly as thin cm-scale layers within small haematite-stained areas near the centre of the various pan depressions on the chott floor (Figure 11.6c). The carnallite is ephemeral and it redissolves with each new flood of the chott. Its mode of occurrence is typical of the hydrologically decoupled mode of salt crusts in many modern artesian fed playas and its preservation potential is very low (Chapter 2).

Sabkhat om Khialate with an area of 75 km^2 is another area of minor potash precipitation. It a small sabkha depression in the interior desert, well inland of the coastal plain and south of Sabkhat el Melah (Figure 11.6a). Fed by continental waters, it is covered by a thin ephemeral salt crust a few decimetres thick, which contains a mixture of halite, gypsum, and thenardite (Na_2SO_4). Further toward the pan margin are thin efflorescent

crusts made up almost solely of the thenardite with minute amounts of carnallite.

Yet another modern area of ephemeral carnallite formation in North Africa is the near coastal mudflats of Sabkha el Melah and the smaller Sabkha el Mehabeul. Both mudflats are situated on the northern edge of the Djefara coastal plain near the town of Zarzis, Tunisia. Sabkha el Mehabeul is the more isolated of the sabkhas; today it is a continental endorheic depression and has not been hydrographically connected to the nearby Mediterranean since the Late Pleistocene. It retains preserved carnallite and kieserite interstitial cements in thin layers deposited in the last 2000 years, along with minor occurrences of magnesite and huntite (Stengele and Smykatz-Kloss, 1995; Schulz et al., 2002). The larger Sabkha el Melah is still hydrographically connected to the open sea by a channel that opens in times of flooding and turbulent seas. Where brine escapes onto the salt flat there are 6-8m dissolution holes in the surface of the sabkha edge. Brines in these sabkhat are homogeneous and contain more magnesium, potassium, and chloride than brines from other less saline coastal sabkhas (Table 11.3).

Evaporites are concentrically zoned in the sabkha salt crusts and in the upper 0.5 metres of underlying sediment. Zonation is

Locality	Na	K	Ca	Mg	Cl	SO_4
Chott el Jerid	100	9.0	0.7	12	197	12
Sabkhat el Melah	45	7.7	0.2	50	200	28
Sabkhat el Adhibate	88	3.6	1.0	12.6	150	37
Sabkhat om Khialate	43	0.8	0.4	3.3	24	74

Table 11.3. Average composition (g/l) of Tunisian chott and sabkha brines (after Kbir-Arigoib et al., 2001).

more evident in Sabkha el Melah where gypsum and anhydrite occur at the rim of the sabkha depression, while increasing amounts of halite occur towards the centres of local depressions that are ephemeral saline pans. Traces of mirabilite and carnallite can occur in the shallow subsurface sediments in the centres of some lows on the sabkha (< 1 m depth), but only in the innermost and lowermost zones of these ephemeral saline pan facies. Polyhalite also occurs in the Sabkha el Melah sediments and, like similar occurrences in Ojo de Liebre Lagoon, Mexico, it forms as a replacement of gypsum under the influence of increasingly saline pore water (Perthuisot, 1975; Pierre, 1985). The separation of the Sabkha el Mehabeul from the ocean since the Upper Pleistocene has enabled a more advanced stage of diagenetic maturity and brine evolution in its sabkha fill. Anhydrite dominates over gypsum across the sabkha and the concentric zonation of the pan minerals in local depressions is much less obvious. Notably, in both these coastal sabkhas, carnallite, is no more than a minor mineral phase and is found mostly as efflorescent crusts, with little preservation potential.

This lack of preserved bedded potash in modern marine-fed depressions characterises Holocene coastal sabkhas and salinas worldwide. Clearly, in terms of marine-fed potash deposits, the present day coastal setting is a poor key to understanding widespread bedded potash accumulations of the past (Chapter 5).

Sylvite in the Amadeus Basin, Australia

To the south of Alice Springs in the Amadeus Basin of Central Australia there are a number of small saline playas (areas < 50 km²) with thin ephemeral sylvite/glauberite crusts (Arakel and Hong Jun, 1994). Yet there are no documented sylvite crusts in any of the larger playas of the region, such as Lake Amadeus (area ≈ 750 km²). The absence of potash precipitates in the larger playas reflects the nature of the inflow hydrologies to groundwater seeps in the region (Jankowski and Jacobson, 1990). Both types of playa experience the same arid climate; median and mean annual rainfall in the region are 190 mm and 220 mm, respectively, mostly falling in summer (Dec.-Feb.); while annual evaporation is ≈ 3300 mm. All the playas are ultimately supplied by a combination of surface runoff and seepage from a large regional groundwater outflow system that discharges into this chain of playa lakes along an outflow zone some 500 km long (Figure 11.8).

The difference in the mineralogy of the surface salt crusts between the smaller and larger playas lies in the depth to

which the various playa groundwater systems tap into the regional hydrology. Throughout the artesian discharge zone, the various playa salt crusts form by capillary evaporation of resurging groundwaters. All the playa sediments entrain highly concentrated brines; typically, these are sodium-chloride rich waters with appreciable magnesium and sulphate and very low concentrations of calcium and bicarbonate (Table 2.6). The larger playas in the chain, exemplified by Lake Amadeus, have dual shallow and deep groundwater inflow paths. The smaller playas, exemplified by Spring Lake and the Na₂SO₄ lakes of the Karinga Creek drainage system, have only shallow inflow paths. Brines in the larger playas such as Lake Amadeus are continually diluted by mixing with upwelling deep groundwaters tapping into the regional hydrology (Figure 11.8). This gives larger playas a stable recharge hydrology so that halite saturation rarely occurs in the playa sediments and thick halite crusts cannot form (Chapter 2). In contrast, smaller playas tend to be uncoupled from the deep recharge system so pore saturation with respect to gypsum/halite is reached rapidly in the capillary zone of their mudflats (e.g. Spring Lake). Subcropping groundwaters in both lake Amadeus and Spring Lake are undersaturated with respect to glauberite and sylvite. Yet both minerals accumulate as ephemeral efflorescent crusts about the edges of Spring Lake not Lake Amadeus due to its inherently higher local salinities and its rapidly transitioning lake surface, which because it is located well above the regional groundwater discharge level can attain short-term bittern saturation (Figure 2.14). The continual recharge of artesian waters beneath both small and larger playa depressions of this region means there is little longterm preservation of any salts, and zero potential for potash preservation.

The hydrology of the large central Australian playas, and, for the same reasons, the artesian outflow hydrologies of the salt lakes/playas to the south such as Lake Eyre and Lake Frome are just not suitable settings for the longterm accumulation of thick beds of potash salts. Their position in zones of regional meteoric outflow means they are too fresh and too deflationary and the underlying groundwater prism is too fresh to allow thick sequences of bedded salts to accumulate. Similarly unsuitable seepage hydrologies are also why there are no substantial bedded accumulations of Quaternary potash in the Chotts of Tunisia. As we discussed in Chapter 5, you need a deep depression with a saline feed and a stable hypersaline brine curtain to accumulate thick sequences of bedded salts, and in the case of potash salts that brine curtain must be maintained at the upper bittern end of the concentration range. Zones of shallow rising meteoric groundwaters never underlie such systems.

Figure 11.8. Lake Amadeus, Northern Territory, central Australia. This salt lake lies in a drainage chain that forms the central part of the 500-km long groundwater outflow belt (and palaeochannel network) along the northern edge of the Victoria desert. (Landsat image courtesy of NASA).

Potash from brine pumping

Potash is not only mined, it is also produced by brine processing in solar evaporation pans. A mother brine liquor can be pumped into solar evaporation pans from nearby salt lakes or salt flats, as for example, potash produced by the solar concentration of Dead Sea waters (Figure 11.9). Or mother brine can be extracted by solution mining of potash horizons some hundreds of metres below the surface, as it is in operations near Moab, USA, and in the Belle-Plaine operation near Regina, Canada where a brine is recovered from the Prairie potash at a depth of 1800m. Often, the solution recovery exploits potash source beds not suitable for extractive mining due to great depth, structural complexity or propensity for water flood in a precursor conventional mine. The latter was the case at Patience Lake Mine in Saskatchewan, Canada, where two floods in the mid 1980s closed down the conventional mine operation. The former underground mine workings were abandoned and allowed to fill with water so that in 1988 the operation converted to a solution mining/brine recovery setup.

Whatever the brine source, in order to recover potash once the brine is at the surface, it must be subjected to varying combinations of mechanical crystallisation, natural crystallisation (solar evaporation) and flotation. A series of linked fractionation ponds have been built to concentrate Dead Sea brine to the carnallite stage in the Southern Basin of the Dead Sea (Figure 11.9). This is done by the Dead Sea Works Ltd. (DSW), at Sedom on the

Israeli side, and by the Arab Potash Company (APC) at Ghor al Safi on the Jordanian side. Potash is extracted from carnallite slurries created by sequential evaporation in a series of linked, gravity-fed fractionation ponds. The area of the concentration pans is some 130 km², within the total area of 1,000 km² of the Dead Sea floor. The first stage in the evaporation process is pumping of Dead Sea water into header ponds to the gravity-fed series of artificial fractionation pans that now cover the Southern Basin floor. Saturation stages of the evolving brines are monitored and waters are moved from pan to pan as they are subject to the ongoing and intense levels of natural solar evaporation (Figure 11.10b, c; Karcz, 1987). As it concentrates, minor gypsum, then voluminous halite precipitates on the pan floor. Unlike seawater feeds to conventional coastal saltworks with salinities $\approx 35\%$, the inflow brine pumped to the header ponds from the Dead Sea already has a salinity that is $>300\%$. Massive halite precipitation occurs once the brine attains a density of 1.235 ($\approx 340\%$) and reaches a maximum at a density of 1.24 (Figure 11.10b). Evaporation is allowed to continue in the halite header ponds until the original water volume pumped into the pond has been halved, then the concentrated brine is pumped through a conveyance canal into a series of smaller evaporation ponds where carnallite, along with minor halite and gypsum precipitates (Figure 11.10c).

The resulting carnallite ($\text{KCl}\cdot\text{MgCl}_2\cdot 6\text{H}_2\text{O} + \text{NaCl}$) is crushed, slurried with the residual brine and then filtered using floating

Figure 11.9. Evaporation pans at the southern end of the Dead Sea. The water surface in the Dead Sea is around 415 m below sea level; the Southern Basin is covered only by a thin ephemeral brine sheet maintained by pumping of brines from the Northern Basin where waters attain depths of more than 300m, seafloor isobaths are in metres below sea level (Landsat image courtesy of NASA).

dredges, which then pump the slurry from the pans to the refining plant. This raw product is used to manufacture potash, salt, magnesium chloride, magnesium oxide, hydrochloric acid, bath salts, chlorine, caustic soda and magnesium metal. Residual brines after carnallite precipitation contain about 11-12 g/l bromide and are used for the production of bromine, before the waste brine is returned to the Dead Sea. Israeli potash production currently exceeds 1.3 million tonnes per year while Jordanian production is around a million tonnes per year.

Potassium chloride (mostly sylvite) was originally refined from the carnallite slurry by hot leaching or flotation at the Dead Sea Works, but with a purer carnallite feed, sylvite is now produced more economically in a cold crystallisation plant. Sylvite is produced in the early stages of slurry processing by addition of water to dissolve the magnesium chloride. If the carnallite slurry contains only a small amount of halite, the solid residue that remains after water flushing is mostly sylvite. Successful cold crystallization depends on a high quality feed. If a large amount of halite is present in the feed slurry, the resulting solid residue is sylvinite, not sylvite. This needs to be further

refined by hot crystallization, a more expensive extraction method based on the fact that the solubility of sylvite varies greatly with increasing temperature, while that of salt remains relatively constant (Figure 11.10a). Potash brine is hot leached from the sylvinite, the remaining halite filtered off, and the brine is cooled under controlled conditions to yield sylvite.

Residual brine then undergoes electrolysis to yield chlorine, caustic soda and hydrogen. Chlorine is then reacted with brine filtered from the pans to produce bromine. The caustic soda is sold, and the hydrogen is used to make bromine compounds, with the excess being burnt as fuel. Bromine distilled from the brine is sold partly as elemental bromine, and partly in the form of bromine compounds produced in the bromine plant at Ramat Hovav (near Beer Sheva). This is the largest bromine plant in the world, and Israel is the main exporter of bromine to

Europe. About 200,000 tons of bromine are produced each year. Residual magnesium chloride-rich solutions created by cold crystallisation are concentrated and sold as flakes for use in the chemical industry and for de-icing (about 100,000 tons per year) and dirt road dedusting. Part of the $MgCl_2$ solution is sold to the nearby Dead Sea Periclase plant (a subsidiary of Israel Chemicals Ltd.). At this plant the brine is decomposed thermally to give an extremely pure magnesium oxide (periclase) and hydrochloric acid.

The artificial salt ponds of the Dead Sea are unusual in that they are designed to trap and discard most of the halite precipitate rather than harvest it. Most other artificial salt ponds around the world are shallow pans purpose-designed as ephemeral water-holding depressions that dry out so that halite can be scrapped and harvested. In contrast, the Dead Sea halite ponds are purpose-designed to be permanently subaqueous and relatively deep ($\approx 4m$). Brine levels in the ponds vary by a few decimetres during the year and lowstand levels generally increase each winter when waste brine is pumped back into the northern basin.

When the plant was first designed the expectation was that halite would accumulate on the floor of the early fractionation ponds as horizontal beds and crusts, beneath permanent holomictic brine layers. The expected volume of salt was deposited in the pans each year (Talbot et al., 1996), but instead of accumulating on a flat floor aggrading 15-20 cm each year, halite in some areas built large numbers of macroscopic mounded reefs (salt mushrooms; Figure 1.25). Then, instead of each brine lake being homogenized by wind shear across these large subaqueous ponds, the salt reefs separated the larger early ponds into thousands of smaller polygonal compartments in which the brines developed different compositions. Carnallite slurries crystallized in reef compartments from where it could not be easily harvested, so large volumes of potential product were locked up in the early fractionation ponds. Attempts to drown the reefs by maintaining freshened waters in the ponds during the winters of 1984 and 1985 were only partly successful. The current approach to the salt reef problem in the early fractionation ponds is to periodically breakup and remove them by a combination of blasting and dredging.

In Israel, Dead Sea Salt Work's (DSW) production rose to 2.9 Mt KCl in 2000, continuing a series of increments from the previous four years and reflecting an investment in expanded capacity, the streamlining of product throughput in the mill facilities, the effects of dredging of salt mushrooms, and increased salinity of the Dead Sea due to extended drought conditions. On the other side of the truce line in Jordan, the Arab Potash Co. Ltd. (APC) output rose to 1.9 Mt KCl in 2000. APC is also in the process of removing salt mushrooms from its ponds which, when completed will increase carnallite capacity by over 50 000 t/y. The company is continuing with an expansion program aimed at increasing potash capacity to 2.5 Mt/y by late 2005.

Brine extraction for potash with subsequent solar pan concentration also takes place on the edges of Great Salt Lake and the Bonneville Salt Flats in Utah (Figure 4.17). On the east and west shores of Great Salt Lake near Ogden, Utah, brines are concentrated in the more than 160 km² of solar ponds within a total area of 4,100 km² of the Great Salt Lake. During normal summer conditions, 90% of the halite present in the

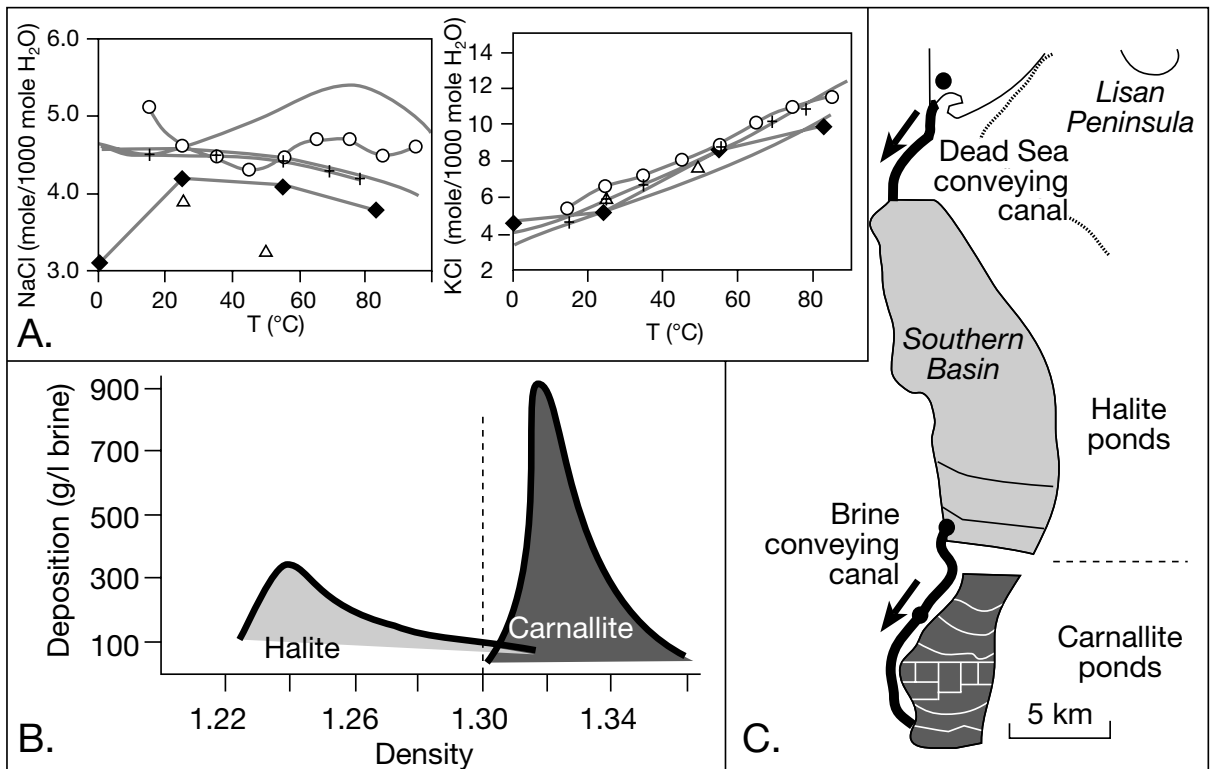

Figure 11.10. Dead Sea potash chemistries and fractionation. A) Halite solubility does not change greatly with temperature while KCl solubility trebles over the same range. B) Showing the relationship between increasing concentration (density) and the transition from halite to carnallite precipitation. C) Design of sequential evaporation pans at the Israeli Sedom plant, southern Basin of the Dead Sea (after Karcz, 1987).

brine is precipitated with little contamination by other salts. Mirabilite is a winter precipitate in the ponds. Once potassium salts begin to precipitate from the saturated brine they form a complex mixture of double salts, such as kainite, schoenite and carnallite, while magnesium precipitates as bischofite, a highly hydrated magnesium chloride. This salt sequence is one of the more complicated solar pond systems in the world. Various salts are sequentially extracted from the fractionation stream and purified to produce the following end products; sodium chloride, potassium sulphate, sodium sulphate and magnesium chloride hexahydrate.

Formerly the solids were harvested from the Great Salt Lake pans using front-end loaders and trucks, and transported to the processing plants. Recently, the Behrens Trench was completed, this is a 35 km underwater canal on the floor of the Great Salt Lake that transports saturated brine product from the western shore solar ponds across the lake to its processing facilities on the eastern shore. Since 2000 the Great Salt Lake plant has produced more than 550,000 tonnes of sulphate of potash. But the earlier history of salt workings about the strandline of Great Salt Lake illustrate one of the major problems in solar pond extraction atop saline mudflats in continental lakes. Record floods in 1984 filled the ponds with fresh water and destroyed much of the infrastructure. Harvesting did not recommence until the early 1990s. Rapid and at times substantial changes in lake level are endemic to saline lacustrine systems and must be planned for in the development of a saltworks.

Potash is also produced by evaporative concentration of solution-mined brine extracted from Pennsylvanian potash evaporites in Paradox member of the Hermosa Formation in the Cane Creek anticline in the northern part of the Paradox Basin in Utah near the town of Moab. There are at least 29 evaporite cycles in the Hermosa Formation, which are dominated by varying combinations of limestone, dolomite anhydrite and halite. Potash occurs near the top of 18 of these cycles, all located immediately above a thick halite bed (Raup, 1966). Eleven of the 18 are of sufficient thickness and quality to be considered economic. The target potash bed is a 3.4m-thick sylvinite bed some 1200 m below the surface and averaging 25-30% K_2O . Salt beds in the halokinetic Cane Creek anticlinal core are characterised by numerous discontinuities and faults and can dip quite steeply.

The Utah brine operation began in 1972, when an unsuccessful conventional mine was abandoned, flooded and converted to the current solution mined- evaporation processed operation. The former mine was not successful due to the high degree

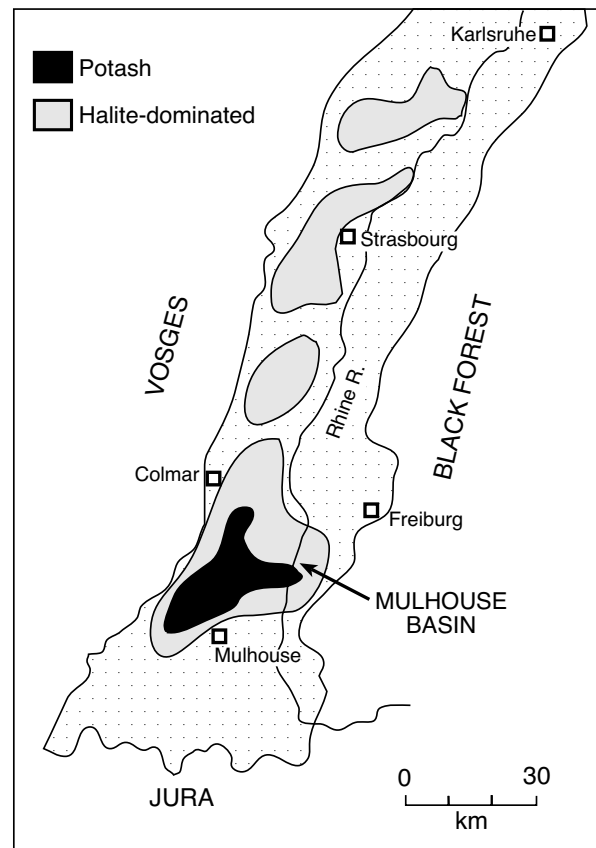

Figure 11.11. Mulhouse Basin, Rhine Graben, showing how the potash dominant section is the southernmost of a number of bedded halite deposits in the graben (see also Figure 5.3).

of deformation of the target ore horizon, which consists of sylvinite layers 2.5-15 cm thick alternating with anhydrite layers less than 3 mm thick. The ore is overlain by 12 m of shaly dolomite and underlain by 43 m of halite. Fold wavelengths are ≈ 30 -120 m and amplitudes range from 6-30 metres (Evans and Linn, 1970). The decision to convert the conventional mine, which had begun operations in 1965, to a solution mine was made after 550 km of 2.7 x 4.9 m rooms and entries had been completed and a number of potentially dangerous "gassy" (methane) intersections had occurred. Brines are today pumped to the surface where they are evaporated in solar pans with the resulting slurry flotated and purified. Solution mining for potash is also profitable in Saskatchewan, where solution mining operations have been active at Belle-Plaine since 1964 and in the abandoned Patience Lake Mine since 1988.

Ancient (Pre-Quaternary) potash

The salt works in the southern end of the Dead Sea are highly efficient producers of potash and account for more than 10% of

the world's annual production. But the other 90% comes from the extraction and mining of potash from ancient evaporite successions. Many of which are saline giants, such as the Canadian deposits and have no modern counterpart (Chapter 5). We shall now look at some of the more important of these ancient potash occurrences.

Rhine Graben

Oligocene evaporites in the Mulhouse Basin in the Rhine Graben contain sylvite with subordinate carnallite, but lack the $MgSO_4$ salts characteristic of the evaporation of modern seawater (Figure 11.11). The Rhine Graben is a Tertiary rift, some 150 km long and 10-25 km wide that straddles the Franco-German border as it runs from Basle in Switzerland to Frankfurt in Germany. With an area of 400 km², the Mulhouse Basin is the southernmost of a number of Oligocene evaporite basins that occupied the graben depression. Total fill of Oligocene lacustrine evaporites is some 1,700m and is dominated by anhydrites, halites and mudstones. The sequence is underlain by Eocene continental mudstones with lacustrine fossils and local anhydrite (Lowenstein and Spencer, 1990; Hardie, 1990; Gely, et al., 1993).

The Oligocene halite section includes two thin, but important, potash zones: the Couche inferieure (Ci; 3.9m thick), and Couche superieure (Cs; 1.6m thick; Figure 11.12). Both potash beds are made up of stacked, thin, parallel-sided cm-dm-thick beds (averaging 8 cm thickness), which are in turn constructed of couplets composed of grey-coloured halite overlain by red-coloured sylvite. Each couplet has a sharp base that separates the basal halite from the sylvite cap of the underlying bed. In some cases the separation is also marked by a bituminous parting. The bottom-most halite in each dm-thick bed consists of halite aggregates with cumulate textures that pass upward into large, but delicate, primary chevrons and cornets. Clusters of this chevron halite swell upward to create a hummocky boundary with the overlying sylvite. The sylvite member of the couplet consists of granular aggregates of small clear halite cubes and rounded grains of red sylvite (with some euhedral sylvite hoppers) infilling the swales in the underlying hummocky halite. The sylvite layer is usually thick enough to bury the highest protuberances of the halite, so that the top of each sylvite layer, and the top of the couplet, is flat. Dissolution pipes and intercrystalline cavities are noticeably absent, although some chevrons show rounded coigns. Intercalated marker beds formed during times of brine pool freshening are composed of a finely laminated bituminous shale with dolomite and anhydrite.

Figure 11.12. Typical section through the potash intervals of the Upper Salt. The log also illustrates the amount and style of total organic carbon (TOC%) extracted from marly layers in the various units. Curve is smoothed using a moving three point average (after Gely et al., 1993).

The sylvite-halite couplets appear to record unaltered settle-out and bottom-growth features of a primary chemical sediment that accumulated in a shallow perennial surface brine pool.

The sylvite layers, like the halite layers, are interpreted as primary subaqueous deposits (Lowenstein and Spencer, 1990). Based on their crystal size, the close association with cumulate halites in the sylvite layers, and the manner in which they mantle underlying chevron halites, sylvites are interpreted as precipitates first formed at the air-brine surface (or within the upper brine) that then sank to the bottom to form well sorted accumulations. Similar cumulate sylvite deposits are found on the floor of modern Lake Dabuxum in China during its more saline phases (Figure 11.2). The current mosaic textural overprint in the Mulhouse sylvite layers was probably produced by postdepositional modification of the crystal boundaries, much in the same way as mosaic halite is formed by recrystallisation of raft and cumulate halite during shallow burial (Figure 1.18). Inclusion studies in both the sylvite and the halites average 63°C, suggesting solar heating of surface brines as precipitation took place. Similar high at-surface brine temperatures are not unusual in many modern brine pools, especially those subject to periodic density stratification and heliothermometry (Figure 2.48).

TOC values in the sylvite interval also imply preservation of a primary sylvite deposit. TOC levels fluctuate in a rhythmic

manner related to the salinity of the depositional brines (Figure 11.12; Gely et al., 1993). The highest TOC values are found in marls near the top of the clay-anhydrite layers and the lowest values are recorded near the top of the halite-rich beds where the sylvite (and the highest brine concentrations) would have occurred. The organic matter is mainly algal (A and B groups), while a third category of organic material (C group) is derived from a mixture of continental inflow and in situ bacterial productivity. The sylvite bed (Ci) occurs at the transition from Type B to Type C, indicating a change of brine chemistry from the hypersaline brines of the halite/sylvite pans to the freshened waters that precipitated the more organic-rich marls (See “feast and famine” discussion in Chapter 9).

Khorat Plateau, Thailand

Potash in the halite-dominated Cretaceous Maha Sarakham Formation is preserved within two basins: the northern Sakon Nakhon Basin (which also extends into Laos) and the southern Khorat Basin. These basins underlie much of the Khorat Plateau in NE Thailand and are separated by the highlands of the Phu Phan Range (Figure 11.13a). It is likely that a single larger evaporite basin encompassing at least the area of the

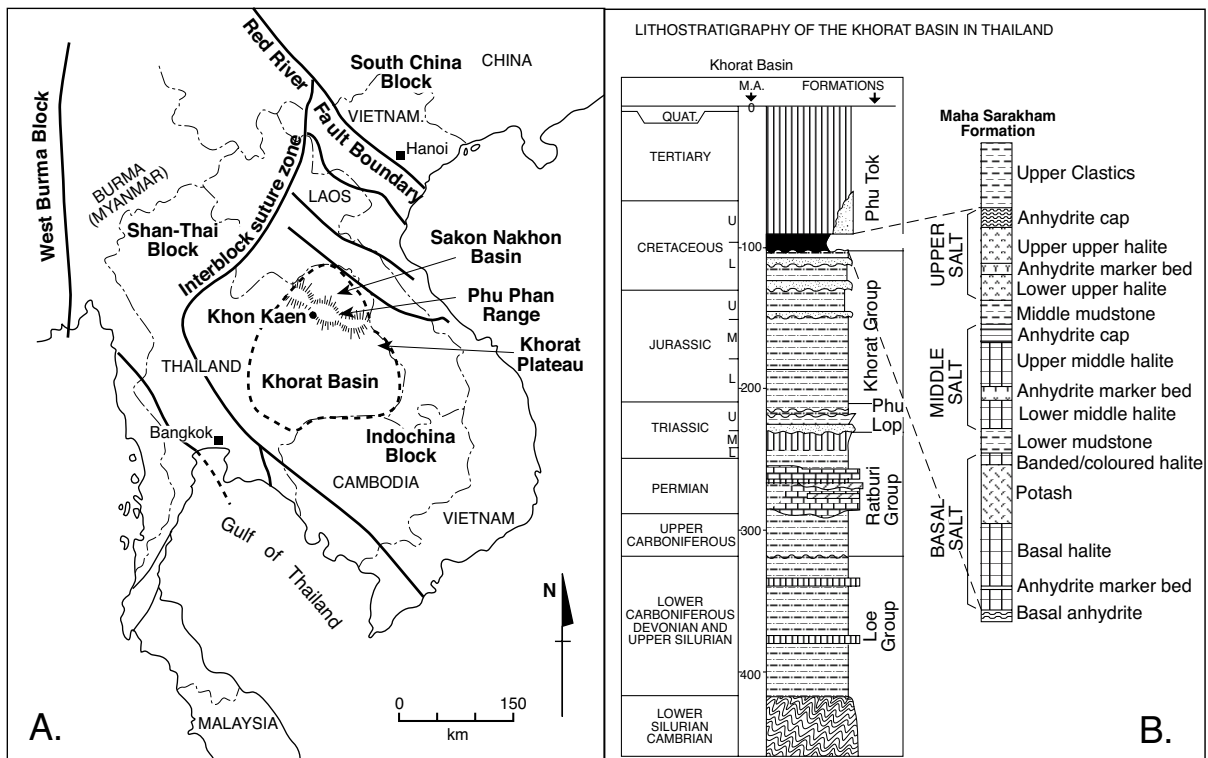

Figure 11.13. Potash in Thailand. A) Locality map showing location and tectonic setting of the Khorat Plateau, the Khorat Basin and the Sakon Nakhon Basin. B) Stratigraphy of the Khorat Basin and the Maha Sarakham Formation, NE Thailand (after Mouret, 1994; Suwanich, 1986).

Figure 11.14. Seismic image of Maha Sarakham Formation, from the Khon Kaen area showing a salt pillow in the Lower Salt Member and the syndepositional reduction in sedimentary thickness in units above this structure (seismic line supplied by CRA-RTZ).

present day Sakon Nakhon and Khorat Basins existed at the time of deposition. These deposits represent one of the last saline giants preserved in SE Asia and suggest an extreme arid period during Cretaceous time within a subsealevel marine-fed depression, possibly created by transpressional collision events that preceded the Himalayan Orogeny (see Morley, 2004 for possible timing of collision). The evaporite sequence lacks $MgSO_4$ salts consistent with our current understanding of the evolution of Cretaceous seawater chemistry (Figure 2.30). The current margins of both basins are dissolutional, as are the upper and lower contacts of the salt units.

In those parts of the stratigraphy largely unaffected by evaporite dissolution the Maha Sarakham is composed of three salt beds—Lower, Middle and Upper Salt members—each overlain by a clastic mudstone—Lower, Middle and Upper Clastic members—(Figure 11.13b). Where the Maha Sarakham has not been thinned, either by dissolution or salt flow, it is 250–300 m thick. In areas of salt dissolution it thins to <100 m, while in halokinetic regions it can be more than a kilometre thick (Figures 7.29, 11.14). Evaporite minerals include halite; the sulphates gypsum and anhydrite, along with a variety of halite-hosted potash phases dominated by carnallite and sylvite with accessory tachyhydrite. Portions of the bedded halite display intricate depositional, dissolutional and diagenetic features that rank amongst the most pristine I have seen preserved in an ancient evaporite (Figure 11.15).

Middle and Upper Salt members are generally flat lying and correlatable from well to well. In contrast, seismic and geomorphologic analysis shows that the Lower Salt of the Maha Sarakham has flowed in some parts of the basin so that thicknesses are much more variable from well to well (Figure

11.14). Textures in the Lower Salt Member range from well preserved depositional textures in its upper part immediately below the potash entraining intervals to pervasive flowage features lower in the section. Petrographic evidence for salt flowage includes overburden-controlled elongate flattening of crystals and pervasive halite recrystallisation that has destroyed original bedding features. In wells that pass deeper into the Lower Salt Member there is often a transition down core from pristine depositional textures into flowage textures, implying that flow into the pillows was fed mostly from the deeper parts of the Lower Salt Member. This is also consistent with the upper portions of the salt unit still being deposited while the lower parts of the same unit were flowing.

At the regional scale, the halokinetic features follow curvilinear trends that are typically subparallel to the present basin margin. Some pillows in the Lower Salt Member, especially those associated with sylvinite along the western margin of the basin, were probably syndepositionally initiated, as they are truncated by sediments of the Lower Clastic Member (Figures 11.13b, 11.14). Locally, other salt flow features are probably still active today, driven by laterally shifting surface river systems, including the Mekong and its tributaries. For example, $CaSO_4$ caprocks outcrop today in Laos in the erosional riverbanks of the Nam Theun river one of the major tributaries to the Mekong (pers. obs; Figure 7.7c).

Initiation of the salt flow in the Maha Sarakham halite is probably diachronous and driven by sediment loading from various depocentres moving across the salt bed. In the Cretaceous the depocentres were tied to the deposition of the Lower Clastic Member; today they are tied to the fluvial deposits of the Mekong and its tributaries. Such feedback systems

Figure 11.15. Typical multistage dissolution collapse and fill in Maha Sarakham Fm. by chevron halite. Cavities are sometimes filled by clear sylvite, not halite.

between depositional loading (sediment thicks) and salt buildups (pillows and anticlines) and salt dissolution characterise the western margin of the Maha Sarakham in the vicinity of Khon Kaen (Figures 11.14). As well as being seen seismically, the relationship between surface landform and the underlying structuring of the salt can be imaged using currently available topographic maps, aerial photography and satellite imagery.

Like much of the halite in the Maha Sarakham, the petrography, depositional style and preservation quality of potash in the Lower Salt Member has been complicated by dissolution and halokinesis (Hite and Japakasetr, 1979; Sessler, 1990; El Tabakh et al., 1995; Utha-aroon et al., 1995). In terms of the potash minerals, carnallite dominates over sylvite throughout the basin, while traces of tachyhydrite are also found preserved as enclosed euhedral to subhedral crystals in halite.

Potash is widely dispersed as minor shows across the

basin. The only well studied and significant potash-rich zones are in the upper section of the Lower Salt Member along the western margin of the Khorat Plateau. The potash interval is dominated by carnallite (up to 20-30m thick), which forms a widespread stratiform unit along the western margins of both the Khorat and Sakon Nakhon basins. It is locally capped by lesser sylvinite (< 6 m) and covered by a bed of colour-banded red and grey halite (up to 6 m thick). This colour-banded halite preserves pristine depositional textures and is in turn overlain by the Lower Clastic Member.

A complete interval in the potash-entraining region at the top of the Lower Salt Member is divisible into (Figure 11.13b):

- (4) Uppermost colour banded halite (0-6m),
- (3) Sylvinite zone (0-6m),
- (2) Carnallitite zone (0 up to 15-30m),
- (1) Lower zone of massive to bedded halite with traces of carnallite (50-300m).

The lower zone (1), is dominated by massive, colourless, inclusion-free halite, which is made up of stacks of beds 0.2-0.5 m thick. The upper portion of this halite interval retains pristine depositional textures, including aligned bottom-nucleated growth forms, clay dissolution stringers and microkarst pits. This halite zone is underlain by clean recrystallised mosaic halite, which may stack into intervals that are hundreds of metres thick in halokinetic zones. Often this clean halite is dominated by biaxially flattened or necked and recrystallised lensoidal textures, a texture indicative of salt flow. Minor anhydrite stringers and nodules (≈ 1 cm thick) crosscut the axes of cores often with steep inclinations that also suggest flowage. This form of anhydrite is microcrystalline and lacks any of the original gypsum ghost structures so well preserved in thicker regional marker beds, especially those in the middle and upper halite members (Figure 11.13b).

The carnallitite zone (2) is typically 15-25 m thick near the western edge of the current structural basin but can also disappear near the outermost parts of the basin where it has been dissolved by surface driven crossflows of meteoric water. Three types of halite are found in the carnallitite zone: (a) inclusion-rich, cloudy, chevron halite; (b) clear, recrystallised, coarsely crystalline halite; and (c) granular, fine-grained halite. The first typifies preserved bottom-nucleated beds, the second typifies massive halite beds with poorly defined upper and lower contacts and suggests textures associated with macro and micro karstification, while the third type is found as disseminated halite in carnallite-filled voids. Anhydrite and other insoluble residues are scarce in the carnallitite zone. Halite that hosts carnallite is often crosscut by dissolution surfaces, clay stringers, collapsed halite beds and karst cavities can be coated with microcrystalline to coarsely crystalline carnallite (Figure 11.15).

Many of the carnallite-filled voids are subvertical and narrow downward. This implies a syndepositional vadose karst prior to the precipitation of the carnallite cement. Textures in this zone are identical to those found in the bedded potash deposits of the modern Qahan Playa and indicate the water table was subject to large oscillations. The carnallitite interval in the Maha

Sarakham was subject to syndepositional brine freshening, subaerial exposure and water table lowering related to climatic changes and tectonic tilting in the depositional basin.

The sylvinite zone (a mixture of halite and sylvite) directly overlies the carnallite zone and is up to 6 m thick. It is not always present. Its contact zone is transitional with the underlying carnallite zone, although sylvite crystal-clusters in the transition zone typically show sharp non-horizontal edges. Sylvite is present in its halite host as: a) individual and small crystal clusters of up to 1 cm size, making up amoeboid-shaped forms; b) coarsely crystalline massive beds up to 5 cm thick; c) even layered, thick beds of up to 4 cm thick; d) irregular medium to coarsely crystalline patches within massive halite beds and as patches sometimes rimming preexisting carnallite crystals; and e) massive sylvite units up to 25 cm across. In almost all cases, dark grey clayey matrix surrounds the larger sylvite crystals and/or alternates with the subhorizontal sylvite beds. Petrographically, sylvite crystals exhibit euhedral crystalline forms, either as individual crystals or as clusters of crystals.

At the transition between the carnallite and sylvinite zones some dissolution cavities can be 25 cm across (in core) and filled with single clear sylvite crystals. Higher in the sylvinite interval the sylvite tends to occur as stratiform primary layers showing subhorizontal bedding, and ranges from 10 cm to 1 m thick. Individual primary sylvite crystals can reach up to 2 cm in size in the primary layers. Macroscopically, sylvite layers are not homogeneous and several types of sylvite may coexist within single layers along with fine clastic components and halite.

Halite beds alternating with sylvite layers range in thickness from 1 cm to 15 cm. Where not destroyed by the processes of dissolution and recrystallisation, these halite beds can still exhibit relict bedding and occasionally are milky from inclusions in the preserved chevrons. But most of the halite in the sylvinite zone is clear and coarsely recrystallised, with geometries suggesting repeated episodes of dissolution followed by precipitation as passive void-fill cements. Traces of anhydrite are present throughout the sylvinite zone, along with traces of tachyhydrite. Anhydritic cm-diameter nodules are locally present, as are white nodules dominated by microcrystalline borate minerals (boracite and tyreskite).

More than one sylvite-rich interval may occur in the sylvinite zone. Workers in the region who have used a strict stratigraphic approach have often reported intervals with more than one sylvite layer as representing fault-repeat sections. Such an

approach underscores the limitations of using a non-process based layer-cake stratigraphy in an evaporite succession. What is occurring is not associated with a fault-repeat of a single sylvite bed, but the vagaries of a sylvite-filled anastomose karst system being intersected a number of times in a single core. Contacts of many of the so-called repeat beds show classic insoluble-rich geopetal linings.

Colour banded halite (4) constitutes the uppermost part of the Lower Salt Member. It is coarsely laminated and retains pristine depositional textures (mostly chevrons) with little or no evidence of recrystallisation. There is often a sharp upper dissolution contact with the overlying Lower Clastic Member, defined by a diagenetic horizon made up of anhydritic dissolution residues (see Chapter 7).

The origin of the richest sylvite zone (3) is related in part to the action of actively refluxing, possibly freshened brines working on an actively rising (pillowing) carnallite/halite precursor. For example, in the Khon Kaen region (Figures 11.14, 11.16a), the Lower Salt Member has flowed into a pillow structure and the overlying strata are truncated beneath an alluvial cover. The synclinal structure associated with the rim of this pillow is also a zone where sylvinite thickens at the expense of the underlying carnallite (Figure 11.16a). This sylvinite is capped by the Lower Clastic Member, which is in turn capped by the Middle Halite Member. Core from the Middle Halite Member in this region shows predominantly undisturbed subhorizontal bedding and still retains perfectly preserved primary textures, such as chevrons and halite intercrystal karst, along with a regional dm-thick marker bed made up of subaqueous swallowtail gypsum pseudomorphed by halite/anhydrite (pers. obs. of core).

Facies geometries suggest that sylvite deposited along the western margin of the Khorat Plateau was: a) precipitated after the deposition of the carnallite; b) prior to deposition of the Lower Clastic Member; c) fed from lateral inflow, probably driven by a potentiometric head generated by relative uplift of an adjacent growing salt pillow; d) related to the cannibalisation of the uplifted carnallite bed atop a growing salt pillow; e) precipitated early, either as pond-bottom nucleates and floundered raft cumulates or as downward-fluxing karst-filling cements in the rising margins of the brine pool; and f) then covered by subaqueous colour-banded halite, fed via the dissolution of halite from a now carnallite-depleted pillow crest (Figure 11.16b). Sylvite precipitation was driven both by solar evaporation on the pond floor (as in the Mulhouse Basin) and by subsurface cooling of downward flushing potassium-saturated brines (as in the Qaidam Basin). Similar potash recycling into

Figure 11.16. Sylvite controls in the Maha Sarakham Formation along the western margin of the Khorat Plateau near Khon Kaen, Thailand. A) Generalised schematic of current sylvite distribution based on well data in the region. B) Sequential development of pillow and the erosion of crest facies controlling first the formation of sylvite and then the colour banded halite within brine-entraining rim syncline depressions (see text for full explanation). Schematic based on author's research and field work in the region.

modern playa depressions in rim synclines is occurring around outcropping crests of diapirs fed by Miocene salt in the Qum Kuh region of central Iran (Figure 3.62). The Iranian potash is probably reworked from a Miocene source layer in the diapiric salt (Rahimpour-Bonab and Kalantarzadeh, 2005).

In terms of potash exploration in Khon Kaen region and elsewhere in Thailand, it is important to note that the thickest potentially exploitable sylvinite fairways lie in rim synclines adjacent to syndepositionally breached salt pillows. They do not form laterally extensive horizons and are not akin to the Devonian sequences of Canada discussed in the next section. These pillows were deforming the carnallite zone and uplifting previously formed carnallite beds into a periodically refreshed

hydrological setting. Simultaneously, sylvite was precipitating on the pan floor and in karstic voids in the halite about the pan rim. It was the super-imposed pillow hydrology that was karstifying the halite at the same time that the upper portion of the carnallite member was dissolving and supplying K-rich brines to the pool floor. The raising of the sedimentation surface, via pillowing, explains why some of the sylvite forms clear coarse-crystal fills in large karst holes in the halite, while other sylvite is a primary precipitate.

The potash geology of the Maha Sarakham has a number of technological challenges for a conventional sylvite mining operation. Its geology should be carefully and publicly documented before the onset of any major mining operation. Maha Sarakham potash tends to occur in the upper part of the lower halite unit, and about the current dissolutional edge of the basin it is sometimes without a substantial thickness of halite atop the potential ore interval. Such a halite bed is a required back when mining as it can support the mine roof as ore is extracted. Mine backs are typically more than 5-10m of halite above the potash level in mines in Canada and New Mexico and 1-2 metres in the robotically extracted potash ores of the Boulby Mine, UK. The overlying

lower clastic unit in the Thai succession is typically not well-indurated sediment, so maintaining mine headwall stability should be a major consideration in mine planning. Likewise, tilting, dissolution and flowage of the Lower Salt means some sylvite layers show bed inclinations of up to 70° to 80° to the drill core axis, implying sylvinite beds have dissolved or flowed. This means the bed thicknesses must be ascertained as a true thickness and not be indicated solely by assay thickness in core or wireline intersections in wells. Such high dips are also problematic in designing a mine plan utilising conventional mine equipment where access and assumptions of stratiform stratigraphy dominate. Within areas where depths to be mined are as shallow as 350-400 metres there may be long term

problems of ground subsidence (see problematic mines and brinefields in Chapter 12). Further out in the basin there may be some intervals of potash in the Maha Sarakham Formation that are more deeply buried and more amenable to solution mining, rather than conventional room and pillar extraction. To date, this has not been the focus of any potash exploration programme in Thailand. All studies of the feasibility of extracting potash in the last three decades have focused on shallower areas of potash about the dissolution overprinted basin edges, where potash tends to occur at depths more amenable to conventional mining (e.g. planned operations at Bamnet Narong and Udon Thani).

Permian potash, Europe and North America

The Zechstein Basin stretches from northern Britain, south-east across the North Sea through the Netherlands, Denmark, Germany and Poland to the edge of the Hercynian massifs (Harz, Rhine and Bohemian mountains). Potash extracted from the Permian Zechstein evaporites provides 20% of the world's potash. The Zechstein succession was deposited in a huge drawdown seaway and is today made up of four evaporite cycles: the Z1-Werra Series, Z2-Stassfurt Series; Z3-Leine Series and Z4-Aller Series (Figures 5.48, 5.49). Each has a general sequence of clastics, carbonates, one or two phases of sodium and potassium salts, regressive halite or anhydrite, and carbonate. Potash beds of Z1 and Z2 are primarily composed of sylvite (KCl), carnallite ($KCl \cdot MgCl_2 \cdot 6H_2O$) and kieserite ($MgSO_4 \cdot H_2O$) and rapid lateral changes are common. The Zechstein 2 potash bed interval locally attains a true thickness of about 15 metres.

German potash

Some active German potash mines in the Stassfurt member (Z3) are more than 100 years old. The Z3 seams are mostly sylvinitic and ore zones are mostly free from higher levels of Mg-salts. In general the average grade of halokinetic potash (sylvinitic type) is 17 to 18 % K_2O , which is low by Canadian standards. However, the extracted products can be utilised economically due to proximity of the market, mining efficiencies and high levels of government farming subsidies throughout the European community.

Two potash cycles are exploited in the Z1 in the Werra -Fulda Basin southeast of Kassel, while two potash beds in the Z2 and Z3 are mined near Hanover. Formations near Hanover in northwestern Germany occur in diapiric salt domes. There the salt and potash mines are located along salt walls that trend

along strike for over 20 km and are 800 to 1000 metres wide (Figure 6.9a). In the Hanover area, potash is mined between depths of 300 and 900 m, along a steeply-dipping seam some 2 to 30 metres in width (the increased width is due to multiple, tight folds). In the southern potash-mining district of Werra-Fulda, two seams are mined at depths of 300 to 900 metres with thicknesses of between 2 and 4 metres. These seams are even lower in grade than in the Hanover area, but unit extraction costs are lower as seams gently dip and are not folded.

Boulby potash, UK

Elsewhere in Europe, potash is extracted from the Aller Series in the Netherlands and the potash member of the Boulby Halite in the Z3 (Teese Group) at the southeast boundary of Cleveland County NE England. The Boulby Potash bed is underlain by a thick sequence of salt that makes up the majority of the Boulby Halite Formation (Figure 11.17). This is in turn underlain by the Billingham Main Anhydrite and Upper Magnesian Limestone Formations of the Teese Group. The Boulby Mine is the only current exploitation of Zechstein potash in England (Holmes, 1991). The first of two shafts at Boulby was completed in 1973 (Figure 11.17). It quickly became apparent that ore grade in this potash deposit, which sits atop the thick halites of the Boulby Halite Formation, was characterized by both brine-controlled mineral migration (karst) and gravity-induced plastic flow of the potash bed. Deformation of the potash bed is ongoing today and has led to a number of mining problems over the years, exacerbated by high temperatures of 40°C or more at the deepest workings (≈ 1300 m below land surface), and occurrence of local highly pressurised nitrogen gas pockets in the salt. Problems include one gas blowout (in 1976) with sufficient pressure to turn a continuous miner onto its side. However, the high-grade of the ore and its relative simple mineralogy (in comparison with many other European Zechstein potash ores) make processing straightforward and so the deposit is economic. The virtual absence of magnesium minerals is particularly relevant to economic processing of the ore stream.

The Boulby Potash interval consists of a sylvinitic bed with gneissic and augen-like flow textures, along with tectonically-rounded rock fragments from adjacent intrasalt beds. The sylvinitic has a bed thickness of < 1 metre to 20 metres over lateral distances of 20 to 30 metres and mined units generally range between 0 and 8.5 metres in thickness. There are five distinct ore types, all of which exhibit rapid lateral changes, although each type may predominate over mine areas more than a kilometre across. The average KCl content in the ex-

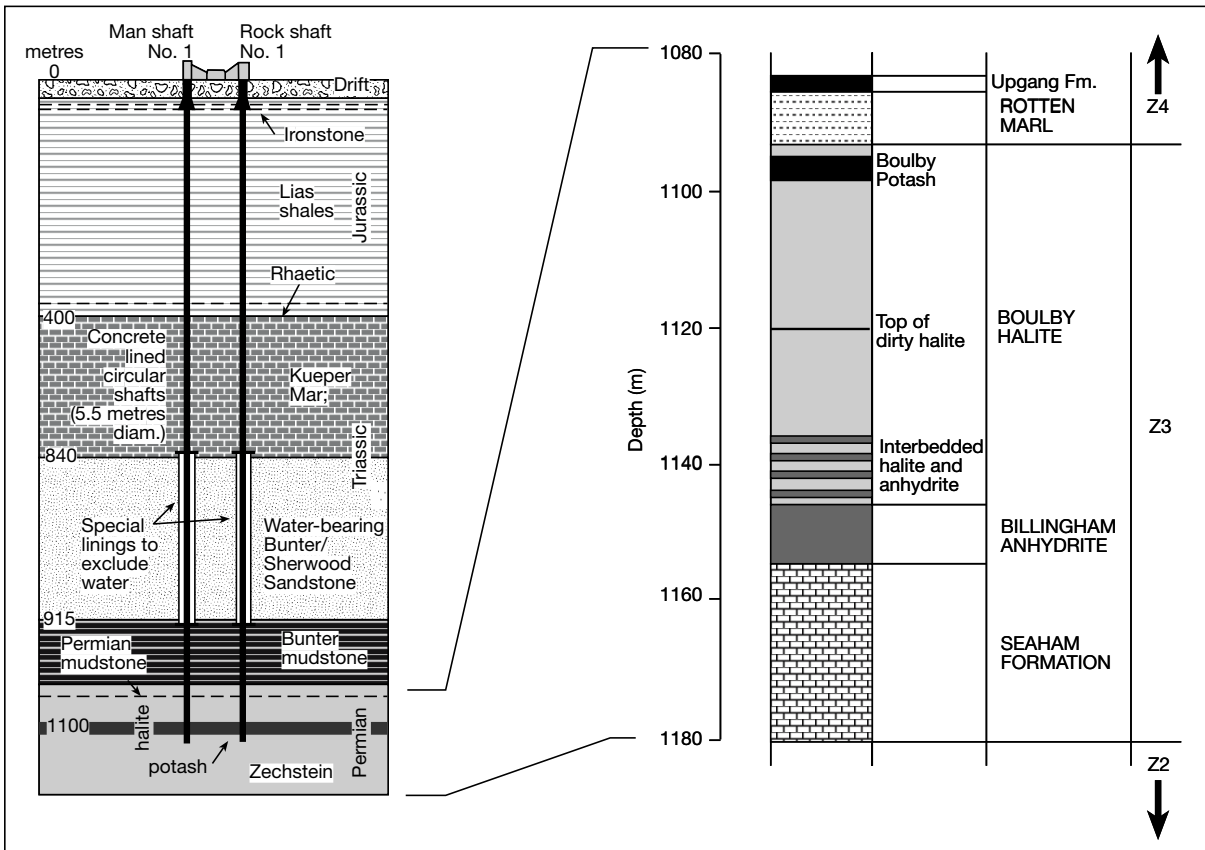

Figure 11.17. Stratigraphy of the Boulby Mine, Sussex, UK (after Holmes, 1991).

exploited parts of the Boulby Halite is 26 % KCl. As in the New Brunswick ores (Figure 11.21b), the Boulby potash sylvinitic ore is characterized by marked thickness changes reflecting flowage thickening and is related to the high differential stresses created by halokinesis of potash encased in halite. Thickening of highly mobile potash intervals can locally enrich several of the ore beds to grades in excess of 50 % KCl.

Locally, clay content in a projected ore zone can be anomalously high and exert a major detrimental effect on ore grade as do unexpected elevated levels of anhydrite, magnesite, pyrite, quartz and boron minerals, which together can exceed 15%.

The Carnallitic (Rotten) Marl Formation of the Staintondale Group, composed primarily of dehydrated clay minerals and halite, overlies the Boulby Halite Formation. As the name implies the Rotten Marl is a "salt-clay." It tends to be structurally incompetent as it lacks any significant cementing mineral binding the soft clay. The bed is further weakened by steeply dipping discontinuities in some parts of the mine area from a combination of flow and dissolution features and it must be

well characterised before mining can proceed. A minimum of 1.5-2 metres of salt in the mine back (roof) is maintained to ensure no significant roof collapse. The Carnallitic (Rotten) Marl Formation sits in sharp contact with the overlying Uppgang Formation, which in turn is overlain by the Upper Anhydrite Formation and Upper Halite Formation of the Zechstein Cycle 4 of the Staintondale Group. The Staintondale Group is in turn overlain by more than a kilometre thick Upper Permian and Triassic marine and continental clastic sediments, which include highly pressurised brines in sands of the Triassic Sherwood Formation (Figure 11.17).

The potash zone is worked using a variation of the room and pillar method. Ore is extracted from the rooms (potash panels) using "continuous miner" equipment, similar to that used in coal mines. Mine development work is carried out in relatively thick stable halite located some 30 metres below the potash zone. Ramps are then driven upward from the development roadway level into the potash zone, which is less structurally stable. Even the access roads are liable to instability due to high lithostatic pressures at these depths; so long horizontal slots

are cut into roadway walls for stress relief. Although the basic concept of roadway development in salt to access room-and-pillar potash panels was sound, determining the most efficient mining system proved difficult and it was not until 1984 that mining costs were sufficiently reduced to achieve profitability. By the mid-1990s, output had stabilised at 16,000t/d – 2.8Mt/y from six production sections. To cope with greater stresses in the ore below 1,200m and to raise output above 3Mt/y, in 2001 the miner operator (ICL Fertilizers) converted its continuous miners to remote-controlled operation (so they can be used safely without prior blasting and gas relief in shaly, gassy sections of the potash ore).

New Mexico potash, USA

Potash is mined from the Salado Formation in the Carlsbad Potash District of the Permian Basin of New Mexico. The area produces more than 70% of all the potash mined in the United States. Potash was first discovered in this region in the mid 1920s during drilling for oil and the first potash mine was opened in 1931. Various potash minerals occur in eleven ore zones numbered 1 through 11 (in ascending order) in a 215 m thick cyclic interval known as the McNutt interval located in the middle of the Salado Formation (Figure 11.18a, Table 11.4; Lowenstein, 1987b). Zone 1 is the richest, but is now exhausted. Production is now mostly from zones 3, 5, 7 and 10. The major ore minerals are sylvite and langbeinite, with accessory leonite, kainite, carnallite, polyhalite, kieserite, bloedite, halite and anhydrite. A typical ore is 60% halite, 30% sylvite, 5% langbeinite, and 2% of polyhalite and insolubles. Langbeinite is produced from zone 4, and mixed sylvite-langbeinite from zone 5. For example, in the IMC Global Inc operation, the ore on the 900 foot (275 m) level is primarily sylvinites with some langbeinite. The 260 m (850 foot) level ore is langbeinite. The 244 and 213 m (800 and 700 foot) level ores are a mixture of the two. IMC Global Inc. produces muriate from sylvinites ore, Sul-Po-Mag from langbeinite, and sulphate by combining the two minerals. Several mines in this potash district have been closed in the last decade, and it is unlikely that they will be reopened.

The potash ore zone in New Mexico lies above and immediately basinward of the older Permian basin margin, as defined by the position of the underlying Capitan Reef (Figure 11.18a). This location corresponds to a likely

surface depression and water sink at the time of deposition. It was probably a zone of differential subsidence in the underlying sediments located at the hinge between indurated platform edge carbonates and muddier basin centre sediments. It was also the spill point of the aggrading basin-filling evaporite cycles that make up the basinwide evaporites of the Castile and Salado formations. The significance of fill and spill hydrology as loci of changes in mineralogy was discussed in Chapter 5. The nearby underlying Capitan Fm. reef crest also acts as a focus to any subsequent rise of artesian or escaping basinal waters (Figures 7.9, 7.45a).

Two types of lithologic cycles dominate the ore zones in the Carlsbad Potash District (Figure 11.18b; Lowenstein, 1987b). Type I cycles begin with mixed siliciclastic carbonate (magnesite) mudstone, followed by anhydrite polyhalite with gypsum crystal pseudomorphs, overlain by halite and capped by muddy halite. Type II cycles begin with halite that grades transitionally upsection into muddy halite and pseudomorphs after gypsum, which retain subaqueous bottom-aligned growth habits or mechanically deposited sedimentary structures (ripples, cross beds, etc.). In the anhydrite-polyhalite parts of the cycles there are many pseudomorphs of primary gypsum textures that are now replaced by anhydrite, polyhalite, halite or sylvite. Sylvite and carnallite are most common in the muddy halite parts of the cycles where they occur as millimetre- to centimetre-sized anhedral crystals. Both the blood-red sylvite and the purple carnallite colours in the ore zone come from micrometre-sized plates of haematite. Potash crystals may be internally zoned; with dark haematite-rich bands developed at the crystal rims, and progressively lighter bands, depleted in

Zone	Mineralogy	Potential
11	Mostly carnallite, minor sylvite and leonite	Noncommercial to date
10	Sylvite, sylvinites	2nd best in district (high clay (6-7%))
9	Carnallite, kieserite, minor sylvite	Noncommercial to date
8	Sylvite	Moderate reserves, future potential, high clay
7	Sylvite	Moderate reserves, moderate clay (3-4%)
6	Carnallite, kieserite, minor sylvite	Noncommercial to date
5	Sylvite and langbeinite	Moderate reserves trace clay (1%)
4	Langbeinite and sylvite	Main source of langbeinite; mixed ore
3	Sylvite	Historically, 3rd in sylvite production
2	Carnallite, kieserite, minor sylvite	Noncommercial to date
1	Sylvite	Formerly major sylvite producing zone (now exhausted)

Table 11.4. Zone and properties of the McNutt ore Zone, New Mexico, listing mineralogy and potential (after Griswold, 1982).

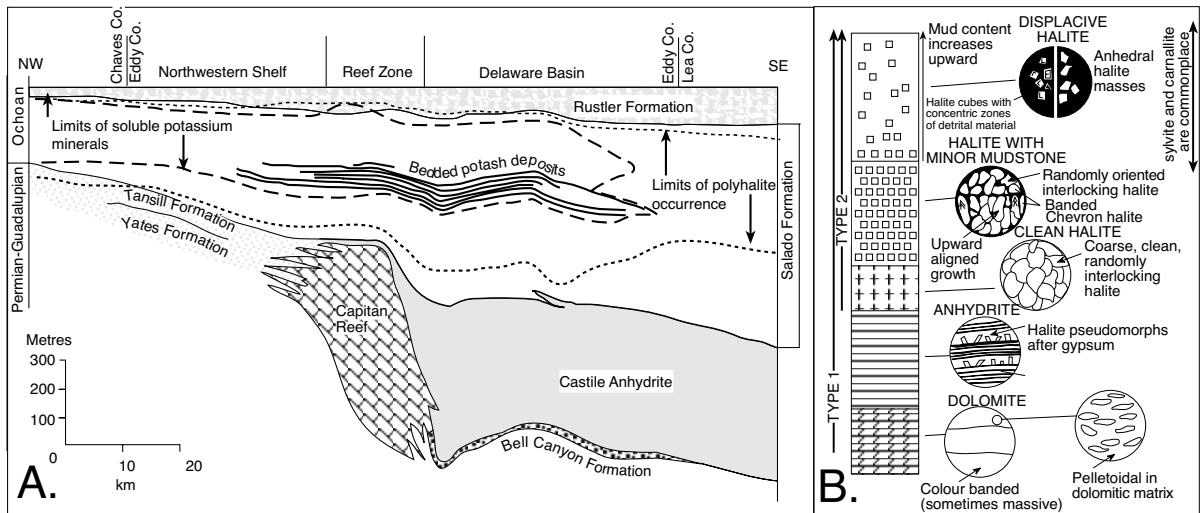

Figure 11.18. Potash in the Carlsbad Potash District, New Mexico. A) Stratigraphic section in southeastern New Mexico showing distribution of bedded potash (McNutt ore zone) about basin margin (after Bates, 1969). B) Idealised halite-dominated depositional cycles that host the ore beds (after Lowenstein, 1987b).

haematite, in the cores of the crystals. Ore zones are hosted in stacked halite beds, up to 1 metre thick with up to 50% sylvite and carnallite. Thin sections of the ore show poikilitic textures, with several halite crystals encased in single carnallite or sylvite crystals. The sylvite and carnallite occupy areas equivalent in size and shape to the void spaces in modern saline pan halites and are interpreted as pore-filling cements (Lowenstein and Spencer, 1990).

Given that Quaternary halite beds lose porosity by 100 metres depth, it is likely that the bulk of the stratiform potash ores within the McNutt potash zone were emplaced syndepositionally or very early during shallow burial. That the ore is early is reinforced by an argon date of 250 ± 0.6 Ma for deposition obtained from langbeinites in the McNutt ore zone, with subsequent local recrystallisation events at 245 and 94 Ma (Renne et al., 2001). Like their more recent analogues, this Permian potash precipitated as stratiform units in depressions in a saltern to mudflat terrain subject to exposure and shallow karsting in bedded halite beds. Much of the ore precipitation was driven by cooling of warm refluxing shallow brine. Later in its burial history the ore zones were subject to recrystallisation from fluid crossflows (descending or ascending), most likely driven by local or region tectonic events. This explains the irregular distribution of the stratiform Carlsbad potash salts and their general lack of fine texture in a halite host that away from the ore zones still retains the original chevron halite texture and why the stratiform potash zone ores frequently cross depositional boundaries in primary halite beds.

West Canadian potash (Devonian)

The Middle Devonian Prairie Evaporite Formation is a potash-entraining halite sequence deposited in the Elk Point Basin, an early intracratonic phase of the Western Canada Sedimentary Basin (Chiple and Kyser, 1989). Devonian halite constitutes a large portion of the four formations that make up the Elk Point Group: 1) the Lotsberg (Lower and Upper Lotsberg Salt), 2) the Cold Lake (Cold Lake Salt), 3) the Prairie Evaporite (Whitkow and Leofnard Salt), and 4) the Dawson Bay (Hubbard Evaporite). At that time the Elk Point Basin covered most of Alberta, the southern half of Saskatchewan, southwest Manitoba and extended south into the USA (Figures 7.5, 11.19a). Its Pacific coast was near the present Alberta-British Columbia border, and the Elk Point Basin was centred at approximately 10° S latitude. The basin was bound to the north and west by a series of tectonic ridges and arches; but due to subsequent erosion, the true eastern extent is unknown (Mossop and Shetton, 1994). Hydrographic isolation of the basin resulted in the deposition of a drawdown sequence of basinwide evaporites in an intracratonic sag and include the various potash entraining intervals in the Prairie Evaporite Formation.

Today the remnants of the Middle Devonian Prairie Evaporite Formation constitute a bedded unit some 500 metres thick, which lies atop the irregular topography of the platform carbonates of the Winnipegosis Formation (Figure 11.19b). Above the Prairie Evaporite Formation is a series of cyclic Devonian limestones, dolomites and evaporites that make up the Dawson Bay, Souris River, Duperow and Nisku Formations. Lying

unconformably on these deposits are the Lower Cretaceous sands of the Mannville Group, which are in turn overlain by younger Cretaceous shales and capped by Quaternary glacial sediments. The Prairie Evaporite Formation is continuous over a large portion of southern Saskatchewan, except where locally removed by dissolution. The dissolution process is ongoing and at various times has created stratigraphic traps for hydrocarbons (e.g. Figure 10.63).

Potash geology

Potash deposits mined in Saskatchewan are all found within the upper 60-70 m of the Prairie Evaporite Formation at depths of more than 400 to 2750 metres beneath the surface of the Saskatchewan Plains. Within the Prairie Evaporite there are four main potash-bearing members, in ascending stratigraphic order they are: Esterhazy, White Bear, Belle Plaine and Patience Lake members (Figure 11.19b). Each member is composed of various combinations of halite, sylvite, sylvinitic, and

carnallite (Fuzesy, 1982). The Belle Plaine member is separated from the Esterhazy by about 15 m of halite, its thickness ranges from 0-18 m and averages around 9 m. The Patience Lake member is separated from the Belle Plaine by 3-12 m of halite its thickness ranges from 0-21 m and averages 12 m (Holter, 1972). In total the Prairie Evaporite Formation does not contain any $MgSO_4$ minerals (kieserite, polyhalite) and indicates a Devonian seawater chemistry somewhat different from today's (Figure 2.30).

As early as 1860, salt springs and seepages near the edge of the Elk Point Basin indicated the presence of widespread salt in Western Canada (Figure 7.5). Rock salt was first sampled in 1907, while potash beds were intersected in Saskatchewan in 1942 during the sinking of oil and gas wells. The potential of commercial grades of potash mineralisation was not recognized until 1946. Canadian potash deposits are among the richest and largest on earth, containing around 5 billion tons of ore in a mineable band up to 50 miles wide, which stretches

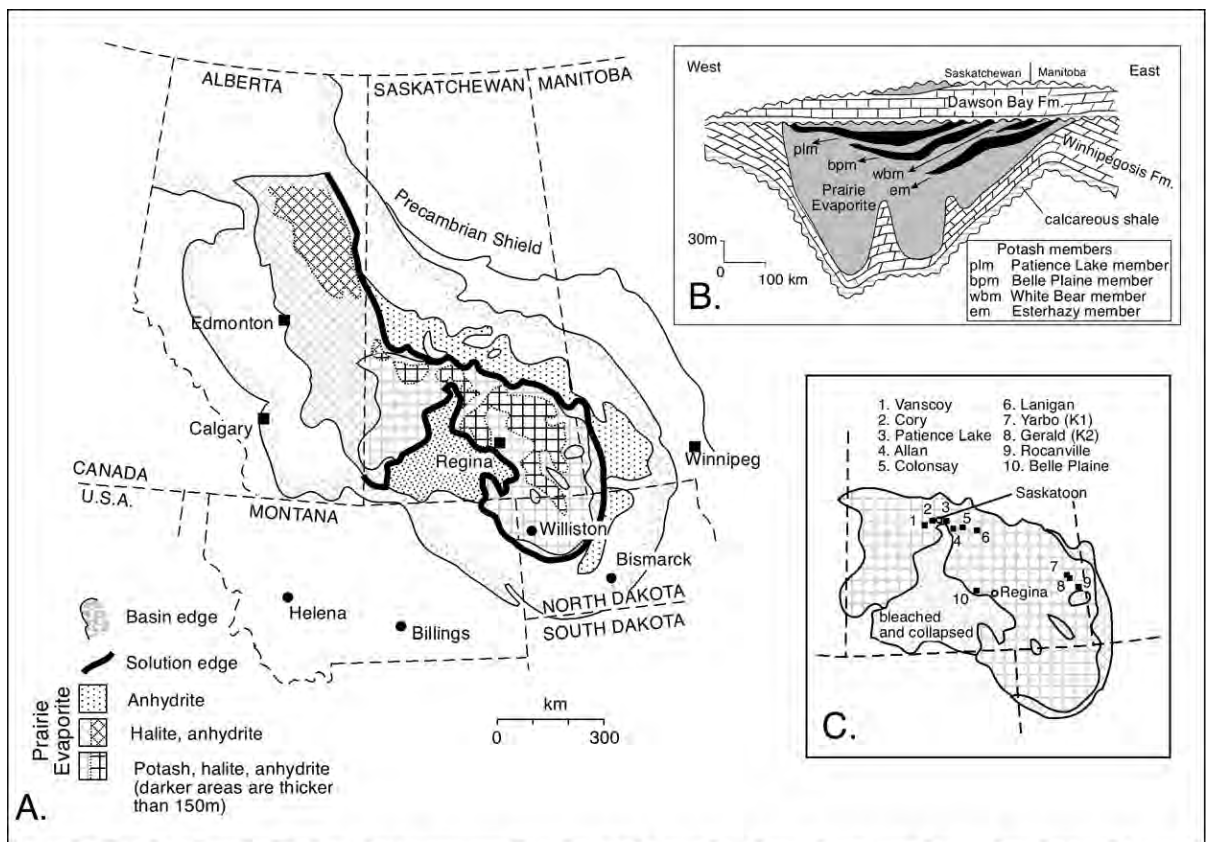

Figure 11.19. Potash in the Elk Point Basin, western Canada. A) Regional geology showing thickest salt and potash intervals in the Prairie Evaporite and its dissolution edge (see also Figure 7.5). B) Cross section of basin showing distribution of potash members. C) Map of potash mines in the basin (compiled and modified from Worsley and Fuzesy, 1979; Fuzesy, 1982; Boys, 1993).

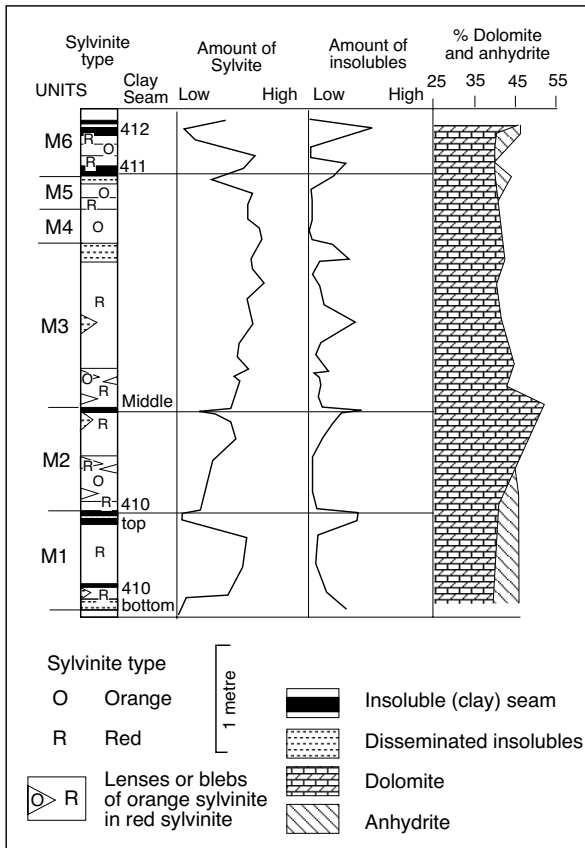

Figure 11.20. Ore section in the Patience Lake member of the Prairie Evaporite Formation in the PCS Cory potash mine (after Boys, 1993).

some 725 km (450 miles) across the province (Figure 11.19). Canada today supplies more than 30% of the world’s annual potash production.

The Prairie Evaporite is more than 200 m thick in the potash mining district in Saskatoon and 140 m thick in the Rocanville area to the southeast. The Patience Lake member is the main target for conventional mining near Saskatoon. The Esterhazy potash member rises close to the surface in the southeastern part of Saskatchewan near Rocanville and on into Manitoba. This is a region where the Patience Lake member is thinner or completely dissolved (Figure 11.19b). Over the area of mineable interest in the Patience Lake member centred on Saskatoon the ore bed currently slopes downward only slightly in a westerly direction, but deepens more strongly to the south at a rate of 3-9 m/km. Mines near Saskatoon are at depths approaching a kilometre and so are nearing the limits of currently economic shaft mining. The main shaft for the Colonsay Mine, which took IMC Global Inc. more than 5 years to complete through

a water-saturated sediment column, finally reach the target ore body at a depth of 960 metres. Such depths and a southerly dip to the ore means that the conventional shaft mines near Saskatoon define a narrow WNW-ESE band of activity (Figure 11.19c). To the south potash is recovered from greater depths by solution mining; the Belle Plaine operation leaches potash from the Belle Plaine member at a depth of 1800m.

The Prairie Evaporite typically thins southwards in the basin; although local thickening occurs where carnallite, not sylvite, is the dominant potash mineral (Worsley and Fuzesy, 1979). The Patience Lake member is mined at the Cory, Allan and Lanigan mines, and the Esterhazy Member is mined in the Rocanville area (Figure 11.19c). Ore mined from the 2.4 m thick Esterhazy Member in eastern Saskatchewan contain minimal amounts of insolubles ($\approx 1\%$), but considerable quantities of carnallite (typically 1%, but up to 10%) and this reduces the average KCl grade value to an average of 25% K_2O . The converse is true for ore mined from the Patience Lake potash member in western Saskatchewan near Saskatoon where carnallite is uncommon in the Cory and Allan mines. The mined ore thickness is a 2.74-3.35 metre cut off the top of the 3.66-4.57metre Prairie Lake potash member. Ore grade is 20-26% K_2O and inversely related to thickness. The insoluble content is 4-7%, mostly clay and markedly higher than in the Rocanville mines.

A typical sylvinitic ore zone in the Patience Lake member can be divided into six units, based on potash rock-types and clay seams (Figure 11.20, M1-M6; Boys, 1993). The units are mappable and can be correlated throughout the PCS Cory Mine with varying degrees of success, dependent on partial or complete loss of section from dissolution. Potash deposition appears to have been cyclic, expressed in the repetitive distribution of haematite and other insoluble minerals. Desiccation polygons, desiccation cracks, microkarst pits and chevron halite crystals indicate that the Patience Lake member that entrains the potash ore was deposited in a shallow-brine, salt-pan environment.

Clay seams form thin stratigraphic layers throughout the potash ore zone(s) of the Prairie Evaporite, as well as disseminated intervals, and constitute about 6% of the ore as mined. Insoluble minerals found in the PCS Cory samples are, in approximate order of decreasing abundance: dolomite, clay [illite, chlorite (including swelling-chlorite/chlorite), and septechlorite], quartz, anhydrite, haematite, and goethite. Clay minerals make up about one-third of the total insolubles: other minor components include: potassium feldspar, hydrocarbons, and sporadic non-diagnostic palynomorphs (Boys, 1993).

Potash salts probably first formed as secondary precipitates just beneath the sediment surface and were modified to varying degrees by ongoing fluid flushing in the burial environment. The cyclic depositional distribution of disseminated insolubles was possibly due to a combination of source proximity and the strength of the winds blowing detritals out over the brine seaway. Possible intrapotash unconformities, created by dissolution of overlying potash-bearing beds, are indicated by an abundance of residual haematite in clay seams. Except in, and near, dissolution and collapse features, the secondary redistribution of insolubles, other than iron oxides, is insignificant.

Bedded halite away from the ore zones generally retains primary depositional textures typical of halite precipitation in shallow ephemeral saline pans (Brodylo and Spencer, 1987). Crystalline growth fabrics, mainly remnants of vertically elongate chevrons, are found in 50-90% of the halite from many intervals in the Prairie Evaporite. Many of the chevrons are truncated by irregular patches of clear halite that formed as early diagenetic cements in syndepositional karst.

Halite associated with the potash ore lacks well-defined primary textures and is atypical when compared with the well-preserved depositional textures in the non-ore sequences. From the regional petrology and the lower than expected Br levels in halite in the Prairie Evaporite Formation, Schwerdtner (1964), Wardlaw and Watson (1966) and Wardlaw (1968) postulated a series of recrystallisation events forming sylvite as a result of periodic flushing by hypersaline solutions. This origin as a secondary precipitate is supported by observations of intergrowth and overgrowth textures (McIntosh and Wardlaw, 1968), large-scale collapse and dissolution features (Gendzwill, 1978), radiometric ages (Baadsgaard, 1987) and palaeomagnetic orientations of the diagenetic haematite linings associated with the emplacement of the potash (Koehler et al., 1997).

Dating of clear halite crystals associated with the ore zone shows that the exceptionally coarse and pure secondary halites forming pods in the mined potash horizons may have precipitated as soon as early burial or have formed as late as Pliocene-Pleistocene. Even today, alteration and remobilisation of the sylvite appears to be an ongoing process, perhaps related to the encroachment of the current dissolution edge or the ongoing stoping of chimneys fed by deep artesian circulation (Figure 7.4).

Halite-sylvite (sylvinite) rocks in the ore zone show two end member textures, the most common is a recrystallised polygonal mosaic texture with individual crystals ranging from millimetres to centimetres and sylvite grain boundaries outlined

by concentrations of blood-red halite. The other end member texture is a framework of euhedral and subhedral halite cubes enclosed by anhedral crystals of sylvite. This is very similar to ore textures in the Salado Formation of New Mexico; which formed by early passive precipitation in karstic voids.

Petrographically, the halite-carnallite (carnallitite) rocks display three distinct textures. Most halite-carnallite rocks contain isolated centimetre-sized cubes of halite enclosed by poikilitic carnallite crystals. The halite cubes are typically clear, with occasional cloudy crystal cores that retain patches of syndepositional growth textures (Lowenstein and Spencer, 1990). The second texture is coarsely crystalline halite-carnallite with equigranular, polygonal mosaic textures. The third type, which is rare, contains interlayered halite and carnallite with a primary bedding style similar to that in the Oligocene potash of the Rhine Graben. In zones where halite overlies anhydrite, most of the halite is clear with only the occasional crystal showing fluid inclusion banding.

Clay minerals, which tend to occur as long continuous seams or markers in the potash zones, are mainly composed of detrital chlorite and illite and authigenic septechlorite, montmorillonite and sepiolite (Mossman et al., 1982; Boys, 1990). Of the two chlorites, septechlorite is the more thermally stable. The septechlorite, sepiolite and vermiculite very likely originated as direct products of settle-out or early diagenesis under hypersaline conditions of what was originally eolian dust settling onto a huge brine seaway. Absence of the otherwise ubiquitous septechlorite from Second Red Beds west of the zero-edge of the evaporite basin supports this concept.

The fluids

Analysis of waters, which are currently found in the various Canadian potash mines and the collapse anomalies in the Prairie Evaporite, further supports the notion that recrystallising fluids had access to the evaporite minerals throughout the burial history of the Prairie Formation (Chiple, 1995; Koehler et al., 1997). Likewise, the Rb-Sr isotope systematics of crystal layers in both halite and sylvite indicate that the Prairie Evaporite was variably recrystallised during fluid events at 371, 284, 241, 185, 147, 85, 35 and 0.5 Ma. These ages are all more recent than original deposition and correspond to ages of various tectonic events that affected the western margin of North America.

Chemical compositions of inclusion fluids in the Prairie Evaporite, as determined by their thermometric properties, reveal at least two distinct waters: a Na-K-Mg-Ca-Cl brine,

variably saturated with respect to sylvite and carnallite; and a Na-K-Cl brine that is the result of fluid-rock interaction and did not result from simple evaporation of seawater to the sylvite facies (Chipley, 1995). This is supported by δD and $\delta^{18}O$ values of inclusion fluids in halite and sylvite, which range from -146 to 0‰ and from -17.6 to -3.0‰, respectively. Most of the preserved isotope values are different from those of evaporated seawater, which should have δD and $\delta^{18}O$ values near 0‰. Furthermore, the δD and $\delta^{18}O$ values of inclusion fluids are probably not the result of precipitation of the evaporite minerals from a brine that was a mixture of seawater and meteoric water. The low latitude position of the basin during the Middle Devonian (10-15° from the equator), the required lack of meteoric water to precipitate basinwide evaporites, and the expected δD and $\delta^{18}O$ values of any meteoric water in such a setting, make this an unlikely explanation. Rather, the δD and $\delta^{18}O$ values of inclusion fluids in the halites reflect ambient and evolving brine chemistries as the fluids in inclusions in the various growth layers were intermittently trapped during the subsurface evolution of the Prairie Formation in the Western Canada Sedimentary Basin. They also suggest that nonmarine pore water has been a major component of the crossflowing basinal brines throughout much of the recrystallisation history (Chipley, 1995).

Other significant potash deposits

Canadian Maritimes (Mississippian of Nova Scotia and New Brunswick)

The Carboniferous geology of the Maritime Provinces and Quebec is characterised by a series of northeast trending fault-bound grabens or half grabens containing clastics and evaporites (mostly halite) up to 10 km thick

(Roberts and Williams, 1993). The Windsor Group (Visean) in Nova Scotia and New Brunswick hosts $MgSO_4$ -poor potash evaporites in several continental intermontane basins that were created by extension-driven post-Acadian strike-slip faulting with the salt then subject to halokinesis first by extension and then subsequent compression. The same evaporite unit that hosts the potash ore also acts as a seal to MVT deposits at Gays River and Jubilee (Figure 11.21a). Exploitable potash at New Brunswick was discovered in the 1970s by the New Brunswick Mineral Resources Branch of the Geological Survey, with the first intersection occurring in 1969-1970 during

Figure 11.21. Potash in New Brunswick and Nova Scotia. A) Schematic cross-section of the stratigraphy and position of the regional Ainslie Detachment, in Nova Scotia, a major allochthon feature associated with salt flow and gravity gliding into the basin. Lubricating evaporites of the lower Windsor Group (Carrols Corner Formation) are shaded grey. Note the salt raft tectonics geometry with thickening of the Mabou Group in the salt-withdrawal sink. Jubilee-style base metal deposits are hosted in the salt tectonites created by the detachment. In contrast, the Gays River-style of deposit is formed at the evaporite-encased underbelly contact adjacent to the salt-encased reefal buildup. In the case of the Jubilee deposit it was focused by the feather edge of the salt unit (after Lynch et al., 1998; Warren, 2000b). B) Distribution of sylvinite ore zone (black), enclosed in halite an anticlinal structure in a New Brunswick potash mine.

a drilling program designed to define a halite resource suitable for hydrocarbon storage.

Of particular interest for potash extraction is the Cassidy Lake Formation in the Moncton Sub-basin. It entrains structurally complex potash ore and is much more deformed than most of the world's conventionally mined potash occurrences, with ore thicknesses ranging from 0-45 metres (Figure 11.21b). Seismic and borehole evidence from the Windsor Group shows that the Cassidy Lake Formation (rock salt and potash) is separated from the underlying Upperton Formation (anhydrite) by a low-angle décollement surface marked by the presence of mylonitic salt and cataclastic limestone and anhydrite. Much of the halokinetic deformation occurred above the regional décollement separating the Cassidy Lake Formation from the underlying Upperton Formation. Flow has been complex within the salt body itself, resulting in structural repeats of the salt stratigraphy through recumbent to inclined isoclinal folds and sheath folds. Deformation was syntectonically mobilised by gravity sliding, thrusting and folding atop the regional décollement surface, with the most intense deformation being taken up in the highly deformable sylvinites.

The Potash Member in the Cassidy Lake Formation consists of cm-scale beds of halite and halite+sylvite and minor rinneite and polyhalite. The exploited ore is sylvinite running 20-30% K_2O . The Upper Salt Member atop the potash ore is 2.5 - 20 m thick and composed of interlayered thin beds and laminae of argillaceous halite, sylvinite and claystone-anhydrite (Anderle et al., 1979). Because of structural thickening in this halokinetic salt, it entrains what is perhaps the thickest exploited bed of KCl salts in the world in a domelike anticline fold with a highly complicated internal structure dominated by isoclinal and sheath folds. The depth to ore in this structure ranges from 580 to 850 m below the surface and in thickness the ore zone ranges from a few metres to 30 metres (Figure 11.21a). The variable inclination and thickness of the ore zone means mining procedures are more variable than those used in extracting potash from the Prairie Evaporite. In intervals where the ore zone is relatively flat, continuous front procedures are used, similar to Saskatchewan. Where the ore zone is more steeply inclined, classic drill and blast procedures are followed.

In Nova Scotia salt, not potash, is the main product from Pugwash Mine within equivalent age evaporites, but the operations in the halite show a similar structural complexity in the salt to the New Brunswick operation. Figure 11.22 shows a refolded fold in the Pugwash Mine: the axial plane

Figure 11.22. Refolded fold in sylvite-halite, Pugwash Mine, Nova Scotia (after Evans, 1967).

of the initial antiform (axial trace 1) was folded and the nose (axial trace 2) of the resultant synform was folded (axial trace 3). The axial planes of each of the folds have the same axial orientations as the axial plane traces of the other two clearly demonstrating an inherently high degree of plasticity during deformation (Evans, 1967).

Borates are commonplace coprecipitates in particular horizons in the Cassidy Lake Formation: for example, danburite occurs in the Basal Halite; while boracite, hydroboracite, szaebelyite, hilgardite and ulexite are found in the Upper Salt Member of the Windsor Group. Where the Clover Hill Formation overlies the Cassidy Lake Formation the contact is typically a thin "residual" bed made up of laminated clayey anhydrite, borates and quartz grains. It is not a depositional contact but the result of ongoing post deformational "sub-rosion" at the evaporite-nonevaporite interface, similar to that documented at the upper and lower contacts of the Maha Sarakham Fm. in Thailand. In 1997, Potash Company of Canada (Potacan) closed its 890,000-ton mine at Cassidy Lake, near Sussex, N.B., because of flooding related to intersection of an unexpected salt "horse." The mine was converted to a solution mine, leaving one conventional mine (Sussex Mine) currently exploiting the New Brunswick potash ore in this structurally complex region.

Cretaceous trans-Atlantic potash: west Africa and Sergipe Basin, Brazil

Cretaceous (Aptian) evaporites were deposited in a series of growing rifts created as Africa separated from South America. Today the remnants of these beds are to be found on opposite sides of the Atlantic in the Sergipe-Alagoas and Gabon-Congo basins. In the Sergipe Basin the evaporite sequence (Ibura member of the Muribeca Formation) is a $MgSO_4$ -free potash deposit composed of stacked cycles of halite, carnallite and sylvite up to 800m thick. More than 750,000 t/yr of potash ore is extracted from the Ibura Member by the Companhia Vale do Rio Doce's at its conventional potash mine in Sergipe State. Several of the cycles in the Ibura Member are composed of thick halite (more than tens of metres thick) containing the highly soluble $CaCl_2$ mineral tachyhydrite (Figure 11.23; Meister and Aurich, 1972; Wardlaw, 1972; Wardlaw and Nicholls, 1972; Borchert, 1977). The Sergipe deposits are characterised by thick cycles with a characteristic upward trend: halite (100%) → halite (35-90%) + carnallite (10-65%) → tachyhydrite (5-100%). Wardlaw (1972) showed that these deposits are primary as they contain bottom-growth features and primary bedding in the halite-carnallite units. Documented textures also suggest that there were episodes of syndepositional karstification and flowage within the carnallite, creating near identical textures to those seen in Thailand and the Qaidam Basin, but not yet documented as analogs when Wardlaw studied the sequence back in 1972. In the upper part of the evaporite sequence a sylvinitic bed sits atop a carnallite + halite bed and is overlain by a halite bed; a mineralogical evolution that is similar to that of the Thai and many other potash successions.

The various potash minerals in the Sergipe Basin show a systematic lateral zonation away from the anticlinal domes that also define the three main oil-producing structures in the Sergipe Basin. This suggests that more soluble potash salts have been leached from the crests of the structures (Borchert, 1977). Near the top of the anticlinal slope there is only rock salt, further out on the anticlinal arms there are intercalated sylvinitic layers, which in turn pass outward into carnallitic and tachyhydritic beds. There are no documented halokinetic structures beneath the anticlines and syndepositional uplift driving the leaching was related to drape over underlying horsts. In my opinion, given the similarity of the sequencing and layering to the Maha Sarakham the possibility of synprecipitational focusing of the ore via halokinesis is a viable alternative.

Similar cyclic potash sequences constitute similar age beds on the African side of the Atlantic, there the beds are also free of $MgSO_4$ salts and may carry thick tachyhydrite units. Beds show a similar layering and sequencing in and around salt domes as in Brazil (Borchert, 1977; de Ruiter, 1979). Within the Congo Basin the most extensive and thickest potash deposits occur in the coastal Kouilou region where ten evaporite intervals are recognised, with a cumulative thickness of potash beds of more than 100m. Carnallite is the predominant potash mineral, while some cycles also contain bischofite and tachyhydrite. Carnallite grades to sylvite in the upper parts of some beds. The region is halokinetic and may be suitable for future solution mining of potash and magnesium. Further inland, for nine years in the 1970s, the equivalents of these evaporite cycles were conventionally mined for sylvite in the Holle mine area. Production was from the uppermost sylvinitic layers atop

carnallite with extraction at rates of 360,000 to 450,000 tonne/year. Geological and water problems prevented the mine from ever reaching its target production level of 720,000 tonne/yr. Operations ceased in 1978 when an aquifer was penetrated and the mine was flooded.

Neither the Sergipe nor the Congo evaporite mineralogies can be derived from the evaporation of modern day seawater. Yet both deposits retain bottom-nucleated crystal fabrics that show that the carnallite is primary implying different seawater chemistry in the Cretaceous (Figures 2.30, 11.23).

Figure 11.23. Similarities in potash sequences from the Sergipe and Congo Basins (after Hardie, 1990). Inset on the right shows primary layering and bottom-growth features of the Sergipe halite-carnallite subfacies (after Figure 2 in Wardlaw, 1972).

B) Stratigraphy and bromine profiles from the Lower and Upper Salt Formations in the Khemisset Basin, northwestern Morocco (after Et-Touhami, 1996).

Moroccan Meseta (Late Triassic)

Salt basins formed in Morocco as rifts evolved into subsealevel intracratonic sags during the Triassic breakup of the supercontinent Pangaea. As a result, nonmarine redbeds and evaporites fill the many Late Triassic (Keuper) to early Liassic half grabens that make up the Moroccan Meseta (Figure 11.24a). Thick basalt flows (up to 500m) underlie and overlie these saline deposits (van Houten, 1977; Clement and Holser, 1988; Lorenz, 1988). In four of the sub-basins, including the Khemisset Basin, evaporites interbedded with basalts carry varying concentrations of potash. The potash intervals consist essentially of halite, carnallite, sylvite and rinneite, with less than 1% of other minerals (anhydrite, kieserite, bischofite, douglasite; Salvan, 1972). Once again this is a $MgSO_4$ -depleted potash sequence and indicate a largely marine-derived Ca-Cl source with ionic proportions different from today (Figure 2.30b).

The most detailed work on the stratigraphy of the potash intervals to date is by Et-Touhami (1996), who studied the succession in the Khemisset Basin. Strata in the centre of the Khemisset Basin are Late Triassic to Early Liassic and made up of five formations (from base to top); Lower Clay Formation, Lower Salt Formation, the Basaltic Formation, Upper Salt Formation and the Upper Clay Formation (Figure 11.24b). Potash occurs toward the top of the Lower Salt Formation (LSF). The LSF is subdivided into two informal units known as L1 and L2. The lower unit (L1) is composed mostly of red-brown chaotic mudstone interbedded with red beds, especially toward its base. The upper unit (L2) is further divided into the L2.1 and L2.2 subunits (Figure 11.24b). Subunit L2.1 is made up of black chaotic to massive banded salt with some local inclusions of potash. Subunit L2.2 is made up of massive banded halite with potash layers (sylvite and carnallite), along with thin stringers of anhydrite and polyhalite. As in Thailand and Brazil, the sylvite unit tends to occur near the top of a colour banded halite unit and sits directly atop a carnallite succession. Locally the halite crystals in the carnallite unit retain relict chevron fabrics and vertically-elongate inclusion-free halites identical to those interpreted as syndepositional relicts in the Mallowa Salt of the Canning Basin, Australia (Cathro et al., 1992). Slumps and synprecipitatorial karstic textures also characterise the carnallite. A bromine profile through the LSF shows the potash was precipitated in the most saline stage of the accumulation ($Br > 100\text{ppm}$; Figure 11.24b).

The LSF in the Khemisset Basin is covered by vesicular to highly altered lavas and flows of the Basaltic Formation, which also retains local lenticular intercalations of claystones, limestones and evaporites. Atop this is the Upper Salt Formation, a unit

composed of generally flat lying salt beds intercalated with siliciclastic mudstones and siltstones. It is divided into Units 1 - 3, with local potash inclusions sometimes found in Unit 3. The bromine profile of the Upper Salt Formation shows lower concentrations than the LSF and does not appear to have attained the bitter stage for long enough periods to accumulate thick beds of potash ($Br < 100\text{ppm}$; Figure 11.24b).

How does potash form?

Our discussions so far suggest there are two groups of processes controlling ore grade in ancient potash salts. One sees the potash salts, carnallite and sylvite, as primary precipitates or as syndepositional to early diagenetic replacements forming within metres of the depositional surface via brine reflux and brine cooling. The other visualises sylvite as forming later in burial via ongoing incongruent dissolution of precursor carnallite. Both views are valid but, if used exclusively, are perhaps a little too dogmatic. My own view is that, owing to its high solubility, the various textures found in ancient potash salts reflect variegated and evolving origins that are dependent on how many times and how pervasively in its burial history an evolving brine chemistry came into contact with the potash beds (Warren, 2000c). In other words, various forms and textures of potash may dissolve, recrystallise and backreact with each other from the time a potash salt is first precipitated until it is exploited. Textural and mineralogical evolution depends on how open is the hydrology of the system at various stages during its burial evolution. Alteration can occur syndepositionally, in brine reflux or during flushing by compactional or thermobaric subsurface waters. Tectonism (extensional and compactional) during the various stages of a basin's burial evolution acts as a bellows driving fluid flow within a basin, so forcing and speeding up the focused circulation of potash-altering waters.

A similar, but less intense, textural evolution can also be seen in the burial history of the less soluble salts. For example, $CaSO_4$ can flip-flop from gypsum to anhydrite depending on temperature, pore fluid salinity and the state of uplift/burial. This means that, as in gypsum/anhydrite sequences, there will be primary and secondary forms of both carnallite and sylvite that can alternate during deposition, during burial and during any deep meteoric flushing.

In Thailand, both primary potash precipitation and shallow diagenetic backreactions seem to have worked simultaneously with hydrologies that were first driven by early salt diapirism. Then alteration continued into deeper burial and finally by uplift, driven by the regional gravity drive of throughflushing

fluids whose flow was focused along nearby clastic aquifers. The Canadian examples show how carnallite/sylvite has continued to evolve with the evolution of basinal and deeply flushing suprasalt and subsalt meteoric waters as they came into contact with variably dissolving salt units.

Whatever model, or combination of models, is used to explain the origin of the major potash salts, the most important economic corollary is that, wherever a potash bed is in contact with mobile pore fluids, these highly soluble salts are continually subject to dissolution, mobilisation and reprecipitation. When trying to understand the distribution of potash ore in a halite-dominated sequence the ability of the potash salts to flow, dissolve, alter and reprecipitate must be accounted for in any predictive exploration model or development programme. Its ability to dissolve at various times in its diagenetic history also explains variations in that most important feature of any mine — ore grade.

Controls on potash quality: Anomalies, leaching and problematic mine waters

Just as the first rule for safe halite mining is “stay in the salt”, worldwide, the problem areas in most potash mines can be related to thinning or disappearing ore seams in zones that show evidence of dissolution and solution collapse (Boys, 1990, 1993; Woods, 1979). Increased water inflows in Saskatchewan potash mines can be consistently linked to salt anomalies, that is, to natural areas of little or no potash within the potash ore bed (Gendzwill and Martin, 1996). Other than intersecting old open well bores in the potash ore zone, most episodes of flooding, including the complete loss of working mines, stem from uncontrolled water inflows that followed from an intersection with an anomalous non-ore zone.

Geology of the potash ore quality in three salt anomalies were studied by Boys (1993) in the PCS Cory mine, Canada, which extracts potash from the Patience Lake member of the Prairie Evaporite Formation. He defined five postburial facies in the vicinity of the salt anomalies, all related to a current or previous crossflow of water undersaturated with respect to potash (Figure 11.25a). Where undersaturated groundwater continually interacts with a sylvinitic bed it ultimately dissolves all the salts to leave behind only insoluble residues in a solution collapse breccia (facies 1). This potash-free interval is at the other end of the facies continuum defining salt anomalies in the PCS mine (Figure 11.25a; facies 1 through 5). At the other end of the groundwater-potash interaction spectrum are beds composed of completely recrystallised and often potash-enriched sylvinitic

(facies 5). These sweetspots lie adjacent to leached beds where recrystallised halite (facies 4) passes laterally into collapse breccias with blocks of anhydrite and halite (facies 3 and 2; solution residues made up of the less soluble salts), which in turn pass laterally into the most mature dissolution breccias of facies 1, where no evaporite salts remain. When a drive or a test hole passes out of the ore into facies 1 the potential for water problems is high.

In his model, salt anomalies indicate proximity to collapse structures that act as conduits for overlying (or possibly pressurised underlying?) formation waters. The crossflow drives a halo of pervasive leaching and recrystallisation in the Prairie Evaporite Formation. The same fluids that cause widespread recrystallisation, and possibly enrichment of the potash salts at the outer edge of the salt anomaly, also dissolve water-filled cavities in the more central parts of the anomalies. The intensity of the leaching and the geometry of the leached halo is variable, while the timing of major leaching events in the Prairie Evaporite is still poorly constrained. Boys (1993) postulates at least two major water crossflow events in the PCS mine, possibly driven by uplift and tectonism: one occurred in the Late Devonian, the other in the Cretaceous.

Similar leached solution cavity-fill features that create salt anomalies occur in the Boulby Potash Mine in the UK, although most of the features are now halite-cemented and consist of lenses of coarse pure translucent secondary halite (Figure 11.25b). Intersected zones are up to 2 metres across and typically overlie a band of halite encrusted with red haematite (Woods, 1979). The amount of anhydrite at the base of many cavities is greater than would accumulate as a simple insoluble residue implying they formed from waters close to CaSO_4 saturation. According to Woods (1979), the cavities formed in the subsurface from CaSO_4 -saturated brines that were involved in dissolving the carnallite and sylvite. The resulting brines became supersaturated with respect to CaSO_4 causing halite to precipitate and accumulate on the cavity floor.

At a smaller scale, I have observed similar CaSO_4 -floored dm-scale cavities in core from the Maha Sarakham potash intervals in Thailand and in this case they formed early, syn-precipitationally to bedded sylvinitic in adjacent salt withdrawal depressions (Figure 11.16). It seems that phreatic dissolution is commonplace in many potash intervals worldwide. The infill, however, is not always halite; and in Thailand, in the heavily recrystallised sylvinitic zones, some of these anhydrite-floored cavities have been filled by coarse-grained clear sylvite made up of single crystals more than 30 cm across.

Figure 11.25. Potash solution features. A) Cross section A-A' through half of an idealised collapse structure in the Prairie Evaporite Formation (after Boys, 1993). B) Recemented solution cavity in the Boulby Halite, Boulby Mine, UK. This is probably equivalent to facies 3 in Figure 11.25a but is located below the main potash zone (after Woods, 1979).

Salt anomalies (barren zones in potash ore) also form crosscutting intervals in the Permian potash ores in New Mexico (Linn and Adams, 1966). Locally called “salt horses” (a miner’s corruption of salt horst), these crosscutting irregular zones range from 0.3 to 100 metres in width and 3 to 200 metres in length. Beds in salt horses are thinner than the equivalent beds in ore. Contacts between salt horses and ore are sharp and colour

of the clay changes from grey in ore to brown in salt horses, perhaps indicating more oxygenated crossflushing waters. Pods and lenses of langbeinite, leonite, kainite, recrystallised halite, and recrystallised sylvite occur in McNutt ore near the salt horses, while disseminated polyhalite of the typical marker bed is locally concentrated into intergranular seams and pods in or near horses. According to Linn and Adams (op. cit.)

the NaCl-saturated brines creating the horses entered the ore zone from below and formed horses by the selective leaching of sylvite. This is a mechanism similar to that of Boys (op. cit.) except that he concluded unsaturated fluids entered from above. Fluid entry from below is not unreasonable in the New Mexico situation, as the evaporites along the western margin of the Delaware Basin sit atop an aquifer that entrains deeply circulating meteoric waters (Figures 7.9, 8.7, 11.59b).

Effects of the leaching events that produce the salt anomalies and loss of potash in Canada or elsewhere, range from weak to strong, from selectively preserving delicate laminae and chevron textures, to deforming and destroying salt beds (Boys, 1990). Good preservation of iron oxides in halite may indicate that the leaching was weak or of short duration. In many leach anomalies fed from above, salinity indicator minerals increase downward in a structure, possibly because fluids exit downward and NaCl-saturated fluids tend to follow the chemical gradient provided by potash beds. Or, in my opinion, it zones downward because all brines tend to density stratify and the denser more saturated waters in a downward growing dissolution feature would tend to have ponded at its bottom. Early stages of stratification are seen in the perched waters on blind-bottomed sub-vertical karst holes in Mt Sedom, Israel (Figure 7.39a).

Identifying proximity to a salt anomaly is obviously important in terms of ore quality and mine safety (Boys, 1990). Geological

indicators of proximity to a halite anomaly include: a change in insoluble seam colour from greenish-grey to mottled brown and greenish-grey (probably corresponds to increasingly oxidised fluids in the crossflow structure), unusual local increases in ore grade, large patches of sylvite-poor potash crosscutting units near the top of the ore zone, and drops in topography >10m of the marker seams across an anomaly. For example, within 5 m of a large salt anomaly, Boys (1990) found large blebs (>200 cm² on the mine wall) of sylvite-poor potash that crosscut the units of an incomplete potash cycle near the top of the main ore zone. Anhydrite, a less soluble salt, is also more common in a salt anomaly than in the adjacent ore. Once into the anomaly facies, possible indicators of a nearby major collapse feature include: stretched clay seams; folded beds; small collapse features (1-20 m scale); and split clay seams with salt appearing to be injected into the seam.

In a study of “barren bodies” in the Subiza Mine, Navarra, Spain, Cendon et al. (1998) recognised a syndepositional mechanism of “salt horse” formation (Figure 11.26). It was controlled by brine pool stratification, not various diagenetic processes tied to subsurface crossflow. The Subiza potash deposit contains a 100 m thick Upper Eocene succession of alternating claystone and evaporites (sulphate, halite, and sylvite). The evaporites accumulated in an elongated basin that is one of the depocentres within the 250 km long South Pyrenean foreland basin (Figure 8.10). Slope instability along the margin of the basin, perhaps

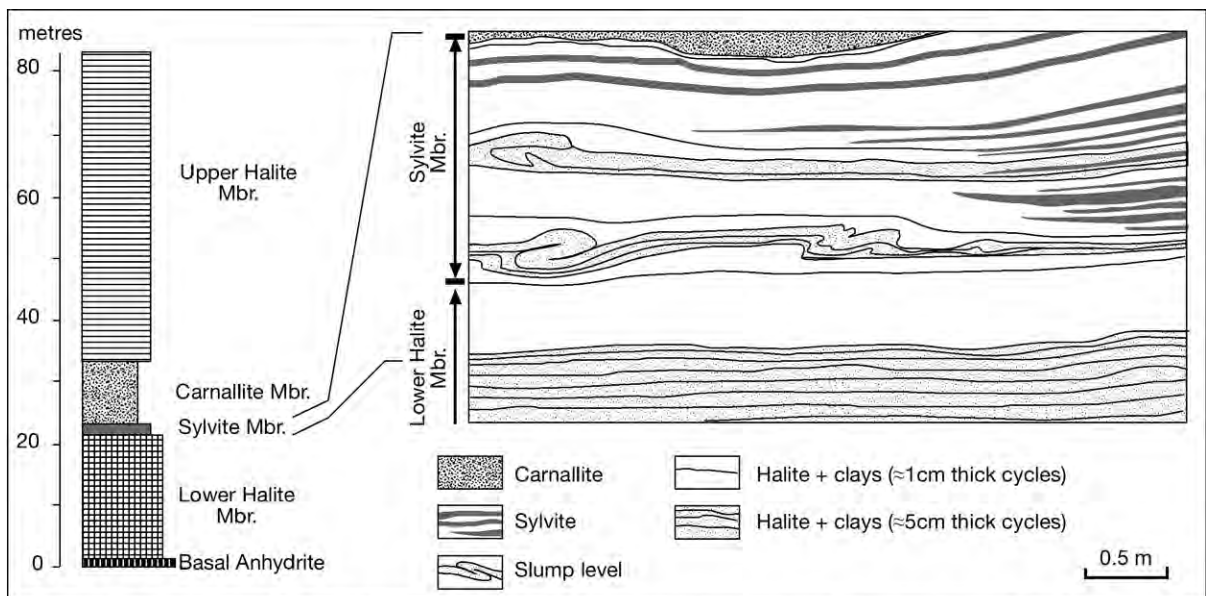

Figure 11.26. Stratigraphy of Upper Eocene potash section based on sequence cored in Biurrun borehole and tied to a mine wall sketch from Subiza Mine, showing barren body made up of two superimposed slump structures with corresponding upper sections, where the overlapping sylvite beds evolve from absent to continuous (after Cendon et al., 1998).

Figure 11.27. Sequence of events controlling the flooding of the Patience Lake Mine (after Gendzwill and Martin, 1996).

promoted by tectonism, created mass wasting of the evaporite beds. This formed subaqueous mounds 0.5-2 m high and tens of metres across. As evaporation progressed, a stratified brine system formed and encroached over the mounds. Halite precipitated at the air-brine interface and sank to the bottom of the basin, along with terrigenous clays. Sylvite, however, precipitated only from the cooling of a lower denser bottom hugging brine. This brine was warm where it formed about the basin edge and cooled as it seeped into the deeper parts of the basin floor. As many mound crests extended into the upper less saline brine, the sylvite could not precipitate over these subaqueous highs. With progressive accumulation, the lower brine ultimately covered the mounds as sylvite beds overlapped the mound tops.

This model, however, is in my opinion problematic in terms of its hydrological restraints: it requires a hydrological system that encapsulates sylvite saturation and precipitation in the cooling lower brine with simultaneous halite precipitation in the upper brine. As discussed in Chapter 3, such a system is extremely difficult to maintain over time frames that allow metre-thick beds of evaporites to accumulate. A more likely hydrology is perhaps a desiccating and concentrating single brine body, which reached halite saturation at the “lake full” stages while the mounds were still covered with brine. It did not reach sylvite saturation until ongoing drying of the brine lake had lowered the level to where the crests of the mounds were exposed. Whichever model is accepted, what is most important in terms of potash geology is that breached syndepositional salt horses or barren zones are less likely to possess subsequent subsurface hydrologies that will flood mines, as compared with horsts induced by subsurface leaching. This type of salt anomaly would not be tied to a zone of potential inflow in an active mine. Using and applying it as an interpretation of salt anomalies in an ore zone outside of the region where it was documented has significant implications in terms of mine safety.

Intersecting unexpected salt anomalies, especially those associated with flowing undersaturated brines should always be noted and dealt with as early as possible in a mine plan. Otherwise these zones can impair or destroy a potash mine. In the 1970s the Patience Lake potash mine operation, located on the eastern outskirts of Saskatoon, encountered a natural collapse structure. Grouting managed to control the inflow and mining continued. Then, in January of 1986 the rate of water inflow began to increase dramatically from the same fractured interval (Figure 11.27; Gendzwill and Martin, 1996). At its worst, the fractures associated with the structure were leaking $75 \text{ m}^3/\text{minute}$ (680,000 bbl/day) of water into the mine. The

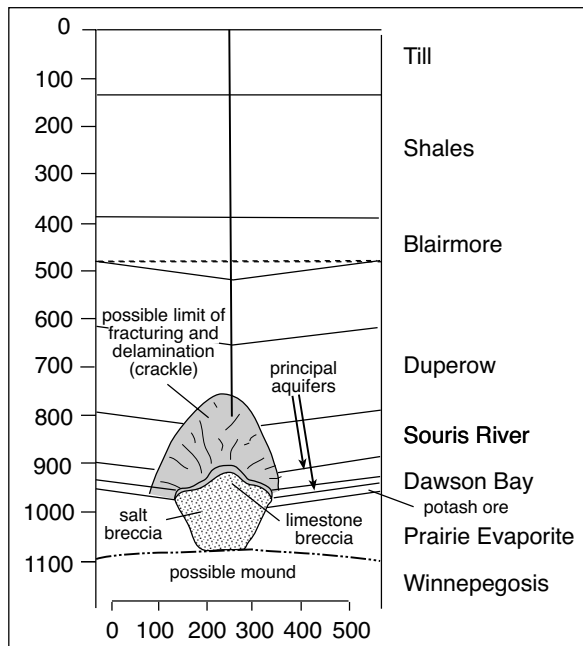

Figure 11.28. Dimensions of the salt collapse chimney that was breached in the Rocanville Mine in 1984 (after Prugger and Prugger, 1991).

water was traced back to the overlying Cretaceous Mannville and possibly the Duperow formations. Finally, in January 1987 the mine was abandoned. It took another 6 months for the mine to fill with water. Subsequent seismic shot over the offending structure suggested that the actual collapse wasn't even penetrated, the mine had merely intersected a fracture within a marginal zone of partial collapse (Gendzwil and Martin, 1996). Part of the problem was that the water was undersaturated and quickly weakened pillars and supports, so compromising the structural integrity of the workings. The unexpected intersection of one simple fracture system resulted in the loss of a billion dollar mine.

Patience Lake mine now operates as a solution mine by pumping KCl-rich brine from the flooded mine workings to the surface. The operation has a capacity to produce more than a million tonnes of potash annually. It works by circulating heated brine through the flooded mineshaft into the former workings, which extend up to 18 km from the main shaft. Heated recovered potassium-rich brines are pumped into surface crystallization ponds where the liquor evaporates and cools. Sylvite, potash, and other salt crystals form and settle to the bottom of the pond. This potash sludge is pumped from a floating dredge to the processing plant, while the cooled NaCl-saturated pond brine is reheated and re-injected into the mine to repeat the process.

Prugger and Prugger (1991) documented the successful treatment of an underground inflow into the Rocanville mine that occurred in 1984. In this case the mine was saved. It began when a mine entry accidentally penetrated a salt collapse structure that then began to leak brine into the mine at rates exceeding $10 \text{ m}^3/\text{min}$ (90,576 bbl/day). Seismic showed that the structure was roughly circular and relatively small in size (300m in diameter), and was isolated from other collapse structures (Figure 11.28). A grout well was drilled from the surface and encountered the collapse upon penetrating the carbonates of the overlying Duperow Formation, suggesting that fracturing associated with the collapse structure had extended as a blind chimney a considerable distance up from the Prairie level. Unlike the Patience Lake Mine flood, a combination of grouting and bulkhead emplacement in Rocanville succeeded in sealing off the inflow, thus saving the mine. Also unlike Patience Lake, the brine from the breached structure was halite-saturated so limiting the amount of dissolution damage. Different outcomes between the loss of the Patience Lake Mine and recovery from flooding in the Rocanville Mine may reflect the difference between intersecting a chimney that made its way to the Cretaceous landsurface and is now overlain by a wide-draining set of sediments versus intersecting a blind chimney that never broke out at the landsurface.

Other economic salts

So far we have discussed potash and concluded that the larger accumulations are marine-derived and accumulated in tectonic (mega-halite) basins with no Quaternary counterpart. We shall now discuss various accumulations of other evaporite salts that are exploited as economic resources. Almost without exception, they are lacustrine precipitates, formed by the evaporation of waters with nonmarine ionic proportions and in depositional settings that have same-scale Quaternary counterparts.

Borate salts (tincals)

Boron (from the Arabic *Buraq* or the Persian *Burah* meaning to glitter or shine) is a highly dispersed element in nature - averaging 3-20 ppm in the earth's upper crust, as estimated by various authors, and 4.6 ppm in seawater. It is both a volatile and mobile element and so tends to be enriched in the later stages of both magmatic crystallisation and volcanic eruptions and a few small economic deposits are found in skarns where late stage magmas have intruded carbonates. But most recoverable deposits of borate salts involve lacustrine deposits

Borate Mineral	Composition	B ₂ O ₃ %	Remarks
<i>Na Borates</i>			
Borax (tincal)	Na ₂ B ₄ O ₇ ·10H ₂ O	36.5	Major ore mineral in USA and Turkey
Kernite	Na ₂ B ₄ O ₇ ·4H ₂ O	51.0	Major mineral often converts to borax
Tincalconite	Na ₂ B ₄ O ₇ ·5H ₂ O	47.8	Intermediate or accessory mineral + manufactured endproduct
<i>Na-Ca Borates</i>			
Ulexite	NaCaB ₅ O ₉ ·8H ₂ O	43.0	Major ore mineral particularly in South America
Probertite	NaCaB ₅ O ₉ ·8H ₂ O	49.6	Secondary/accessory mineral
<i>Ca Borates</i>			
Colemanite	Ca ₂ B ₅ O ₁₁ ·5H ₂ O	50.8	Major ore mineral, particularly in Turkey. Secondary after inyoite
Meyerhoffite	Ca ₂ B ₅ O ₁₁ ·7H ₂ O	46.7	Intermediate ore mineral, rarely survives at surface
Priceite (pandermite)	Ca ₂ B ₄ O ₁₀ ·7H ₂ O	49.8	Ore mineral in Bigadic, elsewhere minor
Inyoite	Ca ₂ B ₆ O ₁₁ ·13H ₂ O	37.6	Minor ore mineral
<i>Other Borates</i>			
Sassolite	B(OH) ₃	56.4	Natural boric acid (fumarole, hot springs), once extracted in Italy
Hydroboracite	CaMgB ₆ O ₁₁ ·6H ₂ O	50.5	Secondary ore mineral
Szaibelyite (Ascharite)	MgBO ₂ (OH)	41.4	Ore in Russia and China (meta-evaporite ores)
Boracite	Mg ₃ B ₇ O ₁₃ ·Cl	62.2	Associated with potash especially in Europe
Howlite	Ca ₂ SiB ₃ O ₈ (OH) ₅	44.5	Accessory mineral
Bakerite	Ca ₄ B ₄ (BO ₄)(SiO ₄) ₃ (OH) ₃ ·H ₂ O	42.1	Accessory mineral
Tunellite	SrB ₆ O ₉ (OH) ₂ ·3H ₂ O	55.1	Accessory mineral
Tertschite	Ca ₄ B ₁₀ O ₁₉ ·2H ₂ O	65.1	Accessory mineral
Kurnakovite	Mg ₂ B ₉ O ₁₁ ·15H ₂ O	37.3	Accessory mineral

Table 11.5. Boron minerals in various exploited deposits.

in arid settings that were strongly influenced by volcanic activity at the time lake deposition occurred. They tend to involve abundant tuffs and basalts in the drainage basin, a semi-arid climate and a standing body of brine that at times becomes sufficiently concentrated to accumulate boron salts. A protective layer of other impervious less-soluble evaporite salts, such as gypsum or anhydrite, typically forms a carapace that prevents subsequent redissolution.

Four minerals comprise more than 90% of the borate salts used by the borate industry; the sodium borates - borax (tincal), kernite, the calcium borate - colemanite, and the sodium-calcium borate - ulexite (Table 11.5). Water content of the various borates tends to decrease with burial and to increase with exposure and weathering. Borax is the primary mineral in many US deposits, but with burial and dewatering it converts to tincalconite and kernite. If kernite is exposed to weathering or throughflowing groundwater it reconverts to borax.

US Borax, a member of the Rio Tinto Borax Group, is the largest global miner of B₂O₃, mostly of tincal ore. The company is also

the world's largest manufacturer of refined borate products. US Borax supplies almost half of the world's demand for industrial and speciality borates from its Kramer borate deposit at Boron in southern California's Mojave Desert. Turkey is the world's largest producer of borate ore, mining more than 1 Mt (1.1 million st) of salable product each year (Figure 11.29) including refined materials from Kirka and Bandirma. This makes Turkey the second largest producer of refined boron compounds after the USA. The government organization, ETI Holding A. S., is the sole producer of Turkish borate compounds through its subsidiary ETIBORA. S. Combined production of Turkey and the United States accounts for more than 50% of the global borate output on a product-ton basis. Additional volumes of mineral concentrates and refined products are also produced in South America, Russia and China. South American production is concentrated in Bolivia, Peru, Chile and Argentina.

In terms of dollar value the most commercially dominant boron salt is the pentahydrate salt (Na₂B₄O₇·5H₂O; tincal). It is used in very large quantities in the manufacture of insulation fibreglass and sodium perborate bleach. Boric acid is also an

important boron compound with major markets in textile fibreglass and in cellulose insulation as a flame retardant. Next in order of importance is borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$; sodium tetraborate decahydrate), which is used principally in laundry products. Use of borax as a mild antiseptic is minor in terms of both dollars and tons. Amorphous boron is used in pyrotechnic flares to provide a distinctive green colour, and in rockets as an igniter. Boron compounds are also extensively used in the manufacture of borosilicate glasses. Other boron compounds show promise in treating arthritis. The isotope boron-10 is used as a control for nuclear reactors, as a shield for nuclear radiation, and in instruments used for detecting neutrons. Boron nitride has remarkable properties and can be used to make a material almost as hard as diamond. The nitride also behaves like an electrical insulator but conducts heat like a metal. It also has lubricating properties similar to graphite. The hydrides are easily oxidized with considerable energy liberation, and have been studied for use as rocket fuels. Demand is increasing for boron filaments, a high-strength, lightweight material chiefly employed for advanced aerospace structures. Boron is similar to carbon in that it has a capacity to form stable covalently bonded molecular networks.

Historically, borates (as a component of natron salts) were used 4000 years ago in mummification. At the same time borax (in a purer form than natron) was imported from the Far East for use as a gold flux by the ancient Babylonians. The word tincal comes from the Babylonian *tincar* meaning "Far East." By the 8th century AD, the Arabs around Mecca, Medina and Baghdad were using imported borax (*tincar*) as a kiln additive or flux to

Figure 11.29. Borate production (thousand metric tons of boric oxide B_2O_3 equivalent), compiled from USGS on-line data tables downloaded from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005.

braze or harden precious metals, especially gold. Borax glazes were used in China from AD 300, and boron compounds were used in glassmaking in ancient Rome. By the Middle Ages, borax from Tibet was regularly imported into Europe. At the time borax was very expensive, and this limited its use principally to the precious metal trade where goldsmiths used it as a soldering agent and in the refining of metals and assaying of ores. Quantities traded were small, its method of production was a tightly held secret of the alchemist's guild, and its source in the borate pavements precipitated in the salt lakes of Tibet remained a mystery until the second half of 18th century. As such it was a valuable traded commodity along the Tibet to Europe trade route travelled by Marco Polo. Tibetan borax was transported over the Himalayas into India in bags tied to the necks of sheep.

Today, borate's supply routes are much more mundane, but the volumes consumed in the chemical industries are huge (Figure 11.29). Currently, borax (tincal) is the preferred sodium borate ore as it needs little processing, crushes freely and dissolves readily in water with a rate of solubility that increases steeply with increasing temperature. "Tincal" is the old general name for borax in the chemical industry and is sometimes used to distinguish the naturally occurring borax ore mineral (tincalonite) from the chemically identical manufactured salt called tincal. Kernite (a source for boric acid manufacture) is present in large tonnages in the USA and Argentina. It is less suitable as an ore salt than borax or tincalonite despite its high B_2O_3 content. Kernite has excellent cleavage, but crushes into fibres that tend to mat and clog handling equipment. It also is much less soluble in water than borax and so is less suitable as a feedstock for the manufacture of pentahydrate. Colemanite is the preferred calcium-bearing borate; it is the least soluble of the commercial borates and only slowly dissolves in water, but is highly soluble in acid solutions. Szaebelyite, a magnesium borate, was the principal source of borate in the former Soviet Union and is the main ore mineral in the Proterozoic meta-evaporite ores of the Liaoning Province, China.

Turkish borates

The borate district of western Anatolia has 5 districts, from west to east they are: Bigadic, Sultancayir, Kestelek, Emet, and Kirka (Figure 11.30). Turkish borates have been mined for the last fifteen centuries. Proven borate reserves are 532 million tonnes with total estimated reserves of 987 million tonnes. Colemanite is mined at Bigadic, Emet, and Kestelek, ulexite is mined at Bigadic, and tincal at Kirka. Borax and colemanite ores are refined and concentrated at the Kirka and Bandirma plants. Bigadic borates are extracted from what is

the largest colemanite/ulexite deposit in the world, with high-grade colemanite and ulexite ores running 30% and 29% B_2O_3 , respectively.

The Kestelek deposit is 27 km southeast of the town of Mustafa Kemalpaşa in the province of Bursa. The borate ore zone there makes up part of an interbedded succession of marl, limestone, tuffaceous limestone, tuff and borate layers (Figure 11.30; Helvacı and Alonso, 2000). Borate layers are typically hosted in clays. Colemanite is present as nodule to boulder size masses (up to 1 m in diameter), and as thin layers of fibrous and euhedral crystals. Colemanite, ulexite and probertite predominate and sparse hydroboracite is also present locally. The Kirka stratigraphic succession comprises borates that are intimately interbedded with and penetrating into marls, claystones, zeolitized tuffs and tuffaceous epiclastic materials in bedded lacustrine sediments. The main boron mineral is borax with lesser amounts of colemanite, ulexite and other borate minerals. Volcano-sedimentary rock units in the Sultancayir deposit include borate-bearing gypsum intercalated in a sandy claystone unit. Calcium borates, mainly pandermite (priceite) and howlite, but also colemanite and bakerite, are interspersed within the Sultancayir gypsum.

All the exploited Turkish borate ores were originally precipitated as early Miocene (16–20Ma) perennial saline lake sediment within a series of northeast-southwest-trending elongate basins, which are underlain by a Palaeozoic and Mesozoic basement composed of ophiolites, marbles and schists (Figure 11.30; Helvacı, 1995). The Bigadic, Emet and Kirka lacustrine basins of western Turkey are hosted by Tibet-type extensional graben structures. The grabens developed during Miocene continent-to-continent collision along the Izmir-Ankara suture zone complex, where calc-alkaline volcanism was simultaneous with borate sedimentation. This volcano-sedimentary sequence consists of (from bottom to top) basement volcanics and volcanoclastics, lower limestone, lower tuff, lower borate zone, upper tuff, upper borate zone and olivine basalt (Figure 11.30). Borates in the upper zone occur in units up to 30 metres thick beneath a sediment cover that is 25 to 410 metres thick, while the lower borate zone is up to 65 metres thick and is found at depths between 150 and 950 metres.

All these Neogene borate deposits have thin sedimentary covers and have never been deeply buried (Helvacı and Orti, 1998). Borate precipitation occurred mostly in subaqueous settings, but in lake systems encompassing a range of evaporitic settings, from stable playa mudflats to deeper perennial lakes, the latter typically shoaling to shallow lakes and playa lakes.

Figure 11.30. Representative sections of the various Miocene borate deposits in western Turkey. All occur in local extensional rifts in a volcanogenic continent-to-continent collision setting (after Helvacı and Alonso, 2000).

Shallowing-upward cyclicality is commonplace in all ore beds and all ores precipitated in lakes in a hydrothermally active volcanogenic terrain (Figure 11.30). Colemanite tends to occupy the deposit's depositional margins, while laminated borax is more common in the centres of the lacustrine basins, with a zone of ulexite separating the two (Inan et al., 1973). This mineral zonation is syndepositional and cannot be ascribed to later burial diagenetic processes.

When details on these obviously primary deposits began to come to the world scientific literature in the mid 1970s the prevailing notion of borate or zones as thermal replacements during deep burial (based on the US deposits and the work of Foshag, 1921 and Garrels and Christ, 1959) were challenged. When details of the primary borate textures in South American deposits became known in the mid 1980s even some of the strongest proponents of the thermal replacement model for borate ores began to admit the possibility of a primary or syndepositional origin for the zonation of the world's borate deposits.

Borate minerals at Bigadic form two ore zones, now separated by thick tuff beds that have been transformed to montmorillonite,

chlorite, and zeolites (mainly heulandite) during diagenesis (Figure 11.31; Gundogdu et al., 1996; Helvacı and Orti, 1998). Colemanite with lesser ulexite predominates in both zones; but other borates, including howlite, proberite, and hydroboracite are present in the lower borate zone; whereas inyoite, meyerhofferite, pandermite, tertschite(?), hydroboracite, howlite, tunellite, and rivadavite are found in the upper borate zone (Helvacı, 1995). Calcite, anhydrite, gypsum, celestite, K feldspar, analcime, heulandite, clinoptilolite, quartz, opal-CT, montmorillonite, chlorite, and illite are also found in the Bigadic deposit.

Nodules of colemanite and ulexite predominate in both borate zones at Bigadic (Figure 11.31). Agglomerated colemanite and ulexite nodules construct alternating bedded horizons with relatively sharp boundaries. Because these minerals are readily dissolved and reprecipitated, early secondary masses of pure and transparent colemanite and ulexite are often encountered in cavities, nodules and cracks. Some nearsurface colemanite and ulexite beds are now so weathered they are completely replaced by calcite.

processes also produced small howlite nodules embedded in unconsolidated colemanite nodules.

In contrast to the colemanite-ulexite dominance at Bigadic, laminated lacustrine borax is volumetrically and economically the most important zone in the Kirka borate deposit (Helvacı and Orti, 2004). The deposit is symmetrically zoned in a lateral sense with a central body of Na borate (borax), an intermediate zone of Na–Ca borate (ulexite), and a marginal zone of Ca borate (colemanite; Figure 11.32a). The same mineral zonation is also developed in a vertical sense, although it is somewhat asymmetrical because of the presence of a discontinuous Mg borate horizon overlying the central body of borax. Older studies, based on analogies with US borate deposits, attributed the zonation to a diagenetic overprint on the margins of the original syndepositional borax-clay laminates of the lake (Inan et al., 1973). More recent work has shown that the Kirka sequence is depositionally fractionated and that the zonation represents a hydrologically controlled separation of evaporite minerals in a lake basin actively accumulating sediment (Helvacı and Orti, 2004). Lateral gradients in salinity in the mudflats passing into the perennially subaqueous centre conditioned the concentric pattern of the facies at Kirka. Thus, the various borax lithofacies zones (chemical, clastic, mixed) seen in the central ore body reflect precipitation in a lake that evolved with subsidence and climate. Conditions oscillated from predominantly subaqueous with variable brine depths (perennial lake stage), to an interstitial sabkha or mudflat setting (playa-lake stage). The evaporative concentration of

the boratiferous waters in the lake, together with the periodic changes in temperature of the water mass are the main controls on the crystallization of borax.

Helvacı and Orti (2004) found no petrographic evidence for a thermally induced inyoite-to-colemanite transformation, as previously proposed by the diageneticists and went on to argue

Figure 11.32. Depositional setting and zonation of Turkish borate deposits. A) Two models used to explain the zonation of Turkish borates; one uses diagenetic flushing by Ca-rich subsurface waters (after Inan et al., 1973), the other explains the zonation as a depositional separation (after Helvacı and Orti, 2004). B) playa stage of the Bigadic Deposit (after Helvacı, 1995). Deposition occurred under arid to semi-arid conditions within separate or interconnected perennial saline lakes located in an active volcanic area within lakes fed by borate-rich thermal springs.

that the moderate burial depths in all the various Turkish borate deposits are insufficient for the generalized transformations required by the diageneticists (Figure 11.32a). Rather the Mg borates represent evaporitic precipitates from the fractionation of the initial boratiferous inflow, they are not burial driven reaction products between pre-existing borates and groundwaters. Thus the mineral zonation in Kirka is primary, not only for borax and ulexite in the subaqueous dominated parts of the lake, but also for both the colemanite forming the marginal playa dominated zones and for the Mg borates overlying the central body of borax in Kirka. This same argument of syndepositional not burial flushing can be applied to Bigadic, which is then seen to be a deposit accumulating under predominantly playa conditions (Figure 11.32b).

Almost all workers now accept that the borax-clay laminite texture that dominates the core of the Bigadic deposit is subaqueous. Crystal outlines have a characteristic growth-aligned borax (palisade) texture in mm-cm thick layers separated by clay segregations. This is a texture similar in many ways to the hydroboracites of South American salars (Figure 11.34) and the Kramer deposit in the USA. Borax crystals in the lower portions of the lower borate unit in Kirka show zigzag tops mantled by clay, while borax layers in the upper parts of the same unit show erosional tops. The same textural transition from zig-zag to truncation is seen in meromictic gypsum lakes as the depositional surface aggrades across the zone of saturation in a permanently subaqueous brine lake (Figure 2.49). The nodular Turkish borate ore of the playa margin is more enigmatic; it may be an early diagenetic playa mudflat precipitate or it may be an early alteration halo created by centripetal flushing of the borax core by subsurface waters (Figure 11.32a).

Initial volcanogenic waters that fed the alkaline perennial saline lake(s) were low in Cl and SO₄, and high in boron and Ca, with subordinate Na. Boron isotope data from the Turkish deposits are consistent with colemanite being precipitated from a more acidic brine than ulexite, with borax being precipitated from a brine that was more basic (Helvacı, 1995; Palmer and Helvacı, 1995, 1997). Borax precipitation and replacement to create ore grade beds typically occurred in a laminated gypsiferous host, either syndepositionally or in very early burial, perhaps in stratified brines where solar-derived brines mixed with upwelling boron-rich hydrothermal solutions (Figure 11.32). With further burial the anhydritisation of gypsum began at depths that were less than 250m. At the same time, anhydrite also replaced some of the earlier formed borates (priceite, bakerite and howlite), along with associated celestite. Subsequent uplift and exposure of some parts of the sequence rehydrated nearsurface anhydrite

to secondary gypsum and partially transformed priceite and howlite into secondary calcite.

South American Borates

In the Andes of South America there are more than forty borate deposits hosted in Cenozoic volcanogenic-sedimentary rocks in a 880-km-long stretch along the common borders of Argentina, Bolivia, Chile and Peru (Figure 3.38). This area is a high plateau that was created in the late Cenozoic during a non-collisional compressional orogens. Most deposits are small aprons or cones of borax and ulexite near volcanic vents, with reserves measured in thousands of tonnes. But in the larger endorheic basins, where volcanogenic brines can pond and concentrate, there are beds of ulexite, borax and inyoite in salars ranging up to hundreds of square kilometres in area, with reserves of ulexite ore measured in millions of tonnes (Figure 3.37). Two main styles of occurrence characterise the borate salts in this region; 1) nodular borate locally known as “papas” (potato or cottonball borate), and 2) bedded borates usually interbedded with lacustrine muds and locally known as “barras, bars or bancos”. Nodules are often the preferred texture to mine as they tend to create a purer product when cleaned and air dried (can be > 28% B₂O₃; Garrett, 1998).

The main borate reserves are in the Argentinian Andes in the Pastos Grandes Basin within a 1500-m-thick volcanoclastic and lacustrine stratigraphic unit known as the Sijes Formation. During deposition of the Sijes Formation there were 3 major pulses of borate generation. These pulses are easily identifiable in the central part of the basin but become indistinct and tend to thin out toward the edges (Helvacı and Alonso, 2000). Along its approximately 30 km outcrop, the Miocene Sijes Formation is characterized by a string of borate deposits and occurrences. The borate-bearing members of the Sijes formation are from the base to top as follows: Monte Amarillo (hydroboracite), Monte Verde (colemanite-inyoite) and Esperanza (colemanite). The Tincalayu and Loma Blanca areas are important principally for borax occurrences whereas in modern active salars, borax and ulexite are the dominant borate salts (Helvacı and Alonso, 2000). Ulexite was also the first evaporite to precipitate in the Pleistocene Blanca Lila Formation near Salar Pastos Grandes, followed by gypsum then halite (Vandervoort, 1997).

Typically, South American salars with substantial borates have a central zone, consisting of a relatively thick halite, surrounded by a thinner marginal sulphate zone consisting of a variety of sulphate minerals, as well as variable amounts of halite, ulexite and other borates (Figure 11.33a; Ericksen, 1993; Helvacı and

Alonso, 2000). Salars that are filled mostly with gypsum lack this zonation. The borate zonation may be symmetrical (bull's-eye pattern) with sulphate surrounding a central halite core, or asymmetrical with the halite zone crowded against one side of the salar. This is the situation in Salar de Atacama where tectonic tilting has displaced the lowest part of the brine sink to the southern end of the playa (see Figure 11.41). Both the halite and sulphate zones are typically underlain by gypsum and this in turn by siliciclastics. Alternating arid and pluvial climatic episodes in the Andes since the mid-Miocene, means the playas are filled by alternating salt beds and siliciclastics (Figures 3.40, 3.45).

Most borate-rich salar deposits in South America have undergone relatively little deformation since they were first emplaced. As a result, borates are extracted from a number of open pit operations in the Andean Altiplano (Alonso, 1991). Borax Argentina, a member of the Rio Tinto Borax Group, extracts sodium borate ores at its Tincalayu Mine, high in the Argentinian Andes Mountains (altitude of 4100 metres). Nearby, hydroboracite is extracted at Sijes, and ulexite from two dry lakebeds, Salar Cauchari and Salar Diablillos, all in the Salta province. Originally developed in 1976, Tincalayu is now Argentina's largest open pit operation measuring more than 1.5 km (1 mile) across and 100 m (330 ft) deep and extracts ore at a rate of 100,000 tons per year. In Bolivia, ulexite is extracted from mines in the Salar de Uyuni (Figure 3.42). In Chile, borates are extracted from Salar de Surire; the largest single ulexite deposit in the world with reserves reported to be ≈ 1.5 million tonnes of 35% boron oxide. The salar is located some 4,250 metres above sealevel and within the borders of the Monumento Natural de Surire national park of Chile.

Almost all the borate salts described so far are enigmatic, perhaps syndepositional replacements of gypsum, but in the Sijes Formation (Miocene, central Andes, NW Argentina)

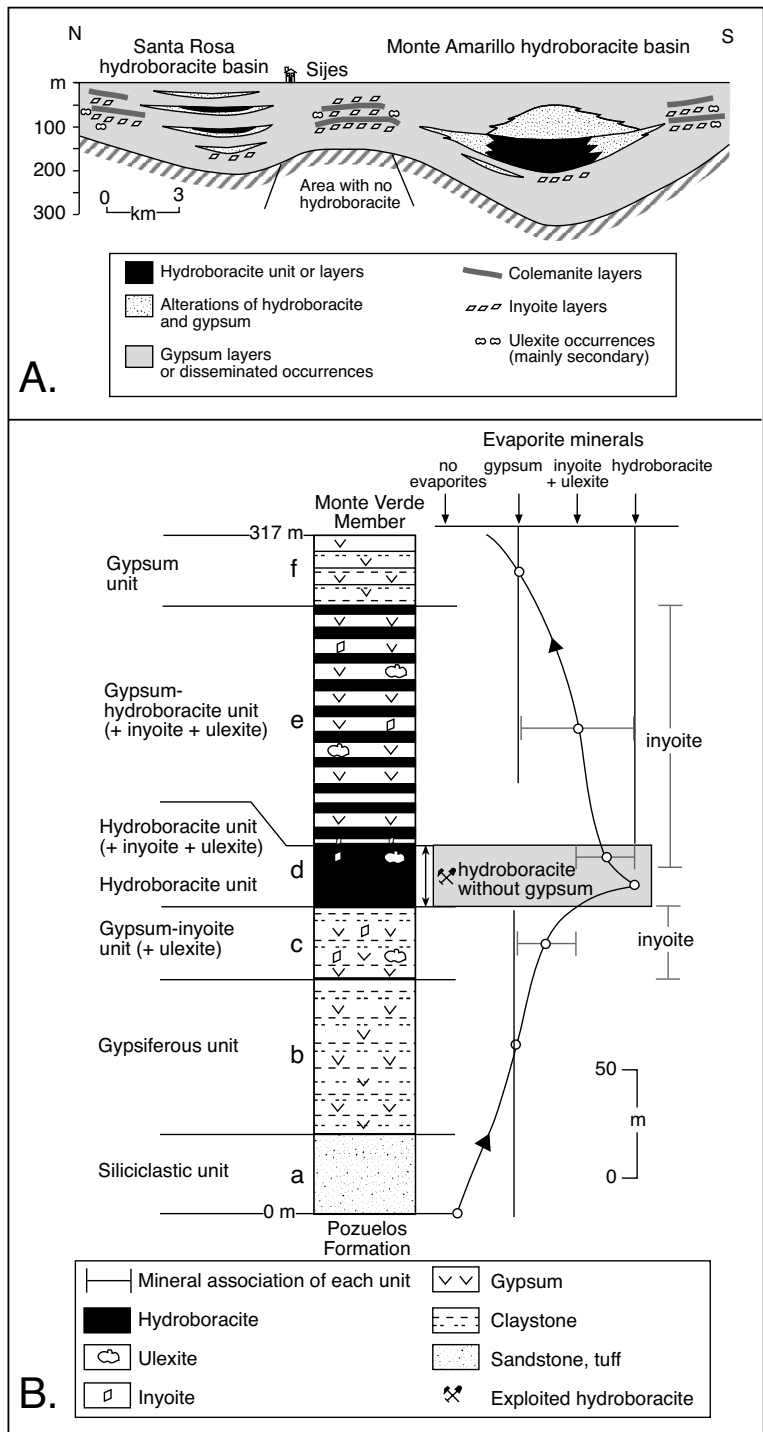

Figure 11.33. Hydroboracite in the Monte Amarillo Member, Sijes Sierra, northern Argentina. A) Borate facies distribution in the Santa Rosa and Monte Amarillo basins. B) Type section of the Monte Amarillo Member showing distribution of the various borate minerals and the relative position of the exploited horizon (after Orti and Alonso, 2000).

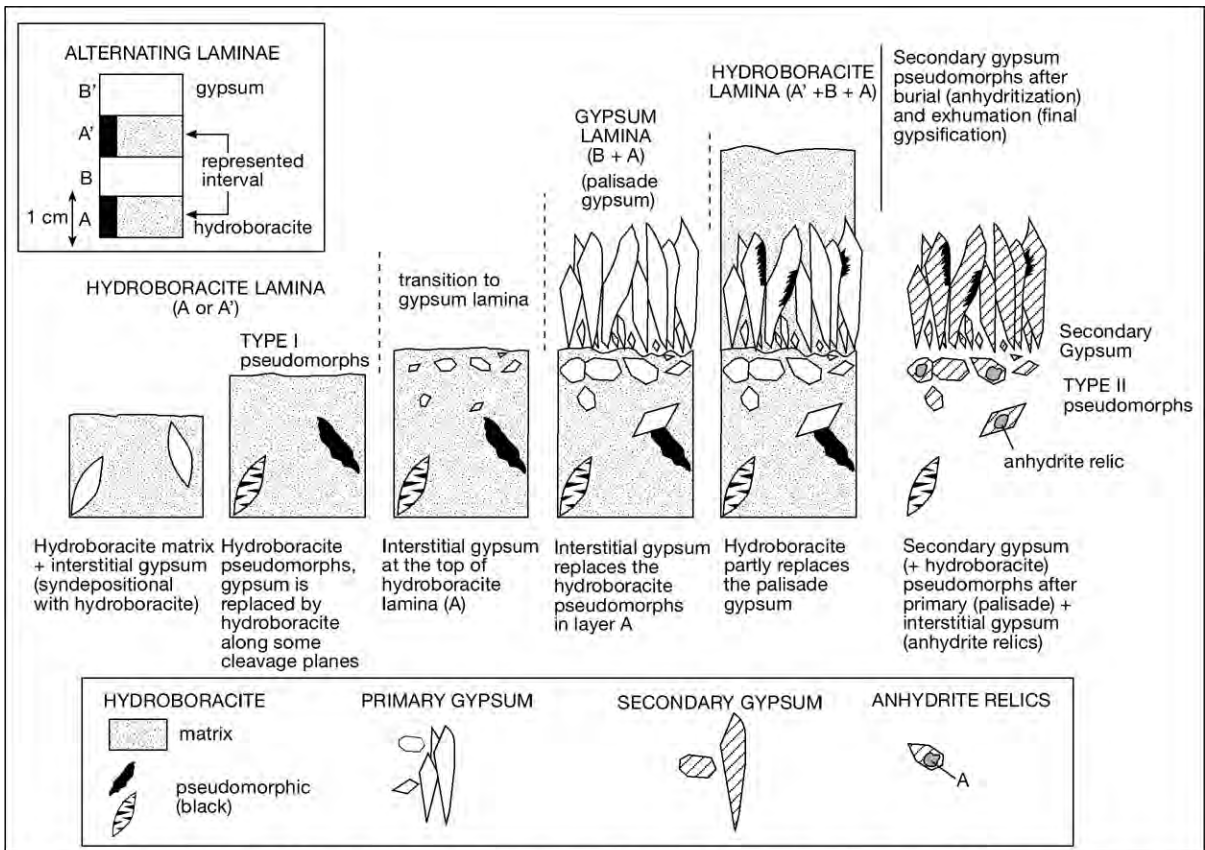

Figure 11.34. Syndepositional formation of hydroboracite pseudomorphs after gypsum in primary hydroboracite successions composed of alternating cm-scale beds of hydroboracite and gypsum precipitates. Most of the hydroboracite is primary, not secondary (after Orti and Alonso, 2000).

some of the hydroboracite is thought to be a primary precipitate (Orti and Alonso, 2000). This area encompasses the largest known hydroboracite accumulation in the world. In outcrop, the sulfate minerals in the Sijes Fm, are mostly secondary gypsum and minor anhydrite, while the borate minerals are hydroboracite with subordinate inyoite and colemanite, and some ulexite. The Sijes Formation (Miocene) has four members; three of them are fine-grained siliciclastic, tuffaceous, and chemical-evaporitic in nature (the Monte Amarillo Member, the Monte Verde Member, and the Esperanza Member), while the other member is dominantly a coarse-grained siliciclastic (the Conglomerate Member). The overlying Blanca Lila Formation (Pleistocene) is made up of claystone and evaporites (including borates). Much of the hydroboracite resides in the Monte Amarillo member.

The Monte Amarillo Member accumulated in two coeval, shallow lacustrine Miocene subbasins (Figure 11.33a): 1) The Monte Amarillo hydroboracite subbasin, and 2) The Santa Rosa

hydroboracite subbasin. The Monte Amarillo hydroboracite subbasin encompasses the borate districts to the south of the Sijes village and is an area where hydroboracite has been mined since 1985. This district is located at an altitude of 3900 m and lies near the palaeogeographic center of the Monte Amarillo subbasin. The Santa Rosa hydroboracite subbasin, includes the borate districts to the north of the Sijes village and is located at an altitude of 3900 m. This subbasin occupies a marginal position with respect to the Monte Amarillo subbasin. In these subbasins, the hydroboracite layers are fine-grained, light brown, and difficult to break with a hammer. Because of these characteristics, they had for long time been confused with limestones. In both subbasins, gypsum accumulated in the margins and the hydroboracite in the centers, the intermediate zones being characterized by mixed gypsum hydroboracite layers.

The type section of the Monte Amarillo Member is 317 m thick, contains an inyoite unit 36 m thick at the base, which is overlain by a hydroboracite unit 137 m thick (Figure 11.33b;

Alonso, 1986). This hydroboracite unit has variable amounts of inyoite and ulexite. Gypsum layers are ubiquitous in the Monte Amarillo Member. Samples of two tuff levels located close to the base and at the top of this section were dated as 6.81 ± 0.18 and 6.25 ± 0.15 Ma, respectively, which indicates a depositional period of about 630,000 years for the Monte Amarillo Member during the Upper Miocene (Alonso 1986).

Alternations between gypsum and hydroboracite laminae are present in the transition from gypsum units to hydroboracite units in the Monte Amrillo member and contain fabrics that indicate both the borates and the gypsum-anhydrite were primary or syndepositional precipitates (Orti and Alonso, 2000). Fine-grained hydro-boracite matrix commonly cements and partly replaces the precursor gypsarenite crystals in the gypsum laminae (Figure 11.34). In addition, micronodules of hydroboracite can displace or replace gypsum laminae. Two styles of pseudomorphs after interstitially grown (precursor) gypsum are preserved in hydroboracite laminae. Type I corresponds to hydroboracite pseudomorphs after euhedral, lenticular or tabular gypsum crystals. Many of these pseudomorphs are thin, curved, lenticular or slightly deformed, and now composed of fine-grained hydroboracite crystals. Others are made up of parallel prisms of hydroboracite that project inward from the boundaries of the pseudomorph with the centre commonly occupied by secondary gypsum bearing anhydrite relics. Parallel arrangement of the prisms suggests replacement of the precursor gypsum along the main cleavage plane (010). Type II corresponds to secondary gypsum pseudomorphs after equant to prismatic, commonly zoned (precursor) gypsum crystals. These pseudomorphs are located in the uppermost parts of hydroboracite laminae and grade into secondary gypsum pseudomorphs that constitute the overlying gypsum lamina. Type II pseudomorphs crosscut and replace type I pseudomorphs suggesting that type II pseudomorphs postdate type I.

Alternations between gypsum laminae (with aligned crystal outlines) and hydroboracite laminae imply bottom precipitation in a shallow subaqueous environment, where fine-grained, soft hydroboracite mud encased the gypsum in the laminated gypsarenites. The prevalent microcrystalline or fibrous textures of hydroboracite suggest a primary origin for these alternations in which precipitating conditions oscillated from gypsum to hydroboracite. Hydroboracite matrix appears to have precipitated interstitially within the open fabric of the (precursor) gypsarenite under syndepositional conditions (Orti and Alonso, 2000). This precipitation, together with associated partial replacement of (precursor) gypsum crystals, occurred during the sedimentation of the overlying hydroboracite lamina (Figure

11.34). In the hydroboracite laminae, type I pseudomorphs seem to correspond to (precursor) gypsum crystals that grew interstitially in the hydroboracite matrix when the borate concentration of the brine was relatively low. It appears that these crystals were very soon replaced by the hydroboracite matrix. The deformation of the pseudomorphs that are formed by fine-grained hydroboracite suggests that the replacement process took place in a soft matrix under syndepositional conditions. However, when this replacement occurred as a growth of prisms along the gypsum cleavage planes, the pseudomorphs remained undeformed and consistent. In general, this mechanism was less penetrative, and many pseudomorphs had a mixed hydroboracite–gypsum composition. Presumably, in these mixed pseudomorphs, the anhydrite replacement of the gypsum postdates the partial hydroboracite replacement. These pseudomorphs changed to hydroboracite–anhydrite during burial, and to hydroboracite–secondary gypsum in final exhumation. Type II pseudomorphs seem to correspond to (precursor) gypsum crystals that grew interstitially toward the tops of the hydroboracite laminae during precipitation of the overlying gypsarenite layer.

Beds dominated by primary gypsum (gypsarenite) and syndepositional anhydrite were first precipitated during deposition of the Monte Amarillo Member, in association with limited amounts of calcium borates (colemanite, inyoite). This was followed by beds containing hydroboracite (calcium/magnesium borate) and alternating gypsum and hydroboracite layers also formed. The hydroboracite at this level in the stratigraphy is mainly a primary mineral, although it also replaced some gypsum under syndepositional conditions (Figure 11.34). The formation of colemanite, which occurred during early diagenesis, is linked to brines precipitating calcium sulphates (gypsum and anhydrite), whereas inyoite coexists with brines precipitating both calcium sulphate and magnesium-bearing borates. Transformations among the various borate minerals during burial diagenesis were not detected by Orti and Alonso (2000). Primary gypsum was transformed into anhydrite from the onset of early diagenesis through to moderate burial diagenesis. The boron source of these deposits is volcanic/hydrothermal activity in the central Andes during the Miocene.

North American borates

The United States is the world's largest producer of boron compounds and the second largest producer of borate ore. Domestic producers exploit saline brines and bedded playa deposits such as Searles Lake in California (Smith, 1979) or their Tertiary counterparts at Boron and the nearby Death Valley area (Kisler

and Smith, 1983). In the Death Valley area the borates were deposited 6 Ma and there are more than 23 deposits. In all the borate ore is contained in the lower 150m of the 2,100m thick Pliocene Furnace Creek Formation. The interiors of most of the ore deposits preserve unaltered bedding planes and uniform depositional patterns. There are few to no indicators of syndepositional alteration (slumps, pseudomorphs) in the centres of the deposits but considerable evidence for alteration and replacement about the deposit's edges. The agglomerated nodular structure of much of the originally exploited ore meant that earlier miners in Death Valley described the various exposures of borate ore as ^{11,2}cottonball or cotton-tail (like a fluffy rabbit tail). Regionally a series of projected shoreline features can be traced from the Billie to the Boraxo to the Sigma-White Monster mines and residues of ancient geothermal spring mantle deposits are locally present (Garrett, 1998).

The exploited massive borate facies in the various Death Valley deposits are made up of thick, massive borate layers, locally containing host rock clasts with sharp to diffuse boundaries. Borate formation first took place at or below the sediment/water interface. The composition of the borate deposits in Death valley varies from mainly colemanite to zoned accumulations, with colemanite surrounding a core of probertite and ulexite. High Ca/Na ratios favored primary deposition of hydrated Ca-borates, which early workers argued were subsequently transformed by diagenetic dehydration to colemanite (Foshag, 1921; Christ and Garrels, 1959). Gradual depletion of Ca and decreasing Ca/Na ratios in the mother brine resulted in Na-Ca-borate precipitation, while any renewed onset of elevated Ca/Na ratios again caused Ca-borate deposition.

These older models for the formation of colemanite as a burial replacement of ulexite and inyoite via flushing by "intruding warm borax solutions" never clearly addressed a number of textural and conceptual problems, namely (Garrett, 2001); 1) Where did these conversion liquours come from? 2) How did they maintain their chemical uniformity? 3) How did they totally and completely pervade and replace what where impermeable units, 4) What was the required voluminous Ca source needed to accomplish the transformation and 5) Where did the residual brine go? In addition, why are there no widespread disruption texture and slump structures both within and above the bedded salts and why are commonplace colemanite alteration minerals like priceite, ginorite, nobleite and gowerite absent. A similar

^{11,2}Interestingly, the mineral name colemanite is named after one of the early miners in the Death Valley region, Mr. William T. Coleman, he could really say that he made a name for himself mining cottonball.

set of problems beset the older notions that the dehydration of borax to kernite indicates a deep burial conversion process. The problems are yet to be solved.

One of the largest deposits in the Death Valley area is the Billie orebody, a 1,100m long lens of ulexite, proberite and colemanite, interbedded and surrounded by limey laminated lacustrine mudstone and shale. Fault activity controlled the position of the lake bed borates and some beds now have local dips of upwards of 45°. The Billie orebody is currently mined by the American Borate Company; the deposit has an average thickness of 45 - 55m and a width of 220m, and a regional dip of 20-30° toward the southeast. Reserves are 2,700,000 metric tons of ulexite-proberite at 27% B₂O₃ and 11,000,000 metric tons of colemanite and 21% B₂O₃ (Garrett, 1998).

The borate ore zone at Billie Creek is hosted by shales of the Furnace Creek Formation and is made up of metre-scale units of nodular borate, mainly colemanite, interbedded with laminated mudstones deposited in a saline lacustrine environment during extension of the basin. The hosting laminites lack features of syndepositional exposure or wave-reworked deposition, indicating that the borate-hosting sediment first accumulated on the floor of a density-stratified perennial lake (Tanner, 2002). The presence of interbedded sulphate minerals in this facies suggests that salinity in this lake was elevated. Metre-scale mounds of porous limestone with a clotted-micritic fabric define spring-apron tufas that formed where groundwater discharged along fault-fed outflows about the edge of a more saline water mass.

The Kramer deposit near Boron, California, in the Mojave Desert is 140 km north northeast of Los Angeles. The total borate area (including the ulexite and colemanite rims) is 8 km (east-west) by 1.6 km (north-south). The Kramer deposit within this area is about 1600m long, 800m wide by 100m thick, and consists of a lenticular central mass of borax/kernite with interbedded montmorillonite-smectite clay. Borate ore reserves currently exceed 100 Mt (110 million st). The original borax target was 45-305 metres deep and dipped 10-15° to the south. The deposit was discovered in 1913 and was developed as an underground operation during the 1920s. It was converted to an open-pit operation in 1957. Since that time, the operation has grown to become the largest mining operation in California. The pit is now more than 2.4 km (1.5 miles) wide and 245 m (800 ft) deep. Ores are part of the shale member of the Kramer beds, which include an arkose member above and the Saddleback Basalt below.

The age of the deposit is 19 ± 0.7 Ma and it defines a small sub-basin in a much larger Tertiary lacustrine basin. It is encased in arkosic sands, silts and minor volcanics and limestones. Sedimentation in the basin was interrupted by flows of acidic lava (olivine basalt to latite) known as the Saddleback Basalt, it constitutes the base to the borate ore zone and also interfingers with other sediments of the basin fill. The upper part of the basalt in the mine area has fractures filled with ulexite and searlesite and its contact with the overlying sediments is defined by an "apple green" siliceous shale that contains ostracod carapaces. The color of the shale reflects its creation by the basalt reacting with lake waters. Bernard and Kistler (1966) defined the sedimentology of borate beds above the Saddleback Basalt. First is a 7.6-15 m thick footwall shale, further divisible into an initial barren (≈ 3.7 m) shale and then a ulexite zone. This is a layer of greenish-gray at times black fissile shale that is thinly laminated, micaceous and at times contorted. Locally it encloses lenses of arkosic sandstone and coarse conglomerate. Above this are the borax beds interbedded with clay and shale along with some beds and lenses of tuff, arkosic sand and conglomerate. The low permeability of these lacustrine shales is thought to have helped preserve the borax by preventing entry of groundwaters. Laterally and vertically away from the deposit's borax/kernite core, the borate facies changes to ulexite and colemanite, and the levels of shale interbeds and clay impurities in the borates become more significant (Bowser

and Dickson, 1966). The deposit is believed to have formed in a shallow Mid-Miocene saline lake, fed by Na- and B-rich thermal springs, a response to the later stages of volcanism. Saline sodium-borate-bearing thermal spring waters, being denser, sank to the lake bottom, cooled, and precipitated borax as they cooled. The original lake position was controlled by faulting contemporaneous with the accumulation of the borax. Continued fault movement, associated with the middle Pliocene uplift of the Mojave Block, tilted and dropped the lake sediments, which are now buried by more than 760 m of late Miocene and Pliocene arkosic sediment. Older models argue that deeply buried portions of the borax deposit were altered, via water loss, to kernite at this time. Renewed movement in late Pliocene–Pleistocene uplifted the deposit and drove some erosion of the original borate so that the outer portions of the kernite facies were rehydrated at that time. The deposit was then covered by 9 to 21 m of Pleistocene and Recent sands and gravels (Barnard and Kistler, 1966, Siefke, 1991).

Searles Lake in southeastern California is located in the lower central portion of a small block-faulted desert valley with a drainage area of 1600 km² and located midway between Boron and Death Valley (Figure 11.35). In the Pleistocene counterpart to the lacustrine evaporites that entrain the exploited Neogene deposits of Boron and Death Valley. The central pan, some 103 km² in extent, overlies a crystalline mush of mixed salts

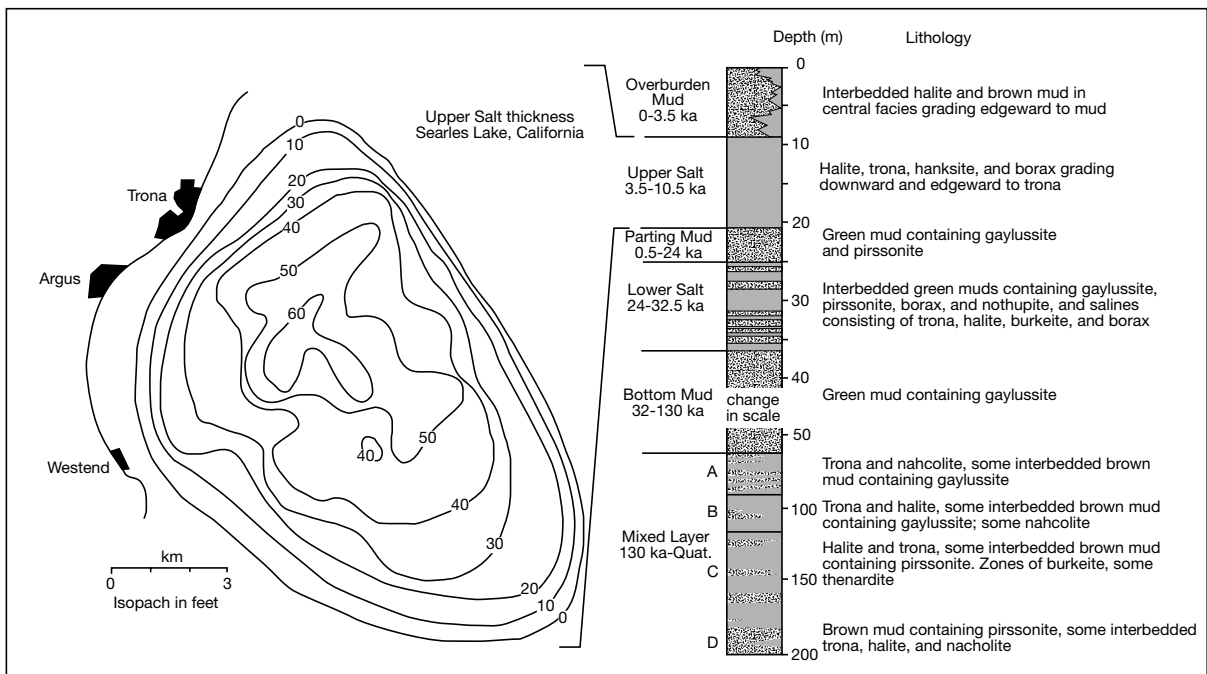

Figure 11.35. Searles Lake, California showing isopach of the "Upper Salt" in feet and the stratigraphy of the three salt layers and the intervening clays (after Smith, 1979).

dominated by sodium carbonates, but also with borax, clays, and hypersaline interstitial brines. The brine recovery operation is a multicomponent chemical system and borax is only one of the products recovered; others include sodium sulphate, lithium compounds, potash, bromine and other salts. Boron was supplied to the lake via thermal springs along the Sierra Nevada frontal faults in Long and Owens Valleys (Smith, 1979).

There are two main solution-mined salt horizons beneath the central pan: the “upper salt,” some 9 to 27 m thick (averaging 15 m), with a brine content averaging 1.0% B_2O_3 ; and the “lower salt,” some 8 to 14 m thick, (averaging 12 m), with a brine content averaging 1.2% B_2O_3 . The upper salt is overlain by a recent surficial mud and salt crust some 7 to 9 m thick and is separated from the lower salt by 3 to 6 m (average 4 m), of relatively impervious clays called the “parting muds” (Figure 11.35) The upper two salt beds accumulated in the period 3.5-40 Ka. There is also a much deeper salt bed with a mineralogy dominated by trona-nahcolite-halite with lesser amounts of burkeite-thenardite.

The salt mush in both the upper and lower salt beds is quite porous (0.35-0.40) and the stored brine is pumped via a series of wells into adjacent saltworks where borate, sodium bicarbonate and sodium sulphate salts are recovered. A constant resupply of brine to the mush beds is maintained by natural recharge and percolation of dilute refinery effluent, which is pumped back into the mush beds. The two salt horizons are pumped separately as they differ somewhat in chemical makeup and therefore require different plant treatments. Historically, until 1979, the upper salt was the solution mining target, since then the lower salt has been mined as a trona target and processed using carbonation.

Other Borate deposits

Borates in China are found in salt lakes on the Qinghai-Xizang (Tibet) Plateau, where typical lake waters contain 85 mg/l of boron oxide (Figure 11.2; Sun and Li, 1993). The maximum value of boron oxide in the brine is around 1,500 mg/l. However, the largest economic borate reserves in China occur not in Quaternary/Tertiary lakes but in the Precambrian meta-evaporites of Liaoning Province. Reported reserves are 44 million tonnes of boromagnesite with 8.4% boron oxide content. The deposits in the Liaoning Province represent 64% of the country's total boron resources and 90% of these deposits are associated with banded iron formations.

The world's only exploited marine borate deposit is in the Inder district of Kazakstan (former USSR), north of the Caspian Sea. The borates form bedded lenses that are up to 3 metres thick and hosted in the gypsiferous caprock in the 100+ km² crest of a large Permian salt dome. Ores are magnesian borates, rather than the more commonplace sodian-calcian borates. Mineralisation is centred on fractures near the top of the dome, where borates have precipitated in a matrix of gypsum, clay and anhydrite. The fluids precipitating borate are thought to be derived from intrusive geothermal springs (Garrett, 1995) Boron is also extracted from the brines of nearby Lake Inder. This salt lake has a surface salt crust along with about 30m of brine-saturated salt, which contains potassium chlorides and bromides as well as borax (Kisler and Smith, 1983). Unlike the other economic borate deposits of the world, this deposit is sourced by dissolving Permian marine salts, it is not tied to volcanism, hence the association with the magnesian salts.

Its marine origin is obvious in its boron isotope signature, which is clearly much more enriched in ¹¹B than nonmarine sediments (Figures 2.25; Swihart et al., 1986). The clear separation of nonmarine and marine borate salts using boron isotopes is also used to define parentage of various meta-evaporitic tourmalines in the meta-evaporites of Liaoning, China. Isotope analysis is a useful technique for determining boron source long after the original salts have evolved into lattice components of high temperature and high pressure minerals (see Warren, 1999; Chapter 6).

There are more than 112 separate borate deposits (12 contained 98% of the reserves) in the Liaoning area on the Liaoning Peninsular in northeast China the main ore mineral is szaibelyite (aka ascharite) and szaibelyite-ludwigite, with some suanite. All are Mg-borates and are hosted along with magnesite and magnetite in fractured marbles. Deposits are thought to be meta-evaporitic skarns originally deposited as lacustrine borates interbedded with volcanic tuffs (Peng and Palmer, 2002).

Borate minerals do occur in marine evaporites other than the Inder deposit, but not in sufficient amounts to be economic targets. For example, potash ore processing of the Zechstein potash ores in Germany leaves behind borates in the mud residues. At times this borate has been recovered as a small-tonnage byproduct (Garrett, 1998). Borates such as priceite and howlite are present in minor amounts in the Cretaceous marine evaporites of the Maha Sarakham Fm. in Thailand, in the Mesozoic evaporites of the Atlantic margin in Nova Scotia, Brazil and west Africa, and in the Permian evaporites of the Delaware Basin, USA (Chapter 7). In all cases it seems that the

levels of boron in the marine bitters were never sufficient to create economic levels of borate salts, that requires hydrothermal circulation, usually in a volcanic basin.

Rock gypsum and rock salt

The depositional, diagenetic and geological settings of halite and gypsum/anhydrite (the most commonplace evaporite salts) were discussed in detail in earlier chapters, and will not be repeated here, only aspects relevant to economic exploitation and production are presented.

Gypsum

Annual world production of gypsum exceeds 100 million metric tonnes (Figure 11.36). Seven countries account for some two-thirds (66%) of world production. In descending order of production they are; the United States (23%), Iran (9%), Canada (8.5%), China (8%), Spain (7.5%), Mexico (6.5%) and Thailand (4.5%). Canada, Spain, Mexico and Thailand export much of their crude gypsum, while Iran and China internally consume most of the gypsum they produce. About 75% of US gypsum production comes from Oklahoma, California, Iowa, Texas, Nevada, Michigan and New Mexico.

Gypsum's main usage is in the construction industry, mostly as calcined (burnt) gypsum in the manufacture of wallboard. In

fact, the word gypsum is derived from the Greek word *gypsos* meaning "to cook" in reference to calcined gypsum. Because gypsum quarries in the Montmartre district of Paris furnished calcined gypsum to much of Europe since the Middle Ages the calcined product is sometimes called "Plaster of Paris." Gypsum's utility to the construction industry stems from its hydrated character. When gypsum is calcined at 160°C it loses 1.5 moles of its combined water to form calcium sulphate hemihydrate (CaSO₄·1/2H₂O) or "Plaster of Paris." When mixed with water the hemihydrate can be spread, cast or moulded into the desired form, which then sets to a rocklike hardness. When spread between sheets of heavy paper and allowed to set it makes the plasterboard or wallboard used worldwide in the "dry wall" industry. Uncalcined finely crushed gypsum and anhydrite are used as retarding agents in Portland cement; the set of the cement is slowed, but the tensile strength is not lessened.

When applied as soil conditioners, gypsum and anhydrite can have beneficial effects. They decrease the salinity of salty soil, improve the permeability of clayey soil and provide sulphur, calcium and catalytic support, so decreasing fertilizer use and maximising the economics of crop production. Uncalcined gypsum is also used as a filler in a diverse range of products including paint, paper and toothpaste, as a flux in the smelting of certain nickel ores, in the manufacture of crayons, in asbestos packing gaskets and when in the form of alabaster as a medium for sculpting. Natural anhydrite is also crushed to

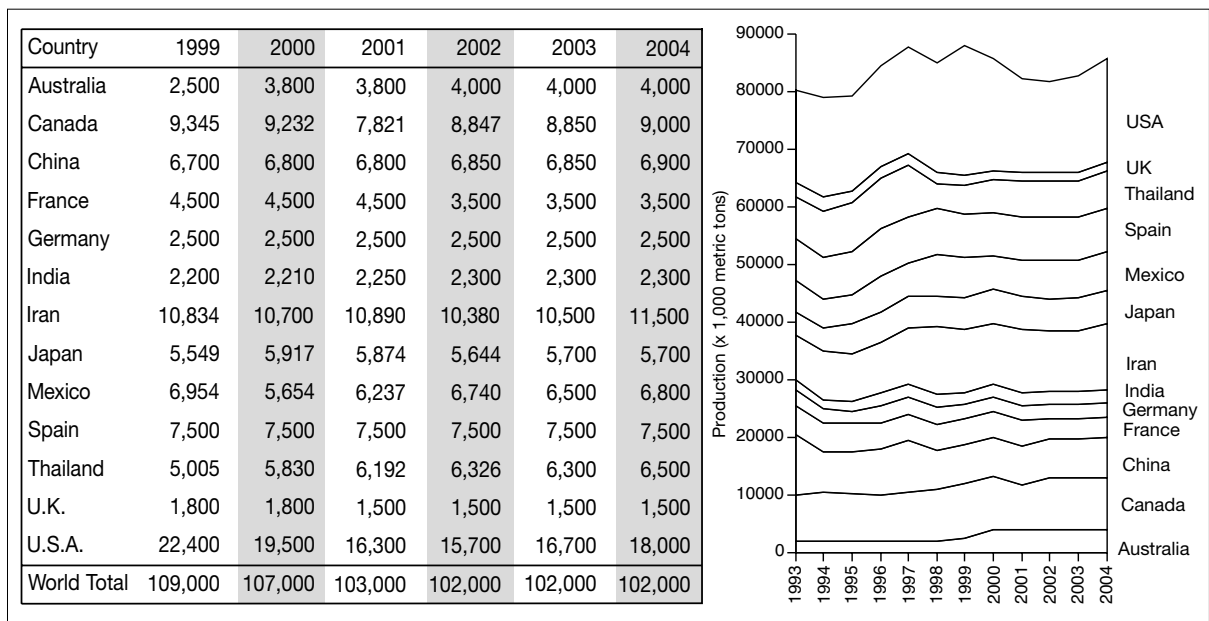

Figure 11.36. World gypsum production (in 1,000s metric tons) of nations producing more than 1,500,000 metric tons per year (compiled from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005).

less than 7mm (30% of which is dust), then mixed with water and an accelerator (Fe_2SO_4 and K_2SO_4), to form quick-setting, high strength roadside packs. Aerated anhydrite products are sometimes used to fill cavities in mines or in spaces above road arches. Anhydrite has been used as a filling and packing material in the coal mining industry of West Germany since the mid 1960s. Other minor uses for calcined gypsum include dental plaster, modelling casts, moulds, surgical casts and drilling muds.

Most CaSO_4 production is either from quarrying or mining. In North America and Europe, gypsum is mined at relatively shallow depths in areas where ancient buried anhydrite beds or diapir caprocks have reconverted to gypsum during uplift and erosion. The Maritimes region of eastern Canada and the USA produces the most gypsum from a single area in the world, with more than 6 million metric tonnes extracted each year from Mississippian strata of the Windsor Group. There is also substantial US production from Tertiary playa deposits in the Salton Trough, California. Spain is Europe's leading gypsum producer, with the main production from bedded Tertiary lacustrine deposits. In Germany, the greater volume of its gypsum is mined from the rehydrated crests of near surface salt structures of Permian Zechstein salt. Secondary targets are the Middle Muschelkalk and minor production comes from the Keuper. In the UK, the most important beds are Permo-Triassic in age, except for those in Sussex, which are Jurassic. In the southern Hemisphere, substantial volumes of high-grade gypsum are quarried, processed and shipped from

Holocene coastal lakes in southern (>1,000,000 tonnes/year) and western Australia (300,000-500,000 tonnes/year). This production supplies the construction industry of Australia and many other parts of Southeast Asia. Small amounts of coarsely crushed gypsum are used as aggregate to pave unsealed minor roads in many places in southern Australia. Under the region's semi-arid to arid climate gypsum aggregate tends to compact and set into a hard flexible crust.

Rock salt (halite)

Annual world production of rock salt has today reached more than 210 million tons. Approximately one third of the total is produced by solar evaporation of seawater or inland brines; another third is obtained by mining of rock salt deposits. The balance is obtained from processing of recovered brines, mainly via solution mining. The largest volumes of salt production are concentrated in 15 nations, which together produce more than 80% of the world's total production (Figure 11.37). Important commercial rock salt deposits are found in the Silurian of northeastern North America; the Devonian of western Canada (also a major producer of potash); the Permian of Russia, western Europe, the midwest of North America, the Jurassic of the US Gulf Coast and the Miocene of the Middle East. In Europe and North America the salt is recovered either by hard rock mining (mostly room and pillar methods) or by solution mining where water is pumped down a well to dissolve the salt and then recovered as brine. In warmer climates, such as Australia, Spain and Mexico, large volumes of salt are

Figure 11.37. Salt (NaCl) production from countries producing >2,000,000 metric tons (values in thousand metric tons - (compiled from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005).

recovered by solar evaporation of seawater or less commonly of inland playa waters.

World resources of rock salt are practically unlimited and total production levels have remained near static since the early 1990s. The majority of usage worldwide is in the chemical industry, some 60% of total rock salt production is processed to supply sodium and chlorine chemicals that are then used to manufacture a multiplicity of products (Table 11.1). The principal basic chemicals, chlorine and sodium hydroxide (caustic soda) are manufactured from brine via electrolysis. Sodium chloride is reacted with limestone in the Solvay process to produce sodium carbonate (soda ash), and with sulphuric acid to produce hydrochloric acid and sodium sulphate (salt cake). The chloralkali industry also uses substantial quantities of salt. Most of its output is polyvinyl chloride and vinyl chloride monomers; chlorine is another product. The second largest user of salt is mankind itself. Humans metabolise around 30% of the total salt produced to support their physiological functions and eating habits. Salt for food is probably the most "taken for granted" commodity in the world today, available from thousands of sources in hundreds of qualities as table, cooking and industrial salt for food production (see history of salt usage, earlier in this chapter). Salt usage in the northern hemisphere increases in the winter months when salt is used to de-ice frozen roadways ($\approx 10\text{-}15\%$ of world annual production).

Iodine, bromine and lithium salts

Iodine is either recovered from saline brine associated with natural gas production (e.g. southern Kanto gasfield, Japan), oilfield brines (e.g. Woodward, Oklahoma) or mined from lakes and saline soils (Atacama Desert - Chile). Subsurface brine now provides more than 80-85% of iodine produced each year. Japan today controls over 30% of the world capacity, Chile 54% and the USA about 10% (Figure 11.38). Reserves of iodine brines are vast in Japan, nearly inexhaustible, but production rate is limited by problems of land subsidence. Chilean reserves are also vast, but producers can experience climate-related variations in ore quality that affect production costs. Compared with Japanese and Chilean reserves, the US reserves are smaller, but are still estimated to be sufficient for domestic use for another century at current production rates.

Chile is now the largest producer of iodine in the world and the sole producer of commercial quantities of iodine from a non deep-brine source. For example, substantial iodine is recovered as a byproduct in the processing of Chilean nitrate

Figure 11.38. World iodine production (in thousand kilograms of elemental iodine - compiled from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005).

deposits in the Atacama Desert (e.g. at Coya Sur, in northern Chile - see nitrates in following section). The ultimate source of Chilean iodine is thought to be leaching of Tertiary volcanics (Ericksen, 1993). Iodine salts occur in caliche ores, largely as the minerals lautarite (CaI_2O_6) and dietzite ($7\text{CaI}_2\text{O}_6 \cdot 8\text{CaCrO}_4$), and is leached from the nitrate ore using an alkaline solution during the extraction of potassium nitrate and sodium sulphate. Ore layers are 1-3 metres thick and overburden is less than 1 metre. The nitrate deposit with which it is associated is huge, it is some 15 to 75 km wide and parallels the coast for more than 720 km (Figure 11.42). Processing of the quarried ore involves crushing, leaching with fresher water, thickening, filtration, and calcium iodate (with sodium nitrate) precipitation. Many of the iodine plants use solar evaporation ponds to thicken the leachate.

In contrast to the volcanic association of iodine in the Chilean deposits, most of the iodine in the subsurface brines of marine sedimentary basins comes from an organic source (Worden, 1996). In fact, many such subsurface waters are enriched in iodine by up to three orders of magnitude relative to seawater evaporation. Organic material is the main reservoir of iodine in recent marine environments. Organic-rich sediments or their volatiles (hydrocarbons) are the main sources of iodine in

most sedimentary basins. Iodine enrichment in brines is often tied to proximity to hydrocarbon pools and iodine increases in concentration in pore waters with increasing depth of burial at a faster rate than bromine (Martin et al., 1993).

Downstream uses of iodine include animal feed supplements, catalysts, inks and colorants, pharmaceuticals, photographic equipment, sanitary and industrial disinfectant and stabilisers.

An effort is now underway to eliminate iodine-deficiency disorders by fortifying world salt supply with iodine. Iodine deficiency is the Third World's leading cause of mental health problems in the form of severe retardation, deaf-mutism and partial paralysis, along with more subtle problems such as clumsiness, lethargy, and reduced learning capacity. Globally, 2.2 billion people live in iodine-deficient areas, especially in mountainous areas located well away from the sea coast. Iodine is an essential part of the thyroid hormone, a substance that contributes to brain development during foetal life and later metabolism.

In Tibet for example, some remote mountain villages have birthing data that show 13% of newborns suffer from cretinism. This is because of low iodine levels in the soils and the fact that local salt is harvested from salt lakes where glaciation and deep weathering have long ago removed iodine from soils. The present soil waters and runoff, that ends up collecting and evaporating in the salt lakes, contains little or no iodine (Lee, 2001). Salt harvested from the lakes, when carried to the villages and sold, is 50% cheaper than local salt that has

been fortified (sprayed) with iodine. A lower cost makes natural salt a more attractive product to peasants in the villages, most of whom are subsistence-level farmers. Harvested salt is usually bartered or exchanged for an equivalent weight in rice. In an attempt to improve the health of the people, selling non-iodised salt has been made illegal by the Chinese government. But a lower price and the fact that the salt harvesters usually barter their salt for an equivalent weight in rice, and have done so

for hundreds of years, make the harvested natural salt more attractive than the more expensive iodised product. To maintain their own subsistence level livelihoods, the salt harvesters are spreading rumours that animals and people fed iodized salt will be infertile.

In rural China and Mongolia, the government's policy of introducing iodized salt to the agrarian population has been much more successful. In the 1980s the rates of goitre (indicated by an enlarged thyroid and an indicator of iodine deficiency) in the general population of China were as high as 40%. By making noniodized salt illegal and keeping the price of the iodised salt low, the current rate of goiter in the general population is now somewhere near 5%. Iodization programs in salt and milk products in the western world since the 1920s had largely eliminated the problem of iodine-deficiency by the 1960s. Ironically, in some in parts of the western world now lacking a government-enforced iodine program, the popular anti-science "new-age" push for healthier back-to-nature and organic food products is an evergrowing market trend. Accordingly, there has been a move away from iodised salt and iodised milk to make it more "natural." Now the rate of incidence of iodine-deficiency in the general population, and in children especially, is growing once more. In Australia, for example, the iodine intake in the population is currently half what it was five years ago, but most Australians are unaware that a problem exists (Li et al, 2001; MacDonnell et al., 2003).

The word bromine comes from the Greek *bromos* meaning stench and was discovered in 1825 when Antoine Balard extracted it from seawater bitterns. The United States and Israel dominate the world's elemental bromine output of about 5.2 Mt (5.7 million st). Azerbaijan, Ukraine, France, United Kingdom, China, Japan and India contribute most of the rest. Bromine is recovered from modern brines in Searles Lake and the Dead Sea, as well as from formation waters in the Gulf of Mexico and the Michigan Basin, and seawater in Japan and Spain (Table 11.6, Figure 11.39). For example, a brine averaging 5000 ppm Br is recovered for processing from depths around 2500m in the upper Reynolds Oolite Member of the Upper Jurassic Smackover Formation in Union Co, southern Arkansas (Kyle, 1991). The elevated Br content in this brine indicates natural leaching of the underlying Louann Salt. Since 1957 bromine has been produced at Beersheva, Israel, as a byproduct from bitterns associated with potash, chlorine and caustic soda production. There solar evaporation concentrates lake brines pumped from the Dead Sea and derived from Miocene evaporites buried beneath the lake floor (Figure 11.9). After the potash slurry is processed, residual bitterns are treated with chlorine

to recover bromine. The bromine-free bitterns are then further processed to recover magnesium. The Dead Sea effluent feed-brine for bromine recovery contains 11,000-12,000 ppm of bromine and is one of the richest bromine brine feeds currently in commercial operation. Brine reserves are also huge, with the Dead Sea waters containing more than 1 billion tonnes of bromine. In Germany, bromine is produced as a byproduct of potash mined from the Zechstein salt.

Since 1973, when the United States produced 71% of the world supply, its market share has decreased; a result of environmental constraints and the emergence of Israel as the world's second largest producer. Today, the United States produces 40% of the world's bromine, Israel 38%, China 8%, the United Kingdom 9% and other countries combined 5% (Figure 11.39).

Traditionally, the major market for bromine was in the production of ethylene dibromide; a lead scavenger in gasoline antiknock compounds. However, this market has been in

Figure 11.39. World bromine production (in metric tons of bromine content - compiled from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005).

Table 11.7. World lithium production (metric tons) and sources (compiled from USGS on-line data tables, downloaded from <http://minerals.usgs.gov/minerals/pubs/commodity/myb/> last accessed 30 September, 2005). w = withheld to avoid disclosing company proprietary data.

decline in past three decades as more and more countries legislate to adopt the catalytic converter and lead-free gasoline. Flame retardants are now the largest end use and account for more than 30% of the US bromine market. Other uses include intermediates in chemical manufacture of dyes, fragrances and pharmaceuticals; it is also used in photographic compounds, as bleach, as an additive in drilling fluids, and in the production of methyl bromide, a pre-plant soil fumigant.

Lithium occurs in more than 140 minerals, with mined production of lithium ore concentrates mostly from nonevaporitic spodumene pegmatites. Three major lithium miners supply the majority of worldwide demand for solid lithium ore concentrates. They are; Sons of Gwalia in Australia (largest), Tanco in Canada, and Bikita Minerals in Zimbabwe (Table 11.7).

Cheaper prices and abundant supply means there has been a move away from ore to brine as the major source of lithium in the past two decades and brine is today the major supplier of the world's lithium market, with Chilean salars as the dominant source. Production of lithium carbonate from a brine rather than an ore concentrate is much less energy intensive and much more environmentally friendly. Today there are substantial lithium carbonate brine operations in Salar de Atacama, Chile and Salar del Hombre Muerto, Argentina, along with smaller volumes recovered from multicomponent brine operations in Searles Lake, California, and Clayton Valley, Nevada. Salar operations can now produce lithium throughout the year whereas histori-

cally the brine extraction operations were seasonal and subject to downtime related to solar floods.

The highly competitive nature of the current supply market makes some published lithium figures suspect. It is a market where availability of known reserves exceeds projected needs by a ratio of more than 2:1 and lithium carbonate from brine is perhaps now supplying as much as 60-80%

of the world's needs. A ready cheap supply of lithium from brine operations has led to a fall in the real price of lithium by up to 50% since the mid 1990s. The market today is highly competitive with more spodumene operations and low capacity brine operations closing each year. United States production from brine was surpassed in 1998 by Chile and today only one lithium carbonate focused brine operation is still active in the USA (Table 11.7). The United States remains the world's largest consumer of lithium.

Lithium compounds are consumed in the production of ceramics, lubricants, glass, and primary aluminium. Lithium is electrochemically reactive and has unique properties, so there are many ongoing commercial lithium usages in the new high tech fields of industrial production, including the rapidly expanding lithium battery technologies. Lithium needs may expand much faster than currently projected and so ameliorate

Table 11.8. Lithium contents of some salar and playa brines.

the current oversupply and consequent low price.

Only the geology of the saline brine sources is discussed in detail in this section, the interested reader is referred to Garrett (2004) for a full discussion of all lithium raw materials. Subsurface lithium in playa sediments typically occurs either as a brine component (Table 11.8) or as lithium bearing minerals such as hectorite — $[\text{Na}_{0.33}(\text{Mg},\text{Li})_3\text{Si}_4\text{O}_{10}(\text{F},\text{OH})_2]$ — a clay mineral of the smectite group where the replacement of aluminium by lithium and magnesium is essentially complete. Hectorite is still mined in its type area, near Hector, California. It has a soft, greasy texture, a candlewax-like appearance and feels like modelling clay when squeezed between the fingers. As a colloid, hectorite's unique thixotropic properties for emulsion stabilizing, gelling, suspending, binding, bodying and disintegrating, means it sells for more than US\$2,000 a ton. Associated authigenic clays include stevensite and saponite and it lies adjacent to a colemanite deposit. It, along with associated authigenic clays and zeolites, is the diagenetic result of alkaline brines flushing volcanoclastic playa sediments.

Lithium carbonate is still produced from playa brines in Searles Lake, California and Clayton Valley, Nevada. Historically, the Clayton Valley playa has produced about one-third of the US lithium requirements, but its economic viability is now suffering from fierce market competition. The playa has an area of 50 km² and an elevation of 1400 m. It lies in the rain-shadow of the Sierra Nevada, with an annual rainfall \approx 130 mm and an evaporation rate of \approx 1380 mm. Near surface sediments consist of a mixture of clays (smectite, illite, chlorite, kaolin) and salts (halite and gypsum) and widespread pedogenic calcite. Lithium in the brines is derived by the weathering and leaching of the volcanoclastics of the Tertiary Esmeralda Formation and Quaternary ash-fall tuffs (Figure 11.40; Davis et al., 1986). Lithium content is highest on the eastern side of the playa adjacent to the outcropping marls of the Esmeralda Fm. Before it is leached, lithium is held in the clay fraction of the playa sediments and is probably part of the clay structure (hectorite is a widespread minor component in the Clayton Valley clays).

Lithium-rich brine, averaging 0.023% (230 ppm) lithium in a background NaCl concentration of 200,000 ppm, is pumped

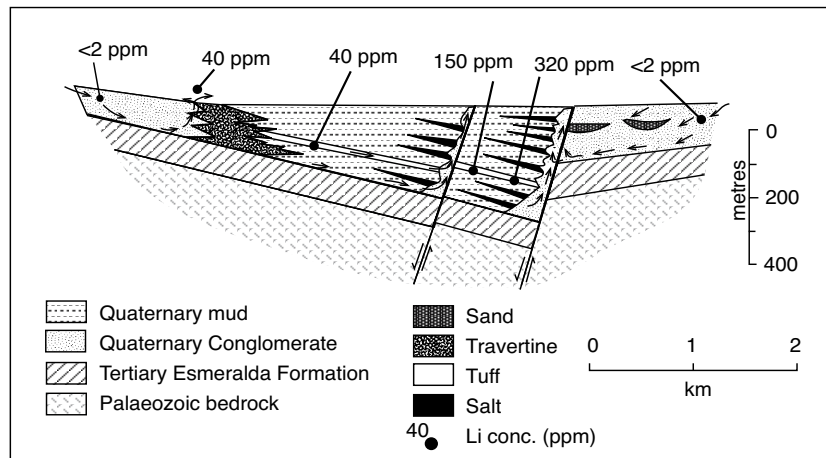

Figure 11.40. Generalised cross section of Clayton Valley Playa, Nevada. Shows the relative position of the major tuff-bed aquifer, inferred directions of groundwater flow and representative lithium concentrations (ppm) in the various aquifers and springs (after Davis et al., 1986).

from depths of 100–300m in the Clayton Valley playa via a number of gravel-packed wells. It then progresses through a series of fractionating evaporation ponds. Some of the brine feed also shows elevated levels of radon gas. Lithium concentration in the liquor increases to 6,000 ppm over the course of 12 to 18 months in the solar evaporation pans. When the lithium chloride level reaches optimum concentration, the liquor is pumped to a recovery plant and treated with soda ash to precipitate lithium carbonate, which is then removed through filtration, dried, and shipped.

Chile has emerged in the last decade as the most important lithium carbonate producer from a lake brine, largely through the exploitation of Salar de Atacama, Chile (Figure 11.41). The salar lies on the Tropic of Capricorn at an altitude of 2,300 m in the Desierto de Atacama, some 200 km inland from Antofagasto. In its more central portions this salt-encrusted playa contains a massive halite unit (nucleus) that is more than 900 m thick, with an area \approx 1,100 km². Fringing saline muds, with an area \approx 2,000 km², surround this nucleus (Figure 3.45).

The current salt crust atop this halite nucleus contains a sodium chloride interstitial brine that is rich in Mg, K, Li, and B (Alonso and Risacher, 1996). Lithium contents of the pore brines range from 200–300 ppm in the marginal zone, some 500–1,600 ppm in the intermediate zone and 1,510–6,400 ppm in the salt nucleus. This central zone averages 4,000 ppm lithium. Main inflows to the salar drain volcanic formations of the Andean Highlands located to the east of the basin (Figure 11.41). Salts dissolved in inflow waters have a double origin. Weathering of volcanic rocks supplies K, Li, Mg, B and, to a lesser extent, Na and

Ca. Leaching of ancient halokinetic evaporites with a mother salt layer beneath the volcanic formations provides additional amounts of Na, Ca, Cl, SO_4 to the most saline inflow waters. The mass-balance of the upper nucleus of the salar centre shows a strong excess of NaCl with respect to the bittern solutes Mg, K, Li, B. According to Alonso and Risacher (1996) this suggests that the nucleus did not originate from evaporation of inflow waters similar to the present. Rather the excess of NaCl is due to NaCl-rich inflow waters that formerly drained the Cordillera de la Sal, a Tertiary-age evaporitic ridge along the western rim of the present-day salar.

The average sedimentation rate of halite in the lake centre is ≈ 0.1 mm/year, based on the age of an ignimbrite interbedded with the salt. This slow aggradation rate implies a climatic setting of long dry periods and inactivity alternating with short wet periods during which large amounts of water, and so large amounts of salt, accumulated in the basin centre. The lack of peripheral lacustrine deposits and the high purity of the salt also suggest that the main salt unit is not the remnant of an ancient deep saline lake, but originated mostly from evaporation of waters supplied by subsurface and subterranean saline seeps.

Brines are pumped from 30 metre deep holes in the salt into solar evaporation ponds. In the ponds they are concentrated by a factor of 25, generating a final brine strength of 4.3% Li. During evaporation processing and the production of potassium chloride and potassium sulphate the ion ratios are constantly monitored and adjusted to avoid the precipitation of lithium potassium sulphate. The high initial lithium content of the brines and the extremely arid setting (3200 mm pan evaporation and <15 mm precipitation) means that only 90 hectares of evaporation ponds are required for the current operation, this is only 5% of the area required at Clayton Valley, Nevada. Borate (as perborate) is recovered at levels of 0.84 g/l during lithium extraction. Increasing volumes of lithium are also produced by new salar brine processing facilities in Salar de Hombre Muerto, Argentina and Salar de Uyuni, Bolivia.

Nitrate salts (nitratite and salt petre)

Nitrogen is abundant on and near the earth's surface where it makes up 78% of the world's atmosphere. It, along with potassium and phosphorus, make up the three essential plant nutrients. Natural deposits of nitrate are rare because of the extreme solubility of nitrate salts in water; synthetic sources

of nitrate today far outweigh the natural sources, with natural sources supplying less than 0.3% of the world's nitrogen needs.

Nitrate salts precipitate as efflorescent crusts in several of the world's deserts including; the Namibian Desert, the Abu Dhabi sabkhas and Death Valley. They are only present in mineable quantities in the Atacama Desert of Chile, where deposits occur in a narrow zone between the low-lying Pampa del Tamarugal to the east and the hills of the Coastal Range to the west (Figure 11.42a; Ericksen, 1981, 1983; Searl and Rankin, 1993). This area contains nitrate-rich soils, as well as surfaces encrusted with nitrate-bearing salts, saline-cemented regolith, and nitrates accumulating in closed basin playas or salars. Commercial concentrations develop in and atop weathered rock

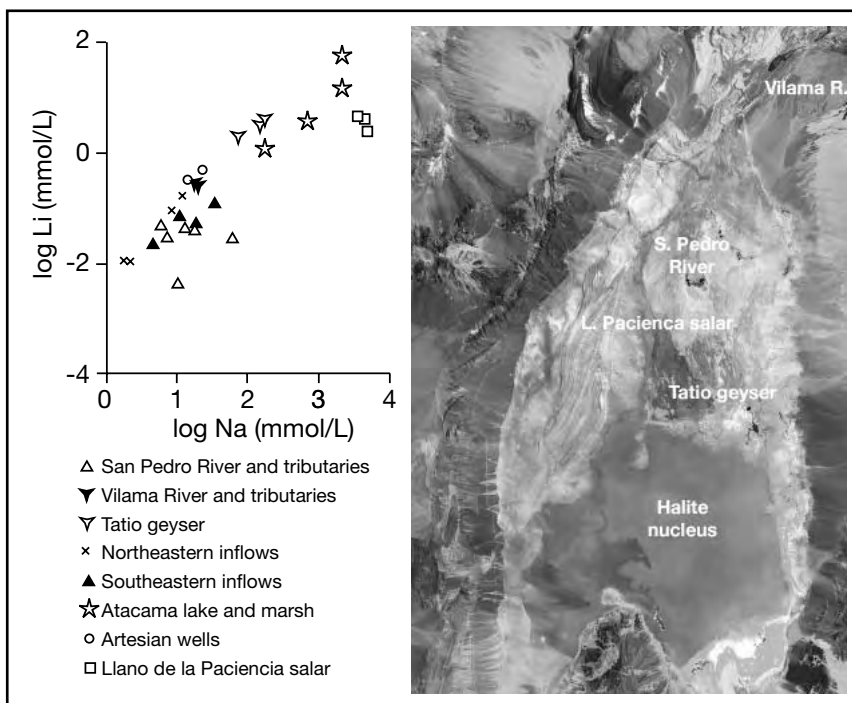

Figure 11.41. Lithium content of waters in the Salar de Atacama basin, Chile (after Carmona et al., 2000). Tectonic tilting of the basin floor has crowded the halite nucleus up against the southwestern margin of the playa and controlled halite thickness within the salar (see Figure 3.45; Landsat image courtesy of NASA).

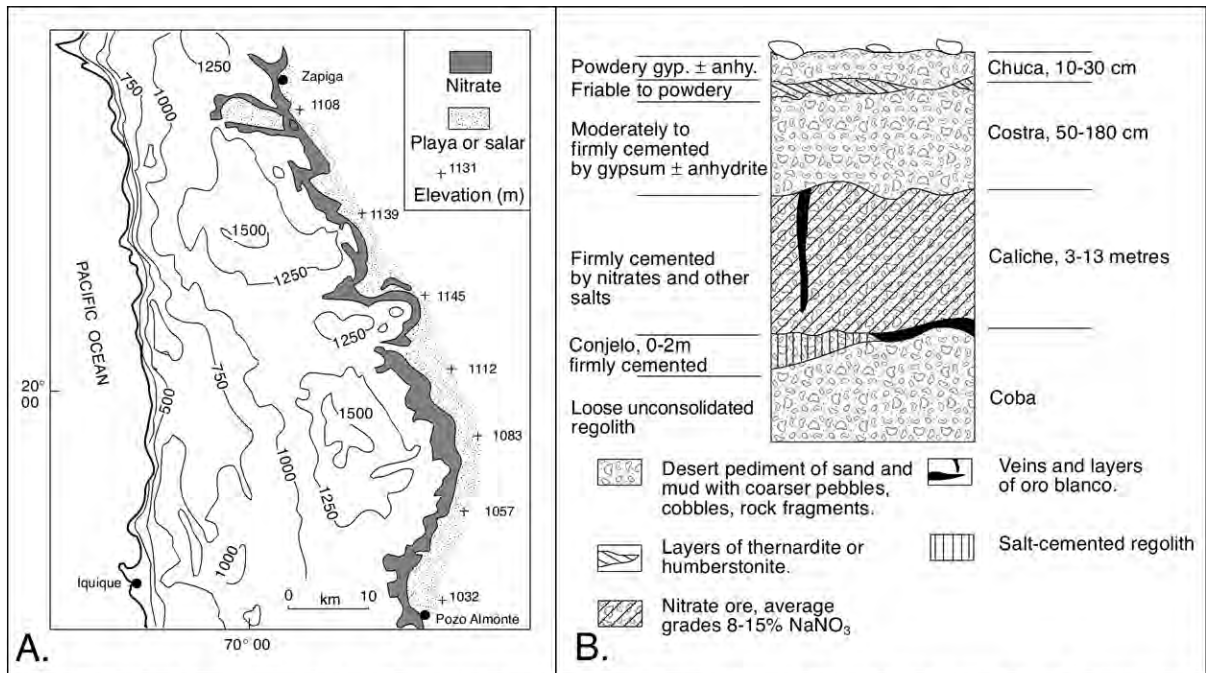

Figure 11.42. South American nitrates. A) Sketch of northernmost Chilean nitrate field, which is located along the eastern side of the Coastal Range, and marginal to salars and clay playas on the western side of Pampa del Tamarugal (see also Figure 3.37). B) Typical regolith profile through alluvial-type nitrate deposits in a Chilean nitrate field (after Ericksen, 1981, 1993).

types ranging from granite to limestone and shales. Nitrates can be found in all topographic positions from hilltops to hillsides to playa and valley floor. The richest accumulations tend to be on the lower slope of hills situated marginal to salars and playas (Ericksen, 1993).

Prior to the invention of synthetic sources by Germany in the First World War, the Chilean nitrates were the main source of salt petre in gunpowder, nitroglycerin and other explosives. At its peak in the first twenty years of last century there were more than 250 actively mined concessions in the Atacama Desert, with production of 4 million tonnes/year and a local population of more than 300,000 people. At the time the local name for the nitrate ore was “oro blanco” or white gold.

Chilean ores have an average composition of: 7-10% NaNO₃; 4-10% NaCl; 10-30% Na₂SO₄; and 2-7% Mg, Ca, K, Br, and I (Table 11.9; Ericksen, 1983; Searl and Rankin, 1993). Highest purity nitrate ore occurs as stratiform pedogenic seams about 20 cm thick, located some 3-7 m below the desert surface. The ore, a form of

hypersaline desert caliche, is part of a sequence of pedogenic layers; with coba at the base, through caliche and costra, to chuca as the overburden. The nitrate-entraining caliche zone is typically 1-3 m thick (Figure 11.42b). It can be alluvial caliche, where the saline minerals, including the nitrates, cement the regolith; or it can be bedrock caliche, where the economic salts form impregnations, irregular masses, veins and fracture-fills in porous or fractured bedrock.

The dominant nitrate in the Atacama is mostly nitratite (=soda nitre or Chilean salt petre). A number of other unusual highly soluble salts have also accumulated, along with the nitrates, and include iodates, perchlorates, chromates and dichromates, as well as the more familiar borates, sulphates and chlorides. It is the only known region in the world that contains natural perchlorate. The salts formed at the more saline end of a phreatic precipitation sequence made up of progressively more soluble

Mineral	Composition	Characteristics	Occurrence
Nitratite (soda nitre)	NaNO ₃	Rhombohedral cleavage	Main ore mineral in Atacama Desert
Nitre (salt petre)	KNO ₃	Acicular	Secondary salt
Darapskite	NaSO ₄ · NaNO ₃ · H ₂ O	Monoclinic	Minor salt
Humberstonite	K ₃ Na ₇ Mg ₂ (SO ₄) ₆ (NO ₃) ₂ · 6H ₂ O	Prismatic	Minor salt

Table 11.9. Typical nitrate minerals in the Atacama Desert, Chile.

evaporitic minerals: silicates (zeolites); calcite; Ca-, Na-, (K-) and Mg-sulphates; Na- and K-Mg-nitrate-sulphates; nitratine; and small amounts of iodates, Na- and K-Mg-iodate-sulphates, chromates, borates and perchlorates (Pueyo et al., 1998). Two specific precipitation trends were distinguished within this more general regional sequence; a Na-trend characterised by an association of glauberite-darapskite-(hectorfloresite), and a K-Mg-Na-trend related to bloedite-polyhalite-humberstonite-niter-(fuenzalidaite).

The only remaining active nitrate mine in the Atacama Desert is an open pit, the Maria Elena deposit, which exploits nitrate ore from stratiform seams just below the desert surface (Callao et al., 2002). Ores are hosted mostly by breccias or sandstones (volcaniclastics and tuffs) with the ore minerals occurring as mm-metre scale rinds about breccia or sandstone clasts. Nitrate contents in the ore seams vary between 7.5 to more than 20 wt % and NaCl between 8.6 to 40 wt %. Locally abundant are the sulphates thenardite, anhydrite, bloedite, polyhalite, hexahydrate and glauberite, which reflect part of 7.5 to 19.7 wt % content of Na_2SO_4 . Other salts present in minor contents include a variety of sulphates (kieserite, woodwardite, loeweite); nitrates (humberstonite, darapskite and nitre); borates (calciborite, strontiborite); chlorides (sylvite, nantokite) and iodates (bruggenite). The IO_3 contents vary between 0.026 to 0.074 wt %.

What is most amazing about the Atacama deposit is the age of the desert host and stability of its geomorphic features; nitrate soils are thought have been at the surface since the mid-Miocene, so allowing the gradual buildup of large volumes of pedogenic salines in the soils including the exploited nitrates (Table 11.9; Alonso et al., 1991). The Atacama Desert is one of the driest places on earth, its hyperaridity is the result of the rainshadow effect of the High Andes and the strong atmospheric temperature inversion along the coast (Figures 2.2a). Average annual rainfall in the Atacama Desert is less than a centimetre, and as much as twenty years can pass between rainstorms and similar conditions have prevailed since the middle Miocene.

Parental brines for the deposits are the hypersaline discharge portions of a regional phreatic system, which Pueyo et al. (1998) consider to be older than 6 Ma. At that time the main physiographic features were similar to today, but the climate was more humid. The precipitating parental fluids were derived from a variety of meteoric sources: westward flowing Andean groundwater, coastal fogs, occasional rainfall and Andean-derived surface floodwaters. Evaporation was involved in the nitrate paragenesis; it is the only mechanism effective

enough to saturate a brine with these very soluble supersaline minerals. Nevertheless, the nitrate ores do not show typical displacive nodular and enterolithic evaporitic textures, rather, the salts tend to passively infill veins, fractures or pre-existing matrix porosity and the various salts have largely accumulated through passive growth. Locally, some of the host silicate and carbonate lithologies have also undergone a small degree of active salt replacement.

The unusual mineralogy of the nitrate ore reflects the extreme chemical evolution of the precipitating brines through multiple episodes of salt precipitation and remobilisation during transport to the nitrate horizons. The ultimate source of the nitrate is tropospheric nitrogen first carried inland as nitrate in sea fogs (Rech et al., 2003; Ericksen, 1993). The upwelling coastal waters of Chile and associated coastal fogs contain high concentrations of nutrients and dissolved solutes. The average concentration of dissolved solutes in Chilean coastal fog are: 9.1 ppm SO_4 ; 0.8 ppm NO_3 ; 1.8 ppm Cl; 4.81 ppm Na; 0.4 ppm K; 1.0 ppm Ca; 0.6 ppm Mg. Sea spray moves these solutes as aerosols into a coastal fog; sulphate in sea spray comes mostly from outgassing of biogenic marine sulphur (e.g. Figure 2.19). As sea fog moves inland over the Atacama, it evaporates and so deposits dissolved solutes, which are then fractionated by pedogenic and downslope meteoric processes. To form an ore grade buildup in the soil requires multiple pedogenic fractionation episodes driven by dissolution, reprecipitation and recrystallisation within hyperarid desert soils. Millennia of these processes vertically separates the highly soluble nitrate salts from less soluble sulphate salts in the overlying profile (Figure 11.42b).

Magnesite and magnesia salts

Magnesium is the eighth most abundant element in the earth's crust and is widely distributed in numerous minerals. Magnesium is named after ancient *Magnesia*, a district in Thessaly, Greece. Among the more commercially important magnesium minerals are magnesite, brucite, dolomite, olivine, talc and serpentine (Table 11.10), as well as the magnesium sulphate and chloride salts recovered from natural brines and concentrated

Mineral	Formula	Deposit Exploited
Magnesite	MgCO_3	Sparry or cryptocrystalline
Dolomite	$\text{Ca}_{(1-x)}\text{Mg}_x(\text{CO}_3)_2$	Not utilised
Brucite	$\text{Mg}(\text{OH})_2$	Weathering byproduct
Brunnerite	$\text{Mg}_{(1-x)}\text{Fe}_x(\text{CO}_3)_2$	Sparry (magnesite associated)

Table 11.10. Sedimentary minerals and deposit types used as a source for magnesium oxide or magnesium metal.

seawater (e.g. epsomite, bischofite, carnallite). World resources of magnesite, dolomite and magnesium-bearing evaporite minerals are enormous. Magnesium-bearing extractable brines are estimated to constitute a potential resource measured in billions of tonnes, and magnesium can be economically recovered from seawater off arid coasts.

As well as being extracted by concentrating seawater, magnesium is also produced by processing of continental evaporitic and subsurface basinal brines in the USA, the Netherlands, Israel and Mexico. In the Netherlands the brine is formed by solution mining of magnesium/potassium-bearing horizons (carnallite, bischofite and kieserite) in the Permian Zechstein section (Figure 12.5b). Mg-rich continental brines of the Dead Sea are also processed for magnesium after bromine is extracted. When pumped into the saltworks, Dead Sea brine already contains 42,430 ppm of magnesium (30 times seawater levels), which when evaporated and processed produce caustic-calcined and ^{11,3} dead-burned magnesia, along with small amounts of magnesian chloride.

Electrolytic processes recover much of the world's currently produced magnesium. The majority of magnesium compounds are used for refractories in the die casting industry and due to a high strength to weight ratio usage in the automobile industry is expected to double in the next decade. Currently, the aluminium industry is the largest consumer of magnesium, where it is a constituent in aluminium-base alloys used for packaging, transportation, and other applications. The remainder is consumed in agricultural, chemical, construction, environmental, and industrial applications. Annual world magnesia production (from magnesite) is more than 3.1 Mt (3.4 million st), mostly from China, USA, North Korea, Russia and Turkey. Although no specific production figures are available, China and the United States probably account for more than one-half of the world's capacity for the production of magnesium compounds from seawater and brines.

^{11,3} *Dead-burned magnesite* (or refractory magnesia) refers to the granular product produced by firing magnesite, magnesium hydroxide, or other materials reducible to magnesia at temperatures in excess of 1,450°C

Calcined magnesia is the result of 800 to 1,000°C heat being applied, frequently in a rotary kiln, to magnesite or other materials reducible by heat to magnesia. It is heated to such a degree that less than 10% ignition loss remains and the product displays absorptive capacity or activity.

Fused magnesia is produced by heating high grade magnesite to a molten state for up to six hours in electric arc furnaces to temperatures approximately 3,000°C. The resultant product, at 96 to 98% MgO, has a favorable high density of 3.50 g/cc and relatively high chemical stability, strength, and resistance to abrasion.

Geological occurrences of magnesite are either microcrystalline (micritic) or macrocrystalline (sparry). There are three geologic modes of magnesite occurrence: 1) Small scale micritic deposits accumulating in Quaternary alkaline lake and mudflats (Table 11.11); 2) Laterally continuous, stratiform sediment-hosted deposits, which can be cryptocrystalline (micritic) or coarsely crystalline (sparry). Sparry deposits tend to occur more frequently in Precambrian strata; 3) Clustered hydrothermal deposits that form sparry magnesites at or near ultramafic complexes of all ages. Styles 2 and 3 form almost all of the currently exploited geological sources of magnesite. Discussion of style 3 lies outside the sedimentological focus of this book and the interest reader is referred to Pohl and Siegl (1986). Sparry style 2 occurrences constitute a large portion of current refractory magnesia ores. Style 1 deposits offer small-scale analogues for the sort of low temperature brine chemistry that has produced many sedimentary magnesite deposits. It suggests a requirement of waters enriched in magnesium, commonly hypersaline, and an association with microbes.

But, as with ancient evaporitic dolomite (Warren, 2000a) and ancient marine-fed evaporites (Chapter 5), there are fundamental problems when comparing brine chemistries of recent and ancient sedimentary magnesites. Today magnesite is a nonmarine evaporite precipitate (Table 11.1). Magnesite is easily manufactured in the lab using inorganic chemical techniques, but as for inorganically produced dolomite, it requires temperatures much too high to be realistic in a modern marine sedimentary system. Likewise there are intrinsic problems with comparisons of scale and diversity, leading many to express their studies of ancient magnesite in terms of "solving the magnesite problem." Modern sedimentary magnesite occurrences are nonmarine bedded, micritic, laterally limited and lacustrine; most ancient sedimentary magnesites are marine-associated, stratiform, microsparry to sparry, laterally and vertically extensive, and diagenetically altered.

Within Style 2, magnesite occurs in two commercially exploited forms, coarse crystalline (sparry) magnesite and cryptocrystalline magnesite (Pohl, 1990). Sparry magnesite deposits tend to be larger and purer (70-90% MgCO₃) than most cryptocrystalline magnesite deposits (purity <12% MgCO₃) and are the preferred ore deposit style. Much of the world's sediment-hosted coarsely crystalline magnesite is Precambrian and typically occurs as variations on a theme of fault-controlled, high temperature, hydrothermal alteration of dolomitic shelf sediment. Magnesites (sparry and micritic) are much more widespread in the Precambrian than the Phanerozoic leading to suggestions that magnesite was a primary evaporitic carbonate or even a normal marine mineral in Precambrian seas.

Location	Style	Reference
Coorong lagoon, southern Australia	Primary magnesite precipitates (with magnesian dolomite) in a number of hypersaline-schizohaline coastal lakes fed by continental brines. Nearby lakes contain hydromagnesite-aragonite associations.	Alderman and von der Borch, 1963; Warren, 1990
Clipperton Atoll, Pacific Ocean	Magnesite occurs at the bottom of the atoll lagoon. Some 2,850 years ago the lagoon became sufficiently isolated to be density stratified. At present the upper 14 to 15 m of the water column has a salinity of 14‰, while the underlying water mass up to a maximum depth of 34 m is marine (salinity of 33 to 34‰).	Bourrouilh-Le Jan et al, 1985
Lake Bonneville, Great Salt Lake depression, Utah	Magnesite was found in association with aragonite and dolomite in five cores taken through saline laminites near the shore of former Lake Bonneville. The dark layers contain about twice as much magnesium as the light layers. The light-colored laminations contain more clay minerals than carbonate.	Graf et al., 1961; Bissell and Chilingar, 1962
Lake Yao, Chad	Magnesite occurs in beaches of Lake Yao, a saline lake in northern Chad. Occurs in a sequential paragenesis going from the lake up to the beach: changes from calcite, aragonite, magnesium calcite, dolomite, huntite, magnesite, sodium carbonates (nahcolite, thermonatrite, trona), sodium sulphates (burkeite, thenardite), halite and sylvite. Accompanying brine has pH≈10.	Gac et al., 1977
Lake Walyungup, (coastal lake) Western Australia	Hydromagnesite in the littoral zone replacing aragonite, particularly within the mesoclot fabric of stromatolites, but also in sediments (strandline and dune sand, crusts) derived by erosion of stromatolites.	Coshell et al., 1998
Playa Pito and Playa Gualla, salt lakes southeast of Zaragoza, Spain	Diagenetic association with dolomite, calcite, gypsum, halite, thenardite, and bloedite, increases with depth (from 5 to 30%). Tends to form in mixing zone about playa edge where hypersaline lake brines mix with brackish groundwaters.	Pueyo-Mur and Inglés-Urpinell, 1987
Tuz Gölu, Turkey	Magnesite and huntite are early diagenetic minerals in saline mudflat formed by transformation of dolomite in the presence of pore fluids with a high Mg/Ca ratio.	Irion and Mueller, 1968; Camur and Mutlu, 1996
Sabkha El Melah, Tunisia	Minor phase in coastal sabkha, probably replacing aragonite.	Perthuisot et al., 1972
Sabkhat of Abu Dhabi	Magnesite is a minor phase (possibly after huntite) found only in the upper 10 - 20 cm of the Abu Dhabi supratidal.	Kinsman, 1967; Bush 1973
Salda Gölu, Turkey	Extensive areas of hydromagnesite shorelines and basin center turbidites formed by mechanical breakdown of hydromagnesite microbialites.	Braithwaite and Zedef, 1993, 1996
Saline lakes, British Columbia, Canada	Simple monomineralic biolaminated carbonate or sulphate layers as well as beds composed of complex mixtures of aragonite, magnesite, hydromagnesite, mirabilite, gypsum, epsomite, and/or bloedite.	Last, 1997

Table 11.11. Selected examples of Holocene occurrences of sedimentary magnesite.

Major Phanerozoic cryptocrystalline magnesite deposits occur in Australia, Greece, Turkey and India, most are considered potential, rather than actual, ore deposits. Worldwide, almost all Phanerozoic cryptocrystalline magnesite sediments are evaporitic lacustrine sediments, but like their Holocene counterparts, most deposits are too small or too impure to be commercially viable. The huge Tertiary lacustrine/pedogenic deposits in the vicinity of Rockhampton, Australia, are a possible exception, as are the Neogene huntite-magnesite-hydromagnesite lacustrine deposits in the Kozani Basin, Northern Greece and the Bela Stena region of southeastern Serbia (Stamatakis, 1995).

Extensive drilling in eastern Australia in the 1980s, centred on Rockhampton, outlined several large lacustrine magnesite deposits, namely; Marlborough, Kunwarara, Merimal and Yaamba.

Of these, the most viable, but as yet not yet fully realised, economic accumulation is the Kunwarara deposit. It contains some 550 million tonnes of potential magnesite ore, including 260 million tonnes in a soil-covered nearsurface "blanket" ore composed of 40-45% cryptocrystalline magnesite.

The Kunwarara deposit, situated some 60 km northwest of Rockhampton, has a proven area of 31 km². All this magnesite is stratiform, micritic, and constitutes a blanket deposit that varies in thickness from 1m to 26m, with an average thickness of 7.75 m. It lies below a humus-rich black clay ranging in thickness from 0.4 to 12m, with an average thickness of 7.75m (Figure 11.43; Burban, 1990; Hill, 1993). Experimental extraction at Kunwarara commenced in the mid 1990s; in 2001, Australian Magnesium Corporation Limited mined 2.7 Mt of crude magnesite ore at Kunwarara, which was beneficiated to produce

594,674 tonnes of magnesite. This produced 117,872 tonnes of dead-burned magnesia, 54,346 tonnes of calcined magnesia and 21,781 tonnes of electro-fused magnesia.

Most of the Kunwarara magnesite occurs as mm-metre diameter nodules and lumps in a matrix of soft magnesitic mudstone that is underlain by dolomitic mudstone, sandstone or gravel. The deposit is thought to have formed via secondary alteration of magnesian-rich lacustrine sediments. In the Marlborough area, magnesite occurrences are more lenticular and occur in palaeochannels in the regolith, as well as in nodules, veins and stockworks in the weathered zone of ultramafic basement rocks. The formation of all the Queensland magnesite deposits involved erosion of deeply weathered lateritic soils on magnesium-rich serpentinites with subsequent deposition as fluvial/lacustrine sediments, which were then subject to further evaporatively-driven pedogenic enrichment.

A partial modern analogue for Kunwarara is the magnesite-rich sequences of Salda Golu in southern Turkey (Figures 1.6, 4.29; Schmid, 1987). Based on this comparison, the following conditions are thought to have formed the Kunwarara deposits:

- Deep weathering of primary stockwork-bearing serpentine rocks and subsequent erosion by heavy rains.
- Water and groundwater transport of eroded and dissolved magnesian materials into a lake depression.
- Deposition and crystallisation of magnesite muds in an ephemeral mudflat (capillary evaporation). Agglomeration of material into cryptocrystalline nodules.
- Periodic waves and sheet flooding carries away non-crystallised impurities such as SiO_2 , Al_2O_3 and CaO .

- Flushed impurities deposited in adjacent shallow lakes, which, with a lowering of lake levels, then acted as matrix for later magnesite nodules.
- Magnesite layers were compacted and covered by soil. Pedogenesis also formed a silica-rich skin on the nodules, while pedogenic magnesite continued to crystallise in the nodule horizon.

In contrast to the pedogenic precipitation of pedogenic magnesite in Tertiary lake depressions, much of the cryptocrystalline magnesite in Precambrian sediment is thought to be a primary precipitate from marine-fed brines. The “Magnesite Problem” is most obvious when comparing the disparity between the abundance of primary or syndepositional cryptocrystalline magnesite in Precambrian restricted marine settings and the paucity of cryptocrystalline magnesite in similar modern marine-fed evaporitic settings. Magnesite in the coastal lakes of the Coorong forms from evaporation of continental not marine waters (Figure 4.4). The disparity probably reflects differences in the ionic proportions in Precambrian and modern oceans, especially the relative lack of sulphate and calcium, as well as extreme carbonate saturation in Precambrian oceans (Chapter 2).

Two well-documented examples of widespread Precambrian magnesite are the Palaeoproterozoic Tulomozerskaya Formation of the Fennoscandinavian Shield (Melezhik et al., 2001) and Neoproterozoic Skillogalee Formation of the Flinders Ranges in southern Australia (Frank and Fielding, 2003). The latter is currently exploited in a small way (10,000 t/year), but its primary sedimentary structures are very well preserved and in the vicinity of Leigh Creek its inherently high purity

Figure 11.43. Kunwarara mine operations near Rockhampton, Queensland.

Figure 11.44. Stable isotope signatures of sparry, lacustrine and cryptocrystalline Precambrian magnesites (in part after Melezhik et al., 2001).

gives it the potential for much higher levels of exploitation (Keeling and Mauger, 1998). Metamorphism and coarser recrystallisation has destroyed more of the fine primary detail in the Fennoscandinavian strata. Both areas still retain abundant textures from their primary marine-fed evaporite association (stromatolites, mudcracks, tepees, evaporite pseudomorphs, intraclastic horizons, dissolution breccias). Some more highly metamorphosed Precambrian sparry ore deposits can be huge; a single Proterozoic sparry magnesite deposit in Liaoning Province of China extends for some 60 km and reportedly contains some 130 Gt of ore.

Warren (1999, Chapter 8; 2000b) notes that extensive stratiform Proterozoic sparry brunnerites and siderites in northern Australia sit atop halokinetic autochthonous and allochthonous dissolution breccias. The spars formed as subsurface replacements of precursor platform carbonates in suprasalt overburden. Extensional tectonics focused the escape of subsalt ferroan basinal brines via withdrawal breaches in the salt and then up along active suprasalt growth faults. The same faults also supplied dense metalliferous brines to brine lakes on the seafloor to create the laminites of base metal (sedex) deposits (Figure 9.46). Some of the sparry textures in these replaced platform carbonate were misidentified in earlier work as sparry replacements of

lenticular gypsum (Muir, 1979). They are not. The magnesite, brunnerite and siderite crystal clusters grew poikilotopically in buried but relatively permeable horizons within open marine platform carbonates and in thin section many lenticular crystals still retain poikilotopically enclosed marine allochems. The lenticular crystal shapes, especially of siderite and brunnerite are that of nascent precipitates fed by ascending Precambrian brines. Brunnerite formed when Fe-rich brines permeated dolomite beds, while siderite was the favoured precipitate in pores of a limestone precursor.

A somewhat analogous halokinetic Phanerozoic system is seen in the Upper Burano (Triassic) evaporites of the Apennines. It is a highly deformed halokinetic evaporite-sparry magnesite hydrothermal replacement system, with fluid crossflow focused along extensional fault conduits that feed replacement haloes in platform dolomites (Figure 7.26; Lugli et al., 2002).

A comparison of stable isotope signatures from various types of magnesite deposits shows a clear separation in oxygen isotope signatures between Neogene lacustrine magnesites, Precambrian cryptocrystalline magnesites, and Precambrian sparry magnesites, with each group showing successively more negative values (Figure 11.44). This difference, at least

Figure 11.45. World soda ash production (in thousand metric tons) (compiled from USGS on-line data tables, compiled from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005).

in part, reflects the higher hydrothermal temperatures that characterise the sparry magnesite association. Within the cyptocrystalline magnesites it also reflects the likelihood that Precambrian carbonates have in general experienced higher burial temperatures for longer periods than Neogene lacustrine precipitates (Melezhik et al., 2001). Carbon isotope signatures are much more variable and relate in part to the variable supply of carbon from pre-existing carbonate minerals, levels of organic contribution and amounts of meteoric input.

Sodium carbonate salts (trona)

The word trona is a derivative of the Arabic word *natrun*, from which we also derive the English word natron. Mineralogically natron (not *natrun* as originally used by the ancient Egyptians and then the Arab alchemists) describes the decahydrate form of sodium carbonate and is one of a number of sodium carbonate minerals (Table 11.12). Sodium carbonate (aka *soda ash*) end usage is mostly in glass manufacture followed by chemicals, soap and detergents, pulp and paper manufacture, water treatment, and flue gas desulphurisation. Sodium carbonate's prime use in ancient Egypt, in the form of *natrun* quarried from salt lakes (a trona-halite mix), was an integral part of the mummification^{11.4} process.

In many countries local supply of sodium carbonate (aka soda ash) is synthetic, created using the Solvay process, which utilises halite and limestone as raw materials with an ammonia catalyst within the carbonating towers. Annually, roughly twice as much

^{11.4} Ancient Egyptians are famous for their perfection of the art of mummification. A key ingredient in the process was *natrun*, which is composed of halite+trona. The ancients knew its preservative properties rivalled those of halite and it also absorbs water readily, making it an excellent desiccant/preservative. *Natrun* is found in large quantities in the beds of several Egyptian playa lakes (Wadi Natrun and El Kab, as well as Behiera in the nearby Libyan desert) and it has been mined and traded from these localities for thousands of years. Writings as old as the reign of Ramese III (1198-1166 B.C.) refer to these deposits. The preservative qualities must have been immediately apparent to the ancient Egyptians from its effects on any wild life, which had died in these lakes. There is some evidence that the Egyptians artificially precipitated *natrun* by isolating shallow basins of lake waters for faster evaporation, as is still done in parts of the depression today. For purification and preservation, *natrun* was preferred over halite because it chemically attacks and destroys grease and fat and so is a superior drying agent (as is sodium borate). It is found not only in tombs and in pits, along with other discarded embalming materials, but also forms nodules and residues in the mummies themselves.

There is some debate over the method in which the *natrun* was used for mummification by the ancient Egyptians. Some argue it was used in a way similar to the contemporary method for "salting" fish. Dry *natrun* would be sprinkled over the body, perhaps with sawdust, or spread with linen cloths. Others with a more prosaic bent, believe the body was immersed in vats containing a *natrun* solution. Such a wet method would have been odiferous and accelerated putrefaction, thus counterproductive to the preservation of the body, although it makes for good Hollywood images. A dry body is also more readily bandaged as well as being more amenable to the attachment of amulets and other jewellery. Although mummification has supernatural trappings in popular culture, its basis is rooted in simple chemistry and processes as mundane as salting fish.

Mineral	Formula	Na ₂ CO ₃ (equiv.%)
Trona	NaHCO ₃ ·Na ₂ CO ₃ ·2H ₂ O	70.4
Thermonatrite	Na ₂ CO ₃ ·H ₂ O	85.5

Table 11.12. Minerals containing sodium carbonate.

soda ash is produced worldwide by the Solvay process than by trona extraction. Major producers using the Solvay method include; China, Germany, India and Russia (Figure 11.45). Until the 1960s, soda ash in the USA was almost totally derived from Solvay plants situated near industrial markets in the country's northeast. Today the position in the USA is reversed: trona is mined from the Eocene Green River Basin, Wyoming, or processed from lacustrine brines in Searles Lake and Owens Lake, California. Large-scale subsurface operations in Wyoming mine trona using various combinations of room-and-pillar, longwall and shortwall extraction methods.

Solution mining and multicomponent recovery methods process brines extracted from trona beds in Searles Lake (Figure 11.35). Dilute sodium hydroxide (NaOH - commonly called caustic soda) is injected into the lake beds to dissolve trona. The recovered solution is treated with carbon dioxide gas in carbonation towers to convert the sodium carbonate (Na₂CO₃) in solution to sodium bicarbonate (NaHCO₃), which precipitates as nahcolite and is filtered out (Figures 2.13, 12.9). The crystals are again dissolved in water, precipitated with carbon dioxide, and filtered. The product is then calcined to produce dense soda ash. Sodium bicarbonate, sodium sulphate, potassium chloride, potassium sulphate, borax, and other minor minerals are produced as coproducts from sodium carbonate production from brines in Searles Lake, California. Likewise, sodium bicarbonate, sodium sulphite, sodium tripolyphosphate, and chemical caustic soda are manufactured as coproducts during processing of mined trona at several of the Wyoming soda ash plants. A number of naturally occurring evaporite minerals

contain Na₂CO₃, but only trona is economically extracted or solution mined at this time (Table 11.13).

There is a common misconception among some geologists that the presence of thick-bedded trona indicates a carbonatite-rift source area. Certainly there are some geologically scenic trona deposits in the African rift that are surrounded by volcanoes spewing natrocarbonatites, but these are volumetrically minor deposits, even in terms of the volume of rift sediment fill and especially compared to the volumes of ancient trona precipitating in evaporitic seaways of the Archaean (Figures 2.31, 2.32). Even today, all that is needed to form sodium carbonate brine is a suitably alkaline inflow water, depleted in sulphate and chloride. Most continental ground waters in metamorphic, volcanic, or igneous terrains will produce alkaline solutions upon evaporation (Hardie and Eugster, 1970). The relative absence of chloride and sulphate in these types of rocks permits solutions to become relatively enriched in Na and CO₂ and so follow the appropriate "closed basin" concentration pathway leading to trona/nahcolite (Figure 2.12). Mechanisms driving the appropriate chemical evolution leading to trona are varying combinations of mineral precipitation, selective dissolution of efflorescent crusts, degassing of brines, and/or redox reactions (Jones et al., 1977).

Ground water percolating through siliceous soils, such as those developed on granite or windblown sand, can become highly alkaline and enriched in sodium carbonate (Garrels and Mackenzie, 1981). Very high carbon dioxide concentrations (up to 10% of soil gas) can be the result of intense biological activity in the depositional brine. The Pretoria pan and the Sua Pan in Botswana are examples showing elevated sodium carbonate in soil waters. The construction of solar evaporators using this water can produce substantial volumes of trona each dry season. In soda lakes such as Lake Magadi and Lake Natron, the deposition of monomineralic beds of trona may be aided by the continual generation of biogenic CO₂ from the halobiota flourishing in alkaline lake waters (Chapter 9; The Flamingo connection).

In regions characterised by an abundance of limestone or dolomite, or even a drainage basin leaching older marine evaporites, the inflow waters to the saline depression contain too much chloride, sulphate, and calcium to produce a trona brine. Even in some areas draining igneous and volcanic terrains, the inflow waters mix with other basinal waters or with other rock and soil types and so trona cannot precipitate.

Trona in North America

The lacustrine Green River Formation (Eocene) in the Green River Basin in Sweetwater County, southwest Wyoming contains the world's largest known resource of natural sodium carbonate in the form of bedded trona (Figure 11.46). The scale of current extraction, and the possibility for future expansion for the various Wyoming operations is huge. For example, General Chemical's Green River Basin plant has identified trona ore reserves of more than 500 million tonnes and currently maintains more than 200 km of underground workings. Total identified trona resource in the basin is more than 47 billion tonnes, dwarfing any other known natural trona resource. For comparison, the combined identified total resource for Searles and Owens lakes is slightly in excess of 815 million tonnes. America today produces over 10 million tonnes of trona per year and is a net exporter of product. Lesser production is periodically extracted from Quaternary Lake Magadi in the East

African rift ($\approx 250,000$ metric tonnes/year) and from alkaline lakes in Mexico.

The Eocene Green River Formation is divided in ascending order into the Tipton Shale, Wilkins Peak Member, and the Laney Shale. The trona resource lies wholly within the lacustrine Wilkins Peak Member. The Wilkins Peak ranges from about 183 to 410 m (600 to 1,350 feet) in thickness and consists of marlstone, oil shale, trona, siltstone, mudstone, and numerous laterally persistent thin layers of tuff. These sodium carbonate-rich sediments were deposited in two large lakes that occupied several lacustrine sedimentary-structural basins in Colorado, Wyoming, and Utah (Figure 11.46; Dyni 1996). These basins include the Green River, Washakie, and Sand Wash Basins in southwest Wyoming and northwest Colorado, the Piceance Creek Basin in northwest Colorado, and the Uinta Basin in northeast Utah. Eocene Lake Gosiute is the northern

	Eocene Green River Fm. Wyoming (conventional and solution mining)	Area of more than 3,100 km ² . Contains 42 trona beds, 25 of which have a thickness of 0.91 m or more (which is considered the lower limit of economic significance) and each covering an area of about 175 km ² . Eleven of these beds exceed 1.83 m in thickness.	See this chapter and Chapter 4 for detail
	Wucheng deposit, Eocene, Henan Province China (conventional and solution mining)	Ore body contains about 77% trona and 23% nahcolite, and lies 650 to 970 m deep in beds 0.3-3.0 m thick. 36 ore beds each associated with oil shale (similar to Eocene Green River).	Zhang, 1985
	Beypazari trona deposit, Miocene of NE Turkey, 30 km west of Ankara	Areal extent of the trona deposit is estimated to be 8 km ² . Deposited as two lensoidal trona bodies within a 70- to 100-metre-thick zone in the lower part of a lacustrine shale. Total of 33 trona beds: 16 in the lower trona lens and 17 in the upper. Total thickness of the lower sequence is 40-60 m; upper trona ≈ 40 metres. The interval between the lower and the upper trona sequence is 30-35 metres.	Helvacı, 1998

Table 11.13. Selected trona occurrences, their properties and method of exploitation.

lake that once occupied the Green River, Washakie, and Sand Wash Basins. The southern lake, Eocene Lake Uinta, occupied the Uinta and Piceance Creek Basins in Utah and Colorado. The Uinta Mountain Uplift, an east-west positive structural element, separated the two lakes, although they may have been connected during part of their existence on the east side of the uplift. At its maximum extent, Lake Uinta covered about 57,000 km² (22,000 square miles), and Lake Gosiute, about 38,850 km² (15,000 square miles).

During much of Green River time, the lakes were closed with no outlets (Figure 5.10). The Green River Formation consists of a variety of lacustrine sedimentary rocks, including sandstone, claystone, shale, dolomitic marlstone, oil shale, and numerous, generally thin beds of volcanic tuff deposited in the two lakes (Dyini 1996). Typically, the Green River sediments grade from fine-grained sandstone, mudstone, claystone, and shale in shoreward areas of the lakes into carbonate-bearing sediments enriched in organic matter toward basin centre (Dyini, *op. cit.*).

The lateral transition from siliciclastic to carbonate-enriched rocks is also reflected in vertical sequences of the Green River Formation in the Green River, Piceance Creek, and Uinta Basins. This indicates increasing salinity of the alkaline lake waters as divalent cations of calcium and magnesium were precipitated as calcite, Mg-calcite, and dolomite in lake fringe mudflats, while dissolved sodium, bicarbonate, and chloride continued to accumulate in waters in saline pans in the lower parts of the basin. A lack of sulphate in the trona pans perhaps reflects bacteriogenic sulphate reduction in the lake brines, as is occurring in modern lakes in the African rift valley. Associated hydrolysis of detrital silicate minerals and glassy volcanic ash (zeolites) also contributes additional dissolved bicarbonate, sodium, and other ions to the lake brines. Tuffaceous debris amounts to roughly 5% of the total sediments in the Green River Formation.

During drier periods the Eocene lakes shrank and large volumes of saline sodium bicarbonate minerals were deposited,

either as bottom nucleates in shallow brine sheets or as displacive intrasediment nodules in mudflats. The more abundant sodium salts include trona, nahcolite, shortite, dawsonite, halite, and less commonly eitelite and wegscheiderite. The most important lake desiccation event occurred during Wilkins Peak and Parachute Creek time when vast deposits of trona and nahcolite were precipitated in the Green River and Piceance Creek Basins, respectively (Figure 11.47). During two later desiccation events, nahcolite was deposited as nodules and possibly some thin beds in the Birds-nest zone in the eastern Uinta Basin, Utah. Finally, during a later desiccation event, bedded sodium salts were deposited in the Uinta Basin near Duchesne, Utah (Dyini, 1996). Interbedded dolomitic oil shales separate these desiccation events and represent biochemical deposition from relatively dilute lake waters during expanded lake phases. Trona beds were deposited in the lowest sectors of the various basins during times when surface waters were extremely shallow to ephemeral with brine chemistries akin to those in

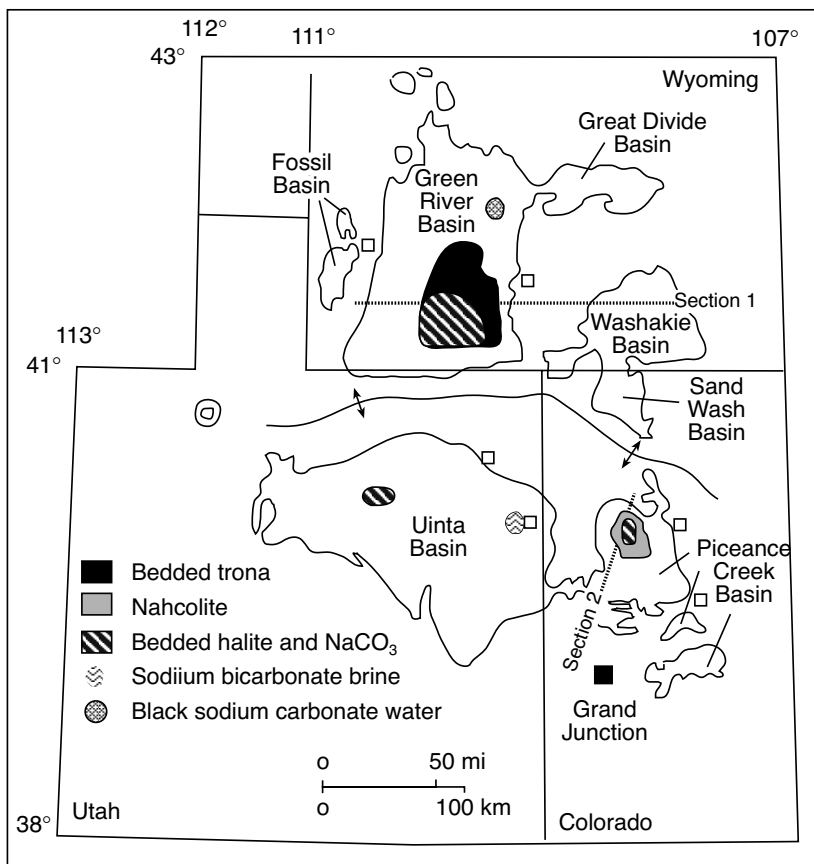

Figure 11.46. Areal distribution of the Green River Formation and the locations of sodium carbonate deposits in Utah, Colorado, and Wyoming (after Dyini, 1996).

modern Lake Magadi (Surdam and Wolfbauer, 1975; Fischer and Roberts, 1991). Centripetal groundwater inflows subsequently dissolved some of the sodium salts, as evidenced by the presence of solution breccias and solution cavities in cores collected in marginward parts of the Green River Formation. At least two areas today contain sodium carbonate brine pools of unknown size, but that are possibly exploitable brine resources (Figure 11.46).

Currently mined trona ore in the Green River Basin is restricted to the Eocene Wilkins Peak Member of Wyoming. Culbertson (1966) defined 42 beds of trona, up to 14 metres thick in the member, at depths ranging from 120m to over 1,000m. He numbered the thickest and economically most important of these beds from 1 to 25 in ascending order (Figure 11.48). These trona beds are remarkable for their purity and continuity compared to other large lacustrine trona deposits elsewhere in the world. Sulphate minerals are essentially absent, and other than halite, the chief impurities are thin dolomitic marlstone stringers and vertical seams of mudstone created by extension and injection of water saturated mud. Faults cutting the trona are rare and bed dips are typically less than a degree, making them eminently suitable for mining. Toward the depocentre in the southern part of the basin some of the trona beds grade laterally into mixed halite and trona (south of dashed line in Figure 11.48). Nahcolite is abundant in some beds in the lower part of the evaporite stratigraphy making them less suitable mining targets. Dyni (1996) also notes that nahcolite, wegscheiderite, northupite, and possibly shortite become locally abundant, as well as quartz, toward the depositional centre of the mixed halite and trona interval of bed 17 (one of the most important ore targets) when it is traced into the southern part of the basin.

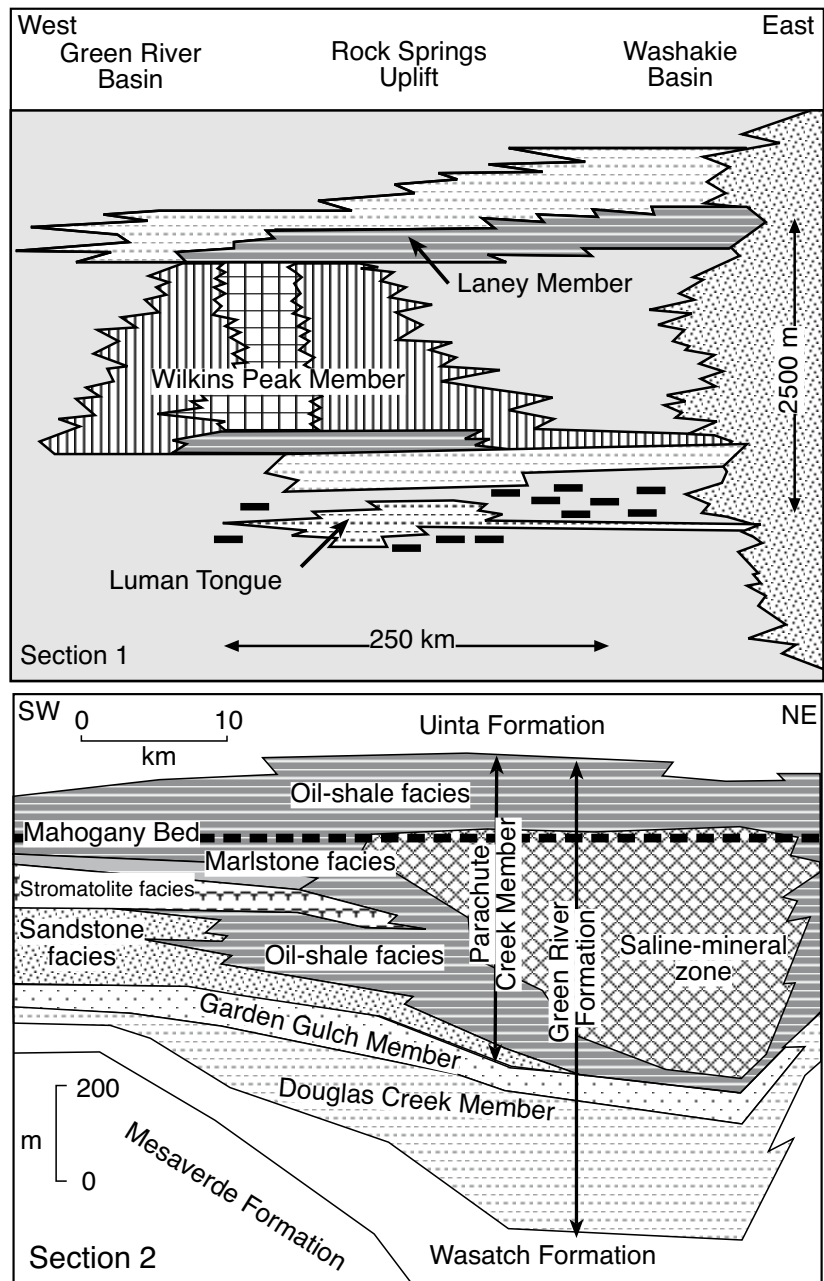

Figure 11.47. Stratigraphy of the Eocene Green River Formation showing interrelationships between various members and facies in the Green River Basin (section 1) and the Piceance River Basin (section 2). Locality of sections indicated on Figure 11.46.

The Wyoming trona district currently produces about 8.2 million mt (9 million tons) of refined soda ash annually from five underground mines that extract a total of about 16.3 million mt (18 million tons) of trona ore (Dyni, 1996). Trona bed 17 where it is more than 1.2 m (4 feet) thick, underlies about 2,000 km² (775 square miles) of the basin and ranges from 1.2 to

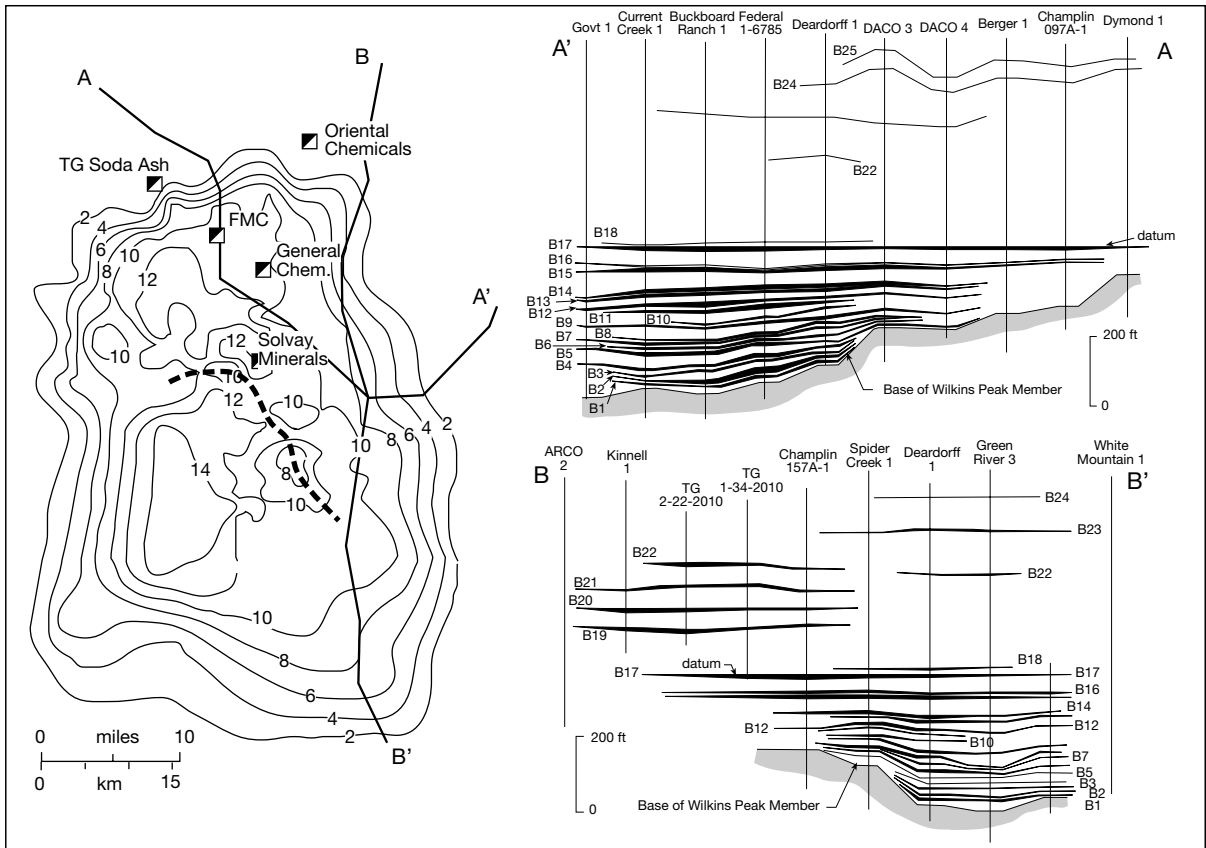

Figure 11.48. Trona distribution in the Wilkins Peak Member of the Eocene Green River Formation in Wyoming. Isopach is of Bed 17 and is in feet. Heavy dashed line indicates approximate northern extent of halitic facies. Cross sections use Bed 17 as a datum; halitic facies are not shown and the wells are equally spaced in the cross sections (after Dnyi, 1996 and Wiig, Dnyi and Grundy, 1995).

5.2 m (4 to 17 feet) in thickness (Figure 11.48; Dnyi, 1996). Twenty-two of the 25 numbered beds listed by Dnyi (1996) are estimated to contain 115 billion mt (127 billion tons) of trona ore, or 69 billion mt (76 billion tons) of trona in beds containing less than 2% halite. These 22 beds, where they are 1.2 or more metres (4 or more feet) thick, underlie areas ranging from 130 to more than 2,000 km² (50 to more than 775 square miles) at depths of 200 to 915 m (650 to 3,000 feet) below the surface. The trona contains 70.3 wt.% sodium carbonate and it takes about 2 tons of trona ore to produce 1 ton of soda ash. Currently, FMC, General Chemical, and Solvay Minerals mine trona bed 17, TG Soda Ash mines bed 20, and Oriental Chemicals mines beds 24 and 25.

Mining is by vertical shaft using room-and-pillar, short- and long-wall techniques (Dnyi, 1996). At three mines, additional sodium carbonate is recovered from wastewaters from the processing plant, which are used to slurry tailings to abandoned parts of the mines. These waters dissolve additional trona

from the pillars and are then pumped back to the surface to recover the sodium carbonate. The post-mining brine recovery technique has proven to be economical and will probably soon be employed by other mines in the district. Earlier attempts to solution mine trona from vertically drilled holes have been unsuccessful due to nahcolite ‘blinding’ (Figure 12.9).

In the last decade small scale solution mining began in the Parachute Creek member in the Piceance Creek Basin using horizontally drilled holes with nahcolite, not trona, as the planned feed source. If the blinding problem is solved a similar horizontal drilling method may be especially useful in the southern part of the basin where the trona beds are thicker and lie at greater depths. In mid 2004 operations at this facility were scaled back and today it is no longer actively extracting or processing brine (see Chapter 12).

The Parachute Creek Member in the deeper northern part of the Piceance Creek Basin contains a saline facies, which includes

beds of nahcolite and halite, along with scattered crystals, nodules, and coarse-crystalline aggregates of nahcolite commingled with high-grade oil shale (Dyner 1981, 1996). Also included in the saline facies is dawsonite as microscopic crystals in the microcrystalline matrix of the oil shale. The top of the nahcolite-bearing oil shale is a dissolution surface above which meteoric waters have dissolved nahcolite and halite forming a "leached zone" of vuggy brecciated oil shale (collapse breccia), which is up to several hundred feet thick. The leached zone extends upward into the lower part of the Mahogany oil-shale zone, a unit of high-grade oil shale traceable throughout the basin (Figure 11.47). The top of the leached zone is defined by the stratigraphically highest occurrence of the solution breccia (Dyner, 1981). This top can be considered to be the top of the original bedded saline facies in the Parachute Creek Member, although crystal cavities and vugs are found scattered through the upper part of the Parachute Creek Member well above the Mahogany oil shale in a zone 168 to 335 m (550 to 1,100 feet) thick.

The potential nahcolite resource in the Piceance Creek basin is estimated at between 29 and 32 billion short tons (26 to 29 billion mt; Dyner, 1996). It is unlikely that this resource will be exploited as oil shale cannot be removed or damaged under current sodium leasing regulations. The major part of the potential nahcolite resource, which occurs as crystalline aggregates scattered through oil shale, will be difficult to economically mine for soda ash alone. Any solution mining of nahcolite beds in this part of the basin may render portions of the overlying oil shale unsuitable for future in situ or underground mining.

Trona in the African rift

Outside of the USA the largest documented production of natural soda ash is from Lake Magadi, located some 120 km southwest of Nairobi, Kenya. The lake is situated in the lowest part of the East African Rift Valley and has a total area of 100 km² (Figures 4.34, 4.36). It contains more than 30 billion metric tons of trona in a bed between 7 and 40 metres thick and believed to have formed in the last 9,000 years. Thermal springs, driven by the area's volcanic activity, are the major source of sodium in the lake and are sourced from a deep actively circulating groundwater reservoir. Trona precipitates in the more central areas of Lake Magadi as a bottom-nucleated crystal pavement. The annual crop is estimated at 1.5 million tonnes/year, although the bulk of this crop (~75%) redissolves each wet season. When trona-saturated surface brines in Magadi dry up, the brine level stays close to the trona pavement surface. Even during exceptionally dry years the brine surface drops only 1 or 2 cm into the trona bed.

Trona in Lake Magadi has been mined since 1914 and is currently quarried from the pavement using dredging barges. As the solid material is removed by the digger belt, liquor from the surrounding trona drains into the resulting cavity, forming a pool or 'paddock' in which dredges float and move forward. Crystals of trona produced by the dredges are coarse crushed, mixed with lake liquor and pumped as a slurry back to the factory where the liquor is discarded and the crystals washed and centrifuged. The damp crystals are then fed into calciners where the residual moisture, water of crystallisation and carbon dioxide gases are driven off leaving normal soda ash. If for any reason a dredging barge breaks down for more than a day or two, trona precipitating in the paddock about the base of the barge can lock the barge in place. This trona has to be physically chipped away before dredging operations can continue. Replenishment of trona in the lake is so rapid that at present extraction rates the Magadi trona is a renewable resource.

Sodium sulphate salts (Glauber's salts)

Sodium sulphate (salt cake or Glauber's salt) is a common salt in many salt lakes and playas (Tables 11.14, 11.15). Thenardite and mirabilite, respectively, the anhydrous and decahydrate single-sodium sulphate salts, are the commercially important ore salts, with lesser production from glauberite and bloedite (astrakanite) ores. Thenardite, named for the French chemist Louis J. Thenard, is a colourless to white mineral with a specific gravity of 2.67 and a hardness of 2.5 - 3.0. It is stable below 33°C and is extremely hygroscopic below 25°C, converting to the decahydrate mirabilite (Figure 11.49). This mineral contains 55.9% water of crystallisation and forms opaque to colourless needle-like crystals sometimes referred to as Glauber's salt.

Mineral	Formula	Na ₂ SO ₄ (%)
Thenardite	Na ₂ SO ₄	100.0
Hanksite	2Na ₂ CO ₃ ·9Na ₂ SO ₄ ·KCl	81.7
Sulphohalite	2Na ₂ SO ₄ ·NaCl	73.9
Glauberite	Na ₂ SO ₄ ·CaSO ₄	51.1
Loewite	2Na ₂ SO ₄ ·2MgSO ₄ ·5H ₂ O	46.3
Ferronatrite	3Na ₂ SO ₄ ·Fe ₂ (SO ₄) ₃ ·6H ₂ O	45.6
Mirabilite	Na ₂ SO ₄ ·10H ₂ O	44.1
Bloedite	Na ₂ SO ₄ ·MgSO ₄ ·4H ₂ O	27.2
Tychite	2NaCO ₃ ·2MgCO ₃ ·Na ₂ SO ₄	42.5
Aphthalite	(Na,K) ₂ SO ₄	21-38
Tamarugite	Na ₂ SO ₄ ·Al ₂ (SO ₄) ₃ ·12H ₂ O	20.3
Mendozite	Na ₂ SO ₄ ·Al(SO ₄) ₃ ·12H ₂ O	15.5

Table 11.14. Minerals containing sodium sulphate.

	Location	Na-sulphate minerals and modes of occurrence	Reference
QUATERNARY	Cold climate saline lakes, Great Plains, western Canada	Mirabilite and thenardite precipitate at onset of winter cooling. Numerous lakes with a combined recoverable reserve \approx 80 Mt.	Last, 1993b, 1994 (see text for details)
	Laguna del Rey playa, Mexico (brine recovery and concentration)	Bedded crystalline mush that is a mixture of glauberite and astrakanite with sodium sulphate reserve of 350 Mt.	Garrett, 2002
	Gulf of Kara Borgaz, Turkmenistan (brine recovery and concentration)	Bedded crystalline mush that is a mixture of glauberite and astrakanite with sodium sulphate reserve of 2 Gt.	Garrett, 2002
	Lake Acigol, Turkey	Brine-soaked Holocene mudflats locally contain efflorescences of halite, bloedite; thenardite and/or mirabilite, all precipitating from the evaporation of artesian groundwaters.	Mutlu et al., 1999
	Intermontane playa, Tibet plateau, Mongolia	Holocene lacustrine setting depositing upto five mirabilite beds, some with borax minerals, retention of mirabilite in bed indicates episode of colder dry climate in basin.	Wei et al., 2002

Table 11.15. Selected Quaternary occurrences of evaporitic Na-sulphate miner-

Common nongeological usage of the term Glauber's salts can be confusing, it usually refers to mirabilite rather than glauberite (named after the 17th century German iatrochemist, Johann Glauber). The mineral name mirabilite comes from the Latin *sal mirabilis* or "miracle salt" possibly referring to its pharmacological use as a cathartic or laxative in the Middle Ages and its utility in treating a wide variety of gastric complaints.

Solubility related to temperature has an important effect on the crystallization of the various sodium sulphate salts in natural brines, as well as in its commercial production. Sodium sulphate solubility in water generally increases as a nonlinear function of temperature. Below 1.2°C, ice and mirabilite form (Figure 11.49). As the temperature increases above 0°C, increasing amounts of sodium sulphate become soluble. At 32.4°C, a transition point on the solubility curve is reached, whereby the decahydrate melts in its own water of crystallization and

thenardite (the anhydrous form of sodium sulphate) crystallizes. With increasing temperatures, its solubility decreases somewhat. The presence of other dissolved salts changes the transition temperature and solubility characteristics of sodium sulphate (see discussion of double salt effect in Chapter 2).

Natural temperature drops in sodium sulphate-saturated brines are sufficient to allow mirabilite to crystallise in Canadian salt lakes during the autumn transition to winter, and even during cooling on summer nights in higher altitudes. In many places, mirabilite crystals redissolve into the lake brine with the next passage to warmer temperatures, this can be on the next day or with the passage of winter into spring.

Natural sources of sodium sulphate make up over 60% of world production, the balance is a byproduct of various chemical and waste recovery processes. Spain and Mexico are the world's

Figure 11.50. World production of sodium sulphate (in metric tons) (compiled from USGS on-line data tables, downloaded from <http://minerals.usgs.gov/minerals/pubs/commodity/myb/> last accessed 30 September, 2005).

highest tonnage miners of sodium sulphate, followed by a group comprising the USA, Canada, Turkey and Iran (Figure 11.50). Of the exploited natural sodium sulphate sources, three are from bedded Quaternary playa deposits namely: Laguna del Rey, Mexico; Searles Lake, California; and the Gulf of Karabogaz, Turkmenistan. There are also natural mirabilite deposits that form annually by winter brine cooling in modern saline lakes such as the Great Salt Lake, Utah, Lake Kuchuk in Russia, some restricted parts of the Aral Sea and numerous small saline lakes on the Great Plains of Canada. Then there are the ancient (Tertiary-age) lacustrine deposits of Spain and Turkey where glauberite and thenardite are the main ore minerals and the modern pedogenic deposits in the Atacama Desert of Chile.

The bulk of sodium sulphate usage is in the manufacture of glass and powdered detergents. It is also used in the pulp and paper industries. Commercial sources of sodium sulphate are mostly crystalline mirabilite, with lesser volumes of thenardite or glauberite and it is typically extracted as brine or mined from salt beds in playas and saline

lakes within cold or arid settings. Sodium sulphate can also be obtained as a byproduct from the production of ascorbic acid, boric acid, cellulose, chromium chemicals, lithium carbonate, rayon, resorcinol, and silica pigments.

Figure 11.49. Stability diagram of minerals in an NaCl-saturated NaCl-Na₂SO₄-MgCl₂-H₂O system (after Braitsch, 1964).

Canadian deposits

There are an estimated 5.5 million saline lakes in the moraine plain of Canada, creating a concentration and diversity of salt lake environments unequalled in the world (Last, 1989a, b, 1992). Virtually all water chemistry types are represented in these lakes, with Na-Mg-SO₄ brines dominant. Over 80 species of endogenic precipitates and authigenic minerals have been identified as lake precipitates, the most common being calcium/calcium- magnesium carbonates (calcite/dolomite) and sodium/sodium- magnesium sulphates (mirabilite/gypsum). All the Canadian production of sodium sulphate in southern Saskatchewan and southeastern Alberta comes from present day or earlier Holocene late autumn-early winter cooling/freezing of playa brines. Precipitation of the ore salts is mostly as mirabilite, which may convert to thenardite with warming. Ore formation is a cryogenic, not solar evaporative, process. Most mirabilite-accumulating lakes are small (< 100km²), shallow (brines < 3-20m deep), with permanent salt beds found only in the lowest portions of some of these hydrologically closed meromictic depressions (Last, 1989a, 1994). Only around

a hundred lakes have salt reserves of more than 100 kt of Na₂SO₄ and their combined recoverable reserves are around 80 Mt (Garrett, 2002).

Large tracts of hummocky and icethrust moraine dominate the region and, in combination with the limited efficacy of fluvial processes under a subhumid to semiarid temperate climate, results in more than 45% of the region being endorheically drained into perennial saline lakes in depressions in the glacial drift. Some of these depressions are elongate and probably occupy pre-ice age river valleys (Little Manitou Lake), others were created by the melting of huge relict blocks of ice left in the moraine after the main front of the ice sheet had retreated (Ingebright Lake), Groundwater seeping from the surrounding moraine, through the underlying valley sands and across underlying bedrock supplies much of the dissolved content, but there is still no consensus as to the ultimate origin of the sodium and sulphate (Last 1989a). The geographic coincidence of many of the more productive lakes to the subsurface solution edge of the Devonian Prairie Evaporite lead Grossman (1968)

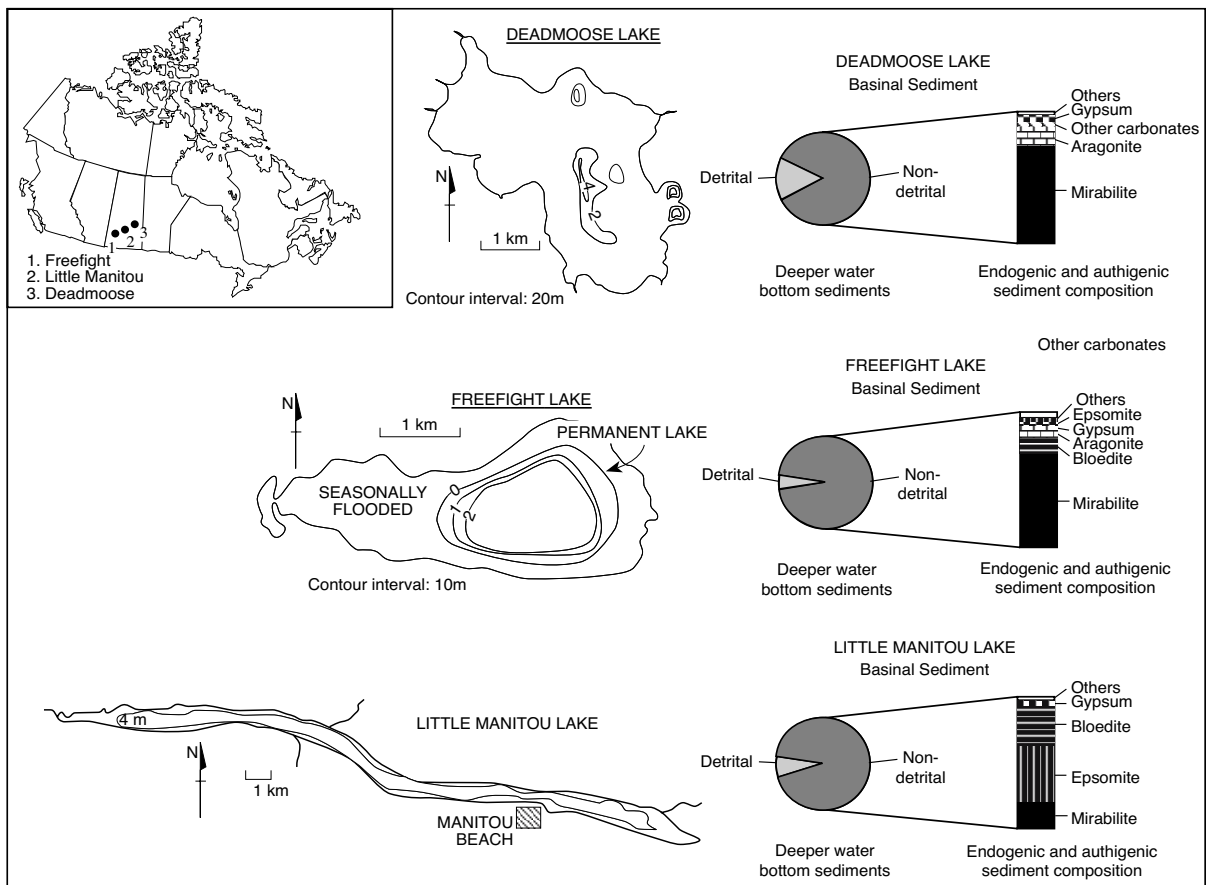

Figure 11.51. Sodium sulphate lakes, Canada, showing bathymetry and bottom sediment composition (after Last, 1994).

to suggest dissolution-derived salt-rich resurging groundwaters were the ultimate source. Others have argued that weathering and leaching of pyritiferous glacial flour is the likely source for the ions, independent of the underlying Devonian salts (Wallick, 1981).

Coldwater precipitates are dredged each year from suitably saline lakes before the mirabilite crusts redissolve with the passage in to the warmer lake waters of spring. Thicker-bedded crystalline thenardite deposits (transformed from primary mirabilite) have accumulated on the bottom of some lake depressions. Each year they retain a saturated brine layer from few centimetres to metres deep but their bottom waters are subject to seasonal warming. Waters in the upper water mass of all the deeper perennial lakes are replenished annually by spring melt. Cryogenic cycling whereby some of the mirabilite redissolves due to heating, can produce lake-bottom brines with salinities that may exceed 400‰. This maintains a perennial curtain or plume of saturated pore brines that preserve thick salt beds in the lower parts of the lake depression.

The saline lakes region of Saskatchewan encompasses some of the largest (Quill, Old Wives) and deepest (Freefight), perennial hypersaline lakes in North America, capable of accumulating bedded salts more saline than evaporitic carbonate. Ingebright Lake in southern Saskatchewan, although it is small in area (< 2km²) has, at 25-40 m-thick, the thickest Holocene evaporite bed in North America and it is dominated by primary precipitates of thenardite, Mg-carbonates and gypsum.

Two recognizable brine styles drive NaSO₄ precipitation and accumulation in the various lakes; intermittent saturation and permanent saturation (Last, 1994). Intermittent brines form seasonally on the bottom and along the shores of the lakes. There mirabilite crystallizes and largely redissolves with each seasonal cycle of cooling and warming. Mirabilite precipitation-dissolution cycles in such lakes can occur in a matter of hours, but as winter sets in, redissolution wanes, causing the crusts to become thicker and more compact. Spring meltwaters in a few lakes with such intermittent brine hydrologies carry in sufficient volumes of fine detritus to mantle salts in the shallower parts of the lakes and so preserve some of the lake precipitates year round. Such beds range in thickness from less than one to several metres, they are relatively impure, and made up of thenardite interstratified with thin layers of mud, clay, and organics.

Thicker purer beds of NaSO₄ tend to accumulate and be preserved beneath the permanent meromictic waters of the deeper

lakes. Hence, Deadmoose, Little Manitou, and Freefight Lakes are lacustrine depressions in the moraine plain where soluble and sparingly soluble NaSO₄ salts accumulate beneath relatively deep permanent brine bodies (up to 20 m deep; Figure 11.51). Both Deadmoose and Freefight Lakes are hypersaline and meromictic systems, with strongly anoxic hypersaline bottom waters. Little Manitou is also hypersaline, but the seasonal density and chemical stratification in the water column usually breaks down in early to midsummer, so allowing mixing of the upper and lower water masses down to the sediment surface.

There are four distinct styles of salt occurrence in these perennial lakes: a) crusts and hardgrounds of the lake edge, b) massive and bedded salts of the lake centre, c) spring or seep deposits, 4) subsurface and groundwater related interstitial and replacive cements (Last, 1989a, b). Relatively thick sections of subaqueous evaporites (mostly thenardite) have accumulated on the bottoms of some of these deep perennial lakes making them one of our better examples of textures in modern "deepwater" evaporites (Last, 1994). These deepwater salts are generally coarsely crystalline, massive to thickly bedded, and interfinger laterally with laminated organic-rich clays and poorly sorted carbonate-clastic debris washed in from nearshore areas. As in the Dead Sea, it seems that the deep water signature to a salt body accumulating in deeper hypersaline waters is not a laminate, but an aggregated bed of coarse crystals growing at the base of a holomictic brine column as crystal meshworks showing little or no preferred growth direction.

Figure 11.52. Extraction methods in various Saskatchewan sodium sulphate deposits (after Garrett, 2002); 1) Evaporative concentration of lake brine in crystallization pond, followed by precipitation of crystals of Glauber's salt (mirabilite) as the brine cools in autumn; 2) Solution mining of thick crystal beds. The brine return is treated as in 1; and 3) Dredging of lake bottom crystal beds.

Ingebright Lake is the largest salt lake still in production, bed thickness once averaged 6.7 metres of permanent salt. In 1954 the reserves exceeded 11 million tons beneath a lake area of 280 ha (Garrett, 2001). The lake and its drainage area is not large and no streams flow into it. It is fed by numerous springs and seeps about the lake edge, including five large springs that flow year round, supplying a dilute high-sulphate medium carbonate/bicarbonate water to the upper water mass (TDS of 2800 ppm; Cole, 1926). Subaqueous springs also cut up through the mirabilite bed that covers the lake floor. Springs tend to be cold (7°C) in the northern part of the lake, and warmer (15–18°C) and more saline in the south. Each winter these more saline southern springs precipitate large ephemeral mirabilite mounds that are up to 3 metres tall and 6 metres across. The fresher nature of the water supply to the northern springs means they are capable of dissolving all the mirabilite on their rise to the lake floor and so are defined by mud pipes or chimneys cutting up through the mirabilite ore bed (Last, 1993a). This metres-thick mirabilite bed, which covers the perennially subaqueous lake floor, is compact and friable. In the northern part of the lake it contains numerous clay layers that are mostly cm-scale, but as thick as 1 metre at the 7.6 to 9.1 metre level in the lake (Cole, 1926). In the south there is much less mud in the salt and it is more indurated. In the thicker ore bed of the southern part of the lake there are two zones where the mirabilite bed is thicker than 30 metres and one borehole intersected more than 42 metres of relatively pure sodium sulphate.

The mirabilite extraction industry in Canada is in decline, most of the remaining commercial lakes are in southern Saskatchewan. In the early days operators merely mined mirabilite by scraping or blasting, later some of the mirabilite was solution mined (Garrett, 2002). Traditional brine extraction involves pumping of surface brines into storage reservoirs during the summer and then allowing the lower autumn and winter temperatures to precipitate mirabilite (Figure 11.52). The mirabilite is then trucked to the processing plant, where water of crystallisation is removed and product then dried to salt cake in a rotary kiln.

Spanish deposits

Tertiary lacustrine sediments are the major source of sodium sulphate within three large Tertiary basins in Spain that together contain as much as 3 Gt in the form of glauberite or thenardite (Garrett, 2002). Spanish operations recover solid ores for processing, not brine. Ore is mined via room and pillar methods or in-situ leaching extracted via planned face retreat. The “El

Castillar” mine in Toledo Province yields mostly thenardite from an ore averaging 67% Na₂SO₄, 19% CaSO₄ and 12% clay and marl. The ore bed thickness averages 9 metres and it lies atop a 13 metre-thick halite bed. Glauberite is extracted at Cerezo de Riotiròn, Burgos Province, where the deposit is practically horizontal, undisturbed and made up of glauberite in four beds hosted in Miocene lacustrine marls.

The salts have a primary paragenesis of glauberite + anhydrite + dolomite ± chalcedony; the secondary minerals related to hydration and incongruent dissolution of glauberite are mainly gypsum and calcite (Menduina et al., 1984; Salvany and Orti, 1994). Glauberite types are varying combinations of: 1) massive glauberite within fining-upward sequences containing nodular anhydrite; 2) millimetre-scale glauberite layers alternating with dolomicrites; 3) single glauberite crystals dispersed in dolomicritic matrix (Figure 11.53a). There is no mirabilite phase preserved in these deposits.

A ‘perennial saline lake’ model with warm extensive saline mudflats explains the deposit (Figure 11.53b; Salvany and Orti, 1994). Solutes were derived from the phreatic dissolution of Mesozoic evaporites, mainly Ca-sulphates and halite, in the nearby mountains (Figure 8.10; Pyrenees and Iberian Ridge). The precipitation sequence was: carbonate, gypsum-anhydrite, glauberite, halite-polyhalite. Indicators of backreactions of glauberite with gypsum/anhydrite are commonplace because of dissolution resulting from interactions of primary precipitates with less concentrated (meteoric) brines and seeps feeding into the basin margin and supplemented by occasional storm runoff.

That is, glauberite, anhydrite and polyhalite were early diagenetic minerals, which formed via backreactions with a solid precursor (typically gypsum) during early diagenesis. The brines that drove this early alteration reacted with the solid precursor in two ways: 1) reaction of the concentrated brine with the solid phase precipitated during episodes of lowered salinity (e.g. anhydrite alters to glauberite; glauberite alters to polyhalite), and 2) reaction of dilute brines with solid phases precipitated in episodes of higher salinity (e.g. glauberite alters to anhydrite, polyhalite alters to glauberite or anhydrite). Burial led to further transformations of gypsum to anhydrite, and during exhumation and exposure all preexisting sulphates (anhydrite, glauberite, polyhalite) were transformed near the surface into gypsum and now form the weathered cover or carapace seen atop many ore profiles (Figure 11.53a).

Figure 11.53. Miocene glauberite in Spain. A) Profile of the ore zone in the Villaconejas Mine, Spain. B) Sedimentological model for deposition of Spanish glauberite deposits (after Salvany and Orti, 1994).

Turkish Deposits

Sodium sulphate salts are extracted from the Upper Miocene Kirmir Formation at Cayirhan Mine, Turkey (Figure 11.54; Orti et al., 2002). Unlike the Spanish ores, thenardite (after mirabilite) is a significant depositional component the bedded evaporite portion of this lacustrine ore association. However, none of the mirabilite remains as it converted to thenardite with moderate burial. The Evaporite Member of the Kirmir Formation, which is composed of secondary gypsum at outcrop, can be subdivided into a bedded lower unit and a massive upper unit (Figure 11.54a). Most of the current outcropping and subcropping gypsum of the bedded lower unit has been transformed during exhumation from a glauberite parent. Glauberite layers ("clear glauberite") still remain at depth, as in the Cayirhan mine, where textures suggest it was deposited as a primary, subaqueous, cumulate precipitate on the saline lake floor (Figure 11.54b). But more typically, the glauberite textures are nodular, suggesting it was an early (syndepositional to precompaction) interstitial precipitate, indicating crystal growth occurred just below the sediment surface as passive and displacive crystals within a poorly lithified clayey magnesitic matrix. Thenardite layers in the glauberite beds in the Cayirhan mine, show disruption structures created by syndepositional dissolution and infill (Figure 11.54c). These structures, together with their pseudomorphic textures, suggest mirabilite was the original sodium sulphate lakefloor precipitate. If so, the current thenardite ore is a secondary phase, formed by mirabilite dehydration during early to moderate burial.

The massive upper unit, in which evidence of any sodium-bearing minerals is absent, is characterized by laminated to banded gypsum, with nodular gypsum dominant in the marginal areas of the evaporitic basin. Thick, clast-supported gypsum breccias prevail in the northern, deeper part of the basin. The brecciation of these calcium sulphate layers occurred as a result of syndepositional, gravitational slumping into the deeper parts of the perennial lake during times of lake flow instability driven by active tectonism (Orti et al., 2002).

As well as this ancient resource there are three playa lakes where sodium sulphate is produced from winter brine; they are Acigol, Tersakan and Bolluk and all three use the same basic production method. Surface brine is pumped into a series of solar ponds or small depressions on the lake floor in the summer and autumn. The inflow in some is supplemented by spring or aquifer waters as well as interstitial brine from lake bores or seepage trenches in areas on the lake floor outside of the pans. Salinity of brine in the pans is monitored so that it does not become saline enough to precipitate halite nor fresh enough to dissolve the pan floor where a seed bed some 20-30cm thick of thenardite (with minor mirabilite) was left from the previous year's salt harvest. As the concentrated brine cools from October to December a 50-60 cm thick layer of mirabilite crystallises in the centre of the ponds. From January and on into early spring the residual brine and any spring rainfall is drained from the pan. The flush of this fresher water through the lower part of the now metre-thick salt bed helps re-establish the integrity of the seed layer that will be left behind after harvesting. The

B) Depositional settings of the lacustrine evaporative system at the time it was precipitating sodium sulphates of the bedded lower unit (Evaporite Member of the Kirmir Formation). C) Interpretation of the genesis of mirabilite and its syndepositional dissolution and final conversion to thenardite during (moderate) burial.

mirabilite slowly dehydrates and by the end of June the bed is largely composed of thenardite, which is scraped from the lake surface and loaded into bags.

The textural transitions associated with this process are interesting and as it ultimately forms a vadose product with textures that are somewhat different to the perennial lakes of Canada but more analogous to the Tertiary deposits just discussed. The mirabilite has two forms, either large thin interlocking elongate hoppers or fine radiating spherules made up of acicular crystals (Garrett, 2001). The 0.6 m-thick mirabilite crust precipitated each winter is characterised by a thin uppermost layer or lamina of thenardite-mirabilite crystals, with some astrakanite. This is underlain by downward-pointing dog-tooth spar crystals of mirabilite, which constitute the bulk of the winter precipitates. They are downward-pointing as mirabilite tends to form rafts or hoppers at the contact between cool air and brine and not to grow upward from the lake floor. Below the coarse crystalline mirabilite is a thin layer of smaller equant mirabilite crystals defining the base of the winter precipitate layer. As the mirabilite bed dehydrates in the following summer it forms small powdery crystals that are easily blown about in the wind and escape the

pan. As summer temperatures reach 30-35°C the mirabilite bed “melts leaving behind some 15% of its former mass as thenardite and a saturated sodium sulphate solution that then continues to precipitate more thenardite. The resulting thenardite layer is composed of hard compact transparent crystals, which can contain numerous solid phase inclusions.

Other sodium sulphate deposits

Most US production of sodium sulphate comes from multicomponent brine processing in Searles Lake, California. As discussed earlier in the sections dealing with borates and trona, this brine resides in the interstices of the lake's salt beds, which contain some 369 million metric tons of Na_2SO_4 and 65 million metric tons of K_2SO_4 , representing $\approx 35\%$ of the total lake brine. These volumes rank it as one of the world's largest exploitable sodium sulphate accumulations. Brine processing in Searles Lake began in 1873 and the first sodium sulphate from brine was produced in 1914. North American Chemicals, Inc. today operates two facilities near Searles Lake, the West End plant and the Argus plant (Figure 11.35). The West End plant

is North America's only source of sodium sulphate where it is recovered as the primary product along with secondary soda ash and borax. Mixed brines are processed (carbonated) with carbon dioxide to precipitate sodium bicarbonate, which is then removed by filtration. The decarbonated brine is cooled three times to produce two successive batches of borax and one of Glauber's Salt (mirabilite). By heating, the sodium bicarbonate is converted to soda ash and the borax is either crystallized as a hydrate or dehydrated to its anhydrous form. The Glauber's salt is washed, melted, and recrystallized as anhydrous sodium sulphate; 99.3% purity can be obtained in this process.

In the brines of the Great Salt Lake, Utah, about 12% of the dissolved salt is sodium sulphate, representing about 400 million tonnes of potential resource. Mirabilite crystallizes naturally during the winter and sinks to the bottom of the lake so that in a cold winter a layer of mirabilite 0.15 to 0.30 m thick occurs seasonally over large portions of the lake floor. It redissolves with the passage into spring. Under favourable conditions, mirabilite rafts are carried by wind and currents to the shore where it can accumulate to a depth of 0.3 m or more. Strand deposits as thick as 3 m have been observed in some very cold windy years.

In the recent past the Great Salt Lake Minerals and Chemicals Corp. has made use of the annual cooling process in its brine pans to manufacture sodium sulphate salts as a secondary product. It operates a facility on the edge of Great Salt Lake for the production of a halite feed to its chemical plant and the coproduction of potassium sulphate and magnesium chloride. Brine is pumped from the Great Salt Lake into solar evaporation ponds where sodium chloride precipitates. Sodium sulphate crystals precipitate in a fairly pure state when winter weather cools the residual brine in the pans to -1 to -4°C. Crystals can be picked up by large earthmoving machinery and stored outdoors each winter until further processing takes place. The harvested salt is melted and anhydrous sodium sulphate precipitated by the addition of sodium chloride to reduce its solubility through the common ion effect. The final product is 99.5% pure NaSO₄. Thus, sodium sulphate is a byproduct of the halite process, but low prices meant it has not been harvested for the last few years.

Beneath the south and southeast parts of the lake there is a metre-thick mirabilite bed below 0.5 m of oolitic sand. To the north, immediately west of Promontory Point, there are much thicker accumulations of bedded mirabilite making up an irregular, 21-metre-thick mirabilite deposit, which is interlayered with clay beds between 4.5 and 9.1 metres thick (Figure 4.19c).

The mirabilite probably accumulated as bedded salt in the colder conditions of the last glacial (probably under a meromictic hydrology similar to that in Ingebright Lake today). Historically, the bed has been blasted and dredged in different parts of the lake and a processing plant was set up on the shores of the lake in the 1930s and 40s.

Ancient lacustrine deposits in the USA containing bedded sodium sulphate are considered non-commercial today, but have been mined in the past at Mesa Verde, Arizona and Rhodes Marsh near Mina, Nevada. The thenardite deposit at Mesa Verde is the only large well-defined ancient sodium sulphate deposit in the USA with projected reserves ≈ 100 Mt (Garrett, 2002). It also has the distinction of probably being the oldest mining operation in the United States. A tunnel in one of the halite beds at the base of the deposit yielded Indian artifacts around 2,000 years old. During the 14th and 15th centuries it was mined more intensively by the Mesa Verde and Rio Verde cliff dwellers, who removed a few thousand cubic metres.

One of the world's larger sodium sulphate deposits and Mexico's major sodium sulphate resource is the brine resource in the Laguna del Rey playa, Coahuila. Today it is a dry playa some 10 km long and 4 km wide. Operating on the lake shore is the world's largest sodium sulphate brine plant (Figure 11.55a). It uses a captive brinefield to solution mine brine from a bed containing 50% glauberite, 20% bloedite (astrakanite), 28% clay and various other sodium and magnesium salts including 1% halite. Minor mirabilite and epsomite are locally present as a cement between the glauberite crystals (Garrett, 2002). The salt body lies some 1-2 metres beneath the present playa floor, is lenticular in cross section, dips slightly to the east and thickens to the south. It has a maximum thickness of 35 metres and an area of 40 km² and contains a resource of some 350 million metric tons of sodium sulphate and 77 million metric tons of magnesium sulphate.

The lower parts of the flat playa surface are marked by an ephemeral halite crust, broken in places by relicts of a now largely inactive dune field. Above the halite crust is a green clay containing abundant gypsum and lesser glauberite and halite. Below the green clay is a red clay bed that immediately overlies the target salt bed. A similar, but much thicker red clay also underlies the main salt mass. Porosity in the salt mass is around 26% and is filled with a brine that when pumped from this salt bed contains more than 26% sodium sulphate (Figure 11.55b). A brinefield of more than 70 wells pumps brine to the surface from a depth of some 24-25 metres below the playa surface. Wells are gravel packed for the lower 12 m and the

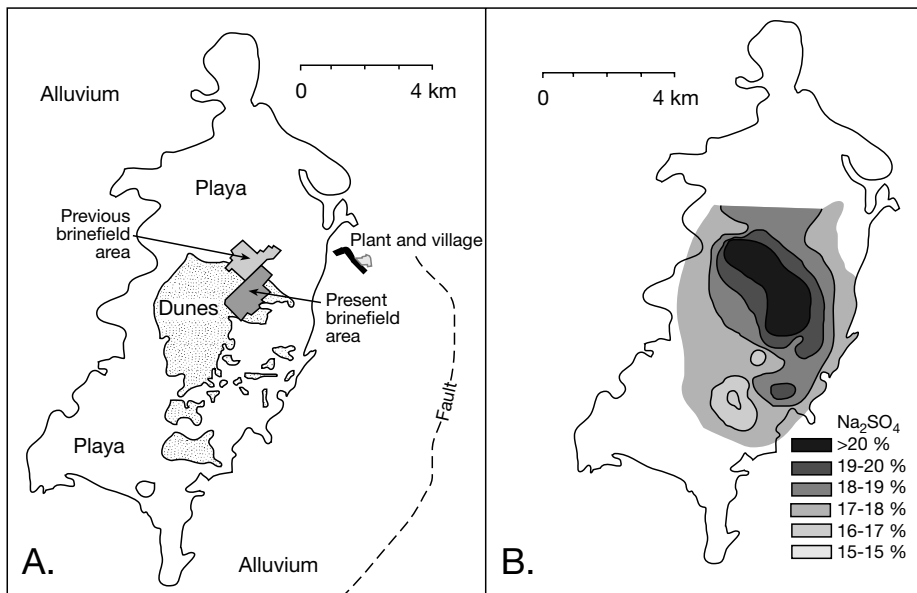

Figure 11.55. Laguna del Rey, Coahuila, Mexico. A) Distribution of surface features, brinefields and production plant. B) Distribution of Na_2SO_4 in brines in the shallow subsurface bed in the salt bed (after Garrett, 2001).

brinefield pumps around 113 litres/sec of 25°C 200 g/l sulphate to the recovery plant (Garrett, 2002). The ultimate source of the ions now accumulating in the playa depression is thought to be halokinetic gypsum capped marine evaporites that subcrop in the surrounding highlands.

Modern saline lakes, similar to the cold playas of Canada, are the major source of sodium sulphate in the former USSR and extend from the Black Sea to western China. Examples include Selenga Lake in the eastern Transbaikal, Lakes Azhbulat, Ebeity and Tengis in Kazakhstan, and the Batalpashinsk and Tambukan Lakes between the Black and Caspian Seas. The enormous potential of these deposits can be illustrated in Lake Azhbulat where some 40 Mt of mirabilite is deposited each winter. On the Kulunda Steppe, western Siberia, lacustrine deposits consist of sodium chloride in the upper layers and mirabilite below. The largest sodium sulphate lake in the region, Lake Kuchuk, southwest of Novosibirsk, covers an area of some 150 km^2 . It contains an estimated 600 Mt of sodium sulphate in brines and underlying strata and each winter between 380,000 and 640,000 tonnes of mirabilite drop out of solution.

Sodium sulphate also occurs as mirabilite-glauberite beds in the shallow subsurface of the Kara-Bogaz-Gol (Gulf of Kara Bogaz) on the eastern side of the Caspian Sea (Figure 11.56a). For much of the Holocene Kara-Bogaz-Gol has been connected via a narrow 500m-wide inlet to the Caspian Sea, which flows

water from the Caspian to Kara-Bogaz-Gol at a rate of 25-44 metres/minute. The inflow is replacing water lost by evaporation from Kara-Bogaz-Gol and the water level in the gulf is consistently 0.5-3 metres below that of the Caspian Sea. This makes it one of the few modern examples of a drawdown basin with a highly restricted hydrographic connection between one isolated seaway and another ($A_0:A_1 = 2 \times 10^7$; Figure 5.28). It is sufficiently restricted to allow gyparenite to accumulate on the brine-covered lake bottom. Water level in the Caspian Sea has varied considerably

over the Quaternary and so Kara-Bogaz-Gol may have periodically lost its supply from the Caspian. In earlier times of cooler temperatures that allowed winter freezing of a perennial water body, some 3 to 8 metre-thick beds of cryogenic sodium sulphate formed and are today composed of varying amounts of calcite-hydromagnesite-gypsum-halite-epsomite-mirabilite-glauberite.

In Turkish, Kara-Bogaz-Gol means "lake of the black throat," so named because the gulf is continually gulping down the waters of the Caspian. There is an interesting anthropogenic aspect to the natural loss of water from the Caspian to the Gulf and the periodic salting of Kara-Bogaz-Gol. Early last century (prior to 1929) the Caspian sealevel was around -26 masl and Kara-Bogaz-Gol was almost entirely water-filled (as it is today; Figure 11.56b). The water-covered surface area was around $18,000 \text{ km}^2$ and its maximum water depth was around 9 metres. The annual volume of water flowing through the inlet was high, somewhere between 18 to 26 km^3 and the difference in level between waters of the Caspian and Kara-Bogaz-Gol was around 0.45 metres. From 1929 until 1940 there was a 1.8 fall in the level of the Caspian Sea and by 1948 the Caspian level was -27.87 m. The volume of inflow to the Gulf fell to 12 - $14 \text{ km}^3/\text{yr}$ by the late 1940s and to $8 \text{ km}^3/\text{yr}$ in 1956. Differences in water level between Caspian and the Gulf increased to 3.17 m in 1947 and 3.80 m in 1955. By 1957-1959 the water-covered

area in Kara-Bogaz-Gol had fallen to around 13,000 km². By 1977 water levels in the Caspian was -29.02 masl, it had fallen fell by more than 3 metres since 1929 (Figure 11.56b) and the 1977 water surface in Kara-Bogaz-Gol was 4.5 metres lower than the Caspian. The strandline of southern Kara-Bogaz-Gol had retreated by 50-60 km in 50 years. This ongoing drop in water level in Kara-Bogaz-Gol since 1929 meant numerous salt works flourished in the increasingly exposed and accessible brine flats.

The ongoing fall of the Caspian Sea level from 1929 and well into the 1970s, was thought by the Russian Government to be related to the continuous loss of water from the Caspian to Kara-Bogaz-Gol. After all, the climate in the Kara-Bogaz-Gol was arid, the annual evaporation rate was 1000-1500 mm and annual rainfall around 70 mm. Russian government scientists argued that damming the entryway would stop the Caspian spilling into the Gulf and so arrest the fall in the Caspian water level. This notion of interfering in a natural saline system was opposed by a number of Turkmeni scientists who argued that the rise and fall of the Caspian and the variable filling in Kara-Bogaz-Gol were natural processes and had been noted in the texts of ancient Islamic scholars living in the region. Ignoring the argument that rise and fall of brine level in isolated saline waters bodies, such as the Caspian, was the normal situation, a decision was made in 1977 by the central administration in Moscow that the entryway would be dammed. Central administration scientists had concluded that sufficient water would still remain in Kara-Bogaz-Gol after damming to allow the salt industry to continue its operations. The dam was not actually constructed for another 3 years. Ironically, the

natural fall in the level of the Caspian had reversed in 1977 and had began to rise once more, with a corresponding rise in waters levels in the Gulf. From 1977 until 1995 the Caspian level rose by the same 3 metres it had dropped since the 30s. However a decision had been made back in 1977 to dam the

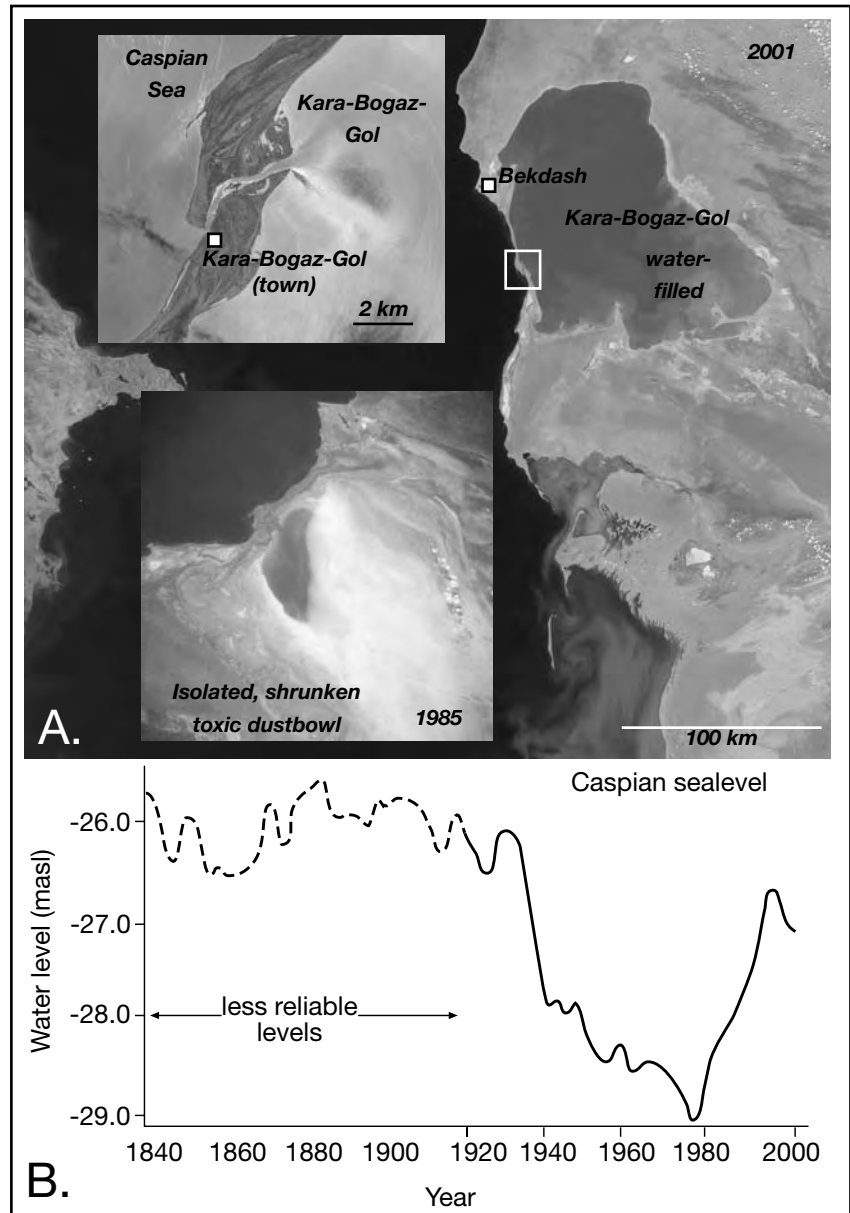

Figure 11.56. A) Kara-Bogaz-Gol (Gulf of Kara Bogaz), Turkmenistan, located on the edge of the Caspian Sea. The compilation of images shows the current water-filled situation (in 2001) after the artificial dam across the entryway was breached. Upper inset shows the nature of the very narrow entryway between the Caspian on the left and the outflow plume in Kara-Bogaz-Gol on the right (position of image indicated by rectangle). Lower inset shows the desiccated and dusty situation in Kara-Bogaz in 1985 when the entryway was dammed. (Images courtesy of NASA). B) Historical levels of the Caspian Sea.

entryway, so in 1980, even though the Caspian water level was rising once more, Russian engineers dammed the entry strait between the Caspian and Kara-Bogaz-Gol.

This complete loss of hydrographic connection to the Caspian did not have the desired effect, which was by then an irrelevancy, but egos and the authority of the Russian Empire was involved. Rather, the damming of the inflow resulted in rapid desiccation of Kara-Bogaz-Gol, so that by 1983 only a small brine covered area remained in the lowest part of the gulf depression (Figure 11.56). Much of the former brine lake floor had turned into a saline dust bowl, blowing high levels of sodium salts onto downwind irrigated pasture lands. By 1984 the villages surrounding Kara-Bogaz-Gol had turned into ghost towns. In 1984, in an attempt to restore the ecosystem, eleven large diameter pipes were laid across the dam so that Caspian water could be pumped back into Kara-Bogaz at a controlled rate. In 1992, after the fall of the Soviet Empire, this approach was abandoned and the dam was completely demolished by order of the president of the newly independent Turkmenistan. As it refilled from 1992 to 1995, the gulf water level rose by some 6 metres and since then its water level has once again matched that of the Caspian Sea and it is once again fulfilling its role as a natural desalinator of the waters of the Caspian.

Today, the water chemistry of the main open water body in the centre of the gulf is an Na-Mg-Cl brine, with a density of 1.2 g/cm^3 , and pH values that range between 7.2 and 9 (Giralt et al., 2003). Surface water temperatures range from 4°C in December to 25°C in July. These temperature fluctuations are seen in the precipitation of different mineral phases during the year. Calcite, aragonite and perhaps hydromagnesite usually precipitate from lake waters in spring, gypsum in summer (via solar evaporation), and crusts of cryogenic mirabilite and halite precipitate on the shores and mudflats of the embayment edge throughout the winter. Gypsum (as lenticular sand-sized grains) is the only sulphate phase seen in cores sampling surface sediments from beneath today's central water body (Giralt et al., 2003).

In the last 0.5 million years three separate Mg-Na-SO₄-rich salt layers (glauberite/bloedite/halite) have formed across the gulf, perhaps forming best in glacial episodes when the connection to the Caspian was reduced compared to today, and year round temperatures were much lower. Such glacial conditions favoured a perennial lake to pan mode of cryogenic mirabilite precipitation, much like winter salting in saline lakes in Canada today. Today a gypsum/glauberite layer is forming from the summer transformation of the mirabilite, epsomite and bloedite that accumulates each winter about the edges

Kara-Bogaz-Gol. A somewhat similar glauberite/bloedite/mirabilite/gypsum mineralogy started to form in the 1980s as capillary efflorescences across the whole floor of the gulf. At the time the Kara-Bogaz-Gol depression was converting to a saline dust bowl. But since 1992, with a return to the high water levels of today, glauberite no longer accumulates on the floor of the lake, only gypsum. The only glauberite forming today is that accumulating about the exposed margins of the gulf where high-calcium groundwaters dissolve and transform earlier winter precipitates of astrakanite, epsomite and mirabilite into capillary precipitates of glauberite.

Natural winter precipitates of sodium sulphate salts in this natural evaporation basin have been used commercially since at least the 1920s. Back then, the produced commodity was just whatever accumulated on the shore from wave action, especially on the southern shores of the Gulf during winter. The salt was scraped and harvested by hand and shipped to the Caspian using animals and barges. In the early 1930s, the port town of Kara-Bogaz-Gol was established on the Caspian side of the entryway, in order to trans-ship salt from the barges to the Caspian. Its population grew to a peak of 7,000 in 1936, (Figure 11.56). By the late 1930s, the gulf had become too shallow for barge traffic and the port town of Kara-Bogaz-Gol was abandoned in 1941. The falling water levels in the gulf also meant that by the end of the 1930s manual collection of naturally formed salt in the southern part of the gulf had stopped as well. The industry had to shift north to its present centre located inland of the town of Bekdash, which is a town of about 10,000 people on the shores of the Caspian Sea. Canals were built inland of Bekdash on the increasingly exposed mudflats that defined the strandzone of the Gulf. The canals were designed to feed gulf waters into large settling basins, which were filled with lake brines in the summer and left to cool in winter when mirabilite precipitated. Bekdash eventually became the centre of the salt industry of Kara-Bogaz-Gol and in the 1960s and 70s supplied chemical feedstock to much of the Russian chemicals industry in the satellite states surrounding the Caspian Sea. By the end of the 1930s, the falling water level drove increased salinities and a shift toward higher volumes of sodium chloride precipitates from ponded gulf waters, an unwanted by-product in the sodium sulphate industry. Profitability fell, and the salt pan-based industry waned through the 1940s. In the 1950s production technology shifted to extraction and processing of subsurface brines. Bekdash was reinvigorated as it was connected to a major brine extraction site via a 24-km pipeline. In 1963 construction began at Bekdash on a modern plant for increased year-round production of salines, independent of natural evaporation. This plant was completed in 1973.

The brines for the processing plant are extracted from the buried glauberite/bloedite/epsomite beds beneath the margin of the gulf. These beds still constitute a huge potential resource containing more than 3 Gt of sodium sulphate. Currently, sodium sulphate brines are solution mined using a single high capacity captive well and a mine planning approach that is a leftover from the former Soviet Union (see Chapter 12). Unlike the monitored gentle extraction of 113 litres/sec of intercrystalline sodium sulphate brine spread over more than 70 wells in Laguna del Rey brinefield, this single well into the Kara-Bogaz salt layers blasts out 126 litres/sec to the pipeline feeding the processing plant. Within the first 10 years of operation it had largely drained all the high salinity brines from its immediate vicinity and created a short circuit for less saline brine entry into the well bore. Ongoing drawdown and associated coning meant brine strength supplied to the plant has dropped to almost unusable levels. Once set up, coning from overpumping is difficult to reverse. The highly competitive state of today's sodium sulphate industry probably means that, without new capital injection for a better planned and monitored set of brinefields, the Kara-Bogaz salt industry will have to close.

A new anhydrous natural sodium sulphate operation in China, with an annual capacity of 200,000 tons, came onstream in mid 2003. The plant, operated by Dayang Chemical Limited Company, is located in Xishunhe Town, Hongze County, Jiangsu Province. The company, which is a joint venture between a Chinese company and an Indonesian firm, extracts mirabilite

from a large sodium sulphate deposit in east China. Little has yet been published on the geology of this lacustrine deposit. It has a proven area of more than 8.4 square kilometres, and a likely reserve of up to 150 million tons. In combination with a second facility with an annual capacity of up to 600,000 tons, and in production since the year 2000 (operated by Jiangsu Nanfeng Chemical Co. Ltd., which is a joint venture between Shanxi Nanfeng Group and Hongze Chemical Group, which is the Chinese operating arm of the Spanish Crimidesa Group), this now makes China the world's largest natural sodium sulphate producer with a combined capacity of 800,000 tons per year.

Sulphur salts (brimstone)

Sulphur may be found alone as native or elemental sulphur, or as a gregarious element in combination with many other elements, including metal sulphides and evaporitic sulphates. It is a common byproduct of bacterial and thermochemical sulphate reduction with the sulphate supplied by dissolving anhydrite or gypsum. Worldwide, documented resource of elemental sulphur amounts to about 5 billion tonnes. It occurs in evaporite and volcanic deposits or as sulphur associated with natural gas, petroleum, tar sands, and metal sulphides. Current uses for sulphur are: phosphate fertilizer production - 70%; petroleum alkylation catalysis (the conversion of one kind of hydrocarbon into another) - 15%; metals industry processes (leaching and pickling) - 7%; chemicals - 4%; and other uses - 4% (Ober, 2000).

Figure 11.57. World production of sulphur (thousand metric tons - compiled from USGS on-line data tables, compiled from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005). Grand total is an estimate of total world sulphur, not just tabulated major producers.

Usage history and industry trends

Native sulphur was known to the ancients as brimstone or “the stone that burns” (following details on historical usage are taken in large part from US Geological survey, <<http://pubs.usgs.gov/openfile/of01-197>> accessed December 28, 2004). Early man used sulphur as a colorant for cave drawings, as a fumigant, in medicine, and as incense. By 2000 BC, the Egyptians began using sulphur in the bleaching of linen textiles. Homer refers to its use as a fumigant in the Odyssey. During the Peloponnesian War, in the fifth century BC, the Greeks used burning sulphur and pitch to produce suffocating gases. The Romans combined brimstone with tar, pitch, and other combustible materials to produce the first incendiary weapons. This technology was lost in the “Dark Ages.” Muslims, through the use of alchemy during the “Golden Age of Arabic Science” around AD 700, probably were the first to produce sulphuric acid and this is

today the major use of sulphur. Sulphuric acid is a chemical workhorse throughout the world's chemical industries. Early uses of sulphur were relatively limited in terms of quantities and the small quantities needed were mined, typically from volcanic vent deposits.

Sulphur is a necessary ingredient in gunpowder, which was developed by the Chinese during the time of Confucius (557?-479 BC). Crusaders returning from the Holy Land in the early 1300s brought with them the knowledge of gunpowder. Gunpowder was first used effectively in Europe at the Battle of Crécy (1346). Its introduction led to profound social and political changes and for the first time made sulphur an important tradeable mineral commodity. Sicilian sulphur deposits, hosted in Messinian evaporites, satisfied European demand throughout the Renaissance and continued to supply much of the world's

sulphur into the last century. But attempts to stabilize the price of Sicilian sulphur at high levels by French controlling interests in 1838 led to the development and use of alternative sources. In 1833, a French chemist, Michel Perrett, developed a reasonably economical method of obtaining sulphur dioxide by roasting pyrite. His invention led to the development of a rotary furnace in 1870 that made pyrite a profitable raw material for sulphuric acid production. By 1880, sulphuric acid throughout the world was being produced from pyrite, except in the United States where import tariffs on iron and copper sulphides prevented a shift away from native sulphur. These import tariffs were removed in 1890 and 1894 respectively, and by 1900 burnt pyrite had become the principal acid-making material in the United States.

Native sulphur deposits occur in a number of evaporite basins in America and Europe, and several attempts were made to mine sulphur from salt dome cap rock in Louisiana between 1870 and 1890 using conventional underground mining techniques. These efforts were all frustrated by the patchy nature of caprock sulphur ore and

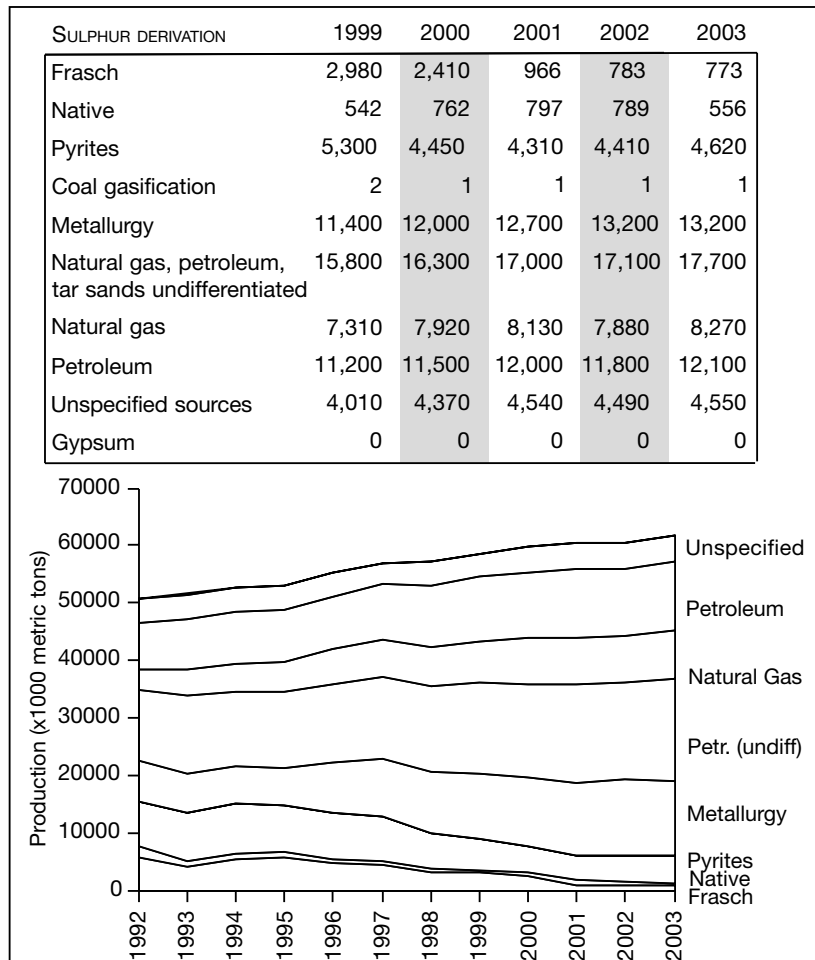

Figure 11.58. Processes of sulphur manufacture - worldwide (in thousand metric tons) compiled from USGS on-line data tables - compiled from <http://minerals.usgs.gov/minerals/pubs/commodity/> last accessed 30 September, 2005).

collapse-prone overburden. In 1894, Herman Frasch developed a method of recovering native sulphur using hot water and compressed air. It is a form of chemically-targeted solution mining and comprises a well made up of three concentric pipes (casing) ending in the ore zone. Pressurized superheated water is pumped down the outermost pipe in the string. The resulting steam melts the sulphur, while air pressure applied via the innermost pipe forces the molten sulphur to the surface via the intermediate space in the pipe string. Sulphur was first commercially obtained using the Frasch method in 1895 by the Union Sulphur Company at Sulphur Mines dome, Calcasieu Parish, LA. The Frasch method was also employed in 1912 at Bryan Mound, Brazoria County, Texas, and later at many other domes scattered about the US Gulf Coast.

Worldwide, the production of mined or extractive sulphur has been falling since the mid 1990s. Poland is the only country still producing more than a million tonnes of native sulphur from evaporite-related deposits, using either the Frasch method or conventional mining (Figures 11.57, 11.58). In August 2000, Freeport Sulphur closed its Main Pass Mine, offshore Louisiana, which was extracting sulphur from a diapiric caprock, it was the country's last remaining Frasch mine. Freeport has sold the mine's assets and it is unlikely that it will ever reopen. In the previous year, Freeport had closed the Culberson Mine in west Texas, which was using the Frasch method to recover sulphur from bacteriogenic deposits hosted in bedded Permian evaporites. Polish Frasch sulphur production still remains above 1 Mt/yr and is likely to stabilize at this level, although production is now threatened by low international prices due to flooding of the market with byproduct sulphur.

Mined sulphur production in Iraq in 2000 was estimated to be about 200 kt (220,000 st). Iraq, though, has the potential to produce between 1 and 2 Mt/a (1.1 million and 2.2 million st/yr). Production is currently at a low level because United Nations sanctions emplaced in the 1990s forbade exports. So Iraqi production is being run at a level sufficient only to meet domestic demand. Today, small quantities of native sulphur are still mined in Asia, Europe, and North and South America. The use of pyrite as a sulphur source has significantly decreased in the last two decades because of pollution concerns. China, South Africa, and Spain are now the only countries in the top 15 sulphur producers whose prime sulphur source is pyrite; together these three nations account for more than 80% of all pyrite-based production.

Although mined sulphur production is decreasing worldwide, world production of recovered sulphur is increasing (Figure 11.58). The growth comes from sulphur recovery from sour gas processing plants and from the refining of sour crude oils. Chemically recovered elemental sulphur is now the predominant sulphur source in Canada, France, Germany, Iran, Russia, Saudi Arabia, and the United States, and an important sulphur source in Japan and Mexico (Figure 11.57). In many countries this form of sulphur is recovered in compliance with environmental regulations that restrict the sulphur content of the fuels sold or used by a processing facility. Growth in sulphur recovery continues to out pace sulphur demand, resulting in increased stocks worldwide, as increasingly stringent environmental regulations force producers to limit atmospheric emissions of sulphur dioxide.

In addition to the currently known native sulphur resource, the amount of natural sulphur held as sulphate in gypsum and anhydrite is almost limitless. Some 600 billion tonnes are contained in coal, oil shale, and shale rich in organic matter, but low-cost recovery methods are lacking.

Types of sulphur deposits

Most large nearsurface accumulations of natural sulphur are the results of chemoautotrophic bacteria living on hydrocarbons or organic matter and dissolving anhydrite/gypsum, either in diapiric caprocks or in stratiform layers near the dissolving edges of anhydrite/gypsum beds. (Ruckmick et al., 1979). Such deposits are classified as biopigenetic and are intimately linked to the formation of microbial calcite. Bacteriogenic production can take place up to a kilometre or more below the landsurface (Figure 9.42). The same bacterial sulphate reduction process also forms much small volumes of native sulphur in modern anoxic marine or lacustrine muds, termed biosynthetic deposits by Ruckmick et al. (1979). These are not economic. Thermogenic deposits of molten sulphur form as the result of thermochemical sulphate reduction acting at much higher burial temperatures in association with natural sour gas (Figure 9.45). There are also deposits of native sulphur in volcanic terrains, usually as vein and fracture fills; a few still are mined in a small way and may be locally important (see history). Lastly there is oxidative native sulphur, which according to Ruckmick et al. (1979) are widespread but typically small sulphur occurrences formed at surface or at depth wherever hydrogen sulphide (regardless of origin) is oxidised. An example would be the dispersed native sulphur that occurs in the Carlsbad and Lechuguilla caves in New Mexico (Figure 7.45). We shall only discuss biopigenetic occurrences in this section.

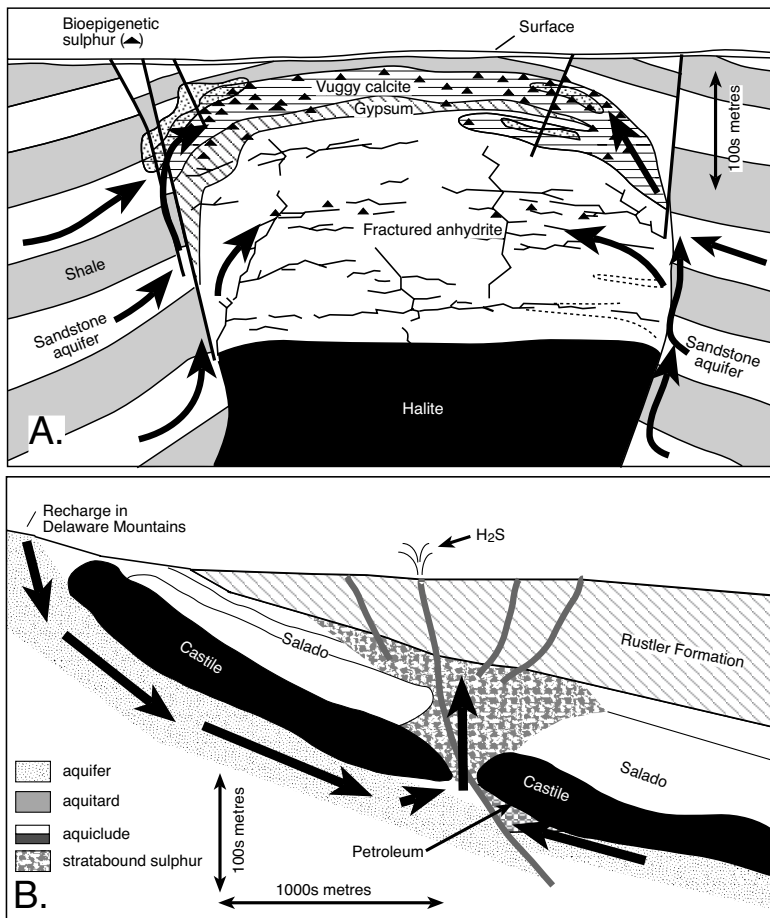

Figure 11.59. Conceptual models for the origin of evaporite-related elemental sulphur. A) Genetic model for diapir caprocks. B) Genetic model for stratabound or stratiform sulphur and the formation of subsurface castiles in the Permian Castile Formation of west Texas and New Mexico (after Ruckmick et al., 1979 - see also Figure 7.45a).

Biology of native sulphur

Native sulphur is microbially produced from calcium sulphate by the bacterial degradation (sulphate reduction) of anhydrite and gypsum in the presence of organic matter or hydrocarbons at temperatures of up to 110°C (Figure 9.42);

Sulphate-reducing bacteria chemoautotrophically metabolise migrating hydrocarbons and sulphate minerals within the evaporites to produce hydrogen sulphide and vuggy bacteriogenic calcite. The H_2S is then oxidized by infiltrating meteoric water to form elemental sulphur. This reaction takes place in the mixing zone between shallow meteoric waters and deep basin fluids in both bedded and diapiric precursors

(Aref, 1998b). Fine specks of sulphur and calcite replace gypsum in the early stages. With increasing replacement, sulphur and calcite form networks and patches within the gypsum (rehydrated anhydrite), which expand until gypsum remains only as relict splotches in massive vuggy calcite with pores lined with sulphur.

Dominant species of bacteria acting on the CaSO_4 change with salinity and temperature (Figure 9.11b); *Desulphovibrio desulphuricans* is active at normal shallow subsurface temperatures, *Desulphovibrio orientis* is active at moderate temperatures and *Clostridium nigrificans* dominates in hotter conditions. These bacterial reducers consume organics or hydrocarbons as a source of energy, but use sulphur instead of oxygen as a hydrogen acceptor and so produce hydrogen sulphide, calcite and water as byproducts. In addition to west Texas and the Gulf of Mexico, large deposits of bioepigenetic sulphur replacing gypsum/anhydrite occur in the Mishraq sulphur deposits (Barker et al., 1979), in the Polish sulphur deposits (Pawłowski et al., 1979), and in the Gulf of Suez (Youssef, 1989; Aref, 1998b).

Occurrences and textures

In sulphur-entraining caprocks atop diapirs in the Gulf Coast and Mexico, the CaSO_4 ore host is first created by dissolution of halite in the rising salt stem (Figure 6.64). This leaves behind a residual carapace or caprock of anhydrite that phreatic groundwater flushing then converts to gypsum at shallower depths (Figure 11.59a; Ruckmick et al., 1979). In the stratiform sulphur ore district of Culberson County, west Texas, requisite ore-forming fluids including basinal hydrocarbons and deeply circulating meteoric groundwaters migrated upward from underlying carrier beds, along steeply dipping normal faults, into the Salado Formation host (Figure 11.59b). Likewise, native sulphur occurs in the Red Sea Coast at Ras Gemsa, where an uplifted horst block, containing middle Miocene oil and gas bearing strata, is overlain and sealed by evaporite-carbonate layers (Youssef, 1989). In all cases the native sulphur resides in pores and vugs of these bio-epigenetic limestone beds.

In its unaltered subsurface state the Castile Formation of the Delaware Basin is made up of laminar anhydrite. Its underside acts as a seal and a focus for hydrocarbons seeping up from the oil kitchen in the deeper parts of the Delaware Basin and for deeply circulating meteoric waters (Figures 7.45a, 11.59b). Previously mineralised castiles now outcrop and subcrop about the edge of the Delaware Basin. The trap was naturally prepared for sulphur accumulation by a series of faults and collapse anticlines, activated or reactivated by evaporite dissolution about the basin edge. These extensional fractures acted as hydrological foci during the creation of porous dissolution collapse breccias or chimneys that crosscut the anhydrite beds of the Castile and the overlying Salado and Rustler formations (Figure 11.59b). Once the dissolution breccia/karst system was created it focused the ascent of petroleum-bearing waters from the underlying carrier beds (Bell Canyon Sandstone aquifer). As hydrocarbon-bearing waters flushed through the breccia, sulphate-reducing bacteria converted anhydrite to limestone and deposited sulphur in newly created fractures and vugs.

Locations of stratiform sulphur in this style of deposit are always structurally controlled. Individual sulphur deposits in west Texas are generally small, although the now closed Duval Mine in Culberson County, Texas, had original sulphur ore reserves of more than 55 Mt, between depths of 70 and 380 metres (Davis and Kirkland, 1979). The Fort Stockton Mine in Pecos County was located on the culmination of a leaky northwest-southeast trending anticline in the Salado Formation with a structural closure of 20 m (65 ft) in mine area (Figure 11.60; McNeal and Hemenway, 1972). Sulphur ore was largely confined to diagenetic limestone hosts that made up the A, B, and C units. Tops of the B and C units were defined by radiogenic clay marker beds and the top of the A was defined as the top of the Salado Formation. Sulphur in the ore zones sat mostly within dispersed vugs, fractures and fenestra in solution collapse breccia units, so it was more amenable to Frasch processing rather than conventional mining. As the ore was mined by steam injection, the more permeable megavug,

mesovug and megafenestral ore zones were prime targets in the steam-mined interval. Intervals with mesointercrystalline and mesofenestral porosity greatly increasing the efficiencies of recovery by facilitating improved steam circulation through sulphur impregnated intervals.

Similar stratiform sulphur occurs along the Red Sea coast of Egypt where accumulations range from small and noncommercial (Gebel Abu Gerfan and Ras Dip) to economic deposits (Gemsa; Aref 1998b). Sulphur crystals vary in morphology, colour, and size, it forms fine disseminations at Abu Gerfan, Gemsa and Gebel El Zeit; fracture and cavity fillings at Gemsa and Little Zeit; and sulphur nests at Gemsa and Shagar. The size of the sulphur aggregates ranges from a few millimetres to 5 cm diameter and crystal morphologies range from anhedral to subhedral to euhedral orthorhombic. Occurrences vary in colour from clear or turbid yellow crystals that may be encrusted with bitumen, to brown or black bitumen-stained sulphur varieties. Within outcropping calcite castiles along the Red Sea coast these epigenetic sulphur crystals can fill vugs or fractures in the host rocks, or they can replace gypsum or anhydrite along cleavage planes or intercrystalline crystal boundaries. They also may pervasively replace gypsum and calcite units to form network or meshwork patterns.

Figure 11.60. West-East cross section through the Fort Stockton anticline showing sulphur occurrence is largely confined to the dissolved remnants of the Castile and Salado Formations (after McNeal and Hemenway, 1972).

Bio-epigenetic sulphur was mined in Poland as early as the fifteenth century, and although declining, annual sulphur production in Poland still exceeds 1-2 million tonnes. Native sulphur deposits today occur beneath fluvioglacial outwash in the Vistula Valley, some 190 km south of Warsaw, and in the area around Lublin. All deposits lie within a Middle Tortonian gypsum host and are part of the 3,000 m thick fill of Miocene sediments that accumulated during the Alpine Orogeny in the foredeep north of the Carpathian Front (e.g. Figure 12.17a).

Polish sulphur is either extracted by conventional open-pit mining or by the Frasch hot-water/steam method (Pawlowski et al., 1979). The sulphur occurs in several styles; the most commercially important is as disseminated microcrystalline sulphur in a fine-grained poorly lithified calcitic marl host. This form of sulphur makes up 15% to 80% of the exploited rock mass and averages 30%. It is pale coloured and may occur in rounded concretionary masses, in thin irregular stringers, or in thick masses of high purity. A secondary ore mode is as coarser recrystallised forms that are bright yellow and typically occurs as crystals lining vugs and along fractures and seams. Masses of this coarsely crystalline form commonly grade into the microcrystalline form. Non-commercial occurrences constitute finely divided sulphur in interstices in growth-aligned bottom-nucleated gypsum crystals and as dispersed sulphur cements in sandstone beds. Both styles contain less than 15% sulphur in forms that are difficult to concentrate.

The main difference between North American, Polish and Red Sea sulphur occurrences is that the ore host is rehydrated and exhumed anhydrite in North America, while the Polish and Red Sea ore hosts have never been sufficiently buried to convert primary gypsum to anhydrite. This is also the case in the sulphur deposits of Sicily, which are hosted in Messinian gyp-

sum with immature hydrocarbons bleeding from the mine walls (pers. obs.).

Bacterial reduction of sulphate in all native sulphur ore hosts causes significant depletion of $\delta^{34}\text{S}$ in H_2S relative to the parent sulphate and a similar depletion in the sulphur derived from it (Thode and Monster, 1973). Reoxidation of sulphide to sulphate or sulphur by O_2 in the fluid mixing zone does not cause significant isotopic fractionation. Hence the lighter sulphur isotopic composition of oxidative sulphur in Guadalupe Mountain caves ($\delta^{34}\text{S}_{\text{CDT}} = -25.8$) and in the stratiform sulphur of the Culberson mine (-4.7‰) (Figure 7.48; Hill, 1996). A hydrocarbon source of the biochemical reaction is also indicated by the light carbon isotope character of epigenetic calcite in the Culberson mine ($\delta^{13}\text{C}_{\text{PDB}} = -44.2$ to -18.6‰ ; Figure 9.43; Hill, 1995). These depleted $\delta^{13}\text{C}_{\text{PDB}}$ values are significantly lower than would be expected in marine carbonates, which normally fall in the range -4 to $+4\text{‰}$.

Zeolites - molecular sieves

Like clays, zeolites are hydrated aluminosilicates made up of alkaline and alkaline earth metals. Their varying tetrahedral structures break them out into seven related aluminosilicate groups with some non-claylike properties (Table 11.16). Most clays have a layered crystalline structure and are subject to shrinking and swelling as water is absorbed and removed

Mineral structure (channel size in angstroms)	Typical unit cell content	Void volume	Specific Gravity	CEC (meq/gm)
Group 1: Single 4-ring				
Analcime (1.6 x 4.2; irregular)	$\text{Na}[\text{AlSi}_2\text{O}_6] \cdot \text{H}_2\text{O}$	0.18	2.24-2.39	4.54
Phillipsite (4.2 x 4.4)	$(\text{K}, \text{Na}, \text{Ca}_{0.5}, \text{Ba}_{0.5})_x [\text{Al}_x \text{Si}_{16-3x} \text{O}_{32}] \cdot 12\text{H}_2\text{O}$	0.31	2.15-2.20	3.87
Laumontite (5.0 x 5.3)	$\text{Ca}_4[\text{Al}_8\text{Si}_{16}\text{O}_{48}] \cdot 18\text{H}_2\text{O}$	0.34	2.20-2.23	4.25
Group 2: Single 6-ring				
Erionite (3.6 x 5.2)	$\text{K}_2(\text{Na}, \text{Ca}_{0.5})_8 [\text{Al}_{10}\text{Si}_{26}\text{O}_{72}] \cdot 30\text{H}_2\text{O}$	0.35	2.02-2.08	3.12
Group 3: Double 4-ring				
A (Linde: 4.2)	$\text{Na}_{12}[(\text{AlO}_2)_{12}] \cdot 27\text{H}_2\text{O}$	0.47	1.99	3.12
Group 4: Double 4-ring				
Chabazite (3.7 x 4.2)	$(\text{Ca}_{0.5}, \text{Na}, \text{K})_4 [\text{Al}_4\text{Si}_8\text{O}_{24}] \cdot 12\text{H}_2\text{O}$	0.47	2.05-2.10	3.81
Group 5: Complex 4-1, T_5O_{10}				
Natrolite (2.6 x 3.9)	$\text{Na}_2[\text{Al}_2\text{Si}_3\text{O}_{10}] \cdot 2\text{H}_2\text{O}$	0.23	2.20-2.26	5.26
Group 6: Complex 5-1, T_8O_{16}				
Mordenite (2.9 x 5.7)	$(\text{Na}_2, \text{Ca}, \text{K}_2)_4 [\text{Al}_6\text{Si}_{40}\text{O}_{96}] \cdot 28\text{H}_2\text{O}$	0.28	2.12-2.15	2.29
Group 7: Complex 4-4-1, $\text{T}_{10}\text{O}_{20}$				
Clinoptilolite (3.9 x 5.4)	$(\text{Na}, \text{K}, \text{Ca}_{0.5}, \text{Sr}_{0.5}, \text{Ba}_{0.5}, \text{Mg}_{0.5})_6 [\text{Al}_6\text{Si}_{30}\text{O}_{72}] \cdot 20\text{H}_2\text{O}$	0.34	2.16	2.54

Table 11.16. Properties of some important zeolites (in part after Breck, 1974).

between the expanding and contracting lattice layers. In contrast, zeolites lack this expandable layered lattice. Rather, they have a rigid, 3-dimensional crystalline structure consisting of a network of interconnected tunnels and cages, separated by tetrahedral latticework. Water moves freely in and out of these pores, while the zeolite framework remains rigid. A dehydrated zeolite framework, with its honeycomb of passageways, is capable of absorbing large quantities of fluids and gases in place of the removed water, without ever changing volume. In fact, the word zeolite comes from the Greek *zein* meaning “to boil” (lit. *boiling rock*) as described by early chemists who had seen water boiling out of the rock pores when it was heated, but without obvious changes in rock volume.

Their rather unusual cage- or sieve-like lattice structure gives zeolites some useful characteristics (Table 11.16: Breck 1974):

- a high degree of hydration;
- a rigid structure with a low density and large void volume when dehydrated;
- a stable crystal structure when dehydrated;
- a set of mineral specific cation exchange properties;
- a set of uniform molecular-sized channels in many dehydrated crystals;
- a controlled variable set of physical properties such as electrical conductivity;
- an ability to adsorb selected gases and vapours;
- catalytic properties.

Because each member of the zeolite family has a unique aperture size, the molecules admitted to the framework are restricted to those of appropriate dimensions. This selective nature of the various zeolite structures makes them extremely useful as molecular sieves with numerous industrial applications.

Zeolites also have the ability to exchange cations, whereby one charged ion is exchanged for another in the crystal structure. The ability of a zeolite to do this is measured by its cation exchange capacity (CEC; Table 11.16). Compared to clays, zeolites have high CEC's, which are lattice specific and reflect varying degrees of alumina substitution for silica in the lattice tetrahedra to create lattice specific zones of surface charge. Exchange sites on natural zeolites are primarily occupied by 3 major cations: potassium (K), calcium (Ca), and sodium (Na), although other elements such as magnesium (Mg) may also be present. Exchange sites on a particular zeolite may contain nearly all K, nearly all Na, some Ca or Mg, or a combination of these and this controls which zeolites are suitable for a particular application.

In agriculture, zeolites are used as preservative agents (desiccants), soil conditioners, fertilizer extenders, herbicides, pesticide and fungicide carriers, animal food additives and odour controllers. Zeolites with K exchange sites are useful as longterm K release fertilisers. Other uses include dimension stone, lightweight aggregate, pozzolan and numerous filtration/treatment uses, such as natural gas purification, nuclear waste treatment and disposal, and oil spill, sewage and effluent cleanup. Chabazite is used to remove CO₂ and H₂S from sour natural gas, while clinoptilolite can remove ammonia in tertiary sewage treatment and for odour control in pet-litter. It also relieves ammonia stress in cud-chewing animals and it can strip base metals from effluents. Clinoptilolite is also highly effective in the cleanup of radioactive waste as it strongly adsorbs strontium and cesium, two of the longest-lived radioactive ions. It was used in the cleanup of Three Mile Island spill and was fed to children affected by the Chernobyl disaster.

Geological controls on saline zeolitization

There are six major geological settings where zeolites are found, of which saline lacustrine settings are one (Table 11.17). Most zeolites are altered volcanoclastics, with the larger number of exploited zeolite deposits formed by groundwater flushing of volcanoclastics within saline lacustrine settings. Zeolites are not preserved in rocks where metamorphic grade exceeds zeolite facies and so their occurrence decreases with age. More than 30 different zeolite minerals have been identified in Cenozoic rocks, only 7 in Mesozoic strata, 2 in the Early Palaeozoic, 4 in the Late Palaeozoic, one in the Neoproterozoic and none in the Archaean (Iijama, 1980). The interested reader is referred to Mumpton (1981) or Iijama (1980) for a full discussion of all the geological settings forming zeolites, we shall only consider zeolites formed in saline lacustrine settings.

Natural zeolites typically form by the reaction of pore waters with labile material, typically with volcanic glass, but also with poorly crystalline clay, plagioclase or silica. Formation of zeolites is favoured by elevated ratios of Mg and pH to Na, K and Ca in waters interacting with volcanics, conditions that characterise saline groundwaters in many closed hypersaline basins, especially in tectonically active depressions (continental rifts and collision belts). Chemical composition of the protolith glass, grain size and permeability of the host vitric tuff, are the important factors in controlling the mineralogy of a zeolite. A preponderance of sodic-rich zeolites such as analcime, mordenite, phillipsite, natrolite and clinoptilolite is probably a more common outcome in evaporitic compared to nonevaporitic zeolite associations, reflecting high levels of

Mode of occurrence	Temp °C	Zeolite species	Examples
Alkaline saline lake and percolating groundwater, semi arid (in basic tephra)	20-50	Ph, Cp, Ch, Er, Mo, Gi, Fa, Go, Na, An, (He)	Zeolitic tuffs of ancient Lake Tecopa, Shoshone, California
Percolating groundwater in a semi-arid setting (in acid tephra - vitric tuff)	20-50	Ph, Cp, Er, Mo, Fe, Th, Me	Altered tuffs of the John Day Formation, central Oregon
Nearshore or deep sea volcanoclastic sediment halmyolysis	4-50	Ph, Cp, (An)	Massive, clinoptilolite-rich tuff near Kurdzali, Bulgaria
Shallow burial diagenesis (low-temp. hydrothermal)	25-100	Sc, He, St	Massive, clinoptilolite-rich tuff near Kurdzali, Bulgaria
Deep burial diagenesis (mod. temp. hydrothermal)	100	La, An	Massive, clinoptilolite-rich tuff near Kurdzali, Bulgaria
Low grade metamorphic (high temp. hydrothermal)	>200	Wa, Yu, An	Altered tuffs and sandstones Wairakei, New Zealand
Magmatic primary	high	An	Nishi-Iburi District, Hokkaido, Japan
			An: analcime; Na: natrolite;
He: heulandite; Th: thomsonite; Me: mesolite; Sc: scolecite; St: stilbite; La: laumontite; Wa: wairakite; Yu: yugawaralite.			

Table 11.17. Geological occurrence of some natural zeolites (in part after Iijama, 1980; Mumpton, 1983).

Na in most saline brines. Other factors influencing chemical composition of sedimentary zeolites are salinity, pH, ratios of alkali and alkaline-earth ions in the pore waters, along with temperature, pressure and partial pressure of water in the fluid-filled pore spaces.

Of the various factors controlling which portions of a volcanoclastic sequence will be zeolitised in a saline lacustrine basin, pH of the flushing solution is the most important (Hay, 1981; Hall, 1998). Any alteration of natural volcanic glass is pH dependant, silicate glasses are most rapidly decomposed in strongly alkaline solutions. For example, Mariner and Surdam (1970) showed experimentally that the rate of dissolution of rhyolitic glass increases 20-fold as the pH is raised from 8.5 to 11.5 (see also Figure 7.58).

The pH of interstitial water is typically the most important control on zeolitization. Surface water and groundwater in many volcanic areas is acidic, but zeolitization requires neutral to alkaline conditions (Hall, 1998). Therefore, any acidic interstitial water must be removed or neutralized before zeolitization can take place. Conditions favouring zeolitization occur if there is likely to be an influx of slightly alkaline (bicarbonate-bearing) groundwaters. This change in pore water can occur via deposition or redeposition of ash in a standing body of alkaline water (not uncommon in saline depressions), or if there is reheating of ash via hydrothermal circulation pushing alkaline saline groundwater through the ash bed. Alkaline water can come from leaching of overlying or neighbouring limestone. Arid hypersaline depressions are associated with density-induced

circulation cells that favour the replacement of original acidic pore water with more alkaline brackish to hypersaline brines. Zeolites can also form rapidly in alkaline soils where vadose flushing tends to reduce the amount of acidic pore water (Hay 1963; Renaut 1993b). The reaction of volcanic glass with water is itself conducive to a rise in pH, because the dissolution mechanism involves a cation exchange reaction at the glass surface, whereby H_3O^+ enters the glass from the solution, while Na and K enter the solution from the glass (Casey and Bunker 1990).

Saline lacustrine zeolites are commonplace in endorheic alkaline basins in block-faulted terrains (such as the Basin and Range province of the USA; Shepard and Gude, 1968), in trough valley depressions associated with rifting (such as Lake Magadi or Lake Bogoria in the Eastern Rift Valley of Kenya; Surdam and Eugster, 1976) and in Tibet-type grabens formed in depressions in compressional terrains (such as Emet and Kirka basins, Turkey; Gundogdu et al., 1996). Most saline Neogene basins that retain exploitable volumes of zeolites still retain large volumes of highly reactive, silica-rich, vitric, volcanic material and evaporite beds. Bedded evaporites or their dissolution residues in a volcanic terrain are the product of a density-driven throughflushing brine system that must have displaced the original acidic waters. And so evaporite horizons are excellent pointers in a basin to a level in the stratigraphy where ash alteration and zeolites are likely (Figure 11.61).

Zeolites precipitate in volcanic hosts in timeframes measured in thousands to hundreds of thousands of years, depending on

brine alkalinity, the precursor mineralogy and the climate (typically semi-arid rather than hyperarid). Groundwaters driving zeolite formation in saline settings are typically sodium-rich, often with elevated carbonate-bicarbonate contents and a pH level maintained above 9 (soda lakes). Favourable hostrocks are freshly deposited rhyolitic to dacitic, vitric tuffs, especially those levels of the volcanoclastic succession time equivalent to alkali-rich saline mudflats and saline pans. Saline aluminosilicate gels (kenyaiite, magadiite) can form pointer minerals at these levels and can act as zeolite precursors (Chapter 4). Associated saline rocks can be bedded evaporites (trona, halite, borate), with interlayered mudstones, oil shales, diatomites (which can be an additional silica source in many alkaline lakes), bedded or nodular Magadi-style cherts and volcanoclastic conglomerate/sandstone.

Zeolitic alteration haloes in exposed marginward saline sediments of Lake Bogoria in the Kenya Rift Valley provide a useful Quaternary analog for many older saline lacustrine zeolites (Renaut, 1993b). Late Quaternary fluviolacustrine siltstones, mudstones and claystones (Loboi Silts) make up the northern margins of this saline, alkaline lake and contain up to 40% authigenic analcime and minor natrolite. The zeolitic sedimentary layers are reddish brown and up to 1 m thick. The amount of analcime increases upward in the profile, but decreases with distance from the saline lake. Altered sediments hosting the zeolites show many pedogenic features including; zeolitic root mats, rootmarks, concretions and carbonate rhizoliths. Residual patches of calcrete locally cap the zeolitic rocks. The zeolitic profile about the edge of Lake Bogoria is interpreted as an exhumed palaeosol, which defines a former landsurface on the saline mudflat of the paleolake.

Analcime in the Bogoria mudflat is made up of submicroscopic (0.5-2.5 μm) subhedral and euhedral crystals, which have an average Si/Al ratio of 2.33 (as determined by X-ray microanalysis) or 2.18 (as determined from the d-value of analcime peak). Analcime formed diagenetically in these lake-marginal sediments via reaction of silicate detritus with alkaline Na_2CO_3 rich pore waters, which had concentrated during sabkha-like capillary evaporation and evapotranspiration.

Poorly ordered clay minerals were probably the main matrix reactants. Authigenic illite may have been a byproduct of the reactions forming the analcime. The saline pore waters of the mudflat probably supplied additional Na, and possibly K and SiO_2 to the process of zeolitisation. Calcrete and rhizoliths formed during or shortly after the main period of zeolitisation with the Ca sourced by dilute runoff and seepage waters. Authigenic smectite was precipitated in open pores following analcime formation. Zeolites have formed in similar saline mudflat settings in other nearby alkaline lakes such as Lake Magadi, where zeolites are associated with magadiite nodules (Figure 4.39).

Microcrystalline zeolite-bearing vitric tuffs, chiefly composed of analcime, chabazite, clinoptilolite, mordenite, phillipsite and sometimes erionite, are typical of mined saline lacustrine zeolites worldwide. Ore deposits are typically layered and may consist of one to several stacked zeolite layers separated by sub-economic or barren beds. Cutoff grade for zeolite ore varies greatly depending on mineralogy and cementation intensity. For example, a 10 to 20 centimetre thick ore bed at Bowie in North America contains 60 to 80% chabazite. This zone would not be economic if the main ore mineral was clinoptilolite. Most commercial clinoptilolite deposits contain between 50% and 90% zeolite.

Current large-scale commercial exploitation of saline lacustrine zeolites takes place in the Basin and Range province of the United State (Surdam and Sheppard, 1978) and the Andes

Figure 11.61. Schematic showing possible circulation mechanism in a saline lacustrine system where volcanics are altering and weathering to various zeolites.

(Hartley et al., 1991). For example, zeolites are extracted from saline lacustrine strata in the San Simon Valley, Arizona. The valley is underlain by 700 m of Pliocene to Holocene flat-lying fluvial and lacustrine rocks. Ore horizons occur within what is known as the “older alluvial fill,” which is a zeolitised Pliocene tuff and part of a more regional tuff marker bed within the Green Lake Beds (Sheppard et al., 1978). Thickness of individual zeolitic tuff layers ranges from 10 cm to 10 m with areal extents from tens to hundreds of square kilometres. The most common zeolites in this succession are chabazite, erionite and clinoptilolite, with small quantities of analcime in the southern part of the deposit. Parent materials include volcanic glass, biogenic silica, clays, plagioclase and quartz. Non-zeolite authigenic minerals in the tuff include smectite clays, calcite, halite, gypsum and/or thenardite. Chabazite, the main commercial mineral, constitutes up to 80% of the bed in the ore zone.

These zeolites crystallised after the accumulation of volcanic ash as throughflushing saline alkaline groundwaters reacted with the ash in the lake mudflat. Factors controlling intensity of alteration in the Green Lake Beds included the original lake bottom topography, depth and cation content of the saline-alkaline lake waters and proximity to postdepositional erosion surfaces (Eyde and Eyde, 1987). Zeolitic alteration ceased when an extensive system of younger palaeochannels deeply eroded the Green Lake Beds. Erosion indicates a change in the base level and a fall in groundwater level that removed the beds from the zone of active saline flushing. Erosion left only a few dissected remnants of the original tuff marker so that the “high grade zeolite bed” now outcrops in the various channel walls, where it is now mined. Former channels and the Green Lake Beds are now overlain by a section of halite-cemented brown mudstone known as the Brown Lake Beds, which largely prevented any later surface-driven meteoric alteration of the zeolites.

Throughflushing saline waters will first generate analcime and then K-feldspar with more complete alteration. In ancient zeolitised lacustrine deposits this is reflected in a commonplace transition from unaltered finely crystalline volcanoclastic glass and tuff near a palaeostrandline, through a series of immature alkaline silicic zeolites to analcime to potassic and sodic authigenic feldspars in the lake centre (Eugster, 1986; Hay et al., 1991). Volcanic glass is initially converted to zeolites such as clinoptilolite and mordenite before being altered to analcime. Under ultrasaline conditions when the K/Na activity ratio is sufficiently high (from earlier halite precipitation), analcime is then converted to K-feldspar. Tuff beds deposited

during the most saline and alkaline phase of Lake Gosiute in the Eocene Green River Formation typically exhibit such K feldspar alteration. Beds that remain soaked in somewhat less saline brines still remain at the analcime alteration stage (Smith et al., 2003).

Likewise, basin-centre Quaternary deposits in the various saline east African rift valley lakes typically exhibit more alteration in the lake centres, suggesting that as Pleistocene saline lakes shrank and concentrated, sediments in the lowest (central) positions were more exposed to increasingly saline and alkaline fluids.

Such pointers to the intensity of alteration outline Cretaceous Lake T'oo'dichi' in the Four Corners region of the USA (Figure 11.62; Turner and Fishman, 1991). This large alkaline saline lake occupied the entire eastern part of the Colorado Plateau region during deposition of the Brushy Basin Member of the Upper Jurassic Morrison Formation. At its maximum it extended from Albuquerque, New Mexico, to Grand Junction, Colorado, and occupied a region that encompassed the San Juan and ancestral Paradox basins, making it one of the largest ancient alkaline, saline lakes known; it was more than twice the size of Eocene Lake Uinta. As yet, zeolites have not been found in sufficient quantity to be exploited in this ancient lake system.

The lake was typically shallow and frequently evaporated to dryness, although the water table was probably never far beneath the surface and widespread bedded salt did not form (Figure 11.62; Turner and Fishman, 1991). Intermittent streams carried detritus from source areas to the west and southwest far out into the lake basin, a reflection of a low depositional gradient and the ephemeral brackish nature of the lake. Prevailing westerly winds carried silicic volcanic ash to the lake basin from an arc region to the west and southwest. A lateral hydrogeochemical gradient, characterized by increasing salinity and alkalinity from the margin of the lake to the centre, developed in pore waters of the lacustrine sediments and resulted in alteration of the ash to a variety of authigenic minerals that define concentric zones within the lake basin. The basinward progression of diagenetic mineral zones is smectite to clinoptilolite to analcime ± potassium feldspar to albite in the lake centre. A concomitant lateral zonation of mixed-layer illite/smectite developed, from highly smectitic in the outermost zones to highly illitic in the central zone.

Authigenic albite and illitic mixed-layer clay, minerals typically thought to require elevated temperatures for formation in non-saline burial settings, crystallized during early diagenesis

Figure 11.62. Basinward progression of concentric alteration haloes in the tuff lithofacies in the lacustrine Brushy Basin Member of Jurassic Lake T'oo'dichi' (after Turner and Fishman, 1991). This ancient alkaline lake occupied the combined San Juan-Paradox Basin area and was bound by structurally active uplift areas (related to an active volcanic arc that lay to the west).

at syndepositional temperatures in the lacustrine sediments of Lake T'oo'dichi'. Other examples of syndepositional authigenic albite are documented in saline lacustrine sediments of the Eocene Green River Fm. (Cole, 1985), Miocene tuffs near Boron, California (Williamson, 1987) and albite rims to evaporite pseudomorphs in the Triassic lacustrine mudstones of the Passaic Formation of the Newark Basin (El Tabakh et al., 1997).

Throughout burial, and on into the zone of metamorphism, zeolites can continue to react with evolving pore fluids as new minerals are formed by the replacement of earlier zeolites. Ongoing alteration in deep burial also explains the abundance of albitised metasediments and metavolcanics in meta-evaporitic settings and the loss of natural zeolites with increasing geological age.

But not all sodic zeolites in saline lakes need a volcanoclastic precursor. Analcime occurs in the basal anhydrite of the Navarra potash in a late Eocene basin that contained no volcanoclastics. Rosell and Orti (1980) interpreted it as a result of the interaction of highly concentrated brines with detrital clays. Likewise, authigenic analcime is forming today in playa muds in central Australia in endorheic systems that have never entrained volcanoclastics (English 2001). For example, Lake Lewis playa in the Northern Territory lies in a hydrologically closed intermontane basin in a low relief terrain in which clay-rich palaeolacustrine sediments are infused with highly evolved sodic brines. Near-stagnant lake waters, fed by groundwaters flowing through the Proterozoic Arunta granite-gneiss terrain and through arkosic alluvium and its weathering products, source the silica and sodium needed to precipitate analcime. Supersaturation of groundwaters with respect to SiO_2 and the availability of catalytic ions, coupled with high rates of evaporation, favours precipitation of opal and chalcedonic silica from solution near the groundwater discharge zone about the lake strandline. Moganite, a distinctive silica polymorph that is commonly associated with evaporites, is amongst the various silica species precipitated in association with the analcime (Chapter 7).

Downgradient from the zone of silica precipitation, beneath the playa proper, the brines become SiO_2 -deficient. Long periods of weathering and diagenesis of the lacustrine clays, immersed in semi-stagnant brines, has transformed detrital minerals into amorphous or gelatinous aluminosilicates. Hence, various aluminosilicate phases have become metastable in the long-term presence of evolved SiO_2 -deficient interstitial brine. Analcime is stable in this relatively stagnant Na-rich brine and is crystallizing authigenically below the watertable from these amorphous and gelatinous aluminosilicates in the more central parts of the lake depression. No volcanic rocks

or pyroclastic sediments are involved in this diagenetic occurrence of analcime. The appearance of analcime in Lake Lewis probably commenced within the last 100,000 years and is ongoing (English, 2001).

Summary

Evaporite salts and their diagenetic coproducts form mineable resources in a wide range of depositional and environmental settings. Potash deposits range in age from Quaternary to Devonian; no economic potash deposits are known to occur in Precambrian strata. The wide age range of preservation for highly soluble potash beds reflects the impervious nature of a thick salt mass once it is buried. Even though the various potash salts are highly soluble, undersaturated solutions often cannot reach them until a thick protective wrap of tight halite has been etched away. Both enrichment and depletion in the ore itself also reflects the long burial diagenetic history of this relatively impervious salt mass and the focusing of diagenesis about its dissolving edges.

Large potash accumulations, such as in the Zechstein and Prairie evaporite basins form in subsealevel marine seepage-fed depressions (Table 11.18; Figure 5.27). Their size and extent reflects an ongoing supply of brine across depositional areas that were one to two orders of magnitude larger than seen in any Neogene continental salt lake. They formed at times when the basin floor was subsealevel but tectonically isolated from any surface connection with the ocean (soft collision belts, farfield flexures, zipping and splitting stages of supercontinent). Large-laterally extensive ancient potash deposits are not the result of evaporation of nonmarine waters. To form, they needed high levels of salinity on the basin floor to occur for long enough and to be maintained deep enough into the subsurface for thick potash sections to be precipitated and preserved. It requires a brine hydrology that is not present on the earth's surface today. Modern approximations to a potash accumulating system are all lacustrine and are all smaller scale. Our best modern examples come from the highly arid continental salt lakes of the Qaidam depression of inland China.

Aside from ancient marine-fed saline giants and the Chinese foreland collision basins, the other major depositional setting for economic accumulations of potash is active continental rift grabens. Some, such as the Pleistocene Danakil Depression, had a Pleistocene seawater spring feed. Other small potash accumulations, such as the Mulhouse Basin in the Rhine Graben, perhaps had nonmarine feeds. In all cases, the greater volume

of inflowing ions within the depression was via brine springs, rather than surface runoff.

Without exception, nonpotash bedded salt resources (sodium carbonates or sulphates) formed in continental lacustrine or playa settings. They owe their existence to the unusual ionic compositions that come from groundwater leaching, under highly arid conditions, in appropriate bedrock terrains. Quaternary continental examples have same scale and same ionic proportions in the brines as their ancient lacustrine counterparts (Figure 5.3).

It is simply a matter of chemistry that these types of lacustrine deposits do not form from Phanerozoic seawater. Phanerozoic seawater simply never had the make-up necessary to precipitate borates, nitrates, sodium carbonates or sodium sulphates. This chemical evolution can only happen with nonmarine brines, typically where nonmarine waters drain into an arid, highly isolated depression in the continental landsurface. The effect of isolation and concentration in producing appropriate brine chemistries is often enhanced by the presence of nearby mountains. Mountains act both to form a rain shadow zone and to create topographic head, which drives deep circulation of meteoric groundwaters. In continental lakes in both rift valleys and collision belts, the creation of the mountains is tied to an active tectonic regime and volcanism, which in turn tends to create enhanced hydrothermal circulation and labile volcanoclastic aquifers in hydrographically closed depressions where saline waters are ponding. Borates, for example, form via the lacustrine concentration of spring inflows that have passed through active volcanogenic terrain. Likewise, the trona beds of Lake Magadi reflect nonacidic groundwater and hydrothermal/basin brine leaching (low sulphate, high bicarbonate waters).

All bedded non-potash deposits discussed in this chapter accumulated in endorheic depressions, often in the rain shadow of a nearby mountain range. This situation is most obvious in the various South American salars, they lie in intermontane depressions with floors that are thousands of metres above sea level, yet they drain and pond hypersaline waters for long periods of time, sufficient to allow salt beds hundred of metres thick to accumulate. Likewise mountains and volcanoes influenced local climate and helped create the Neogene successions of NE Turkey and the Basin and Range playas in the USA. Long-term aridity for more than 6 Ma tied to rain shadow effects, in combination with offshore upwelling, explains the hyperarid nitrate regolith of Atacama Desert.

Location	Age	Mine-able	Tectonic setting and brine feed	Depositional setting	MgSO ₄	Main potash minerals	Style and origin of potash
Qaidam Depression, China	Quaternary	Yes	Foreland basin	Continental playa	Yes	Carnallite, lesser sylvite	Void filling cements and displacive crystals via cooling of syndepositional sinking brines.
Danakil Depression, Ethiopia	Quaternary	Possibly	Rift aulocogen	Continental playa	Yes	Primary carnallite, kainite, secondary sylvite	Seaward seepage into Pleistocene subsealevel rift depression.
Chott el Djerid, North Africa	Quaternary	No	Endorheic depression	Continental discharge playa depression	No	Ephemeral halite-carnallite crusts	Brine evaporation in an area of regional artesian aquifer discharge.
Small plays in Amadeus Basin, Australia	Quaternary	No	Endorheic depression	Continental discharge playa depression	No	Ephemeral halite-sylvite crusts	Brine evaporation in small playas atop, but not connected to, zones of artesian aquifer discharge (only rare and minor occurrences of potash salts).
Dead Sea Depression, Middle East	Quaternary	No	Continental trans-form or "pull-apart" basin	Artificial brine recovery and pan evaporation	No	Carnallite slurry with sodium and magnesium chloride	Sequential evaporation of brine pumped from pores and dissolution cavities in subsurface Miocene evaporites.
Solfiera Fm., Caltanissetta Basin, Sicily (Messinian)	Late Miocene	Yes	Foreland basin (marine-fed)	Continental depression fed by seawater seepage	Yes	Syndepositional carnallite and early secondary sylvite	Syndepositional carnallite and secondary sylvite via brine cooling within karsted halite host. Deposited in early stage of a basinwide seaway drawdown.
Mulhouse Basin, France	Oligocene	Yes	Continental rift graben	Continental salttern, bedded	No	Primary carnallite and sylvite	Interlayered primary potash and halite cm-scale couplets with settle-out/bottom growth textures.
Maha Sarakham Fm., NE Thailand	Cretaceous	Yes	Continental foreland basin	Continental salttern, now halokinetic in part	No	Syndepositional carnallite and early secondary sylvite, also tachyhydrite	Syndepositional carnallite and secondary sylvite via brine cooling within karsted halite host.
Transatlantic potash basins, West Africa and Brazil	Cretaceous	Possibly	Continental rift graben (marine-fed)	Continental saltterns, now halokinetic in part	No	Primary carnallite and sylvite, also tachyhydrite	Bottom growth textures in both halite and halite layers in cm-scale stacked couplets.
Moroccan Meseta, Northern Africa	Late Triassic (Keuper)	Possibly	Continental rift graben (marine-fed)	Continental saltterns, now halokinetic in part	Rare	Not known - no detailed petrography available	Potash/halite evaporites interbedded with redbeds and basaltic lava flows.
Windsor Group, Canadian Maritime Provinces	Carboniferous (Viséan)	Yes	Continental rift graben (marine-fed?)	Continental saltterns, now halokinetic in part	No	Syndepositional carnallite and sylvite within primary halite. Associated borates	No detailed petrography yet published. Some thickening of potash units on salt pillow margins.
Z1, Z2 and Z3 evaporite intervals in Zechstein Basin, Europe	Permian	Yes	Basinwide marine evaporite (suture) (marine-fed)	Mostly saltterns, occasional deeper water, now halokinetic in part	Yes	Syndepositional carnallite and sylvite within primary halite	Carnallite as void fill during early brine reflux. Incongruent dissolution of carnallite to form sylvite. Potash units thickened by salt flow.
Salado Fm., Delaware Basin, New Mexico, USA	Permian	Yes	Basinwide marine evaporite (suture) (marine-fed)	Mostly saltterns, occasional deeper water, now halokinetic in part	Yes	Syndepositional carnallite and sylvite within primary halite	Carnallite and sylvite precipitated as void fills during early brine reflux.
Prairie Evaporite Fm., Elk Point Basin, Canada	Devonian	Yes	Basinwide evaporite (intracratonic) (marine-fed)	Mostly saltterns, occasional deeper water	No	Syndepositional carnallite and sylvite within primary halite	Syndepositional potash textures, often overprinted by later alteration events related to tectonically driven episodes of fluid flushing by basinal brines or deeply circulating meteoric waters.

Table 11.18. Summary of major potash evaporite occurrences as discussed in this text (see Chapter 5 for geological detail).

Location	Age	Tectonic setting	Depositional setting	Main minerals	Style and origin of mineralisation
BORATES					
Bigadic, Turkey	Miocene	Tibet-style grabens in collision arc	Volcanogenic playa/mudflats	Colemanite, ulexite	Precipitated as secondary nodules and fissure-fills within unconsolidated sediments, just below the sediment-water interface.
Boron, California	Miocene	Basin and Range	Volcanogenic saline lake/mudflats	Borax/kernite core facies with more distal ulexite, proberite and colemanite	Borax/kernite core facies with more distal ulexite, proberite and colemanite.
Salars, South America	Miocene	Intermontane grabens	Saline lakes and mudflats	Borax, ulexite, hydroboracite and inyoites	Borax, ulexite, hydroboracite and inyoites.
Meta-evaporites, Liaoning Province	Proterozoic	Amphibolite-grade metamorphics	Saline playa and mudflats	Boromagnesite	Metamorphosed lacustrine beds associated with banded iron formations and volcanics.
NITRATES					
Atacama Desert, South America	Neogene	Intermontane depressions	Intermontane depressions	Pedogenic nitratite with associated iodates, perchlorates, bromates and chlorides	Hyperarid conditions have prevailed since the mid-Miocene allowing buildup of highly soluble salts in the desert regolith.
SODIUM CARBONATES					
Lake Magadi, East African Rift, Tanzania	Holocene	Continental rift graben	Volcanogenic perennial saline lake	Cumulates and bottom-nucleated trona blades	Trona accretes each year as bottom growths atop 15m thick trona beds, which are sometimes deformed into pressure ridges (petees).
Wilkins Peak Member, Green River Basin, USA	Eocene	Foreland basin	Arid lacustrine interval in Tertiary basin fill	Trona beds and nodules with associated oil shales and dolomites	Subaqueous bottom growth on the floor of saline lakes and intrasediment nodules beneath the surface of desiccated mudflats.
SODIUM SULPHATES					
Continental playas in lowlands of Alberta and Saskatchewan	Holocene	Spring-fed hypersaline depressions on Northern Great Plains of Canada	Hypersaline, meromictic, perennial continental salt lakes	Coarsely crystalline, massive to thickly bedded mirabilite with lesser epsomite, bloedite, gypsum, magnesite and aragonite	Cooling of freestanding lake brine causes subaqueous bottom and nodular mirabilite to form.
Tertiary lacustrine deposits, Toledo Province, Spain	Miocene	Continental foreland basin to nearby Pyrenees and Iberian Ridge	Hypersaline, mudflats of continental salt lakes	Glauberite with lesser anhydrite, gypsum chalcedony, dolomite and magnesite	Glauberite with lesser anhydrite, gypsum chalcedony, dolomite and magnesite.

Table 11.19. Summary of nonpotash salt resources discussed in this chapter (all are continental saline lacustrine deposits).

The high solubility of the nonpotash salt resources, and their formation as lacustrine, not marine, precipitates explains their limited thicknesses, their mostly Neogene ages and their relatively small size compared to marine evaporites (Table 11.19; Figure 5.3). A lacustrine depositional setting, with its inherent lack of a huge isochemical brine reserve (seawater), means bed thicknesses and salt volumes will always be less than that of bedded salts accumulating in marine-fed saline giants. Inherent high solubility of lacustrine salt beds (trona, mirabilite, glauberite) in a hydrology susceptible to drastic changes in water supply and water table, means lacustrine salts are rarely found in rocks with pre-Cenozoic ages.

The Proterozoic borates of Liaoning Province are an obvious exception. The impervious nature of this succession, its metavolcaniclastic host, and the formation of a silicified envelope around the borates, relatively soon after their precipitation, allowed these salts to be preserved, although as a meta-evaporite. As a rule of thumb for salt exploration in a frontier area, those arid basins with post Mid-Tertiary ages should be considered much more prospective than any older basins. You should not expect to find trona or thenardite or other soluble lacustrine phases in large amounts in Palaeozoic successions and will probably not find them at all in Precambrian strata, at least not without a meta-evaporite silica genesis and a transformation into mineral phases such as tourmaline and scapolite.

Chapter 12: Solution mining and cavern use

Introduction

Salt solution mining is just what it says, the mining of various salts by dissolving them and pumping the resulting brine to the surface. It is predicated on the solubility of the targeted salt; the “rule of thumb” in the solution mining industry is that every 7 - 8 m³ of freshwater pumped into a cavity will dissolve 1 m³ of halite. Water or undersaturated brine is injected through a purpose-designed well drilled into a salt bed to etch out a void or cavern. The resulting “almost saturated” brine is then extracted for processing. It usually targets salts at depths greater than 400 to 500 metres and down to 2,000 m (Figure 12.1). The current deepest salt solution operation is in the northern Netherlands in Zechstein salts at a depth of 2,900 metres. At depths greater than 2,000m ongoing salt creep tends to reduce cavern size. Some operating brinefield caverns are as shallow

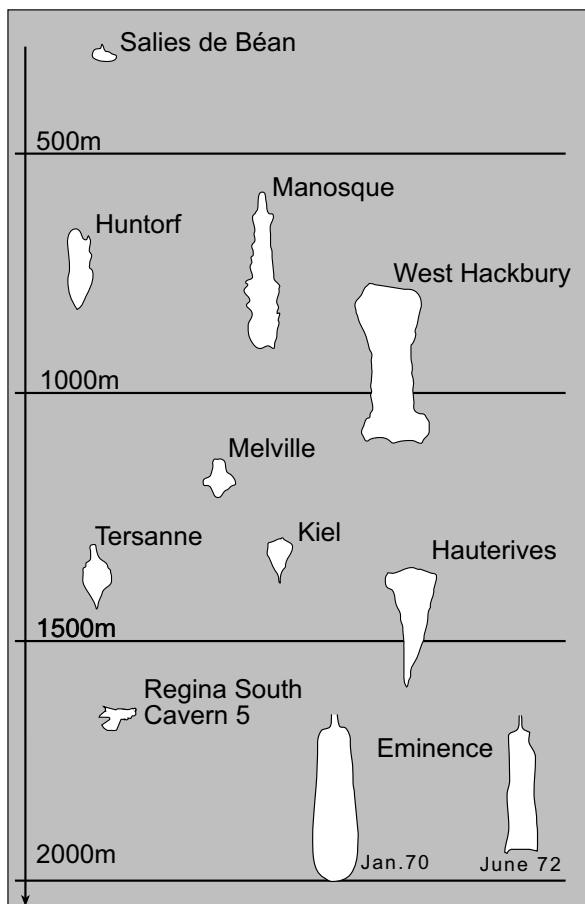

Figure 12.1. Depth profiles of various salt caverns, all are in salt domes except Regina South and Salies de Béan, which are in bedded salt. Eminence shows the volume changes after 18 months due to salt creep (see Figure 12.30).

as 150 metres, but this can lead to catastrophic chimneying and stoping in sediments above cavity. With deeper operations the landsurface tends to subside into a bowl of subsidence, as it does above many conventional mines. Cavern shape and the upward rise of the cavern roof is today controlled by an inert fluid blanket pumped in and maintained at the top of the zone of active brine creation. Early solution wells did not use this blanket technology as brinefield operators expected surface sinks, collapses and regular abandonment of caved wells.

In a solution mining saltworks, where production of various chemical salts is the main aim, saline brine is withdrawn from the expanding cavern and often pumped into solar evaporation pans to manufacture salts of designated grade, mineralogy and quality. Brine product from the pans, either solids or slurries, or a brine feed direct from the solution cavern, is piped to a nearby chemical processing plant designed for particular chloralkali, magnesia or other chemical products. Wells located near the site of a chemical plant and designed to capture brine of a particular chemistry are called captive brine wells.

The advantage of solution mining over conventional mining or surface evaporation pans is that product quality and the extraction operation is not as subject to the vagaries of climate or rock strength. Specific subsurface mineralogies can be targeted by the well bore to obtain a specific feedstock or chemical product without the need to get men and equipment from the surface to the mine face. Solution mining can exploit folded and disturbed beds or deep-lying strata, situations not easily mined using conventional techniques.

As well as halite, which historically has been the most common commercial target, other solution-mined salts include; potash (sylvite, sylvinite, carnallite), trona/nahcolite (sodium carbonate/sodium bicarbonate), borates (borax, ulexite, colemanite), sodium sulphates (mirabilite, thenardite) and magnesium chlorides. Today the cavern produced by solution mining may have a greater value than the extracted brine, particularly for a ubiquitous salt like halite. If appropriately designed, a cavity can be used for hydrocarbon or waste storage and even for energy generation.

Diapiric salt masses tend to be the preferred medium for solution mining as the salt mass undergoing designed dissolution is typically large, thick and tends to be homogenous. This makes it easier to purpose design in terms of both cavern shape and volume. Bedded salts tend to be less vertically homogenous

and more subject to caving and roof collapse, although ongoing improvements in directional and horizontal drilling mean these deposits can be exploited. Rather than the brine product, more and more the cavern itself and its use as a storage vessel, is the rationale for solution mining.

The solution mining process

Solution mining is an alternative to mechanical excavation of salt ores (Richner et al., 1992). Since most waste components in solution mining are not soluble they are left behind to settle to the bottom of the expanding cavern as the brine product is removed to a surface processing facility. Unlike conventional mining, there are no large above-ground waste piles and tailings impoundments. However, the possibility of collapse and karstification atop brinefields means contamination and leakage into nearsurface and surface waters are potential problems. Monitoring of landsurface stability reduces the possibility of such uncontrolled collapse and environmental degradation.

History of salt solution wells

The Chinese have been using brine wells, a form of solution mining, for more than 2,000 years (Yuanxiong and Chengxun, 1983). Designed-use shaft wells were sunk as early as 300 BC in the Szechuan and Yunnan provinces. By 1035 AD the Chinese in the Szechuan area were using percussion drilling to recover deep brines, a technique that would not come to the West for another 600-800 years. European travellers to China in 1400-1700 AD reported salt and natural gas production from brine wells, some of which had been sunk deeper than 450 metres and at least one well was more than 1,200 metres deep. Salt production in China at that time was prodigious, with more than 10,000 wells in operation. Marco Polo reported annual production in a single province of more than 30,000 tons.

Practically all the materials used in Chinese brine recovery wells, including ropes, casing and derricks, were made from wood or wood fibre, mostly bamboo. Bamboo is salt resistant and salt kills microbes and algae that would cause it to rot. Pipeline joints were sealed by mud or a mixture of lime and tung oil. Manpower was used both to power the drilling process and to raise the brine. A sharp iron wedge bit (resembling a spade or shovel) was suspended on a levered rope at the end of a bamboo tube so that it kept pounding and pulverising the rock at the bottom of the drill hole (Figure 12.2a inset). At the surface the drilling tool and drill string (bamboo) were suspended

from the end of a “spring pole.” The raising and lowering of the percussion head at the base of the hole was supplied either by workmen running up a short incline and jumping down, one after the other, onto a small platform attached to the spring pole or by a single workman alternately standing on a wooden lever pole and stepping off (Figure 12.2a; Deutsch, 1978). As the drill assembly was raised after each descent another worker rotated the drill string assembly so it would strike the base of the hole in a different position. After three to five years, a successful well could have penetrated up to several hundred metres to intersect a brine or natural gas target. In 1835 the Xinhai well reached a depth of more than 1 km using this bamboo percussion technology. Interestingly, the deepest percussion well in Europe around the same time was in Germany where a percussion well reached 535m in 1835. A likely reason for this shallower depth was that the Europeans used rope to suspend the drill tool, while the Chinese used bamboo.

Periodically, pulverised rock was bailed from the base of the deepening hole. This was done by pouring water down the hole to create a slurry. The slurry was extracted by lowering a weighted hollowed-out bamboo pipe with an interior leather flap on its lower end. When lowered into the slurry the flap would open and jiggling the pipe up and down when on the base of the hole forced rock slurry into the pipe. Then the pipe was raised with the weight of the slurry forcing the leather flap closed.

Later, once the hole had achieved its target depth, brine in the Szechuan area was often recovered from the well by the same means, namely, using a long bamboo bailer with a leather valve at its bottom. When a brine-filled tube was suspended over a nearby storage tank, a poke from a stick would open the valve releasing the brine (Figure 12.2b). Alternatively, a section of bamboo with pith left in place was cut by a series of holes located just below each pith level creating a series of small buckets. The weighted bailer was lowered into the brine pooled at the base of the brine well and brine flowed into the holed pith sections. Then the bailer was raised and inverted over the storage tank.

Often the storage tank was connected by bamboo piping to the salt boiling house (Figure 12.2c). Other bamboo pipes, located just below a natural gas wellhead were used to capture escaping methane and pipe it to the boiling house to fire the salt crystallisers (iron pans).

From the pipe technology developed at the Szechuan brine works, Chinese throughout the country learned to build irrigation and plumbing systems (Kurlansky, 2002). Farms, villages, and

Figure 12.2. Solution mining and brine recovery technology in saltworks of the Szechuan region of China in the mid-eighteenth century. even houses were fitted with bamboo plumbing. By the time of the Norman conquest of England, Su Dongpo, a bureaucrat born in Sichuan, was building sophisticated bamboo urban plumbing networks. Large bamboo water mains were installed in Hangzhou in 1089 AD and in Canton in 1096 AD. Holes and ventilators were installed for dealing with both blockages and air pockets.

In Europe, near Lorraine, France, much simpler designed-use brine shaft wells were sunk by hand as early as 858 AD (something the Chinese had been doing since at least 250 BC). In 1381 AD the Duke of Lorraine, the Bishop of Metz and the

Duke of Bar, formed a salt cartel that operated brine wells at Chateau-Salins and Salonne (Deutsch, 1978). By 1740 brine was raised in the region using horse-driven pumps and in 1758 steam-driven pumps were drawing brine from wells that were more than 100 metres deep. By 1839 salt was being directly mined in an underground operation at Dienze that employed over 400 miners. By 1830 in the USA there were more than 60 brine wells in operation in Kanawha region near the confluence of the Kanawha and Ohio rivers. Numerous brine wells were in operation in New York State by 1880, while large-scale brine recovery operations in the various playas of the Basin and Range were underway by the early 1900s. Today, steel-cased

Figure 12.3. The solution mining process. A) Direct brine circulation where feed solvent is injected through the tubing string and brine is withdrawn through the annular space between the tubing string and the final casing. Cavern shape tends toward cylindrical with slightly expanded lower section. B) Reverse-circulation where the feed solvent enters the cavity through the annulus and brine is withdrawn through the tubing string. Cavern tends to be wider at top than base ("morning glory"). In both cases the outermost casing allows feed of the blanket solution into the uppermost part of the cavern, so protecting the cavern roof. Varying the volume of blanket in the cavern can be used to help shape the cavity.

brine wells are consistently drilled to depths of more than 1-2 km to extract brine product or to excavate custom-built salt caverns for hydrocarbon or waste storage.

Well and cavern design

The design of a salt solution well consists of two or more columns of steel pipes (casing strings) with the smaller inside the larger. Fresh water or undersaturated brine (feed solvent), needed to drive the solution process in an expanding cavern, is pumped into the well to create a cavity in the targeted salt. The resulting brine is then returned to the surface for processing and recovery.

The first step in solution mining salt is to drill an appropriate-diameter borehole, large enough to accommodate all the required pipes (casing). This means solution wells are wider than most oil and gas or water wells. Near the surface, the borehole is widest to allow for installation of several concentric layers of pipe casing (Figure 12.3). The outermost layer of casing, known as the surface casing, is cemented in place to prevent

any leakage and contamination of nearby groundwaters. Surface casing does not typically extend all the way down to the cavern roof. The final casing string (or long string casing), which is also cemented in place, is set at some depth below the top of the target salt so that during dissolution a reasonable thickness of salt remains in place as a salt roof to the expanding solution cavity. In modern wells there is another string next to the outer casing string that controls the thickness of the fluid blanket.

Generally, one or more non-cemented casing strings, the tubing strings, are placed inside the final casing string. In modern designed-use caverns, non-cemented casing or tubing strings first extend to a depth near the planned base of the cavern. Under this design scenario, strings can be rotated and raised (snubbed or pulled) as the cavern grows and the bottom fills with debris. Depending on the size of the cavern and the amount of impurities present, more than 20 metres of impurities (dolomite-anhydrite residues and fragmented roof blocks) can sit on the bottom of an active solution cavern (Crossley, 1998; Tomasko 1985). Some older interconnected multi-well brinefields did not have non-cemented strings in each well.

Salt subjected to undersaturated crossflow in an expanding solution cavity tends to leach 1.5 to 2 times faster vertically than horizontally (fresher water is less dense than brine and tends to accumulate in the upper part of a cavity). Vertical leaching tends to be even faster if there are gas inclusions in the brine giving it even greater buoyancy. An inert low density fluid blanket is usually pumped into a solution cavern to prevent rapid upward stoping and ultimate collapse of the cavern roof, along with its cemented casing string, into the growing cavity. Roof blanketing, sonar imaging and designed cavern shaping typifies almost all current commercial solution mining operations.

Blanketing fluid is inert so it does not dissolve the target salt, and is always less dense than the feed solvent or the produced brine. It always floats to the top of the cavern where it insulates the roof from the effects of dissolution. Older blankets were one of a number of different types of oil, typically diesel or crude, but today are increasingly composed of other fluids including LPG, nitrogen and compressed air. Nitrogen and less often compressed air tend to be the fluids of choice as they do not have the environmental and safety issues associated with a hydrocarbon blanket. Generating a blanket requires the addition of a devoted column of pipes in the well string and the blanket is usually pumped in/out via the annular space between the outer and middle casing pipes (Figure 12.3).

There are several methods for developing and shaping caverns. In the direct circulation method, feed solvent is injected through the tubing string and brine is withdrawn through the annular space between the tubing string and the final casing (Figure 12.3a). In the reverse-circulation method, feed solvent enters through the annulus and the brine is withdrawn through the tubing string (Figure 12.3b). As less dense water in a salt cavern tends to float on a more concentrated brine, a “morning glory” type cavity with a much wider top than base is likely to be formed by what is called reverse circulation, especially in cavities grown without the aid of a fluid blanket. A more cylindrical cavity is formed by direct circulation. During cavern excavation, the volume of the blanket fluid is increased or decreased to help shape the cavity.

Detailed discussion of the engineering aspects involved in well design and cavern shaping is largely outside the geological focus of this book. Various authors, such as Remson et al. (1966), have outlined the general procedures for controlling the shape of the solution mine cavities, and many articles, such as that of Shock (1985) and Jacoby (1974), have been written on basic solution mining techniques for various salts. Extensive bibliographies also have been prepared on solution mining, such as those by Dahl (1985) and Nigbor (1982). Combinations of these various methods and other more complicated solution mining approaches are now well understood and can be used to obtain any desired cavern geometry or well-to-well interconnections (API, 1994).

If a particular brine product is the goal of a solution mining operation, rather than the cavern itself, then the extracted brine typically is evaporated or treated at the surface to produce a crystallized product. In this case an “almost saturated” brine product is mandatory in the rising casing string. Dilute brine is too expensive to process, while supersaturated brine can

block the raising string with unwanted precipitates. When a single-hole solution mining well is first drilled, the flow rate through the cavity and up the pipe is usually kept very low to maintain higher levels of brine concentration. As the surface area of the cavity and the cavity volume increase with time, the extracted brine flow rate can be progressively raised. In a year or so comparatively high flow rates can be maintained. The life of a successful brine well can be quite long, up to 30-40 years. If the solution process is maintained from a single well the area around the well will eventually subside, or the borehole roof carrying the casing strings will weaken and cave, disrupting the brine flow. Even if the roof doesn't cave, salt will dissolve from around the casing string and it will eventually corrode and fall into the cavity.

Historically, captive wells designed for brine recovery and not for storage were expected to be abandoned or to fail. Most such wells started out as reasonably good producers, but ultimately failed by breakage or damage to the casing string by corrosion, by roof caving or by subsidence-related shearing/collapse of the casing string (Deutsch, 1978). Failure could occur soon after a well evolved into a high-capacity performer or decades later. Most brinefield operators learnt that many of their oldest wells were their most reliable producers. Many captive brinewells “die” during their “infancy,” but if they live through the usual “childhood diseases” of roof collapse and casing shear, the chance of failure lessen as they get older. Some older brinefield wells in bedded salts, that is, wells that had produced for 20 to 30 years, seemed to be immune to caving and were abandoned only when the target salt layer was exhausted.

Predicting which wells survive in a brinefield is difficult. An analysis of some 60 wells drilled between 1887 and 1925 clearly shows this trend of long-lived survivors (Figure 12.4).

Figure 12.4. Schematic of the “life expectancy” of a set of brine wells (Deutsch, 1978).

One possible explanation for “long-life” wells is that early cave-ins distributed fallen rock in such a way that the lowest part of the tubing string was protected from damage by later cave-ins. Alternatively, as the roof of a growing salt cavity reached a greater and greater span, it could either cave with serious results for the well, or it could very gradually subside until it was supported by silt or projections and debris at the bottom of the cavity. A brine well in the latter situation would continue to be a good producer, even with a very shallow cavity. Well failure or poor performance is somewhat random in nature, and can occur unexpectedly. Consequently, and because of slow initial production rates, most captive brinefield operators employ many wells, abandoning nonproducers and bringing new ones on-line.

In all cases, mud and other insolubles, as well as some salt falls accumulate as muddy breccias at the base of the expanding cavity. In wells where salt layers other than halite are the target and are encased in thick halite, the initial borehole is typically drilled through the target bed(s) to some distance into the underlying halite mass. As the cavity then expands, it creates a sump below the target bed where insolubles can accumulate. In any solution cavity it will be necessary to raise the bottom casing string (snubbing) above the level of the insolubles, otherwise the well will need to be plugged and abandoned. This is also true if the casing has been severely bent or damaged by the rock-falls from the roof. Normally these problems occur very slowly, and the cost of the initial capital and well operation is such that the total mining expense is very low compared to conventional room and pillar extraction.

Many land areas above brinefields, which were active in the 18th or 19th centuries and were over-exploited, are today subject to collapse. But few records of well placement or even the position of the brinefield were kept in older areas of extraction (as in Hutchison, Kansas - see case histories later in this chapter). This leads to all manner of environmental and civil engineering problems in the vicinity of many former brinefields. But not all engineering and subsidence problems in areas of nearsurface salt are anthropogenic (Figure 7.41). Salt dissolves and the large collapse cavities form naturally at the landsurface in time scales measured in days or weeks. Outside of areas atop poorly managed or historical brinefields, separating anthropogenic sinkholes from natural dissolution cratering is very difficult. A cynic might conclude that many causative interpretations depend in large part on which interest group is paying the consultancy bill.

Solution well styles

Various techniques have been employed in brinefields over the last 150 years to improve brine production costs and to increase the amount of brine produced per well. Today the dissolution process for single wells can involve multiple concentric or independent tubing strings, various fluid injection/production depth combinations, as well as several different roof-protection combinations involving blankets of different types of hydrocarbons including crude oil, LPG, and gases such as nitrogen and CO₂. Blanket design now also includes solids such as floatable cements and hollow spheres (Richner et al., 1992). Multiple-well interconnections can be achieved in a planned manner using appropriate geological understanding along with combinations of roof padding, well deviation/horizontal drilling and hydraulic fracturing.

Expert design of solution wells is for the most part dependant on geological understanding of the salt to be exploited. Required knowledge includes: dip and thickness variations of the target bed; mineralogical composition, homogeneity, insoluble levels and dissolution behaviour of the target salt bed and adjacent salt layers; distribution and mineralogy of intrasalt beds; structural integrity of confining beds. Caverns engineered in salt domes tend to be more reliable and predictable structures than caverns engineered in bedded salts and are more suited to product storage especially if the product is stored under pressure. Compared to dome salt, bedded salt in the vicinity of a solution well tends to be thinner and bound above and below by more permeable formations. Bedded salt is also more likely to enclose layered intrasalt beds with varying levels of solubility and fracture intensity (anhydrite, shale and dolomite intrabeds) and so tends to supply significantly higher quantities of impurities to the cavity floor. The most stable cavern shape for purpose-designed storage resembles a giant carrot or cucumber embedded deep in a mass of salt. This ideal shape is next to impossible in bedded salt, and to continue the vegetable garden analogy, jack-o-lantern pumpkins are a more likely outcome.

Historically, the earliest single wells had top injection (reverse circulation) and no roof pad or blanket. These Tully-method wells had the advantage of low investment costs along with rapid development of saturated brine flow (Richner et al., 1992). Unfortunately, this technique tended to create unstable morning-glory caverns subject to roof failure and their design inherently limits brine recovery to the upper portions of any targeted salt mass. Casing damage was likely even in the very early stages of cavern growth. “Tully” wells are not used

today and belong to a time in human history when landscape damage was seen as a positive indicator of “progress.” In the 1920s and 30s Detroit-method wells, with direct circulation via a bottom tubing injection, became the preferred method for excavating single well brine producers as they tended to create more stable cylindrical caverns, less subject to early collapse and loss of the well.

In the 1930s the “Trump” method, a multiple well technique, was introduced to exploit bedded salts. It involved direct circulation and the use of a roof pad or blanket (Figure 12.5a). Multiple wells were completed near the base of the targeted salt formation. The aim was to create large diameter undercuts near the base of the target salt bed and then allow the undercut caverns to expand beneath their blankets until adjacent cavities met. Historically, wells utilising the Trump method were between 61 and 183 metres apart. Once an interwell connection occurred, the wells were changed from two independent circulation wells, into two-well or multiple-well operations. One (or more) well(s) became the injector(s) for feed solvent and the other(s) became the brine producer(s) (Figure 12.5a). In this way the salt formation between the two wells was more efficiently recovered by the rising cavity roof and the per well brine production rates and tonnages were markedly improved compared to the older single “Tully” method wells. Using the Trump method entails a 12-24 month period of cavern development during which arrangements must be made for the usage or disposal of unsaturated brine.

recommended a 91m well spacing in bedded salt and about 18 months from the onset of feeder brine pumping to a time when an appropriate and consistent quality brine product could be recovered. He noted that cavity development and brine field subsidence in general can be controlled to a greater degree using the “Trump” procedure rather than a single Tully well. It entails relatively low production costs and high flow rates per mature well. However, the padded rising roof of the cavity is not a structurally competent shape, and roof falls ultimately occur. Constant raising of the casing is often required, especially in the downdip feed wells. The production or uphole wells are

Figure 12.5. Methods of solution mining. A) Joining wells by using an oil pad or blanket in combination with reverse circulation (after Henderson, 1974). B) Schematic of deviated wells in magnesium salts at the NedMag plant in Veendam, Netherlands, showing solution mining method of upward retreating successive cuts with positions controlled by the blanket (after Currie and Walters, 1985).

Henderson (1974) reviewed this multiwell method of solution mining for halite targets. For maximum efficiency, he

particularly vulnerable, and generally weaken and fail first (see the Romanian SALROM disaster in case studies).

Specific examples of the mining of very thin beds of salt using one- or two-hole methods were reported from a brinefield in China by Yuanxiong and Chengxun (1983). Single-well, nonblanketed, production of a salt bed 1 to 6 m thick at a depth of over 1,000 m in 12 wells over a five-year period averaged 20,000 to 30,000 t/yr of salt per well (maximum 70,000 t/yr), with a well life of four to eight months. Both the casing and tubing tended to deform, bend, and break from roof falls. Well life was longer in zones with a more stable roof. However, when oil pads were employed on a single two-pipe well 935 m deep within a 17-m-thick salt, the well was fairly quickly producing 50 t/day of salt as a saturated brine. Well life and productivity were much improved. Two other wells were then connected by using oil pad control to test against the single well extraction method. The wells were 1,042 m deep, 71.7 m apart, and operating in a salt bed some 17 to 20 m thick. Cavity height during excavation was maintained about 2 m above the base of the salt. By 100 days the flow rate in each well was 10 m³/hr with an “almost saturated” exit brine, and in 500 days the wells were interconnected. In a third set of wells at 1,004 m depth, 16-m-thick salt, and 68-m spacing, it only took 180 days to make the connection. About 26,000 tons of salt were “wet mined” in making each cavity, and the daily salt output was 300 to 400 t/day per well at the end of this period. Blanketed reverse circulation (top injection, bottom production) was employed to better control roof height and allow faster horizontal cavity growth. Over 50% recoveries of the entire thin salt beds were obtained with excellent economics and minimal surface subsidence using this procedure.

Today, most single well solution mining operations utilise a modified annular injection method, known as variable point injection, where both the tubing string and the casing string are positioned near the lowermost level of salt to be dissolved. Undercuts of more than 100 m diameter are achieved using a gaseous or liquid roof pad. In captive wells, brine production rates of more than 13 litres/sec have been obtained once the blanket is withdrawn. As solution proceeds both the tubing string and the casing strings are raised clear of the accumulating insolubles (snubbed). This type of well is also capable of achieving planned-cavity shapes suitable for waste storage.

An interesting test of the efficiency of both single-well and two-connected-wells solution mining systems targeting a thin bed of sodium borate was described by Taylor (1970). An 8.8-metre thick layer of borate ore, which was 107 metres below

the land surface with a 72% ore grade, was solution-mined in a series of tests. At the completion of the tests the cavities were physically mined (entered) and inspected. No roof padding was employed during the tests. Hot water at 102° to 110°C was injected as a feed into the 21°C formation and a 15 litre/min flow produced an “almost saturated” borax solution with an exit temperature around 77°C. As the test progressed, feed temperature was steadily decreased and the allowable flow rate of the saturated solution steadily increased. On later cavern entry it was found that broad morning glory holes had formed and large amounts of insolubles had accumulated on the cavern floor. Clay and shales from the roof had fallen as intraclasts with a “sand and gravel” structure. Cavity bottoms were dominated by this material, rather than by fine bottom slimes usually postulated to dominate cavity bottoms. Some slabs of borate remained encased in the pile of insolubles, where they remained buried as unleached blocks.

Techniques in potash operations

Texas Gulf solution mines potash-rich brine from deformed salt beds in the Paradox Formation at Moab, Utah and then uses solar concentrators to achieve a product appropriate for processing. The IMC Kalium operation near Moose Jaw, Saskatoon, recovers potash brine by solution mining a sylvinite bed (Belle Plain Member) 9 to 15 metres thick at a depth of 1,650 m using a patented solution and recovery method (Figure 11.19). To capture the ore, hot undersaturated brine feed is pumped into the dissolution cavity. Concentrated potash brine is then returned to the surface processing plant, which uses a sequential evaporation-crystallization process to recover potash and recycle hot NaCl-rich brine to the subsurface for another leach cycle. In the dry steam driven evaporation stage in the processing plant, moisture is removed and the recovered brine is brought to saturation point. But halite and sylvite have different temperature responses (Figure 11.10a). Halite is crystallized first by evaporating the recovered brine, then potash is recovered by cooling the remaining hot, saturated solution.

The NedMag solution mining facility near Veendam in the Netherlands produces magnesium from magnesium chloride brine by solution mining a Zechstein salt dome, targeting beds that are a mixture of carnallite (KCl.MgCl₂.6H₂O), bischofite (MgCl₂.6H₂O) and halite (NaCl), with some sylvite (KCl) and kieserite (MgSO₄.H₂O). Target beds at Veenham average 100 metres (combined) thickness at depths between 1,400 and 1,800 m. About a 100 metres of halite lies above the target magnesium salts and more than 1,400 m occur below. Beds were accessed by a total of 12 solution wells drilled between

1972 and 1991. Nine of these wells were still operational in 2000 with average brine production per well around 25 m³/h. NedMag has recently excavated one of the deepest solution mining cavities in the world at 2,890 metres. Each year the NedMag plant produces in excess of 150,000 tonnes of high purity synthetic dead-burned magnesia and more than 70,000 tonnes of magnesium chloride in liquid or solid form. A similar solution-mined operation producing MgCl₂ brine by targeting bischofite beds is planned for a large deposit near Volgograd in Russia.

The mining procedure at Veendam utilizes a backstepping solution cavity method (Figure 12.5b). Cavity extent is limited to ≈100 m diameter (perhaps now extended to 150 m), and the brine is maintained at the original downhole (lithostatic) pressure. Wells are designed to be plugged and abandoned at full pressure. Considerable insoluble rockfall and mud deposition is encountered from the laminated intrasalt formations and the various impurities in the NedMag target beds. This requires frequent raising of both the injection (to control the cavity diameter) and the withdrawal of pipes (to prevent blockages; Figure 12.5b).

Cavern pressures are kept relatively low in the producing caverns (average of 10 MPa or 100 bars) and well below the far field rock stresses. This facilitates salt creep into the cavern, but the lower viscosity of the magnesium salts compared to halite means they are preferentially squeezed like toothpaste into an active solution cavern at a rate far greater than the creep of the adjacent halite. Hence, the bischofite beds supply far greater volumes to the dissolution cavern than the adjacent halite beds with convergence rates contributing 30–40% of the produced MgCl₂-brine volume. This method has been called “squeeze mining” and the brine product from squeeze caverns can be very pure. For example, four wells producing brine from “squeeze caverns” at Veendam are almost saturated with respect to bischofite, rendering a high quality brine product with less than 1% by weight of non-magnesium chloride salts.

All of the halite in the dissolution cavern must be leached along with the potash in order to keep the face of the solution cavity open and dissolving rapidly. Otherwise, a buildup of salt and insolubles on the active dissolution face cause blinding. Bottom casings are raised (snubbed) periodically to keep above the buildup of insolubles. As with all solution brine operations, flow rates are kept low enough to produce a transparent “almost saturated” brine. Because the targeted potash bed is thin, well capital and operating costs are comparatively high, but are reported to be still less than conventional potash min-

ing. Relevant published potash solution mining articles and processing patents include; Bach et al. (1985), Day (1967), Dillard et al. (1975) and Schlitt (1982).

Carnallite, like trona, shows incongruent solubility so that in beds composed of mixtures of carnallite, sylvite and halite, the sylvite tends to be left behind as a less soluble component that can slow the rate of dissolution (surface blinding). Furthermore, the solubility of halite, sylvite, and kieserite is very low in strong MgCl₂ solutions. However, by carefully maintaining the proper MgCl₂ concentration in the Veendam cavern brines and monitoring solution flow rates using variably pressurised waters, NedMag has minimised blinding in bischofite beds (Steenge 1979). For successful magnesium chloride recovery, the solution rate, the dissolving surface and the produced brine at Veendam must be maintained at all times at an ‘almost saturated’ condition. The operations at Veendam are a worldclass example of targeted and monitored solution mining with a set of process technologies specifically designed for the brine product. Historically, high levels of carnallite in some potash beds in the Zechstein have made them a poor choice for a KCl targeted beds in both solution and conventional mining operations. But NedMag has recently begun to use a patented process to produce brines that are also saturated with respect to carnallite from carnallitic beds previously considered subeconomic.

Lithology effects shape

So far, much of our discussion of shapes of solution cavities has assumed that the thick salt targeted for dissolution is relatively homogenous. But halite masses typically contain thinner intercalated layers, composed either of less soluble salts, such as anhydrite or dolomite, or of more soluble salts, such as carnallite or bischofite (as at Veendam). An assumption of target bed homogeneity in solution planning can lead to problems during the leaching process.

With less soluble salt layers intersecting a cavern edge there is a tendency to form unsupported ledges and bevels, which eventually collapse to the floor of the expanding cavity. This can damage the roof in the vicinity of the feeder pipe, break the drill string, or force the operator of a suitably designed well to raise the well pipe off the former cavity floor (snubbing). In the case of more soluble beds, their rapid solution can leave behind blocks of unstable halite, which have a propensity for collapse, or it can lead to cavity shapes that become enlarged in one direction and encroach on the structural integrity of the well design, especially when there are adjacent solution cavities.

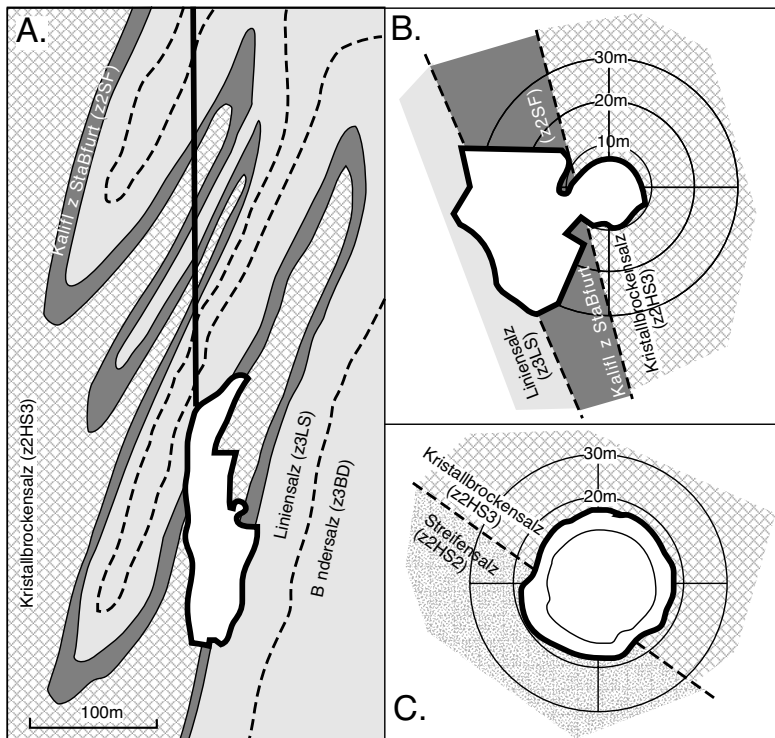

Figure 12.6. Effect of salt geology on cavern shape in diapiric Zechstein Salt. A) Vertical section through a cavity in Zechstein Salt in Germany showing preferential enlargement into potash-rich Kaliflöz Stassfurt horizon (shaded grey). B) Horizontal slice showing strongly asymmetrical shape formed as cavity develops preferentially into the potash facies of the Kaliflöz Stassfurt. C) Horizontal slice in a cavity in two halite lithologies where differences in crystal size and proportion of insolubles create a slight asymmetry that is maintained during growth (after Wilke et al., 2001).

The best studied and modelled examples of lithology variation effecting cavity shape come from the monitored cavities in the Zechstein salts of onshore Germany (Wilke et al., 2001). Of the four major Zechstein formations in the northwest European Zechstein basin, the Staßfurt formation (Zechstein 2) occurs in sufficient thickness (more than 800 m), to flow in to salt pillows and diapirs and so is the most important target unit for solution-leached caverns in this part of Europe (Figures 5.48). The underlying units of Werra formation, along with older salt units of the Rotliegende, are typically inactive and many beds are still attached to the basement. Salt of the overlying Leine formation (Zechstein 3) contains relatively thick beds of anhydrite and dolomite. It has an original thickness of 200 m, lies above the Staßfurt formation and is typically caught up in the Zechstein flows, but it needs the underlying thick halite of the Zechstein 2 to flow and carry it along.

High quality documentation of the internal structures of the German diapirs during potash mining has produced an excel-

lent data set on which to model the likely geological complexity of these Zechstein structures (Figure 6.9a). This work caused the German salt experts, Richter-Bernberg and Horfrichter to conclude that of the Z2 and the Z3 series, the Hauptsalz member of the Staßfurt formation is most suitable for designed-use cavern construction and that the upper part of Staßfurt be avoided where possible due to inherently higher proportions of highly soluble potash and magnesium layers. Likewise the overlying Hauptanhydrit of the Z3 has a propensity to create unstable anhydrite blocks during halite leaching and is not considered suitable for controlled cavity creation. Since their pioneer work, the goal has been to avoid solution mining in this transition zone between Zechstein 2 (Staßfurt Formation) and Zechstein 3 (Leine Formation). Nevertheless several caverns have been leached in these strata, some without any problems, others with intensive preferred leaching directions (Figure 12.6a, b; Wilke et al., 2001).

Structural elements in salt diapirs, largely crystal size and anhydrite distribution patterns in non-potash containing intervals lead to slight changes in cavern development. For this reason a sonar-measured cavern shape can be used to re-interpret a pre-existing geological map. For example, the horizontal section in Figure 12.6c outlines the contact between the Kristallbrockensalz (Z2A-HS3) and the Streifensalz (Z2-HS2), which leaches slightly faster due to its finer halite crystal size and more widely dispersed insolubles. Figure 12.6a, b are examples of preferred leaching along a relatively undisturbed potash seam. It lies several metres above a previously interpreted contact between the Kristallbrockensalz (Z2-HS3) and the Streifensalz (Z2-HS2). This later geological interpretation along the borehole provoked concerns that the potash layer would be intersected as cavern proceeded and led to a modified plan for cavern creation.

Experience in this terrain has shown that where potash layers of the Kaliflöz Staßfurt cross the drill axis a number of times it is not possible to perform a controlled leaching in one step. Rather, the leach design has to be planned as a number of mining steps to avoid a premature achievement of the maximum

allowed cavern diameter in the vicinity of the potash layers (Wilke et al., 2001).

Such a controlled leaching program, tied to lithological variation, is called blanket management and proceeds in a series of back steps as described by Wilke et al. (2001; Figure 12.7):

- Blanket depth is kept below the 50° dipping potassium seam at a distance such that the expanding cavern wall will not touch the seam while it is expanding towards the maximum allowed diameter.
- After reaching 80% of the planned cavern volume below the seam, the blanket is raised to a position slightly above the dipping seam to allow some upwards leaching along its occurrence.
- After some weeks of development of the original borehole, the blanket is pumped down to once again cover the more soluble part of the leached section.
- Continue leaching and continuously add “oversize” amounts to the blanket to be sure the more soluble section is covered.
- Raise the blanket to prepare a new leaching step, before snubbing the pipes. Maintain the blanket in the section of the potassium seam to continue protecting that area.
- Change the injection point depths shortly before the maximum diameter is reached below the seam and while the production point is still sufficiently deep to approach to

the maximum allowable shape in this part of the cavern. All the upper section of the cavern is then allowed to expand toward planned diameter.

In the case of caverns intersecting highly soluble intrasalt beds it is especially important to create “as much as possible” cylindrical caverns below the level of any seam. This approach means that the largest allowable storage volume is created inside the project’s rock mechanical parameters. At the same time the hole shape must be monitored often enough to avoid uncontrolled expansion in the highly soluble (potash) layers.

Well pad design

Some modern brinefields and storage sites are made up of single wells with concentric casings extending into individual caverns. Others consist of several adjacent brine wells extending into a single large cavern. Yet others create multiple caverns off a cluster pad. Brine is withdrawn either through the outer concentric casing in a single well cavern, or through a separate casing in a multiple well cavern. Once active, the size and shape of solution-mined caverns can be measured and controlled with cavern sonar and operating techniques (Crossley, 1997, 1998).

Figure 12.7. Solution mining for a gas storage cavern using a blanket management plan designed to control breakout across an inclined potash bed that cuts the storage cavern twice along its planned length (as shown in 12.6a). The scheme uses a combination of blanket management and sequential snubbing. See text for details (after Wilke et al., 2001).

Single drill pads typically sit atop vertical wells, they offer maximum flexibility in cavern depth range and minimisation of hole damage (Figure 12.8a). Snubbing or pulling pipe is relatively straightforward in a vertical well due to low frictional losses. There is minimal borehole contact and good control on any twisting of the drill string needed to free it if it has become stuck. In all solution wells the initial borehole shape is important as it can strongly influence the shape of the subsequent cavern. Vertical holes suffer minimal borehole asymmetry, which is often created by excessive one-sided hole wear during the drilling phase of an inclined well.

Figure 12.8. Well pad design. A) Single well pads. B) Cluster pad.

Cluster well pads allow multiple caverns to be created beneath a large pad and are a cheaper alternative to single well pads (Figure 12.8b). They have lower infrastructure costs and land area requirements, they need only a single access road, one field pipeline for the brine product, one set of power supply cables to the pad, and the surveillance of only one site. However, compared to single well pads, they suffer from less flexibility in ongoing planning and maintenance. The need for directional drilling and the degree of deviation means it may be difficult or even impossible to turn the leaching strings or the cables after a cluster pad well is activated. Rotating a tubing string is a technique frequently used to free the coupling on the last cemented casing shoe if it has become stuck during production. Once a cluster well group is completed is difficult to later modify production casings, but this can be an ongoing need in some hydrocarbon storage caverns. Cluster wells, which require an S-shaped drilling path, may not be feasible in regions where the targeted salt is shallow. Cluster pads only work if target salt bodies are more than 600-700m below the surface. A rough rule of thumb is that directed drilling can give deviations of some 1.5° every 10 metres of vertical depth.

Casing couplings should be engineered in the early stages of well completion design and are a critical feature in most cluster pad wells, especially those used for hydrocarbon storage. Once operational, it is virtually impossible to turn the leaching string in a deviated well. To compensate, the outermost leaching casing should be fitted with an integral coupling below the casing shoe of the last cemented casing string. That way, couplings do not stick in the vicinity of the casing shoe. When a cavern is to be

used for gas storage the more expensive option of integral couplings should be included in design of the brine withdrawal string. This prevents the sticking of casing in the vicinity of the production-string casing shoe. If a cavity is to be used for gas storage, the brine withdrawal string must be raised under gas pressure as the cavern is first filled with gas.

Deciding on single well pads versus cluster pads influences the design of the casing string and the completion specifications. With a cluster pad the likely depth and homogeneity of the target salt must be known prior to the commencement of drilling. Successful directional drilling of S-shaped wells is best achieved using measurement while drilling (MWD) techniques. MWD techniques are now standard methods in

the oil and gas industry and should perhaps be more widely considered for single well pads. MWD allows the operator to better deal with any unexpected deviations encountered during the drilling of vertical or inclined wells.

Blinding and phase chemistry

Halite is the targeted salt for most solution-mined brinefields and is one of the simplest chemical systems to cope with in the subsurface. Thick halite deposits, if associated with only carbonate and calcium sulphate impurities, are chemically well-behaved during dissolution and their basic brine chemistry was discussed in Chapter 2. But today, there are a growing number of solution mining operations that target salts with more complex dissolution chemistries, such as the borate or sodium carbonate salts, where covering or blinding the cavern surface with a layer of less soluble salts is a strong possibility.

All non-halite targets require a predictive understanding of brine phase chemistry. The intricacies of phase chemistry of brines and salts is largely outside the evaporite focus of this book and a detailed consideration of the various precipitation outcomes requires a book in its own right (see Usdowski and Dietzel, 1998). To illustrate what is possible we will look at some of the complexities and possible problems using current understanding of simple phase equilibria and dissolution kinetics for trona (after Haynes, 1997). Kerr-McGee currently solution mines soda ash at Trona, California and until recently

American Soda operated a directionally drilled solution mine facility for a nahcolite target bed in Colorado.

Phase chemistry - trona solution mining

The ternary phase equilibria of the sodium carbonate system $\text{Na}_2\text{CO}_3\text{-NaHCO}_3\text{-H}_2\text{O}$ is temperature dependant (Haynes, 1997 see also Figure 2.13). When trona is dissolved in pure water it follows the dissolution path A-A' (Figure 12.9a). If the system is at 40°C, an undersaturated brine following the trona dissolution path will encounter the 40°C isotherm at X. Further trona dissolution means the brine is now supersaturated with respect to nahcolite. At some point this mineral begins to drop out of solution, while the brine follows the path X-Y. At Y, solid nahcolite, solid trona and a brine liquor corresponding to point Y (17% Na_2CO_3 and 5.6% NaHCO_3) are all in equilibrium. A similar precipitation sequence will occur at other temperatures from 25° to 87°C, showing that sodium carbonate solubility doesn't change much over this range, while the wt% of bicarbonate doubles in the residual brine (Y to Z). Wagscheiderite forms above 87°C (Figure 12.9b). The formation of the less soluble nahcolite is the reason many early field tests attempting to solution mine trona mention "blinding" of the dissolution surface whereby a coat of nahcolite forms atop the dissolving trona, slowing or preventing further dissolution.

"Blinding" problems can be avoided if temperatures for brine extraction are kept high or if the feed solvent is not pure water but a solution of Na_2CO_3 . The effect of high temperature can be seen as a byproduct of shale-oil recovery experiments conducted by Shell Oil in the Piceance Creek Basin. In 1970-

72, the Company experimented with warm water and steam injection in an attempt to recover oil from nahcolite-bearing oil shales of the Parachute Creek Member on a 10-acre site in Rio Blanco County, Piceance Basin Colorado. In addition to the expected oil, Ireson (1990) reported that large amounts of sodium carbonate brine were co-produced at higher recovered brine temperatures (Figure 12.10).

In 1990, solution mining of Boies nahcolite bed began near Rifle, Colorado. Where mined, the Boies bed is about 7.6 m (25 feet) thick and at a depth of 610 m (2,000 feet; Day, 1974). Such a thin target bed means solution mining is most efficient if it involves directional drilling. A vertical hole is sunk to a hundred metres or so above the target bed, the hole is then turned so it enters the target bed at a slight angle and then is drilled horizontally along the base of the bed. Hot water is then injected into the bed to dissolve the nahcolite and form an expanding cavity. Sodium carbonate brine is recovered from another vertical hole drilled into the cavity some hundreds of feet from the injection hole.

Until 2004, American Soda PPL solution mined nahcolite using this hot extraction methods on a lease near Parachute, Colorado and adjacent to White River Nahcolite's property. First, pressurized hot water was injected into bedded nahcolite at depths of some 450 to 600 metres subsurface. Nahcolite was returned to the surface as a highly saturated NaHCO_3 solution. In the first quarter of 2002, the company drilled 26 wells but anticipated that as the solution cavities expanded, production would be maintained using half that number. Idle wells were to be held in reserve to ensure an uninterrupted source of feed

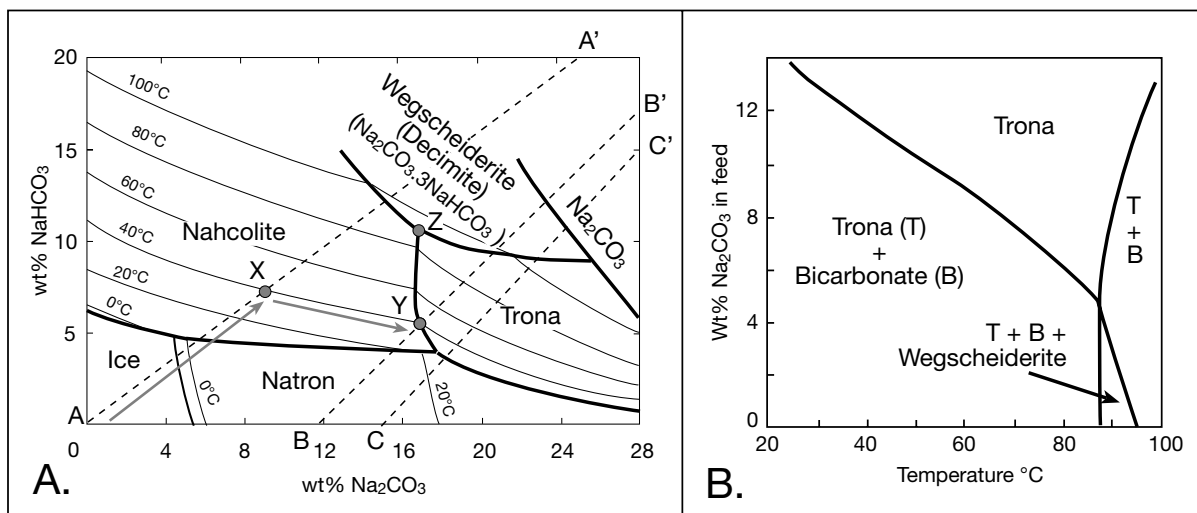

Figure 12.9. Trona stability (after Haynes, 1997). A) Stability of major sodium carbonate minerals in the temperature range 0-100°C. B) Stability fields of various precipitates, trona is in excess in all phases.

Figure 12.10. Daily production of sodium bicarbonate from Shell's shale-oil recovery experiment in the Piceance Creek Basin, Colorado (from Ireson, 1990).

brine. At the brinefield plant, CO_2 was stripped from the well liquor ahead of pipeline transport. This created a brine solution more suitable for pipeline transport and also gave a relatively low-cost source of CO_2 . Brine was pumped 70 km (44 miles) from the brinefield to the Parachute Creek processing plant using an insulated, pressurized, closed-loop pipeline. At the plant, the incoming brine passed through crystallisers, was dried and packaged for shipping. Recycled hot water from the processing plant was then piped back to the minesite to leach more nahcolite. The 1,000-acre upper site was the prior location of Unocal's shale oil upgrading plant and much of the former infrastructure was used by American Soda. Unfortunately, the operation was deemed uneconomic and was shut down in late 2004.

Solution mining nahcolite in the Piceance Creek Basin suffers some unusual problems that can be expensive to control (Dyini, 1996). Problems include: 1) Cavern shapes in the Boise must be tightly controlled and regularly monitored as the Boise bed is very close to a natural dissolution surface in the immediate overburden, a breakthrough into this overlying water-bearing leached zone would be detrimental to controlled solution mining in the target bed; 2) The Boise bed actually consists of two nahcolite beds, the lower one is thinner and also contains halite, so exact bed targeting is very important both during directional drilling and in cavity expansion during production; 3) The Boise bed grades laterally into mixed halite and nahcolite toward the basin's chemical depocentre,

accidentally dissolving halite in this region would contaminate brine product with high levels of sodium chloride; 4) Oil shale which overlies the Boise Bed cannot be mined or damaged under current sodium leasing regulations. Given the major part of the known nahcolite resource today occurs as crystalline aggregates scattered through oil shale, it difficult to target mine for soda ash alone. Current legislation makes the solution mining of soda ash difficult, if not impossible, over much of the extent of the Boise Bed as it could render parts of the overlying oil shale unsuitable for future in situ leaching or underground mining. Under current legislation, any oil shale that is damaged by solution mining must be stockpiled for future oil recovery.

A possible future method to solution mine trona, not nahcolite, could use an initial feed solvent that contains Na_2CO_3 in solution (Haynes, 1997). For example, a 15 wt% Na_2CO_3 solution proceeds along the line C-C' in Figure 12.9a. This intersects the 40°C isotherm well into the trona stability field and no sodium bicarbonate (nahcolite) will form. The line B-B' separates fields at 40°C where nahcolite and trona are likely precipitates and corresponds to a value of 11.9 wt% Na_2CO_3 on the abscissa. This is the minimum feed solvent composition that will insure that no nahcolite is precipitated during the dissolution process. Critical "excess carbonate lines" were similarly determined by Haynes (1997) at other temperatures and are plotted as the solid phase existence fields of Figure 12.9b. Trona is present in all stability fields as it is the excess phase.

Another way to avoid nahcolite blinding in a trona target bed is to maintain a caustic solution for the feed (Haynes, 1997). The phase relationships in Figure 12.9 are well known to the trona industry but their utility is greatly lessened in situations where impurities are present in the dissolving trona or in situations where other reagents need to be introduced to the solvent feed (see Haynes, 1997 for details). Clearly an understanding of the phase equilibria and temperature susceptibility of any targeted salt system is fundamental to any successful solution mining operation.

Cavern Usage	Product stored	Distribution and specifications	Operational mechanism
Hydrocarbons	Liquid hydrocarbons- Crude oil, distillate, naphtha, etc	More than 16 storage sites encompassing more than 190 caverns. Largest volume stored in USA (SPR), storage also in France, Mexico and Germany.	Due to reduced compressibility but relatively low density of product and immiscibility with water, caverns are operated by a brine compensation mechanism. This requires above ground facility (ponds) for storing excess brine when the caverns are filled with hydrocarbons. Brine compensation enlarges the cavern during each recovery cycle, hence cavern shape must be continually monitored throughout life of facility. Less pressure variation occurs in caverns used for liquid storage compared to gas, so caverns can be much larger for liquid storage (more than 1 million m ³) in a single cavern. Salt creep is less critical for liquid storage compared to gas.
	Liquefied hydrocarbons- LPG, ethylene, ethane	Around 110 storage sites with over 190 caverns. Major sites in Sarnia (Canada) and Mount Belvieu (USA). Sites also in Morocco, France and Germany.	
Compressed air storage	Energy generation via electrical demand-peak shaving	Two plants currently in operation worldwide- Huntorf Germany and Alabama Electric Cooperative, USA.	Air is compressed and stored in a salt cavern using cheap electricity. Then stored air is expanded through a gas turbine to produce high value, peak electricity. Caverns cycle daily.
Waste storage	Industrial waste	Limited number of facilities in operation in USA and Europe, most caverns used to store oil-field wastes or industrial chemicals.	Waste is stored as a "final repository" hence cavern must be emptied prior to filling with pelleted waste (avoids groundwater contamination), or an inert blanket of suitable density must be used to separate waste (pasty consistency) from the brine. Waste is also stored as both "inerted" bulk material and in containers in old salt mines in Germany.
	Nuclear waste	Operational site at WIPP, New Mexico, USA. Waste is isolated by plugs made from a crushed mix of salt and compacted clay.	

Table 12.1. Use of salt caverns as storage facilities (after Grappe, 2000).

Use of Salt Caverns

Less and less the rationale to create a solution mined salt cavern is the production of brine or a particular chemical feedstock. In the past few decades, the number of purpose-built storage caverns, shaped using solution mining techniques, has expanded rapidly and an industry centred on the construction of salt caverns for hydrocarbon and waster storage has evolved and continues to expand (Thoms and Gehle, 2000a, b). Today’s commercial brine producers are also aware of potential storage opportunities, they still use controlled solution mining techniques to produce their required brine feed, but at the same time their ultimate goal is to produce a tight cavern suitable for future hydrocarbon or longterm waste storage (Table 12.1).

Hydrocarbon Storage

Crude oil or unrefined petroleum and light hydrocarbons can be safely stored below ground in liquid form in brine-compensated salt caverns (Table 12.2; Veil et al., 1996; Grappe, 2000; Thoms and Gehle, 2000a). Light hydrocarbons currently stored in salt caverns include propane, butane, ethane, ethylene, and other products extracted by refineries that can be transported and stored as liquids. In recent years natural gas^{12.1} has been stored in salt caverns in increasing volumes, this entails much higher storage pressures and a greater need for pressure integrity in

the access well(s) and couplings compared to liquids storage. Natural gas is a clean burning energy source and has become a prime source of energy worldwide, especially in gas-fired power plants, which now constitute some 25% of gas usage in the United States (Thoms and Gehle, 2000a). Earlier last century natural gas was flared as a oilfield byproduct. By the 1970s it was thought to be in short supply, but it is now known to exist in adequate volumes for the foreseeable future.

As early as 1916 there was a German patent taken out to cover the solution mining of salt caverns for the storage of crude oil and distillates. The earliest oil storage in caverns was in bedded salt in Canada early in World War II. A few years later in 1949 liquefied petroleum gas (LPG) was stored in caverns in bedded Permian salts near Kermit, Texas. Crude oil was stored in salt caverns in England during the “Suez Crisis” in the 1950s. In 1975, the US Congress created the Strategic Petroleum Reserve (SPR) program to provide sufficient petroleum reserves to reduce the impact of interruptions to future oil supplies. The SPR today consists of more than 60 caverns in domal salt bodies across the United States, with a total capacity of 680 million barrels (108 x 10⁶ m³).

^{12.1}Natural gas is a naturally occurring mixture of hydrocarbon gases, principally methane with lesser quantities of ethane, propane, butane, and other gases.

Country	Light Hydrocarbons	Crude Oil	Natural Gas
Canada	6,620	-	552,720
Denmark	-	-	xxxx
France	xxxx	-	xxxx
Germany	xxxx	xxxx	5,040
Iraq	xxxx	-	-
Mexico	-	1,500	-
Morocco	xxxx	-	-
Poland	-	-	143,000
Russia	465-750	-	60-180
USA	85,220	102,100	3,423,250

Table 12.2. Hydrocarbon storage (1000 m³) in salt caverns, xxxx indicates storage but volumetric data is not available (after Thoms and Gehle, 2000a).

The first storage of natural gas in a salt cavern was at Unity Saskatchewan in 1959, followed soon after in 1961 in Marysville, Michigan USA. Gas storage caverns were first purpose engineered in 1963 in Saskatchewan, Canada, in bedded Devonian salt at depths of 1,100 metres. This was followed in 1964 by the first purpose-engineered gas cavern in a salt dome at Eminence, Mississippi, at a depth of 1,740-2,040 metres (Figure 12.1). European gas storage in salt domes began in Tersanne, France in 1970 at depths of 1,400-1,500 metres and near Kiel, Germany in 1971 at depths of more than 1,300 metres. Compressed air energy storage (CAES) for peak electricity generation began in 1978 in the Huntorf dome near Hamburg, while in 1991 a second CAES plant was commissioned in the McIntosh salt dome, near Mobile, Alabama.

Hydrocarbons in a salt cavern are stored in what is in effect a pressure vessel, where high pressure fluids are contained within a stiff impervious envelope using a system of pipes and valves that allow fluids to be placed, sealed and periodically withdrawn from the cavity. Salt caverns differ from standard surface storage tanks in the following way (Bérest & Brouard, 2003):

1. The “container” consists of the access well and the cavern proper. Typically, the height (depth) of such a system is ≈1 km. The access well(s) is equipped with several casing strings or tubes, one inside the other, containing fluids (brine and hydrocarbons) at different densities. Even small differences in fluid densities result in very different column weights within the concentric annuli that make up the well. At the same depth, the gap between fluid pressures in adjacent annuli can be several MPa (Figure 12.11). If the concentric fluids accidentally come into direct contact it creates unstable situations where accidents and spills are more likely.

2. The volume of a storage cavern is very large (up to 1,000,000 m³). Even a small pressure drop in the cavern results in a significant change in the volume of the stored product. Liquid compressibility, an often negligible consideration in most above-ground storage tanks, plays a significant role in the safe operation of large underground caverns.

Interactions between these two factors explain most industrial accidents involving hydrocarbons in salt caverns (see case histories).

Storage facilities for liquids (oil, naphtha, kerosene, gasoline) and liquefied hydrocarbons (LPG, ethylene, propylene) are operated by the “brine compensation” method. As brine is injected through a central tube at the bottom of the cavern, an equivalent volume of product is withdrawn through the annular space between the steel cemented casing and the central brine tube. When the cavern is idle, the brine is at atmospheric pressure at ground level. In the brine tube, however, the pressure is in proportion to the depth and specific density of brine, which is around 1200 kg·m⁻³ (Figure 12.11). If the interface between the oil and brine is 1000 m below ground level, the pressure in the brine column at this point is approximately 12 MPa. Brine pressure and product pressure are equal at the interface in the cavern between brine and product. Above this point,

Figure 12.11. Typical pressure regime in a salt cavern used for oil storage. Situation after a blowout is graphed as dashed lines (after Bérest & Brouard, 2002).

the pressure in the product-filled annular space reduces gradually, and more slowly than in brine because the density of the stored product is lower (of the order of 900 kg.m⁻³ for oil, and 500 kg.m⁻³ for LPG).

Thus at any given depth, the pressure in the annular space containing the product is higher than the pressure in the central brine-filled tube. The difference is greatest at ground level, where in a 1 km deep example it is 3 MPa (for oil storage) or 7 MPa (for LPG storage). At the wellhead, the stored product applies pressure to the valve controlling the annular space. If this valve fails, the product is ejected suddenly, and the brine level in the central string drops until a new pressure balance is reached (see West Hackberry blowout in case histories).

For a valve failure in an oil-storage cavern, with an oil density of 900 kg.m⁻³ and with the initial brine oil storage interface at a depth of 1000 m, the top level of the brine in the central tubing will come to rest at a depth of 250 m below the surface (Figure 12.11; Bérest and Brouard, 2003; Bérest et al., 1999). The weights of the brine column and the oil column will then be equal at the interface depth in the cavern. If both fluids were incompressible, the volume of expelled oil following valve failure would be small because the central tube capacity in the access well is only a few tens of litres per metre length of casing. In reality, due to differences in liquid compressibility in oil and brine in the cavern itself, much more oil is expelled. The compressibility factor of brine is $B_b = 2.7 \times 10^{-4} \text{ MPa}^{-1}$; the compressibility factor of the cavern is $B_c = 1.3 \times 10^{-4} \text{ MPa}^{-1}$ (this figure can vary, depending on the elastic properties of rock salt and the cavern shape; see Bérest et al., 1999.); and the compressibility factor of the oil is $\approx B_o = 6 \times 10^{-4} \text{ MPa}^{-1}$. If y is the ratio between the stored-oil volume and the cavern volume, the global compressibility

$$\text{is } B = B_c + y B_o + (1 - y) B_b$$

Figure 12.12. Outline (cross section) of Cavern 5, Regina South cavern field, leached into the bedded salt of the Devonian Winnipegosis Salt, Canada. Shows changes in cavern shape over time (Phase 1 to 5) due to ongoing brine compensation (after Crossley, 1998).

Following the wellhead valve failure, the pressure of the entire body of stored fluids (oil and brine) will be reduced by $\Delta P = 3 \text{ MPa}$ (in a 1 km deep example). If the cavity contains $V = 500,000 \text{ m}^3$ of oil and very little brine ($y \approx 1$), then, because of the compressibility, the amount ejected will be

$$B.V.\Delta P = (6 \times 10^{-4} \text{ MPa}^{-1} \times 500,000 \text{ m}^3) \times 3 \text{ MPa} = 900 \text{ m}^3.$$

For liquefied product, a limited amount of LPG would first be expelled in liquid form. (However, this amount will be larger than in the case of oil, as the compressibility factor of LPG is larger, $B_p = 3 \times 10^{-3} \text{ MPa}^{-1}$). This liquid would evaporate gradually after running over the ground, and a heavier-than-air gas cloud would form. Accidental ignition of such a gas cloud is likely (see Brenham explosion in case histories).

Brine pumped into a cavern to compensate for displaced product must be less than totally saturated with respect to the encasing salt. This prevents any salt crystallising in the access casing, but it also leaches salt from the cavern wall. Regular product cycling using brine compensation increases the size of a salt cavern. Caverns used by oil storage companies in North America typically increase in size by about 1 to 2 percent a year. Some of the older caverns in the USA and Canada are now twice as large as when they were first filled (Figures 12.12, 12.13).

Figure 12.13. Outline (cross section) as of 1993 of Cavern 5, Regina South, leached into the bedded salt of the Devonian Winnipegosis Salt, Canada. It is one of a number used for brine-compensated gas storage. Changes in floor level show how its shape has changed since 1984 (after Crossley, 1998).

Unfettered enlargement of a storage cavern can evolve into a stability problem as the retreating salt roof and walls are increasingly susceptible to sloughing, caving, fusion and associated damage to the long casing string. Cavern expansion has led to industrial accidents at some storage facilities and during the 1980s emphasized the need for better legislative definitions of safe storage and cavern life in the USA (see Mineola fire in case histories). The worst case expansion scenario is total roof failure and the formation of a sinkhole connecting the surface to the underlying storage cavern. This is highly unlikely in modern, well maintained and monitored storage facilities around the developed world. The recognition of such a possibility required the complete drainage of the former SPR facility on Weeks Island, Louisiana (see case histories).

Natural gas storage caverns operate under much higher pressures than those storing liquid hydrocarbons. Internal pressure not brine compensation cycles the stored product. Purpose-designed salt caverns are ideal for the storage of natural gas, especially when excavated in salt domes. They are stable and will not disintergrate in an explosion. They are safe and out of sight and so can be located near demand centres. They act as huge pressurised cavities with low gas cushion^{12.2} requirements of around 33% of the total storage volume. Unlike other gas storage facilities above and below ground, a salt cavern also offers very high deliverability and rapid product cycling.

^{12.2}Cushion gas is the volume of gas needed to fill a cavern to where the gas pressure is sufficient to supply a significant flow of gas to the surface.

Caverns deal readily with peak demand, gas shaving and any rapid demand fluctuations. Operators can change from injection to withdrawal in 15 minutes and back to injection in 30 minutes.

The main disadvantage to natural gas storage in a solution cavern is the relatively high cost of construction compared to other forms of underground storage (e.g. using depleted oil and gas fields or suitable aquifers). But purpose-built salt cavity facilities are consistently safer and cleaner than all other types of storage. As an example of cost, consider the purpose built “Big Hill” facility in Texas; completed in 1992, it

is a 14.3 million cubic metre, solution-mined cavity operated under the U.S. Petroleum Reserve. The leaching cost (in 1992 dollars) was \approx \$1.80 per cubic metre of salt excavated, and the total cost of the project (including land acquisition, design, site development, pipeline development, drilling, hydrocarbon interfaces, etc.) was \$21.80 per cubic metre. Part of the higher cost for salt caverns reflects the need for controlled circulation and safe disposal of large volumes of cycled water required during the construction stage. But construction and maintenance costs are low compared with above ground storage facilities, which also suffer from much lower cycling rates, storage volumes, a higher likelihood of catastrophic damage during an accident and a need for higher gas cushions.

Life expectancy of a storage cavern may be as little as forty years for existing caverns made with older solution leach technologies, or a century or more in purpose-engineered facilities constructed with current technologies. Deep caverns in thicker relatively homogenous salt bodies (as typifies many salt domes) are the safest hydrocarbon storage facilities currently known for natural gas and liquids.

Waste Disposal

Salt caverns can be used for the safe disposal of various types of hazardous waste (Table 12.1; Grappe, 2000; Dusseault and Davidson, 1999). Until recently, the major users of solution caverns as waste repositories were within the same salt-based and hydrocarbon-based industries that generated the cavities.

Nonradioactive waste disposal

Since 1959, alkali wastes from local “soda ash” production has been pumped back into “worked out” solution caverns of the Holford brinefield, located some 30 km south of Manchester, England. The Holford brinefield operator is authorised to dispose of 200 tons per day of brine mud solids from the purification of crude brine, and 250 tons per day of alkali wastes from local soda ash production. In addition, the operator is authorised to dispose of organic residues from the production of perchloroethylene, trichloroethylene, and other related chlorohydrocarbons into specially designated caverns that contain alkaline material designed to neutralise any free acid in the wastes. Brine displaced from the caverns by the emplacement of solids is used to slurry additional solids back to the caverns. The US salt mining industry also disposes of impurities generated during above-ground brine purification processes into salt caverns. Wassman (1983) reported that the Dutch pumped wastes from a brine purification plant in to a nearby salt cavern. Concentrated magnesium chloride brine has also been stored in caverns in the Netherlands. In Mexico, sulphate purged from salt evaporators is being disposed of in salt caverns.

In addition to brine wastes, salt caverns are now also used to dispose of oilfield wastes. The state of Texas recently legislated that six salt caverns can be used for the disposal of nonhazardous oilfield waste and one cavern for the disposal of naturally occurring radioactive waste. The states of Louisiana and New Mexico are developing similar legislation. Canada has recently authorised disposal of oil field wastes into several caverns near Edmonton and Unity, Saskatchewan. Oil field products slated for disposal in salt caverns include; used drilling fluids, drill cuttings, completion and stimulation waste, produced sand, tank bottoms, and soil contaminated by crude oil or produced water.

Disposal caverns used in hydrocarbon waste disposal act like large oil/water/solids separators. The solids in the incoming waste settle to the bottom of the cavern while the lighter oils and hydrocarbons rise to the top of the cavern, where they can be removed. Incoming waste displaces clean brine, which is either sold as a product or disposed of. Cavern pressure integrity in a cavern to be put to such a use should be defined, tested and access controlled before the cavern is filled with oil field waste. It should be regularly monitored throughout the waste emplacement cycle, and optimally, for some period of time after waste emplacement has ended and before the cavern is finally sealed.

The main concern in any waste liquid storage is what will be the longterm response of the cavern once it is filled. Will it maintain its integrity for hundreds or even thousands of years? In a detailed study of rock property responses based on more than a decade of detailed rock mechanics studies in the laboratory, in the field and in abandoned salt cavities, Bérest and Brouard (2001) concluded that storing hazardous waste in salt caverns is an appealing solution when the toxicity of the waste vanishes after a few decades or centuries.

A suitable selection of cavern fluid pressure in the storage cavity will prevent too fast a convergence rate and allow a small amount of rock-mass fluid flow to be directed toward the cavern, preventing any fluid seepage from the cavern. Bérest and Brouard (2001) recommend that such storage facilities be shallower than 1000m to minimise the effects of creep and published cavern convergence curves for both a brine and a fuel-oil support medium (Figure 12.14). As is to be expected, cavern convergence or creep rates are much higher when less dense fuel oil rather than brine is the support medium in the cavern.

Radioactive waste

Radioactive waste disposal in salt caverns is much more problematic as toxicity can remain for millennia and stability must be maintained across such timeframes. Such timelengths include the possible to and fro of icesheets over much of North America and Europe. A key question to be resolved is whether medium and high level waste should be stored above or below the watertable.

Mainland Europe has adopted rigorous technical regulations for hazardous waste management. Germany, for example, requires that all waste, which cannot be stored for extended periods above ground without posing a serious threat to the biosphere, even after undergoing treatment, should be stored underground in suitable geologic formations. In the early 1960s the German Federal Government (former West Germany) decided that radioactive waste is to be stored exclusively in deep geological formations of the continental crust. Whereas the German nuclear industry was to be responsible for waste processing, intermediate disposal and conditioning, the German Government was to be responsible for final disposal. To this end the German Government contracted DBE, a company especially founded for this purpose in 1979, to plan, construct and operate the final radioactive waste repositories of the German Government. Until unification, DBE activities centred on the Gorleben

Figure 12.14 Calculated annual convergence of a sealed salt cavern filled with brine or fuel oil and expressed as percent volume loss (Bérest and Brouard, 2001).

and Asse salt domes and on the Konrad iron ore mine. Up to 1979, the Asse facility was also used as an experimental final repository for low-level wastes. In the following two decades the focus of experimental studies shifted to the purpose-designed Gorleben facility in the Gorleben salt dome.

Since March 1999, the WIPP site in New Mexico, USA, has been receiving radioactive waste for storage. This is a purpose-built salt cavern constructed by conventional mining techniques in bedded salt, not by solution mining. Like an unpressurized solution cavern, it is subject to the same creep, closure, temperature and pressure considerations and its depth of some 500 m below the surface places it in a depth range where karst penetration and lateral discontinuities including upward stoping chimneys are possible, if highly unlikely, in the next few hundred millennia. At this stage no salt solution cavern is used for nuclear waste storage in the USA, because of a legislated requirement for reversibility (Grappe, 2000). Unfortunately in some ways, much of the research effort by the DOE in the USA has focused on the relatively shallow WIPP site in a region of chimneying and deep subsalt artesian circulation and not on the development of deep purpose-built storage caverns in diapiric salt. Then again, no-one wants a radiogenic waste storage facility in the much more highly populated Gulf of Mexico rim.

In the context of the ability of diapiric salt caverns to safely store nuclear waste in a cavern space with adequate confinement and salt cover it's worthwhile looking at the response of salt caverns to nuclear detonations (Thoms and Gehle, 2000a).

Two 5-kiloton devices were detonated in salt as events within the “Ploughshare” and “Project Dribble” test programs. The event “Gnome” of Ploughshare took place in 1961 in bedded salt near Carlsbad, New Mexico, and the event “Salmon” of Project Dribble occurred in 1964 in the Tatum Dome near Hattiesburg, Mississippi. Three additional events involving explosions of natural gas were performed in the cavity in the Tatum salt stock first created by the Salmon event. The salt stock completely contained all the blasts and the original cavern was only enlarged by 17 metres (55 feet) by the original nuclear explosion. To date no leakage of radioactivity has been reported atop the Tatum dome. Salt domes maintain seal integrity even when subject to the rigours of nuclear explosions within the cavern!

The suitability of purpose-built caverns deep in salt domes for the disposal of hazardous chemical and even low level nuclear wastes has been recognised by governments and companies worldwide, but applications to construct such waste disposal facilities have also raised such strong public objections that few permissions have been given anywhere in the developed world. As that famous German, Chancellor Bismarck, once said, “When a man says he approves of something in principle, it means he hasn't the slightest intention of putting it into practice.”

Problems in salt mines, well-bores and storage facilities

Dissolution and collapse of near-surface and at-surface salt is a natural and ongoing process. When such salt bodies are penetrated by drilling or parts of the salt mass are extracted in a poorly supervised fashion, the resulting disturbance can speed up natural solution and collapse, sometimes with unexpected environmental consequences (Table 12.3). In this context it is of interest to quote part of the introduction in a paper by Zuber et al. (2000) dealing with flooding and collapse events in Polish salt mines.

Location	Timing and size	Explanations & implications	Reference
Ocele Mari Brinefield, Romania	Partial collapse of the roof of a much larger solution cavern occurred on 12 September 2001, it formed a large collapse crater and forced a brine flood down a nearby valley. Subsequent collapse and flooding occurred on July 15, 2004.	Poorly monitored salt leaching under the former Soviet regime between 1970 and 1993 created a gigantic cavern as salt pillars separating adjoining caverns were inadvertently dissolved and the cavern roof migrated toward the surface. The resulting cavern was filled with 4 million cubic metres of brine and was more than 350 metres across. It broke through to the surface at its northern end in 2001, with further collapse in 2004.	von Tryller, 2002
Ground subsidence in brinefields near Krakow, Poland (Lezkowice/Barycz brinefields)	At the Barycz brinefield, 33 sinkholes up to 27 metres wide and 27 metres deep appeared between 1923 and 1993, the region is subject to numerous landslides.	A large deep sinkhole which was formed between 1984 and 1986 above the Lezkowice brinefield. Pollution of the ground-water system via poorly managed wells and broken pipes allowed high salinity waters to reach the nearby Raba River. In 1983 the river salinity reached 206 mg/l.	Garlicki, 1993 Zuber et al., 2000
Collapse at Compagnie des Salins Gellenoncourt saltworks near Lorraine, France	On March 4, 1998, a sinkhole more than 50 m across and 40 m deep formed atop the SG4 and SG5 brinefield caverns, France. It was an induced collapse.	The SG4 and SG5 caverns, drilled in 1967, unexpectedly joined in 1971. By 1982 the salt cushion in the roof had dissolved out putting the cavity roof in direct contact with a 25m thick marl. In October 1992 the marls broke free, exposing a large section of the cavity roof to direct contact with the brittle Dolomite de Beaumont. Collapse was induced by enlarging the cavity by injecting 300,000 m ³ of fresh water.	Buffet, 1998
Cargill saltworks collapse, near Hutchinson, Kansas	Collapse started on October 21, 1974. Within 4 hours the crater was 60 metres across and after 3 days had created a circular depression some 90 metres in diameter and nearly 15 metres deep.	Uncontrolled brine extraction since 1888 certainly contributed to the Cargill collapse. Post-mortem analyses showed that several warning signs, especially an enlarging bowl of subsidence, had been noted, but ignored. After the collapse the brine field and the loss of part of the saltworks infrastructure the brinefield was abandoned.	Walters, 1978 Hendron and Lenzini, 1983 Dyini, 1986
Brinefield sinkholes at Windsor, Ontario and Point Hennepin, Michigan	On February 19, 1954, near Windsor, a water filled depression some 120 - 150 metres across and up to 7.5 metres deep formed within a few hours, destroying much of the surface plant. On January 9, 1971 at Point Hennepin the first collapse crater formed, after a few months it stabilized with a diameter of 65 metres. A second crater developed in April and May 1971 measuring some 120 metres across, with a depth of 35 metres.	The similarity in the geology of the Windsor and the Detroit sites as well as the rapidity of the collapse, along with the size and steepness of the collapse craters, led Nieto and Russell, (1985) to question the collapse mechanism of Terzaghi (1971). They argued his notion of steep upward caving from more than 300 to 400 metres below the surface and centred on solution caverns in the Salina Salt could not explain the craters or their subsidence history. Instead, they proposed a collapse scenario based on a loss of cohesion in pressurised Sylvania sandstone and in the presence of water.	Terzaghi, 1971; Nieto and Russell, 1984
Retsof Mine collapse, New York State	Loss of the Retsof Salt Mine began with a magnitude 3.6 earthquake in the early morning hours of March 12, 1994. Two large, circular collapse features some 100 metres apart developed a month apart at the land surface above two collapsed mine rooms.	Catastrophic breakdown driven by collapse of a small pillar and panel section in the mine some 340 metres below the surface. Collapse of the "back" was accompanied by an initial inrush of brine and gas (methane) into the mine and by a sustained inflow of water via the overlying fractured limestone. A month later on April 18 an adjacent mine room collapsed. \	Gowan and Trader, 1999; Payment, 2000

Table 12.3. Events associated with brinefields (see text for full description).

“Catastrophic inflows to salt mines, though quite frequent, are seldom described in literature and consequently students of mining and mine managers remain, to a high degree, ignorant in this respect. Contrary to common opinion, inflows are seldom caused by unavoidable forces of nature. Though some errors were unavoidable in the past, modern geophysical methods are, most probably, quite sufficient to solve the majority of problems (e.g., to determine a close presence of the salt bound-

ary). Detailed study of the recent catastrophic floods, which happened in Polish salt mines, shows that they usually occur, or have strong negative impacts, due to human errors. Most probably similar human errors caused catastrophic inflows to salt mines in other countries. It seems that a knowledge of the real history of catastrophes, better education of mine engineers and the application of modern geophysical methods could lead to the reduction of floods in salt mines.”

Case histories: caving brinefields

Abandoned brine fields can be areas with major environmental problems as many old wells are undocumented and unmonitored. Like areas of natural solution collapse (e.g. Figure 7.42), they can become zones of catastrophic ground failure, this is especially problematic if located near cities or towns (Table 12.3). Some of the most outstanding examples of how not to solution mine a resource and how not to control ground subsidence effects are to be found in east European countries that are still trying to deal with the environmental outcomes of being former satellite states of the Soviet Union.

Ocnele Mari Brinefield, Romania

SALROM, a government-owned company, solution mines Badenian (Miocene) halite in the Valcea Prefecture of Romania (Figure 12.15a). Production from Field 2 was shut down on March 5 1991 when earth vibrations were noted by SALROM workers. A subsequent sonar survey showed that poorly monitored brinefield leaching between 1971 and 1991 had created a gigantic merged cavern as salt pillars separating adjoining caverns were inadvertently dissolved (Figure 12.15b); the upper parts of the captive boreholes 363, 364, 365, 366, 367 and 369 had merged into a common cavern. The cavern was filled with some 4.5 million cubic metres of brine, was less than a hundred metres below the landsurface, was more than 350 metres across and was overlain by loosely consolidated sandy marls (von Tryller, 2002; Zamfirescu et al., 2003). The cavern was overlain by a bowl of subsidence and, even though mining operations in the region of the cavern completely

stopped in 1993, the ground above continued to subside to a maximum of 2.2 metres prior to the September 2001 collapse. In the period 1993 - 2001 the cavern continued to enlarge and the northern part of the cavity expanded by some 25-35 m (see inset in Figure 12.15b showing sonar surveys 1995 -2001).

The 1993 sonic survey of the cavern showed it was so large and shallow that its roof must ultimately collapse, predicting when was the unknown. The fear was that if it collapsed cata-

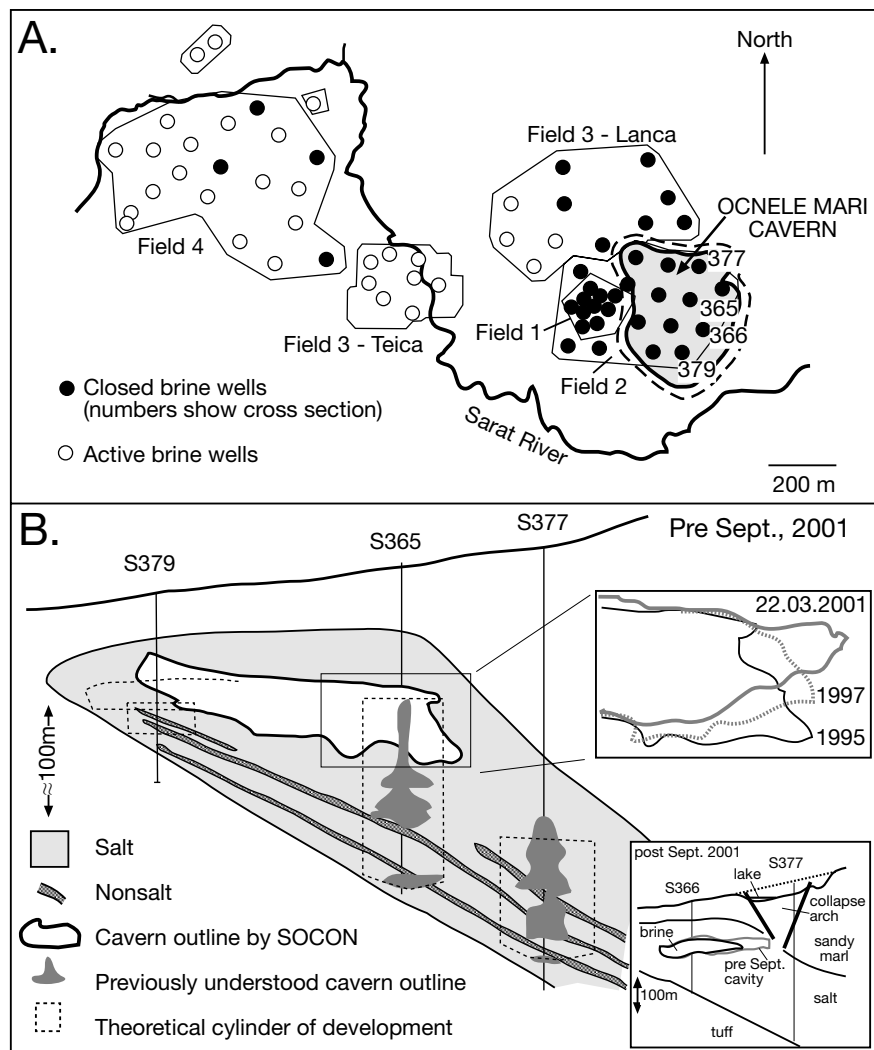

Figure 12.15. Ocnele Mari brinefield, Romania. A) Locality map showing various active and inactive brinefields as well as the likely extent of the large solution cavern defined by SOGON. B) Interpretive cross section showing locality of cavern and proximity to land surface, the inset shows sonar defined outlines and the upward migration of the cavern from 1995 to 2001. This ultimately led to a partial collapse of the cavern roof in this zone on September 12, 2001, as seen in lower inset (redrafted from SMRI data files at <http://www.solutionmining.org>; von Tryller, 2002; Zamfirescu et al., 2003).

strophically, it could release a flood of at least a million cubic metres of brine. Brine could be released either over several hours (least damaging scenario) or instantly forming a wave of escaping water several metres high that would flood the nearby Sarat River valley for many kilometres downstream. There were 22 homes on top of the cavern that would be immediately affected; also at risk were the hundreds and perhaps thousands of residents in the area of the saltworks and river valley below, as well as the local ecology and the civil/industrial infrastructure. Ongoing brine delivery from other nearby operational SALROM caverns to the large Olchem and Govora chemical plants would also be disrupted. When collapse did ultimately occur (twice in the period 2001 - 2004), each episode took place over a number of hours and so a catastrophic wave of water did not eventuate.

According to SMRI (Solution Mining Research Institute) there was no good engineering solution to prevent the Ocele cavern roof from collapsing. Prior to collapse, brine in the cavern exerted pressure against the roof helping to hold it up; removing even a small amount of brine would remove hydraulic pressure that could possibly trigger a catastrophic collapse. Nor was it practical to fill the cavern with sand and industrial wastes as suggested by the Romanian government. It would take too long and it was unsafe to place men and equipment on top of the still expanding cavern. Even if it could be done, only the areas directly below the injection wells would be filled. The best solution was to construct a dam as close to the cavern as possible, and then perhaps trigger a controlled collapse by pumping out the cavern brine.

A partial collapse of the cavern roof atop well 377 occurred on 12 September of 2001, the ensuing brine flood killed a child and injured an older man. The collapse began at 7 pm with brine spilling out of wells 365 and 367. Southward of well 377 a collapse cone some 10 metres across started to form and fill with brine. The cone continued to expand and fill with water until its southern lip was breached. Water spilled out of the cone and down the hill slope. The flow rate of the expelled flow reached a maximum of 17 m³/sec at 3 am on September 13th, with flow continuously exceeding 10 m³/sec for a period of more than 6 hours around that time. By 7 am flow was down to 4-5 m³/sec and by 7 pm, 24 hours after the flow began the flow rate was 0.4-0.5 m³/sec. Some 24 hours after the onset, roof collapse had formed a water-filled lake with an area of 2.4 ha (see inset in Figure 12.15b; Zamfirescu et al., 2003).

A second roof collapse occurred on July 13, 2004. Realitatea Romaneasca, Romania, reported that ground collapse occurred

on 9:30 pm July 13, 2004, possibly triggered by heavy, recent rains. The wellhead of bore 365 was destroyed in this collapse and many other well heads in Field 2 had been destroyed by ongoing subsidence in the period 2001-2004. This collapse was the culmination of a series of collapse-related events that began on Monday July 11. It was planned that a purpose-built earthen dam would contain the brine flood. But when the roof fall occurred at 9:30 pm, the dam was breached 30 minutes later by some 250,000 m³ of salt water. Flow rate through the breach reached a maximum of 6 m³/sec. Collapse did not occur until just after local authorities had evacuated people from 50 homes in the area around the cavern. Most of the brine forced out by the roof collapse escaped into the Sarat (Olt) River. The government attempted to dilute the effects of this flush of salt water by releasing fresh water into the river from nearby dams. Environmental effects of this brine flush on the river ecology are still being evaluated, but fortunately, unlike the 2001 event, there was no loss of life.

Subsidence in Old Belvedere Spinello, Italy

The Old Belvedere Spinello brinefield is located near Crotona, in southern Italy. It was originally operated via brine wells interconnected by hydraulic fractures. This area, now referred to as the "Old Mine," exhibits subsidence effects ranging from sinkholes to bowl subsidence and landslides. The brinefield lies in a valley atop layered salt. The character of the salt varies down the valley from a modestly deformed bi-crested salt anticline in the "Old Mine" area to a laterally compressed and thickened domelike anticline lower down the valley. Brinefield mining began over the less deformed salt in the upper valley and gradually moved down the valley toward thicker more deformed salt. Relatively strong formations overlie the less deformed salt of the "Old Mine" brinefield area. Over the more recently mined domelike salt target, located further down the valley, these brittle formations are replaced by relatively weak overburden strata. For a short distance on one side of the valley near the "Old Mine" the crest of the salt anticline lies against a fault running beneath the toe of a steep hill. From this point the top of the salt dips steeply in the direction of brine wells located some distance away in the valley axis.

A sinkhole first appeared in the vicinity of brining operations in the less deformed salt at the "Old Mine" end of the brinefield. Another sinkhole soon appeared updip beneath the toe of the previously mentioned steep hill and more than 360 m from the nearest active brine well of the "Old Mine" area. Salt solutioning had apparently migrated updip within the salt formation for a considerable distance from the brine wells to

where it had dissolved a large cavity at the toe of the hill. The sinkhole that formed over the uphill cavity destroyed the strength of the soils at the toe of the nearby hill. A landslide plunged into the sinkhole, driving brine from the sinkhole cavity as a destructive downstream flood.

Since then no sinkholes have appeared in the more recently mined end of the brinefield, with its weak overburden materials. Instead, gradual bowl subsidence dominates this part of the field. Solution mining is now carried out in what is called the new Belvedere Spinello Brinefield using a number of single well, sonar monitored salt caverns (Guarascio, et al., 1995).

Brinefield and mine collapse near Krakow, Poland

This former salt mining region, centred on the Wieliczka Mine, lies close to Krakow in south of Poland, and has been mined since the 13th century. There are two main problem sites, Barycz and Lezkowice. The Lezkowice site is near Krakow and lies about 10 km east of Wieliczka (Figure 12.16). The Barycz site, located to the immediate west of Wieliczka Mine, covers an area of one square kilometre, and is two kilometres wide at its maximum extent. It was first solution mined in 1923. Miocene salt at Barycz is relatively flat lying, around 30 metres thick, and some 230 to 280 metres below the land surface. Salt at Lezkowice is steeply dipping and can be found as patchy subcrops as shallow as 40 metres below the surface. Salt was solution mined at Lezkowice from the nearsurface to depths of more than 450 metres. Both sites are covered by

15-20 metres of unconsolidated Quaternary sediments (sands, gravels and peats).

At its most active the Barycz brinefield consisted of more than 900 solution wells about 50 metres apart. In 1993 after 70 years of exploitation the field had produced some 10 million tons of salt, equivalent to a unit 3 metres thick across the whole of the exploited area. There was significant surface subsidence in the brinefield from the onset of solution mining, with ground displacements of 10 to 30 cm noted between 1926 and 1934. Thirty three sinkholes up to 27 metres wide and 27 metres deep appeared in the brinefield between 1923 and 1993, and the region was subject to numerous landslides. By 1993 the field was exhausted and the landsurface was pockmarked by stagnant brine-filled subsidence cones and sinkholes, often centred on abandoned wells. As the land is considered unusable for agriculture it is currently used as a waste dump by the nearby town of Krakow ($\approx 800,000$ inhabitants).

Obvious depletion of the Barycz brinefield meant that in order to maintain a feedstock for nearby chemical industries the saltworks needed to shift to the Lezkowice site in 1968. There the brinefield wells were sited 35 metres apart with a 300 m wide "exclusion" zone between the brinefield and the nearby Raba River. Brine well production was supposed to be limited to 8-10 years and the cavities monitored by sonar to prevent the problems experienced at Barycz. Exploitation actually continued unabated for 20 years until January 1988 when the brinefield was finally shutdown. Overexploitation led to the fusion of

numerous cavities, the unfettered escape of brine into the environment and the nearby Raba River. Some 5.1 million tons of salt were extracted over the 20 year life of the brinefield (corresponds to 17 million cubic meters of brine product). In an attempt to prevent further ground collapse, loam and ash waste from a nearby power station were injected into some of the cavities. Even taking into account the re-injection of some 1.10 million cubic meters of waste, the cumulative volume of the cavities remaining beneath the Lezkowice site in 1990 was of the order of 1.45 million cubic metres.

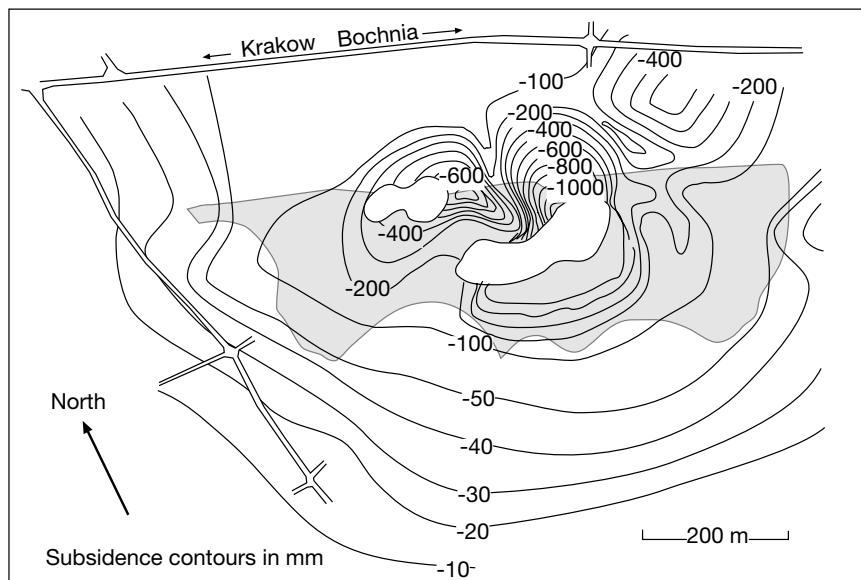

Figure 12.16. Subsidence at the Lezkowice brinefield site between 1974 and 1988, contours in mm. Area of the former brinefield is shaded grey (after Garlicki 1993).

Subsidence measurements were made at Lezkowice from the beginning of the exploitation in 1968. Measurements carried out between 1974 and 1988 show two principal zones where subsidence exceeds 80 cm (Figure 12.16) Garlicki, 1993). The most significant area of subsidence lies at the centre of the brinefield, but extends beyond the exploited zone, in particular in the northeast. Subsidence reaches 1.20 meters in the brinefield centre. The second major subsidence zone, where subsidence was higher than 80 cm, is located in the northern part of the brinefield. There is a third zone of subsidence with depressions of more than 50 cm to the east of the former brinefield.

Between August 1988 and June 1991, subsidence increased by 40 cm in the western part, and 80 cm in the central part; sagging in the central part had lengthened along an east-west axis and the depression bowl had migrated 150 metres east. The first large deep (22 m) sinkhole at Lezkowice started to form in 1984, and continued to grow until 1986. After the first few months the sinkhole was filled by the brinefield operator with more than 250,000 m³ of sandy and argillaceous waste materials. Another large sinkhole formed nearby between 1988 and 1989, but it was no more than 3 metres deep. Still more sinkholes appeared between 1988 and 1990 with a total a volume of more than 300,000 m³, all were filled using waste residues.

Garlicki (1993) estimates that the large deep sinkhole, which formed between 1984 and 1986, was a response to the uncontrolled dissolution of a steeply dipping layer of salt that lay no more than a few metres beneath the Quaternary cover. There was significant salinization of the Quaternary aquifer in the region due a combination of brine leakage from poorly maintained pipelines and casings, and the uncontrolled solution flushing of shallow salt. The resulting brine percolated through sands and gravel aquifers and easily breached the “exclusion” zone to reach the River Raba. River salinity reached 206 mg/litre in 1983 but returned to lower levels after the operator drilled drainage sumps.

Unfortunately, although the two areas are separated by a shallow salt ridge, the world heritage Wieliczka Mine with its unique salt sculptures and carvings in the upper levels of the mine, lies less than a few kilometres from the Barycz brinefield. Throughout its history the mine has been subject to flooding and freshwater influx. Even though a dehumidification program for the mine air has now removed the sculptures and carvings in the mine from the endangered sites list, it is in a constant state of possible destruction by flooding (Zuber et al., 2000). Exploited Miocene salt in Wieliczka mine is made up of two intervals: the lower one consists of layered salt which was

strongly tectonically deformed, while the upper interval consists of salty clays with large salt blocks (Figure 12.17). The salt deposit, and the adjacent flysch sediments were overthrust from the south and are relatively well documented by the mining operations. Tertiary-age water-bearing Chodenice beds make up the northern boundary of the deposit and are much less well studied. They consist mainly of clays, slightly cemented sandstones and sandstone conglomerates that were probably strongly fractured during Miocene folding (Figure 12.17). The main water inflow into the mine network occurs along the southern boundary with the Chodenice beds.

Seven centuries of exploitation, beginning in the 13th century, has created more than 2000 chambers with the total volume of about 7.5×10^6 m³ and over 190 km of galleries in nine main levels and several local midlevels. Throughout the 700 years of mine history there were many catastrophic intrusions of water and loose sand, largely caused by a lack of knowledge of the boundary of the salt and the high permeability of adjacent rocks. Zuber et al. (2000) gives a simplified historical record of inflow rates to the mine in m³ day⁻¹ as: 6 in 1381–1819, 31 in 1820–1919, 50 in 1925–1960, 135 in 1960–1971, 500 to 418 in 1972–1991, and about 900 in 1992. In 1991, there were about 260 inflows with very low flow rates and several larger inflows at the fourth, fifth, sixth and seventh mine levels. These large inflows considerably increased the total water inflow to the mine in the last several decades. One of the most catastrophic inflows started in 1992 in the Mina gallery at the fourth level and was so intense that the lower flooded sections of the mine had to be abandoned (Figure 12.17b). Shortly before the First World War that gallery had crossed the salt boundary and stopped 20 m beyond the salt deposit in gypsum and clay cover (Figure 12.17a). After the Second World War, the gallery was not accessible due to rock falls, and slag used to fill in the Dunajewski chamber cut across the Mina gallery. Water was seeping downward through the slag deposit and exiting at the fifth level (Badeni gallery) at a rate of 4–5 litres per minute and TDS of 300 g/l (Zuber et al., 2000). Serious trouble with inflows started during a reconstruction of the Mina gallery aimed at ponding the inflow behind a dam where it could be pumped from the mine. A catastrophic influx began on the night of 13 April 1992 when the flow rate increased to 200–300 litres per minute (290–430 m³ day⁻¹), i.e., nearly equal to the sum of all other inflows to the mine at that time. Pumps then in use were not able to pump it out. In consequence, the gallery was filled nearly to the ceiling with water and mud, but the water drained or was pumped out after a few days. An even more catastrophic flood began on September 13, 1991 and overwhelmed the pumps and the newly constructed

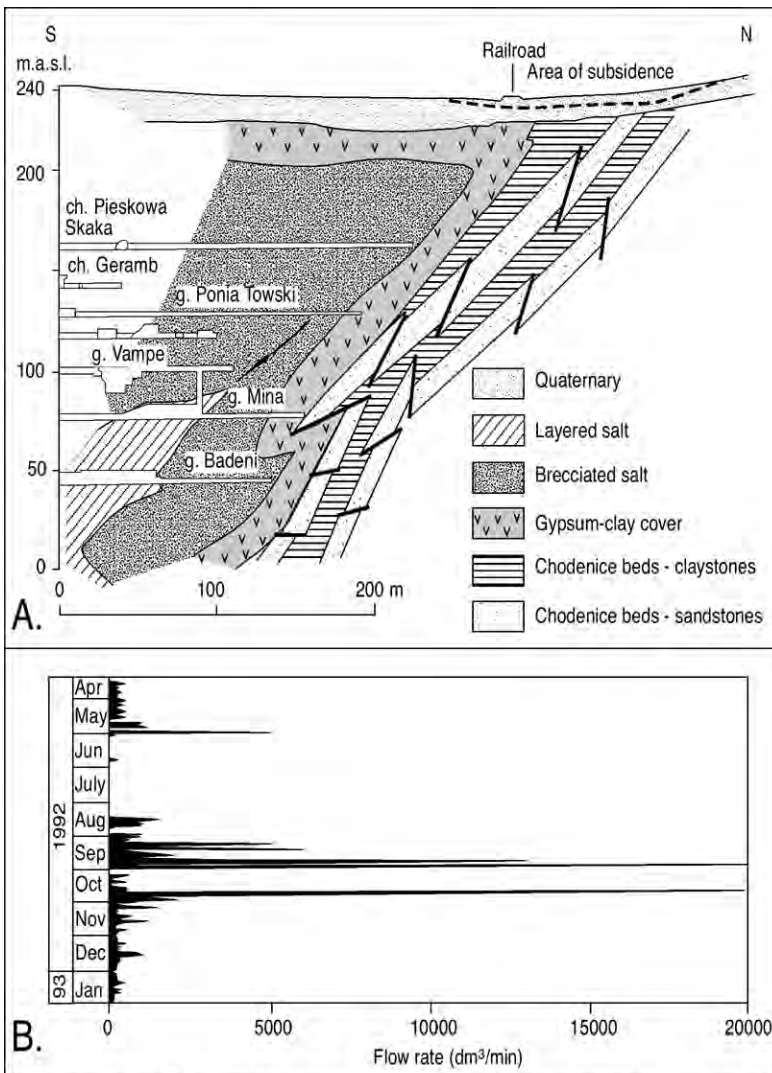

Figure 12.17. A) Wieliczka Mine cross section through the northern boundary in the region of the Mina Gallery. B) Inflow rates into the Mina Gallery during 1992-93 (after Garlicki and Wilk, 1993; Zuber et al., 2000).

dams. Influxes exceeded 10,000 litres per minute. Inflows to the Mina Gallery continued to show a similar pulsing well into 1993 (Figure 12.17b). Operations in the lower levels ceased soon after and the mine today is no longer exploiting solid salt although brine processing still takes place. This processing is expanding the proportion of cavities in the lower levels of the mine and will ultimately destabilise the tourist areas. But if brine is not removed and processed, the resulting rising waters will also enter the tourist levels of the mine.

The pore pressure release created by the flooding drove considerable subsidence at the surface. Walls surrounding a historic

Franciscan monastery partially caved and huge cracks appeared in the walls of the buildings both inside the monastery itself and around it, making some sites structurally unsafe. In October 1992 the surface subsidence in the wake of the successive floods was as deep as 0.5 m.

The pulsed nature of the inflow prior to the final flood argues for more than one water source to the Mina level (Zuber et al., 2000). Initially, the Chodenice beds in the vicinity of the Mina gallery were drained of water, then either waters stored in the Chodenice beds west and east of the Mina gallery were drained, or there was a hydraulic contact established with the sands of the Tertiary Grabowiec beds (Figure 12.17a). The Grabowiec beds are mostly confined aquifers filled with Holocene waters. In any case, the increased influx at the Minas level did not influence the flow rate of other inflows, and the local recharge, especially within the subsidence cone atop the mine, was negligible.

The pulsed character of the measured inflow was probably driven by natural instability of adjacent rocks, and by unsuccessful attempts to stop the inflow. Wash out (suffosion) periods occurred during times with high inflow rates. These were followed by land subsidence, which led to clogging (colmatation) when the flow rates and hydraulic pressures dropped (Zuber et al., 2000). A temporary colmatation lead to an increase of the water table level in the Chodenice beds, this drove an increase in hydraulic head until pressure breakout occurred and the whole cycle repeated.

That the pulsing process is quite complicated is shown by differences in water levels observed in a number of boreholes in the northern region of the mine adjacent to the Mina gallery (Garlicki et al., 1996). In general, when the water pressure builds-up sufficiently, dams, or any other anthropogenic sealing forms in this area of the mine are easily destroyed or moved from their positions because they cannot be anchored in stable rocks. The Chodenice beds are naturally unstable and

additionally deformed and weakened by ongoing exposure to water crossflows. If the exiting water is recharged indirectly through the Grabowiec sands, the inflow rate to the mine can perhaps be reduced, but only if their basal sections are sealed in the region of the contact with the Chodenice beds. If the water comes from the distant parts of the Chodenice beds, the inflow rate can be reduced by pumping in wells installed at distances sufficient to avoid further rock destabilization in the vicinity of the gallery. Undoubtedly, any such operation would be a very expensive undertaking.

When the inflow to the Mina gallery developed to catastrophic dimensions in the early 1990s, the mine management showed a remarkable lack of scientific or engineering sophistication and no understanding of simple hydrological principles. They called on and paid generously for dowsing and witching methods to solve the flooding problem. The dowzers claimed that an underground “river” flows through the mine at the rate of 1.5 m³/s. Following the advice of witches and dowzers, a 100-m-long trail was buried about 1 metre below the ground

surface, it was supposed to stop the inflow of the underground “river” at a depth of 170 m, and to change the “rivers” flow direction upwards (Zuber et al., 2000). Today, the flooding of the lower mine continues, the tourist region of the mine area is still under constant threat of renewed flooding, but the witches and dowzers are happy and counting their spare zlotys.

Induced collapse in the Gellenoncourt saltworks, France

On March 4, 1998, a sinkhole more than 50 m across and 40 m deep formed atop the SG4 and SG5 brinefield caverns in the Gellenoncourt saltworks near Lorraine, France (Figure 12.18; Buffet, 1998). It was an induced collapse designed to prevent a possible uncontrolled future ground collapse. The problem started in 1967 with the beginning of the exploitation of salt layers in the Keuper Fm. In total the Keuper is more than 150 m thick with five salt layers at its base, passing up into variegated and poorly consolidated marls and sandstones and capped by the Dolomite du Beaumont. The top of the

Figure 12.18. Series of chronological panels showing the evolution of the SG4-SG5 cavity in the Gellenoncourt saltworks, France. The larger panel shows the shape and size of the final induced collapse crater (after Buffet, 1998).

salt is some 220 m below the surface and divided into 5 beds numbered 1 to 5 from top to bottom, with the solution mining program designed to leach beds 1 through 3 in the region of SG4 and SG5 caverns (Figure 12.18). Five wells, SG1 to SG5, were joined using hydrofracturing in February 1967. Theoretically the process was designed to leave a substantial salt pillow atop all the cavities and so separate the solution cavities from the overlying marls (Figure 12.18; 1967-1971). The SG4 and SG5 caverns unexpectedly joined in 1971. Brine injection to these two wells was stopped, but crossflowing brines flowing to the producing SG1 well continued to excavate these two caverns. By 1982 the salt cushion in the roof of the SG4-SG5 cavern had completely dissolved away, placing the cavity roof in direct contact with the base of the marls.

From 1982 until October 1992 there was no further upward growth of the cavern roof. Then a 25 m-thick section of the variegated marls in the roof broke free and fell to the cavern floor, leaving a large section of the cavity roof in direct contact

with the brittle Dolomite de Beaumont. This stiff dolomite layer prevented any further immediate collapse of the roof and consequent propagation of the cavity to the surface. But continued growth of the roof span beneath the dolomite would mean a later, larger, perhaps catastrophic collapse. In 1995 the operator tried to induce a controlled collapse by placing a submerged pump in the cavity and pumping out brine to create an exposed upper face. But this didn't work. The next approach was to further enlarge the roof span by injecting 300,000 m³ of freshwater into the cavity. Collapse occurred on March 4, 1998, forming a 50 m wide crater. To protect the surrounding countryside from any brineflood damage a dam was constructed to capture any brine overflow, but in the actual event it was not needed.

Retsof Mine, New York State, USA

The 1994 flooding of the Retsof Mine, New York State USA, took place over a period of weeks. Prior to abandonment, the 24 km² area of workings made it the largest underground salt mine in the USA and the second largest in the world (Figure 12.19). It had been in operation since 1885 and each year it produced a little over 3 million tons of halite. It supplied more than 50% of the total volume of salt used to de-ice roads across the United States.

The eventual loss of the Retsof Salt Mine began in the early morning hours of March 12, 1994 with a magnitude 3.6 earthquake. The quake was caused by the catastrophic breakdown of a small mine pillar and panel section some 340 metres below the surface and was accompanied by surface collapse of an area atop the mine that was some 180 by 180 metres across and 10 metres deep. This all occurred at the southern end of the mine near the town of Cuylerville. A month later on April 18 an adjacent mine room collapsed to form a second collapse crater. The initial March 12 collapse in the mine was accompanied by an inrush of brine and gas (methane) and by a sustained intense inflow of water at rates in excess of 70 m³/min, via the overlying now fractured limestone back (Gowan and Trader, 1999).

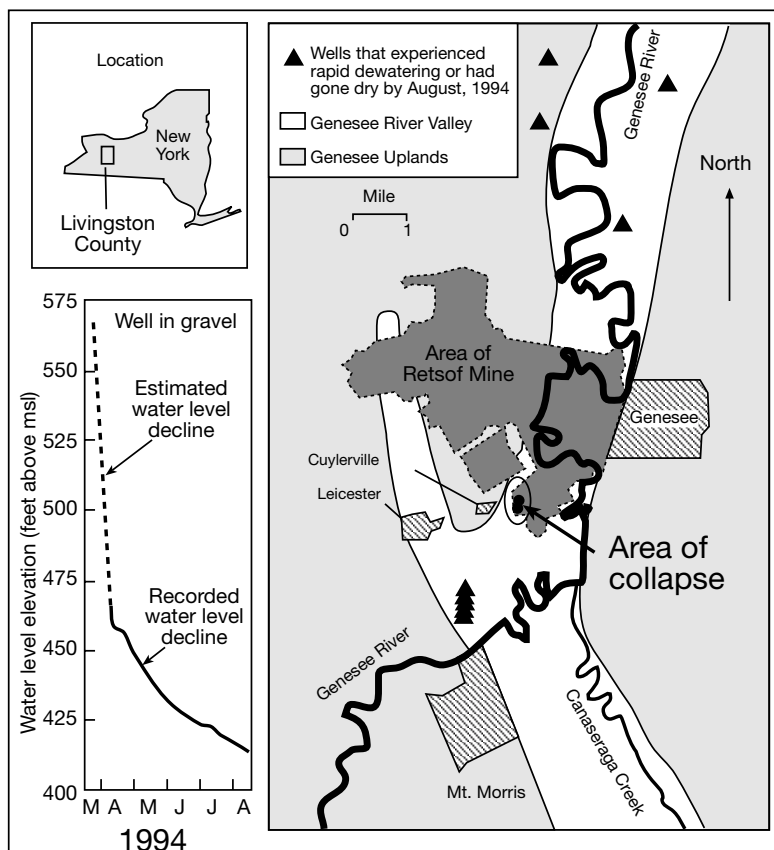

Figure 12.19. Locality plan of the Retsof mine and the area of collapse along with a selected hydrograph from a well in the Genesee River valley (March 12 to August 12 1994; after Tepper et al., 1997).

In a little more than a month, two steep-sided circular collapse features, some 100 metres apart, indented the landscape above the two collapsed mine rooms. The northernmost feature, which was more than 200 metres across, included a central area that was about 60 metres wide and had subsided about 6 to 10 metres. The southernmost feature, which was about 270 metres in diameter, included a central area that was about 200 metres wide and had subsided about 20 metres (Figure 12.19). Fractures extending up from the broken mine back created hydraulic connections between aquifers that previously had been isolated from each and provided new high volume routes for rapid migration of perched groundwaters to the mine level.

Water flooded into the mine at rates that eventually exceeded 60,000 litres per minute and could not be controlled by pumping or in-mine grouting. Within weeks the entire mine was flooded. Associated aquifer drawdown caused inadequate water supply to a number of local wells in the months following the collapse; some dried up (Figure 12.19; Tepper et al., 1997). Aside from the loss of the mine and its effect on the local economy, other adverse effects included abandonment of four homes, damage to other homes (some as much as 1.5 kilometres from the sinkholes), the loss of a major highway and bridge, loss of water wells and prohibition of public access to the collapse area. Land subsidence, possibly related to compaction induced by aquifer drainage to the mine, even occurred near the town of Mt. Morris some 3 miles southwest of the collapse area.

Post-mortem examination of closure data from the two failed mine panels showed an anomalous buildup of fluid pressure above the panels in the period leading up to their collapse. The initial influx of brine and gas following the first collapse coincided with the relief of this excess pressure. Gowan and Trader (1999) demonstrated the existence of pre-collapse pressurized brine cavities and gas pools above the panels and related them to nineteenth-century solution mining operations. They also documented widespread natural gas and brine pools within Unit D of the Syracuse Formation approximately 160 ft above the mined horizon in the Retsof Mine. Such brine accumulations apparently formed long before solution mining began in the valley, driven by the natural circulation and accumulation of meteoric waters along vertical discontinuities, which connected zones of dissolving salt to overlying fresh water aquifers.

Sinkhole problems Cargill saltworks, Kansas

A number of sinkholes appeared in the 1950s and 1970s around brine wells near Hutchinson, Kansas, an area where numerous wells were extracting brine from bedded Permian salts. For

Figure 12.20. Cross section through south sinkhole at the Cargill collapse site showing the fused solution voids in the Permian Hutchinson Salt, which led to catastrophic cavern roof collapse (after Walters, 1978).

example, the Cargill collapse sink near Hutchinson, Kansas, started to form on October 21, 1974. Within 4 hours it was 60 metres across, after 3 days it had created a circular depression some 90 metres across and nearly 15 metres deep. The initial collapse left the tracks of the Missouri-Pacific Railroad spectacularly suspended 6 metres above the water that accumulated in the sinkhole. There was no loss of life at the site.

The Permian Hutchinson salt at this site is about 105 metres thick and occurs at a depth of some 130 metres (Martinez et al., 1998). The salt is overlain by 110 metres of Permian shales, and these, in turn, are covered by about 20 metres of water-saturated, loose Quaternary sands (Figure 12.20). Locations of some of the earliest brine wells in this property are unknown, and the early dissolution methods were not documented (see Hutchinson gas explosion). The sink developed in an area that was part of an active brine field at the time of collapse and would have included both operating and abandoned wells. Embraced within the sinkhole itself was a captive brine well that was drilled in 1908 and plugged and abandoned in 1929.

Earlier uncontrolled brine extraction in the region since 1888 certainly contributed to the Cargill collapse. Post-mortem

analysis showed that several warning signs, especially an enlarging bowl of subsidence, had been noted, but ignored. Post-event drilling revealed a large elongate solution gallery underlay the crater (Dyini, 1986; Hendron and Lenzini, 1983; Walters, 1978). The cavern paralleled a line of brine-producing wells that were hydraulically connected. Prior to collapse the span of the cavern roof was more than 400 metres long and a little less than 90 metres wide. This growing roof span had ultimately exceeded the bridging capacity of overlying Permian shales. Successive overlying rock layers collapsed into the stoping cavity atop the salt, forming an expanding bowl of subsidence at the surface until the uppermost shale layer finally dropped into the water-filled void. At this point, loose water-saturated Quaternary sands quickly sank into the cavity, creating the surface sink. The sand continued to flow until it filled a subsurface chimney some 30 metres in diameter (Figure 12.20).

This, and other nearby sinkholes in the Hutchison region, formed atop breached salt caverns where bedded salt lay at shallow depths in areas with easily broken shaly overburden. As a result of numerous collapses the State of Kansas now requires caverns created by solution wells to be acoustically monitored and a salt roof of at least 12 metres be maintained over captive brine caverns.

Brinefield subsidence, Windsor, Ontario

Subsidence, followed by collapse, destroyed a portion of the suprastructure of an active salt works near Windsor, Ontario. It was the end result of solution mining of the Silurian Salina salt for a period of 50 years. The first well in the brinefield was drilled in 1902, but intensive exploitation began in 1922, from 1922 to 1953 some 25 wells were drilled. Most were completed in

Figure 12.21. Subsidence profile over the margin of the collapse zone in Windsor, Ontario (after Terzaghi, 1971).

the “Lower Salt” at depths around 480 metres (Terzaghi, 1971). Most wells were cased and cemented to depths below the base of the “Middle Salt” between 370 and 390 m. All of the early captive wells circulated water without a blanket, so dissolution was rapid and upward stoping poorly constrained.

Prior to the 1954 collapse an area that was some 300 metres across had subsided some 40 cm over a period of 5 years. Cracks in several buildings on the site were first noted in 1948 and measurements were then made of the subsidence cone up until the collapse. During the first two years of monitoring (1948-1950) maximum subsidence was 6.3 cm (Figure 12.21). The general trend over the 5 years of monitoring was that the cone of subsidence was becoming increasingly deep at increasing speed. By the fifth year of monitoring the depth of the basin had increased another 23 cm making for a total drop of 40 cm in the landsurface since the beginning of monitoring. The rate of subsidence climaxed on February 19, 1954 with a catastrophic failure when a water-filled depression, some 120-150 metres across and up to 7.5 metres deep, swallowed much of the surface plant. Prior to the 1954 collapse an estimated $4.25 \times 10^6 \text{ m}^3$ of salt had been dissolved. Contrary to the initial expectations voiced in 1948, collapse was not centred on wells of the brinefield, but beneath the saltworks itself.

The February 19th collapse event was spectacular, the 9 hours it took to pass to completion shows how quickly such events can proceed. The first signs of a pending collapse were noted between 8 and 9 am with small ground tremors and vibrations. By 10:30 am it was obvious a crater was forming in the centre of the bowl of subsidence, which was visibly sagging. Around midday the crater started to fill with water, first by draining a nearby marsh and later with water from broken pipes. Around 1:15 pm there was a rapid 1 metre drop in the ground defining the edge of the crater accompanied by a 1.2 m high water spout issuing from a crack along part of the crater edge. Throughout the early afternoon other cracks and water jets appeared. The escaping waters were black and smelt of H_2S . By the mid afternoon the collapse had ceased and had constructed a 150 metre wide water-filled sinkhole in the middle of a 600 metre wide cone of subsidence.

Sinkholes in the Detroit River

In 1971 several sinkholes developed in and around Hennepin Point and on nearby Grosse Isle. Both sites are located next to the Detroit River, SE Michigan, near Detroit and 10 km downriver from the Windsor collapse site. The sinkholes were the result of 30 years of solution mining of the “Lower Salt” of

Silurian Salina Group salts at depths of more than 320 metres. Production of brinefield salt at Point Hennepin began in 1943 using unblanketed brine wells. Salt cavities quickly met to form larger cavities. The largest was made up of two galleries called the Northern gallery and Central gallery. Ground subsidence atop this large cavity was first noticed in 1960. The rate of subsidence was constant until the end of 1967. From then it accelerated until the first collapse crater formed above the Northern Gallery on January 9, 1971. Its subsidence history is near identical to the 1954 Windsor site. After a few months of expansion this first crater stabilized with a diameter of 65 metres. In April and May 1971 a second crater then developed above the Central gallery. This crater, some 120 metres across and up to 35 metres deep, was larger than that above Northern gallery. By May, another companion crater, some 60 metres in diameter, had formed next to the larger sinkhole.

The similarity in the geology of the Windsor and the Detroit sites, as well as the rapidity of the collapse, along with the size and steepness of the collapse craters, led Nieto and Russell (1984) to question the upward caving or stoping collapse mechanism of Terzaghi (1971). They argued his notion of steep upward propagation and caving from more than 300 to 400 metres below the surface could not explain the steepness of the three surface craters or their rapid, near catastrophic subsidence. Instead, they proposed a collapse scenario based on loss of cohesion in the Sylvania sandstone layer some distance atop the Silurian salt bed. Their collapse scenario is now accepted for both the Windsor and Point Hennepin events (Figure 12.22).

Intensive solution leaching of the lower layer of Salina salt, and to a lesser degree the two other salt beds in the Salina Group, formed a basin of subsidence in the overlying strata. At the landsurface this cone of subsidence was initially small and slowly evolved outward. It became unstable when it had attained surface slopes of more than 2 mm/m and a diameter of more than 500 metres. As the cone expanded out and up, strata atop the growing cavity salt cavity responded by downwarping

Figure 12.22. Collapse mechanism for the Windsor and Detroit events. **A)** A growing cone of subsidence causes fractures in the carbonate overburden and pervasive disaggregation and cavity growth in the Sylvania sandstone. **B)** Catastrophic collapse of the overburden into cavities in the Sylvania sandstone not into cavities in the Salina salt drives sinkhole formation at the landsurface (in part after Nieto and Russell, 1984).

elastically into the underlying cavity and then fracturing, but not necessarily collapsing. Downwarping created compressive stresses in the higher part of each cohesively downwarping overburden unit. Expanding joints in the lower part of each unit took up the corresponding tensile stress. Compression increased in the higher part of each layer until it reached its compressional limit, the layer then fractured. Like the adjacent carbonate beams, the Sylvania sandstone bed initially deformed elastically until a rupture, driven by internal compression, formed in the higher part of the bed.

What was different in the Sylvania layer compared to the limestone beams atop the cavity was its fracture response to compressional stress. When plugs of the Sylvania sandstone were subjected to triaxial compression testing it was found the plugs failed by pervasive grain rotation, not by fracture (in contrast, plugs of the underlying dolomites all failed by fracture). Instead of a cracked plug at the end of a test, what was left in the stress jacket after a test of Sylvania Sandstone was freeflowing sand grains. In the real world, a network of growing fractures and solution channels in the underlying Bois Blanc and Bass Island formations allowed the disaggregated

Location	Timing and Size	Explanations and implications	Reference
Haoud Berkaoui oilfield, near Ouarlaga, Algeria	In October 1986 a crater 200 metres in diameter, 75 metres deep formed. It has expanded until now when the cavity is more than 230 by 600 metres across. Its outward progression is still continuing at a rate of 1 metre per year (Thought by environmentalists to be the "largest anthropogenic sinkhole in the world").	In 1978, an oil exploration well with a 2500 m Ordovician target was abandoned because of stability problems in Triassic salt at a depth around 650 metres. The well was abandoned without casing near the bottom of the well. A second well was drilled in 1979 located 80 metres from the previous well. In March 1981, the lining of this well broke because of cavity formation at around 550 metres, which is the level of salt. In October a surface crater formed, centred on these two wells. Dissolving salt may be salinising the crossflowing artesian waters, leading to undocumented, but possible, degradation of freshwater oases in the region.	Morisseau, 2000
Wink Sink, Texas, and Whitten Ranch Sink, New Mexico	On June 3, 1980 the Wink Sink formed a 110 m wide and 34 m deep collapse crater. It was centered on the Hendrick 10 A well in the Hendrick oil field. Whitten Ranch Sinkhole or collapse crater formed sometime between August 31 and September 5, 1998 and was up to 23 m wide and 33m deep.	It appears likely that the natural processes of salt dissolution, cavity growth and resultant chimney collapse atop the Permian Capitan reef were accelerated by oil drilling and extraction activity in the immediate area of the sinkholes in the early part of last century. Large water filled sinkholes (as in the "Bottomless Lakes" of New Mexico) are a natural part of the landscape in the region and were collapsing long before the arrival of man.	Baumgardner et al., 1982 Powers, 2000 Johnson, 2001
Panning Sink, Kansas	It formed in April 1959 with a diameter of 90 metres and had a water surface more than 18 metres below the sinkhole lip.	Formed by subsidence and collapse around an already tilted and abandoned salt-water-disposal (SWD) well - Panning 11A.	Walters, 1978, 1991
Lake Peigneur, Jefferson Island Louisiana	On November 20, 1980, Lake Peigneur disappeared in hours as it drained into an underlying salt mine cavern. Within hours, a collapse sinkhole 0.91 km ² in area developed in the SE portion of the lake and in 12 hours the underlying mine had flooded and 2 days later the lake had refilled with water.	An oil well being drilled from barges and platforms in lake intersected an abandoned part of an active salt mine in the salt dome that underlies the lake. Water from the lake and the intervening natural collapse features entered the mine workings. The Lake itself is a natural dissolution depression.	Autin, 2002 Thoms, 2000b Thoms and Gehle, 1994
Sinkhole atop Weeks Island, storage facility, Louisiana	An active sinkhole some 10 metres across and 10 metres deep, first noted near the edge of the SPR facility in May 1992. A second, much smaller sinkhole was noticed early February 1995, but it lay outside the area of cavern storage.	The sinkhole led to the decision to drain the facility of its hydrocarbons. Drainage and remediation was completed in 1999 at a cost of US \$100 million. This facility was not purpose built but was an old salt dome mine facility. In hindsight, based on an earlier event, one might fault the initial DOE decision to select this mine for oil storage. A groundwater leak in the mine in 1978 may have been a forewarning of events to come. Injection of cement grout into the flow path controlled the leak at that time, but it could just as easily have become uncontrollable and formed a sinkhole.	Neal and Meyers, 1995 Bauer et al., 2000
Mont Belvieu sinkhole, Texas	July 30, 1993 a sinkhole crater formed between two brine storage wells. The crater stabilized in a few hours with a diameter of 12 metres and a depth of 6 metres. It was filled with sand a few days later.	Large volumes of brine are periodically cycled in and out of the brine cavern in the caprock. It is used to drive the withdrawal of the stored hydrocarbons in other deeper storage caverns. Using a system that stores saline brine in a caprock, even without the possibility of the collapse of a brine well, means there is a possibility of groundwater contamination from leaked storage brines.	Cartwright et al., 2000

Table 12.4. Events associated with oil wells or storage (see text for full description).

Sylvania sands to infiltrate into the saltwork galleries. Collapse of overburden into resulting cavities in the Sylvania then followed. The catastrophic collapse of the landsurface was facilitated by expanding shallow cavities in the sandstone, not the deeper cavities in the Salina Salt.

Case histories: caving and leaking wells

Petroleum-industry activities have unintentionally aided and produced dissolution cavities via exploration, production or brine disposal wells drilled in, or through, subsurface salt units (Table 12.4; Martinez et al., 1998). Ongoing corrosion of access wells to storage caverns, or the continued expansion of

caverns as stored product is cycled, can also have unexpected and sometimes disastrous results. If a storage cavity becomes too large for the roof to be self-supporting, successive roof failures may cause cavities to migrate upward and reach the land surface. Documented surface collapses and sinks, which can be directly related to oil drilling and poor brine disposal practices, all involve boreholes drilled long ago, typically in the 1920s to 1950s. This was at a time of different public perceptions of development and long before the application of modern engineering safeguards pertaining to drilling-mud design, casing placement and the use of salt-tolerant cements. It can be more than 30 or 40 years after a well was plugged and abandoned before the problem becomes obvious at the surface. There will be more problems related to old wells in the future.

Wink Sink, west Texas

Wink Sink, located 3 km north of the town of Wink in Winkler County, Texas, is centred on an abandoned oil well within the giant Hendrick oilfield. Hendrick 10A had produced oil from 1928 to 1951 and was the foci of the sink crater, while a second nearby operational oil well was plugged and abandoned soon after the collapse began (Figure 12.23). Wink sink first formed on June 3, 1980 and within 24 hours had expanded to a maximum width of 110 metres. Two days later, the maximum depth of the sinkhole was 34 metres with a volume estimated at 159,000 m³ (Johnson 1987, 1989). The collapse was the surface expression of an underlying dissolution cavity that had migrated upward by successive roof failures until it breached the land surface. The instigating cavity had first developed in halite beds of the Permian Salado Formation, some 400 metres below (Figure 12.23).

The location of Wink Sink atop the Guadalupian Capitan Reef trend places it in a region of natural ongoing dissolution of salt and associated chimneying, which first occurred atop

the reef aquifer as early as Salado time (Figure 7.9). Wink Sink lies in an evaporite karst region where water filled sinkholes as large as, and larger than, Wink Sink are a natural part of the subsurface landscape of the Permian Basin (e.g. water-filled sinkholes that make up the various lakes in Bottomless Lakes State Park, New Mexico). Such structures were collapsing long before the arrival of man. Sediments in collapse chimneys in the vicinity of Wink Sink indicate caving events had occurred at various times from the late Permian, to Triassic, to the Cenozoic (Johnson 1987; Baumgardner et al., 1982).

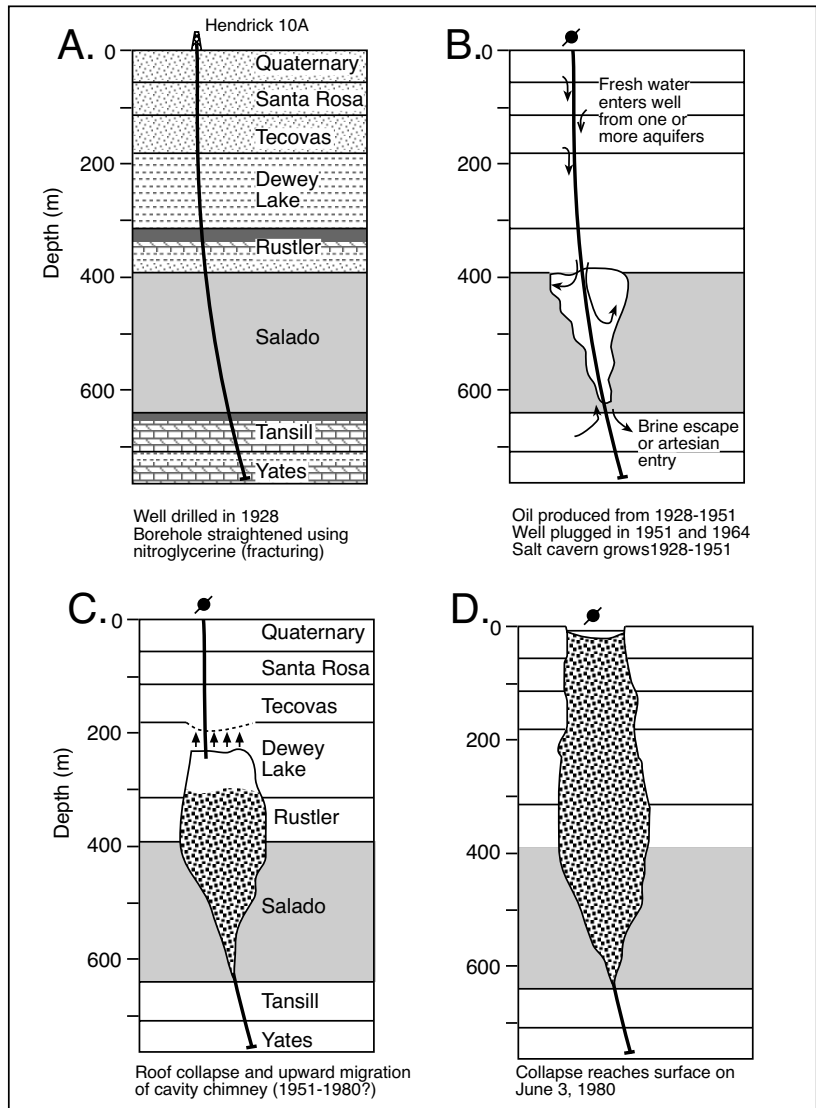

Figure 12.23. East-West section through Hendrick well 10-A in Wink Sink, west Texas (after Johnson, 1987). Undersaturated meteoric and artesian water circulated along borehole margins to dissolve the salt and create a salt cavern, which migrated to the land surface by successive roof failures ("chimneying"). See Figure 7.9 for location of the Wink Sink.

But the natural processes of salt dissolution, cavity growth and resultant chimney collapse were perhaps accelerated by drilling and inappropriate well management practices in the immediate area of the sinkhole in the early part of last century. Drilling and completion of the Hendrick well 10A during the late 1920s was consistent with standard industry practices of the time (Figure 12.23a). But in retrospect, several factors and events related to the drilling and ongoing exploitation of the borehole probably contributed to development of a surface sink centred on the well. These include the probable use of a fresh-water drilling fluid, use of nitroglycerine to straighten the hole, the strong possibility of poor cement jobs that inadequately sealed off the salt beds behind the casing, possible corrosion of casing and cement fretting by salt water, and the removal of some critical casing during the final plugging of the well in 1964.

Poor cement jobs and fractures in cement linings behind the well casings opened a vertical pathway for movement of undersaturated fluid up or down the borehole surrounds (Baumgardner et al., 1982). Surface casing in the well was originally set at a depth of 122 m, approximately at the base of the Santa Rosa fresh-water aquifer. If the casing were set too shallow to seal off the aquifer, or if undersaturated waters were present in some of the siltstone or sandstone beds of the underlying Tecovas Formation, undersaturated waters would have leaked into the borehole surrounds (Figure 12.23b). Also, the cement job at the base of this surface casing in 1928 was probably not suitable for the subsurface conditions. It was done at a time when salt tolerant cements were not yet in use. Fracturing of the original cement possibly occurred during later workover, re-entry, and plugging operations. Fractures could have focused water flow from the Santa Rosa into the borehole surrounds at the level of the Salado Salt (Figure 12.23c).

Baumgardner et al. (1982) pointed out that the absence of cement plugs or cement linings in the Hendrick 10A borehole below a depth of 669 metres during the period from 1928 to 1951 would have allowed water to move upward under artesian pressure from the Guadalupian aquifer at the base of the Salado Formation. In my opinion this is the more likely mechanism driving dissolution as it creates a density inversion in the hydrology that moves fresher waters upward into the salt. Contamination from above requires the less saline (lighter) waters of the Santa Rosa aquifer to displace brine (denser). Casing in the well may have also been perforated by corrosion. In addition the pumping of large amounts of saline water between 1928 to 1951, when it was used as a brine well, would have caused a substantial crossflow of undersaturated water and aided further corrosion of the casing (Hendrick Field brines ranged from 5,000 to 48,000 ppm dissolved solids; Johnson 1987).

Drilling, completion, and plugging procedures combined to create a conduit that enabled fresh water to better circulate in the vicinity of the borehole and so dissolve salt. When the dissolution cavity was large enough, the roof failed and overlying strata collapsed into the cavity (Figure 12.23d). The Wink collapse underlines the importance of appropriate well design specifications, reliable maintenance during well life, and the need for adequate plugging and abandonment procedures specifically designed for wells passing through salt intervals.

Panning Sink, Barton County, Kansas

Panning Sink on the Panning Lease formed in April 1959 by subsidence and collapse around an already tilted and abandoned salt-water-disposal well (Figure 12.24). The Panning 11A well had been abandoned in the previous January because of uncontrolled wellhead tilting. Walters (1978) reported that a 90-metre-wide water-filled sinkhole formed in about 12 hours, with a water surface more than 18 metres below the lip of the sinkhole. Four days later the crater had widened and the water surface was only 4 metres below the crater edge.

The suspect well, originally drilled as an oil producer in 1938, penetrated 91 metres of Permian Hutchinson salt at a depth of 298 metres on its way to the Arbuckle Group reservoir. Freshwater drilling fluids used in drilling the well dissolved the salt in the borehole to an excessive diameter (≈ 1.4 metres) and this washed-out zone was not cemented behind the 15.2-centimeter-diameter casing. Conversion of the borehole to an salt-water-disposal well from 1946 to 1958 injected a large quantity ($\approx 1.6 \times 10^6 \text{ m}^3$) of unsaturated oilfield brines (with a total concentration about the same as seawater) into the well and so further dissolved the salt behind the well casing. Ongoing exposure to undersaturated brine formed a large cavern, and with successive roof falls, this water-filled void migrated upward to ultimately cause the surface crater.

Gorham oil field, Russell County, Kansas,

Some 1,397 oil wells in the Gorham oil field have produced some 100 million barrels of oil, making it a giant oil field. The largely depleted Gorham oil field is now the site of slow subsidence of a major highway (Interstate 70) above salt-dissolution zones in the equivalents of the Permian Hutchinson salt. A number of wells in the field, drilled on 4-hectare spacings in 1936 and 1937, had penetrated 75 metres of the Wellington Salt at depths around 390 metres (Walters, 1991). The wells are now plugged and abandoned, but some of them contain corroded casing that had been left in the boreholes above, within, and below

Figure 12.24. Schematic cross section through Panning Field, Kansas, showing the situation on April 24, 1959 (after Johnson, 2001; Walters, 1978).

the salt unit. As a result unsaturated water has flowed up and down some of the boreholes, dissolving large volumes of the salt. Subsidence was further aided by disposal of waste oilfield brines that were re-injected when unsaturated with respect to halite. Subsidence of I-70 pavement is occurring at rates that are less than 0.3 metre per year, but cumulative subsidence from the highway's construction through to 1987 was 4 metres in two of the sinks atop the field, and 0.3 metre in a third sink. It meant rebuilding parts of I-70 in 1971 and again in 1986. Even so, incidents of rapid dissolution induced subsidence atop wells drilled through the Wellington Salt and its equivalents are rare events, in Kansas the ratio of wells intersecting salt and being associated with at-surface subsidence is something like 1:10,000 (Walters, 1978).

Sinkhole at Bayou Choctaw Dome, Louisiana

In 1954 the "No.7 brine well" in the Bayou Choctaw salt dome, Louisiana, collapsed during brine production, probably because of loss of its salt roof atop a growing solution cavern. A sinkhole formed at the site over a period of several days, and was quickly filled with nearby surface water. A rig that was producing brine at the time fell into the collapsing depression and was never seen again. The collapse created a large near-circular lake, about 210 metres in diameter, which today is still a water-filled structure and known locally as "cavern lake" (Stanczuk, et al., 1976).

Grand Saline sinkhole, Texas

In 1976 the Grand Saline sink emerged at the surface within the city of Grand Saline, Texas. The sink occurred at the site of a former brine well that penetrated the top of the Grand Saline salt dome at a depth of 60 metres and had produced brine from 1924 through 1949. The sink eventually grew to a diameter in excess of 15 metres, and a total of 8,500 cubic metres of silt and clay was displaced into the underground cavity. A house was endangered by this collapse, and, during the collapse a pipeline broke and sewage flowed into the sinkhole.

Haoud Berkaoui oilfield, Algeria

In October 1986 a crater, some 200 metres across and 75 metres deep, formed in the Haoud Berkaoui oilfield, near Ouarlaga, Algeria (Morisseau, 2000). Today it continues to expand and is now some 230 by 600 metres across. Its outward progression is continuing at a rate of 1 metre per year. The collapse is centred on two oil wells drilled in the late 1970s. In 1978 an oil exploration well with a 3200m target was abandoned at a depth of around 600 metres because of well stability problems - 600m is the level of Senonian salt in the region. By this level the well had already passed through 50 metres of anhydrite (220-270m depth), interbedded anhydrite clay and dolomite 270m -450 m depth). These are sediments that, in their undisturbed state, are likely aquicludes to any access by unconfined phreatic groundwaters. Prior to drilling it was thought that the Senonian halite extended continuously to a depth of 600 m in the well and in turn was underlain by 50 m of anhydrite (600-650m depth). Below the halite-anhydrite is a artesian aquifer (Albian) with a hydraulic potential in this area of 2.5 MPa (\approx 250 m head)

The first well was abandoned without any casing near the bottom of the well, probably facilitating the escape of artesian waters. A second well, drilled in 1979, was located some 80 metres

from the previous well. It successfully obtained its Ordovician target. But in March 1981, the lining of this second well broke, probably because of cavity formation at a level around 550 metres (once again the regional level of salt) and the well was lost. On October 1, 1986 a large crater formed, centred on these two wells. The diameter of the initial subsurface cavity that stopped to the surface is estimated to have been around 300 m. Once the cavity breached the surface the initial ascending artesian supply to the cavity was $\approx 2,000 \text{ m}^3/\text{hr}$.

As in Wink Sink, Texas, the loss of these wells, in this case during their active life, emphasises the need for caution when planning abandonment in a salt bed, especially when it is highly likely that the salt is a seal to a regional artesian system. The fact that the first well was lost during drilling argues that a breach was already present in the salt bed and a cavity was already stopping its way to the surface. But it is also possible that the inappropriate completion and cementation of casing levels, prior to the well's abandonment, may have accelerated cavity expansion. In hindsight, the loss of the second well some 3 years later, situated so close to the first and dealing with the same cavern-ridden geology, was highly likely as was cavity collapse 5 years after that.

Lake Peigneur, Louisiana

On November 20, 1980, one of the most spectacular sinkhole events associated with oilwell drilling occurred atop the Jefferson Island dome just west of New Iberia. Lake Peigneur disappeared as it drained into an underlying salt mine cavern and a collapse sinkhole, some 0.91 km^2 in area, developed in the SE portion of the lake (Autin, 2002). In the 12 hours following the first intersection the underlying mine had flooded and the lake was completely drained.

Lake Peigneur is a natural water-filled salt solution depression atop the Jefferson Island salt dome, which is one of the salt cored islands in the Five Islands region of the Gulf Coast (Figure 7.13a). The lake is about 2.4 km in diameter with a bean-shaped configuration with a topographic promontory along the southeast shore of the lake rising to more than 23 m above sea level and the surrounding delta plain. Nearby was the site of the infrastructure of the Jefferson Island salt mine (Figure 12.25a).

Drainage and collapse of the lake began when a Texaco oilrig, drilling from a pontoon in the lake, breached a unused section of the salt mine some 1000 feet (350 metres) below the lake floor. Witnesses working below ground described how a wave of water instantly filled an old sump in the mine measuring

some 200 ft across and 24 feet deep. The volume of floodwater engulfing the mine corridors couldn't be drained by the available pumps. At the time of flooding the mine had 4 working levels and one projected future level. The shallowest was at 800 feet, it was the first mined level and had been exploited since 1922. The deepest part of the mine at the time of flooding was the approach rampways for a planned 1800 foot level. In 58 years of mine life some 23-28 million m^3 of salt had been extracted. Prompt reaction to the initial flood wave by mine staff allowed all 50 personnel, who were underground at the time, to escape without anything more than a few minor injuries.

The rapid flush of lake water into the mine, probably augmented by the drainage of natural solution cavities in the caprock below the lake floor, meant landslides and mudflows developed along the perimeter of the sinkhole, and that the lake was enlarged by 28 ha. The surface entry hole in the floor of Lake Peigneur quickly grew into a half-mile-wide crater. Eyewitnesses all agreed that the lake drained like a giant unplugged bathtub—taking with it trees, two oil rigs (worth more than \$5 million), eleven barges, a tug boat and most of the Live Oak botanical gardens. It almost took local fisherman Leonce Viator Jr. as well. He was out fishing with his nephew Timmy on his fourteen-foot aluminium boat when the disaster struck. The water drained from the lake so quickly that the boat got stuck in the mud and they were able to walk away! The drained lake didn't stay dry for long, within two days it was refilled to its normal level by Gulf of Mexico waters flowing backwards into the lake depression through a connecting bayou. But, since parts of the lake bottom had slumped into the sinkhole during the collapse, the final water level in some sections was higher than before relative to previous land features. It left one former lakefront house aslant under 12 feet of water.

Of course, an anthropogenically induced disaster like this attracted the lawyers like flies to a dead dingo. On 21 November 1980, the day after the disaster, Diamond Crystal Salt filed a suit against Texaco for an unspecified amount of damage. On 25 November, Texaco filed a countersuit against Diamond Crystal. The Live Oak Gardens sued both Diamond Crystal and Texaco. Months later, the State of Louisiana was brought into the suit since the incident occurred on state land. One woman sued Texaco and Wilson Brothers (the drillers) for \$1.45 million for injuries (bruised ribs and an injured back) received while escaping from the salt mine. Less than a week before the scheduled trial, a out-of-court settlement was reached between the major players. Texaco and Wilson Brothers agreed to pay \$32 million to Diamond Crystal and \$12.1 million to the Live Oak Gardens.

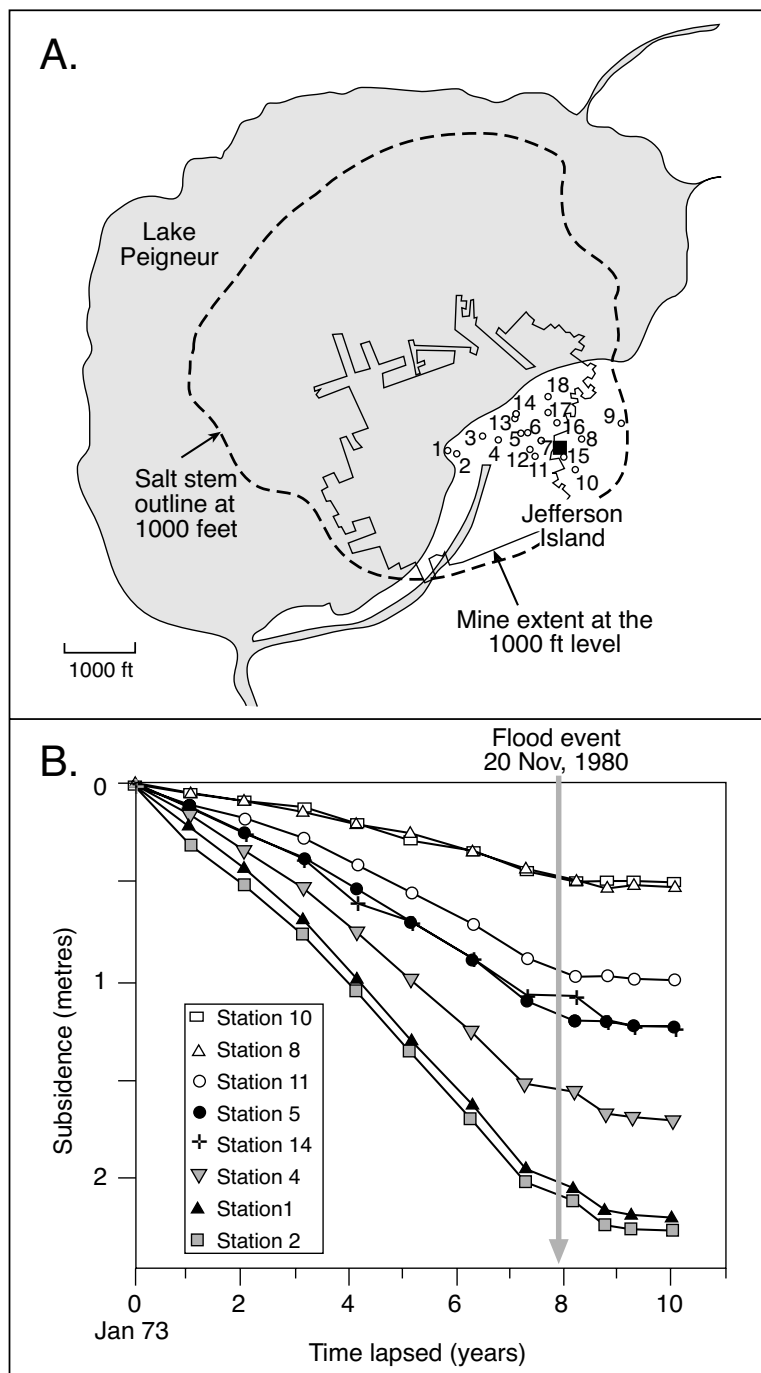

Figure 12.25. Lake Peigneur, Jefferson Island, Louisiana. A) Plan view showing the extent of Lake Peigneur and the position of the surface monitoring stations (1-18) with selected data plotted as 12.25b. Also shown is the extent of the mine workings at 1000 feet subsurface and the outline of the salt stem at the same level. Black square indicates the position of the now flooded No. 1 shaft. B) Ten years of surface subsidence data showing the drastic decrease in subsidence that followed the flooding of the mine workings (see Figure 7.13 for locality; after Thoms and Gerhle, 1994).

An ongoing environmental catastrophe that was anticipated by environmental groups at the time of the accident never materialized. The lake quickly returned to its natural freshwater state and with it the wildlife was largely un-affected. Nine of the barges eventually popped back up like corks (the drilling rigs and tug were never to be seen again). The torrent of water helped dredge Delcambre Canal so that it was two to four feet deeper. And of course, the former 1 metre deep Lake Peigneur was now 400 metres deep in the vicinity of the borehole!

Interestingly, the filling of the mine workings with water drastically slowed the rate of land subsidence atop the mine (Figure 12.25b). Measurements had been carried out between 1973 and 1983, some 7 years before the accident and continued for 2 years afterwards (Thoms and Gerhle, 1994). Slowing reflects the post-accident reduction in the total pressure exerted on the roof of the mine to half its pre-accident levels. Prior to the accident there was no hydrostatic pressure to alleviate some of the lithostatic pressure exerted by the weight of the overburden and so land subsidence above the mine workings was relatively rapid.

Although this incident is not directly related to any solution mining operation and no human lives were lost (although three dogs perished), it clearly illustrates the speed of potential leakage following a breach in a cavern roof in any shallow storage facilities filled with low density fluids. It also illustrates the usual cause of such disasters – human error in the form of a lack of due diligence, a lack of forward planning and a lack of communication between various private and government authorities. It also illustrates that filling a solution cavity with water slows the rate of subsidence atop a large salt cavity and that waters after the disturbance will return quietly to a state of density stratification.

The incident had wider resource implications as it detrimentally affected the profitability of other salt mines in the Five Islands region (Autin, 2002). Even as the legal and political battles at Lake Peigneur subsided, safe mining operations at the nearby Belle Isle salt mine came into contention with public perceptions questioning the structural integrity of the salt dome roof. Horizontal stress on the mineshaft near the level where the Louann Salt contacts the overlying Pleistocene Prairie Complex had caused some mine shaft deterioration. Broad ground subsidence over the mine area was well documented and monitored as was near continuous ground water leakage into the mine workings. The Peigneur disaster meant an increased perception of continued difficulty with mine operations and an increased risk of catastrophic collapse was considered a distinct possibility. In 1985, a controlled flooding of the Belle Isle salt mine was completed as part of a safe closure plan.

Subsidence over the nearby Avery Island salt mine (operated by Cargill Salt) has been documented since 1986. This is oldest operating salt mine in the United States and has been in operation since the American Civil War and the mine has recently undergone a major reconstruction and safety workover. Mine management and landowners did not publicly disclose the technical details of rates of subsidence, but field observations reveal the nature of the subsidence process. Subsidence along the mine edge coincided with a topographic saddle above an anomalous salt zone located inside the mined salt area, ground water flowed into the mine, and there were a number of soil gas anomalies associated with the mine. Small bead-shaped sinkholes were initially noticed in the area in 1986, then over several years, a broad area of bowl-shaped subsidence and areas of gully erosion formed (Autin, 2002). Reconstruction has now stabilised this situation. Much of the subsidence on Avery Island is a natural process that occurs atop any shallow salt structure. Dating of middens and human artifacts around salt solution induced water-filled depressions atop the dome show it is a natural process that extends back beyond the 3,000 years of human occupation documented on the island.

Compared to the other salt domes of the Five Islands, Cote Blanche Island has benefited from a safe, stable salt mine operation throughout the mine life (Figure 7.13; Autin, 2002). Reasons for this success to date are possibly; (i) mining operations have not been conducted as long at Cote Blanche Island as other nearby domes, (ii) the Cote Blanche salt dome may have better structural integrity than other islands, thus allowing for greater mine stability (although it too has anomalous zones, a salt overhang, and other structural complexities), and (iii) the salt is surrounded by more clayey (impervious) sediments

than the other Five Islands, perhaps allowing for lower rates of crossflow and greater hydrologic stability.

Case Histories: storage caverns

The world's demand for fuel means it must be held in sufficient quantities near centres of distribution so as to insure security of supply. Deciding where and how mankind stores substantial volumes of hydrocarbons (or in the future the much more volatile hydrogen) in or near populated areas will always be a problem. There have been a few accidents in below ground storage facilities and some of them are listed in this section. However, when the environmental and safety records of above and below ground fuel storage facilities are compared, the below ground facilities are an order of magnitude safer and less environmentally hazardous. Problems with storage caverns in salt hosts are related either to the utilisation of non-purpose built caverns or to human error and poor management practices.

Weeks Island, Louisiana

The Weeks Island Strategic Petroleum Reserve (SPR) facility on Weeks Island, Louisiana, lay some 30 km SE of Jefferson Island (Figures 7.13a, b, 12.26). It utilized abandoned room and pillar caverns of the Morton Salt Company mine and so was unusual compared to other purpose-built storage caverns of the Strategic Petroleum Reserve (SPR). It was purchased in the 1970s, a time that was early in the annals of the SPR and at the height of the 1970s oil crisis. Occupying a former salt mine it was the shallowest of all the SPR facilities across the USA (150-220 metres below the land surface). It was not a custom built facility nor was it constructed by solution mining technologies.

Following oil fill in 1980-1982, the facility stored some 72.5 million BBL of crude oil in abandoned mine chambers. Then in November 1995, the Department of Energy (DOE) initiated oil drawdown procedures, along with brine refill and oil skimming, plus numerous plugging and sealing activities. In 1999, at the end of this recovery operation, about 98% of the crude oil had been recovered and transferred to other SPR facilities in Louisiana and Texas; approximately 1.47 MMBL still lies in the now plugged and abandoned cavern system.

The cause of this drainage and abandonment was an active sinkhole some 10 metres across and 10 metres deep, first noted near the edge of the SPR facility in May 1992 and apparently formed about a year earlier. The growing depression was located on the south-central portion of the island, directly

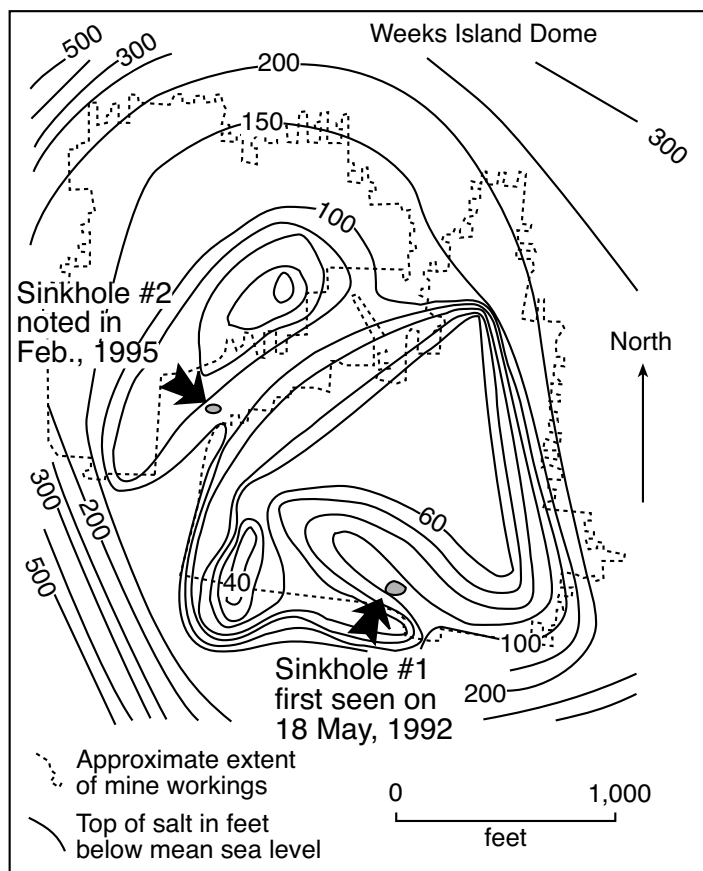

Figure 12.26. Strategic Petroleum Reserve facility, Weeks Island, Louisiana. Top of salt contours showing how sinkholes developed in depressions atop the upper part of the salt. The sinkholes occur in regions near the edge of the cavern with the potential for foundering of the cavern roof into the chambers of the former Morton Salt mine.

over a subsurface trough, which is obvious in the top-of-salt contour (Figure 12.26; Neal and Myers, 1995). Earlier shallow exploratory drilling around the Department of Energy service and production shafts in 1986 had identified the presence of irregularities and brine-filled voids along the top of salt in this region. A second, much smaller sinkhole was noticed in early February 1995, but it did not constitute a serious threat as it lay outside the area of cavern storage.

Neal (1994) pointed out that Kupfer's 1976 map of that part of the mine located beneath the first sinkhole showed black salt. Black salt in Gulf Coast salt mines is often associated with anomalous leached zones where salt was subject to unpredictable movement and sometimes to collapse. The volume of this sinkhole (estimated as 650 m³ when first noted), its occurrence over a trough in the top of salt and its position directly above

the oil-filled mine caverns, meant it was of concern to the SPR authorities, especially in terms of the stability of the roof of the storage cavern.

Investigations undertaken in 1994 and 1995 into the cause of the active surface sinkholes verified that water from the aquifer above the Weeks Island salt dome was seeping into the underground oil storage chambers at the first site (Neal and Myers, 1995; Neal et al., 1995, 1997). The drainage and decommissioning of the Weeks Island facility followed. Beginning in 1994, and continuing until abandonment of the facility a saturated brine was injected directly into the throat of first sinkhole, which lay some 75 metres beneath the surface. This essentially arrested further dissolution and bought time for DOE to prepare for the safe and orderly transfer of crude oil to another storage facility. To provide added insurance during the oil transfer stage, a "freeze curtain" was constructed in 1995. It consisted of a 54 well installation around the principal sinkhole that froze the overburden and uppermost salt to a depth of 67 metres (Martinez et al., 1998). Until the mine was completely filled with brine and its hydrocarbons removed, this freeze wall prevented groundwater flow into the mine via the region of black salt around the sinkhole. Dealing with this sinkhole was costly. Mitigation and the removal and transfer of oil, including dismantling of infrastructure (pipelines, pumps etc.), cost a total of nearly US\$100 million; the freeze curtain itself cost nearly \$10 million.

In hindsight, based on an earlier leak into the mine while it was an operational mine and the noted presence of black salt in a shear zone in the mined salt, one might fault the initial DOE decision to select this mine for oil storage. In 1978 groundwater had already leaked into a part of the mine adjacent to the sinkhole and was forewarning of events to come (Martinez et al., 1998). Injection of cement grout into the flow path controlled the leak at that time, but it could just as easily have become uncontrollable and formed a sinkhole then. But in 1978 the technology needed to understand the salt physics, salt solution and mine conditions and so predict future events had not been developed. The world, and the United States, was in the middle of an oil crisis and as a former US President once observed, "It's hard to drain the swamp when you're up to your arse in alligators!"

Explosions and fires from cavern leakage

Almost all the explosions and fires described in this section are caused either by human error, poor forward planning, a lack of due diligence by the storage company or operator or a combination of these factors. In all cases the salt caverns themselves did not fail. In spite of these accidents, cavern storage is still one of the safest ways to store what are very large volumes of highly explosive materials. Consequences are far graver, and death rates much higher, when explosions and fires have occurred in above ground fuel storage tanks.

The West Hackberry explosion

On September 21, 1978 a blowout and explosion occurred at the West Hackberry salt dome storage facility in southern Louisiana (USA). It killed one worker, released 10,000 m³ of oil to the surface and cost US \$14-20 million (1980 dollars) in cleanup and remediation. The incident occurred during workover operations on one of the access wells to the No. 6 cavity.

Understanding the causes of the explosion requires a few background comments on the casing strings in the well and the workover specifications (Figure 12.11). The well completion was made up of an outer 12.75-in (32.4 cm) casing string cemented to a depth of 2632 ft (816m). Cemented inside was another 9.62-in (24.4 cm) diameter casing string some 2603 ft (807 m) long. This was probably added after the “initial” completion to improve oil tightness when the cavity was converted to oil storage. An innermost 5.5-in (14 cm) diameter pipe string was used to withdraw brine whenever oil was pumped in to the cavity (see Figure 12.27).

Figure 12.27. Schematic of the pressure differentials that caused the West Hackberry blowout and explosion (see also Figure 12.11).

On the day of the explosion the workover consisted of withdrawing the 5.5-in innermost tubing string, repairing a leak on the 12.75-in casing, and reinforcing the wellhead equipment. To accomplish this, the annular space between the innermost pipe string and the 9.62-in casing had been filled with high-viscosity mud. This was designed to bring wellhead pressure in the oil string to zero. Once the annular space was filled, a packer was set at the bottom of the 5.5-in brine pipe to seal it off from the cavity. Work then commenced on pulling the 5.5-in pipe; however, after 14 pipe lengths had been stacked, the packer slipped as increasing differential pressure started to push it up to the surface. As the packer rose, the pressure (brine to oil differential) on it increased. Soon the packer shot up and out on to the surface, forming an oil geyser (blowout) that continued until the pressure differential had dissipated. By that time an estimated 72,000 barrels (10,000 m³) had shot up into the air, caught fire and killed one of the drilling crew.

A poor understanding of the pressure distribution in the fluid columns when the workover was designed is the main reason for the incident. As planned, the workover was extremely delicate, it was attempted without drawing down the oil pressure in the cavern. As the oil was under high pressure (sealed in by viscous mud in oil feeder casing) as the workover began it was liable to expand violently if any mishap upset the status quo. Injecting the viscous mud at the top of the well was a good precaution against any failure of the topside valve on the oil-filled annular space, but it had absolutely no effect on the dangerous situation at the bottom of the cavity and if the packer failed, which it did, there was no way of preventing a blowout.

A comprehensive but simple precaution would have been to release the pressure on the oil in the cavity by drawing down the top surface of the brine in the access well to about one-quarter of its total original height. The volume of oil needed to be withdrawn was, of course, exactly equal to the volume that was expelled in the blowout. This relatively small volume of oil could easily have been stored temporarily in another cavity on the site. So doing would have rendered the workover situation entirely safe.

The Brenham explosion

A disastrous explosion occurred on April 7, 1992, following the outflow of LPG onto the surface from a well atop a storage cavern in the Brenham Salt Dome. The blast occurred some 110 km northwest of Houston. It killed a 6-year old boy and two adults, injured 21 persons, damaged more than 40 homes and snapped trees like matchsticks, while denuding acres of rolling farmland. In all it caused an estimated US\$ 9 million in damage to property within a 5 km radius. Seismographs at three Texas universities within 120 km of the scene recorded surface tremors ranging from 3.5 to 4.0 on the Richter scale. Windows were rattled in homes more than 200 km away.

The Brenham storage facility consisted of a 380,000-bbl (60,000-m³) cavern filled with LPG (a mixture of propane, ethane, n-butane and other gases). The cavern was linked to ground level by a 13-3/8-in diameter, 2,702-ft long cemented casing (Figure 12.28). A central brine pipe (2,871-ft long) allowed injection and withdrawal of brine. LPG was injected to or withdrawn from three distinct pipelines. Brine was provided by two above-ground brine ponds. The wellhead was equipped with a shutdown valve. The Brenham station was operated remotely by a dispatcher in Tulsa, Oklahoma (Bérest and Brouard, 2003).

Figure 12.28. Schematic of the situation at the time of the Brenham explosion.

At 5:43 am on April 7, 1992, additional LPG was injected in the cavern. The brine/LPG interface unexpectedly reached the 1-in diameter weep hole located in the lower part of the central tubing, some 1 ft above the tubing base. The weep hole was supposed to provide warning in case of imminent overfilling. LPG flowed into the central brine tubing, leading to lower density in the fluid in the central column, partial vaporization and expansion of the lighter gases, a pressure drop in the cavern and, ultimately, a large flow of gas through the weep hole and the tubing base alike.

Brine, followed by liquefied gas, daylighted at the brine pond surface. Back-calculation proved that 3,000 to 10,000 bbl (500 to 1,600 m³) of liquefied gases were expelled via the ponds. The release of gas into the atmosphere activated gas detectors

at ground level. (Such activation was apparently a relatively frequent event at this station, and alarms were often unrelated to an actual gas leak). The dispatcher in Tulsa was not able to interpret correctly the somewhat confusing information delivered by the telemetric system - a unique signal was sent, whatever had activated a number of detectors. The shutdown valve (or cavern safety valve) was assumed to have immediately reacted to the high pressure level (100 psi) in the brine tubing at the wellhead, but the system failed.

A subsequent National Transport Safety Board (NTSB) investigation confirmed the local operator had overfilled the storage cavern to where LPG had escaped into an adjoining brine storage pit through the brine injection system via an open valve. Product had then evaporated and, being heavier than air,

formed a low-lying cloud 30 feet high and several hundred yards long. At 7:08 am the “mushroom-shaped” vapour cloud was ignited by an automobile driving into the foggy cloud near the storage facility.

According to the NTSB report, Mapco (the operator of the facility) was not aware of the volume of product in storage at the site. Some 338,995 barrels were actually stored instead of the 288,000 bbl estimated by Mapco. NTSB concluded that the management procedures had lacked oversight adequate to confirm employee measurements. Nor did the company have the ability to balance cavern receipts against withdrawals. In addition, employee measurement procedures did not adequately take into account specific gravity variations of the NGLs in storage.

Aside from the computation errors, NTSB said other contributing factors included:

- a) Inadequate positioning of the brine pipe weep hole - in a post accident redesign it was moved to 6 feet above the base of the brine pipe,
- b) A lack of several fail-safe features on the cavern's shutdown system - this system had included a brine pressure-sensing line designed so that when a large pressure build-up was sensed in the brine line it switched a spring that, when triggered, sent an electrical signal in a chain containing a fusible link whose fusion should have closed the brine safety valve and so prevented product leakage back up the brine pipe. It is extremely likely that one or two manual valves were closed on this sensing line at the time of the explosion, isolating it from the main body of the brine pipe, so making the emergency shutdown system ineffective. Ironically, the shutdown valve was activated when heat from the explosion burned the fuse and triggered valve closure (it shut the barn door after the horse had bolted).
- c) Inadequate emergency response training and procedures, along with poor communication among Mapco employees responding to the alarms and to the obvious surface emergency.

Early media coverage sensationally reported that “A Salt Dome Has Blown Up”. However the cavern storing the leaked liquids later passed a mechanical integrity test and is still in use today. It was operational supervision and safety procedures that failed dismally, not the cavern. After this accident, the Railroad Commission of Texas issued new regulations (effective in 1994) mandating that LPG storage caverns be protected by at least two overfill detection and automatic shut-in methods.

Barber's Hill explosion and collapse

On October 3, 1980 a gas-fed explosion occurred in a residence in Mont Belvieu, a Texan town that sits atop the Barbers Hill diapir, some 60 km west of Houston. Barbers Hill dome is the largest subsurface LPG storage facility in the U.S. with over 126 active solution-mined caverns storing between 75 and 300 million barrels of light hydrocarbon products. The explosion was ignited by a woman who sustained burns when turning on her dishwasher. Two weeks earlier, on September 17, 1980, a drop in pressure had been recorded in one of the nearby cavities storing liquefied petroleum gas (70% ethane, 30% propane). The cavern was emptied of product and filled with brine. Subsequent investigation showed a leak had occurred through a corroded casing joint in the access well. The well in question had originally been drilled in 1958. Leaking gas seeped through the surrounding soil to accumulate in the foundations of the residence where the explosion occurred. In the days that followed, gas daylighted haphazardly in residential areas around the site of the original explosion. Holes were drilled into the water table to find and vent pockets of gas. Residual gas saturations in the soils forced the evacuation of 73 families for nearly seven months and a drastic fall in property values.

A few years later, on July 30, 1993, there was another event that further lowered Mont Belvieu property values. In a few hours a sinkhole crater formed between two brine wells in the EGP Fuel Storage facility (Cartwright et al., 2000). The crater stabilized with a diameter of 12 metres and a depth of 6 metres. A well that was near the problem site had to be abandoned after the sinkhole formed. It was not a hydrocarbon storage well so the environmental implications of a collapse-induced abandonment were not as significant it would have been for a failed hydrocarbon cycling well. The cause of the sinkhole is contentious but it is thought that brine cycling in the two wells may have contributed to the collapse. Detailed subsidence work in the cone of subsidence about the sinkhole suggest that it was there prior to the collapse and if it had been monitored the data could have been used as an indicator of the likelihood of collapse (Cartwright et al., 2000).

Brine injection that drives brine compensated withdrawal of the stored hydrocarbons periodically requires large volumes of brine in short time frames. But in Mont Belvieu there was not sufficient above ground infrastructure to store the large volumes of brine needed for product cycling. To give access to large volumes of brines quickly, brines were pumped down brine storage wells with bases in shallow caprock caverns. Wells adjacent to Mont Belvieu sinkhole were two such wells.

Mineola propane fire

In 1995 there was an underground fire that burned for several days at a salt dome storage cavern operated by Suburban Propane near Mineola in East Texas, some 145 km east of Dallas. The cavern in which the blow-out occurred extended from 1200 ft to 2500 ft (350-750 m) subsurface. The blowout occurred when a salt wall separating two storage caverns had become so thin from the enlargement associated with brine compensation (product cycling) that it cracked (Gebhardt et al., 2001). This allowed stored propane product to flow from one cavern to an adjacent cavern that was empty of product and undergoing testing. Pressurised nitrogen was being injected into the adjacent brine filled cavern as part of a standard mechanical integrity test. The testing may have contributed to the penultimate pressure buildup that allowed propane product to leak into shallow depths via a casing leak (Bérest and Brouard, 2003). The leaking well had originally been drilled as an oil producer in the late 1950s, four decades before the accident. Liquefied gas escaped through the soil in a halo that extended as far as 100 feet from the well. The escaping gas ignited and burned releasing heavy black smoke. Extinction of the fire was not a viable option, as dangerous re-ignition and flash back was likely. The innovative kill techniques applied to this well are described in Gebhardt et al. (2001).

There are potential problems with longterm intercavern integrity as all salt caverns will enlarge during product cycling, so the Texas Railroad Commission now legislates what is an acceptable degree of enlargement before a storage cavern must be plugged and abandoned.

Hutchinson explosion

On January 17, 2001, a gas explosion and fire destroyed two businesses in downtown Hutchison in central Kansas (Allison, 2001). The next day in a mobile home park 3 miles away another explosion occurred and 2 residents died of injuries received. The explosions were tied to geysers spewing gas and water, and their appearance caused the excavation of hundreds of Hutchison residents. Pathways to the landsurface at both explosion sites and to the various active geysers across town were directly tied to abandoned wells that were once used to solution mine the Hutchison Salt.

The January 17-18, 2001 eruptions of gas and brine, driving 30-ft (10m) geysers in the town, resulted from the loss of 143 MMcf of gas from the Yaggy natural gas storage facility located 7 miles down the road from the town community of 40,000

people (Figure 7.8). Oneok Inc., owned and operated the Yaggy field through a subsidiary company called KGas. Upon review of pressure records, KGas officials realized that the S-1 cavern had probably been leaking at a low level at least since the pod of caverns had been refilled with natural gas on January 14, and perhaps longer. At the time, technicians did not think much of a minor pressure drop, as it was a routine situation associated with filling the cavern. When the caverns are pressurized, the natural gas is compressed, raising its temperature. Once in the caverns, the pressurized gas begins to cool and condense, resulting in a slight pressure decrease. It was common practice to then “top off” the cooled caverns with additional gas to fill the caverns to the final storage pressure.

The Yaggy field of salt caverns was originally developed in the early 1980s to hold propane. Wells were drilled to depths of about 650-900 feet (200-300 m), into the lower parts of the Hutchinson Salt Member and cased with steel. The roof of each cavern was about 40 feet (12m) below the top of the salt layer. The company had difficulty making a financial success of the operation and eventually ceased operations. All of the storage wells were filled with brine and then plugged by partially filling them with concrete. KGas acquired the facility in the early 1990s and converted it to natural gas storage (by definition this is a pressurized storage system). Plugged wells were drilled out to return the feeder wells and caverns to use. At the surface the wells in the Yaggy facility are 300 feet (90m) apart. At the time of the crisis, Yaggy had about 70 wells, of which 62 were feeders to active natural gas storage caverns. More than 20 new wells had been drilled and were being used to create new caverns for expansion of the field storage capacity.

At full capacity, the field could hold 3.5 billion cubic feet (Bcf) of gas at pressures of about 600 pounds per square inch and at the time of the accident it was supplying up to 150 MMcf (million cubic feet) of gas per day. Yaggy is the only natural gas storage field in salt caverns in the state of Kansas. Other salt caverns in Kansas are used for brine-cycled storage of liquid hydrocarbons, such as propane, at much lower pressures than the natural gas at Yaggy.

Records show that when KGas drilled the concrete out from the well casing in S-1 well to return the well to operation, they encountered a steel casing coupler that had fallen into the concrete in the well during the plugging operations (Allison, 2001). During the workover this object may have deflected the drill bit against the side of the well casing damaging and weakening it. A post accident down-hole video in S-1 shows a large curved slice in the casing at that depth. The city's

geological consultant described it as looking “like a kitchen knife cutting into a can.” Prior to the Yaggy facility approval by state authorities the S-1 had a satisfactory casing pressure test, as required by the Kansas Department of Health and Environment. The test was thought to demonstrate the integrity of the casing at that time. However, the well at the depth of the leak was never tested to the maximum pressure that would be experienced in service.

The route followed to the surface by the escaping gas is still not completely documented. Initial seismic surveys in early February 2001 at first indicated a possible subsurface sand channel through which the escaping gas flowed up from the storage facility. But that was not borne out by a study of regional well logs or the 22% success rate in drilling for suspected gas pockets (Watney et al., 2003) or subsequent seismic interpretation (Nissen et al., 2004). The most likely candidate carrier is thought to be a fractured intrasalt dolomite, which facilitated drainage to the crest of the anticline culmination that underlies the town of Hutchinson.

There are more than 600 NGL-LPG salt storage caverns in bedded Hutchinson salt in the state of Kansas, the most of any state in the USA. Kansas also has plans for more natural gas storage caverns, although Gulf Coast salt dome caverns are 10-20 times larger. The mix of bedded salt and permeable rock formations around Hutchinson, the presence of natural dissolution irregularities and the fact that Hutchinson has been an area of solution mining since the late 1800s is a real problem for storage of high-pressure fluids. Once the S-1 well was breached, numerous unplugged brine wells that were long ago drilled within the Hutchinson Salt and abandoned, without appropriate documentation, routed the escaping gas to the surface. Such wells are directly tied to the downtown fire that first heralded the problem, and to the two deaths that occurred in the explosion in the mobile home park a few days later. Work since the explosion has pointed out numerous problems to be addressed in a region of bedded salt that appears in many ways not to be a suitable site for future natural gas storage projects. Even so, the salt storage cavern itself did not leak, the access piping was the problem due to well workover damage.

Figure 12.29. After the cavern has formed and is filled, salt creep causes the cavern to shrink from its original size (dashed shape) into a somewhat smaller configuration. This induces subsidence and possible collapse in the zone above the cavern. At the surface this process forms a “bowl of subsidence” (in part after Thoms, 2000).

Recognising and preventing potential cavern problems

Three factors can contribute to the breaching and collapse of solution-mined cavities, namely creep, uncontrolled leaching, and the presence of anomalous zones in what had been assumed to be homogenous salt. Anomalous zones may be unexpected regions of highly soluble salts (potash salts), of fractured intrasalt beds, or zones of much older natural leaching (e.g. black salt), which may contain pressurized brine or gas (methane or nitrogen). In brinefields and some salt mines the anomalous zones tend to occur near intersections with poorly documented older well bores. The same set of factors generates many of the operational problems in conventional salt mines (Chapter 11).

Salt Creep

The principal factors influencing the rate of salt creep are; a) cavern depth and overburden characteristics - pressure and temperature gradients, b) internal cavity pressure, c) cavern shape, salt properties (e.g. variations in halite crystal size, moisture content). Left alone, and not subject to fresh water incursion, salt (especially halite and the potash salt) will creep into an unbreached storage cavern until differential pressures are equalised. Salt cavities are generally stable at depths between a few

hundred metres and about 2000 metres depth (Figure 12.1). Below that depth there is an elastic-plastic transition zone for salt behaviour somewhere below 1000 to 2000 metres. Cavities below this zone can be relatively unstable and show large volume decreases through rock creep with the transition depth depending on the composition of the salt, the geothermal gradient and the overburden pressure. Effects of salt cavity creep, due to inadequate internal pressuring, were first noted in the 1970s by the operators of some large purpose-built storage caverns. The Eminence cavern in Mississippi, built at 1700-2000m, lost 40% of its volume in just two years post construction, while Tersanne in France lost 30% to salt creep (Figure 12.30). Such losses in storage capacity were potentially expensive, but when adjustments were made to cavern depths and minimum gas storage pressures, the volume loss stopped. Today both facilities are still operational and have recovered much of their volume loss (Thoms and Gehle, 2000a). Salt creep occurs at slower rates above the transition zone; measured rates are mm - cm per year in salt mines in Kansas and Texas with depths up to 600 m.

Like mines, salt cavities built above or within the transition zone can be extremely stable and when properly located, designed and operated may lose only a few percent volume a year. Some cavities in salt above the transition zone can remain remarkably stable even if emptied of product. For example, in the 1950s, a lenticular cavern with a roof span 366 metres was excavated by solution mining in the Bryan Mound salt dome in Texas, which is also the site for the later Strategic Petroleum Reserve programme. The cavern has an unusual shape compared to the "carrot" shape of later purpose-designed caverns in the Mound. It was has an average depth of 550 metres, a cavity height of 55 metres and an unsupported span of more than 360 metres. After excavation, it was filled with LPG but subsequently lost wellhead pressure and so was abandoned (emptied). Thirty years later, measurements indicated that this cavern is still

Figure 12.30. Creep effects in Tersanne (France) and Eminence (Mississippi) showing shrinkage with time (Dotted shading indicates the distribution of insolubles in the Tersanne cavern).

remarkably stable, having lost only about 4 percent of its total volume since abandonment.

Salt creep is accelerated by large differences between natural lithostatic pressure (in the salt) and the pressure in the cavern. The rate of creep also depends on variations in the proportions and physical properties of the various salt minerals and the configuration of nearby nonevaporites (e.g. carbonate, anhydrite or potash beds in halite). To minimise creep, operational pressures in a fluid-filled storage cavern should be as high as allowed, this is especially true in facilities used to store natural gas. But this may encourage leakage and gas loss in facilities lacking structural integrity (see Hutchison explosion in case histories).

When a cavern is active, overburden creep will typically drive ongoing subsidence at the landsurface in the form of a subsidence bowl or depression (Figure 12.29). The length of the delay between creep into a cavern and its expression at the surface depends upon cavern depth, mode of cavern operation, thickness of salt cover and character of overburden materials or roof beams (Neal 1991). Ground effects atop shallow caverns usually show up more quickly than those above deeper caverns, subsidence over some storage caverns has been detected only after a decade or more of operation (Thoms, 2000).

Figure 12.31. Preservation of a salt roof or the presence of strong overburden spanning the cavern roof makes cavern collapse less likely.

Salt falls versus roof collapses

Salt fall from the cavern roof, as distinct from catastrophic roof collapse and chimneying, occurs in most caverns especially in bedded salt. In a storage cavern it is part of the preliminary construction/leaching phase and also occurs during later storage cavern expansion driven by product cycling. Providing an adequate salt pillow is left as part of the cavern's design, roof falls are not considered detrimental by most operators, as they generally do not greatly affect containment volume. They may sometimes damage casing strings "hanging" from the roof of the cavern.

Most damaging to a salt cavern and possibly to the surface environment is total collapse of a cavern's roof span. It may ultimately lead to the formation of a sinkhole at the landsurface. Such surface expressions atop a brinefield may be delayed for some time after operations have ceased. Typical causes of sinkholes in brinefields are uncontrolled solution leaching, the unexpected intersection of soluble (potash-rich) seams in the salt roof, or the presence of natural brine lenses from natural karstification near the outer parts of a salt mass (see case histories).

Figure 12.31 illustrates the range of probabilities for salt fall and collapse in salt cavities: a) is an intact cavern with adequate salt cover - salt falls are a part of the operational running of the cavern, b) is a breached cavern with a strong roof, still capable of spanning the cavern - ultimately ongoing salt solution it will drive it into a breached system, while c) illustrates a breached cavern system that may soon develop into a sinkhole at the surface - it is the result of total salt removal beneath a weak cavern roof.

Ongoing brine compensation (product cycling) means any storage cavern has the potential to expand until it collapses. To prevent potentially dangerous collapses and product leakage, the shape of a storage cavern must be monitored throughout its life. Some materials found above salt formations, such as reactive shales exposed to brine, may take time to weaken. This means a delayed collapse event, it can occur years after the cessation of solution operations. Occasionally the salt roof to a cavern in stage b) may be taken out with the intent of instigating

collapse (see the SG4 case history). Deliberate oversolutioning is being considered to create desirable wetlands via sinkholes in the former ICI brinefield near Teeside, England.

Ground subsidence

Salt creep means the ground surface over an intact cavern will deform into a shape resembling a wide shallow bowl, hence the name bowl subsidence. Bowl subsidence over intact salt caverns is a response to movements at depth which are transferred to the surface with diminishing amplitude over a wide cone of influence. Subsidence of the landsurface above a salt cavern is normal and to be expected, especially above shallower storage caverns (Figure 12.32). This surface response is similar to "trough subsidence" at the surface above "long-wall" or "room and pillar" mining operations. As the boundaries of such mines advance the accompanying ground movements manifest as moving linear depressions in the landscape called areas of trough subsidence by mining engineers. Bowl subsidence above a salt cavern is not a problem unless the roof span breaches and the rate of ground subsidence increases.

Measured land subsidence rates vary above salt caverns constructed for storage of US Strategic Petroleum Reserve (SPR). Rates atop storage domes in the 1980s ranged up to 40 - 50 mm/year in SPR facilities in Texas and Louisiana (e.g. Figure 12.32a). Rates above the much deeper Tersanne cavern in France are much lower \approx 6-8 mm/year than those of the Gulf Coast (Figure 12.32b), even after the cavern had shrunk relatively rapidly in the 1970s (Figure 12.30). Since the late 1980s, almost all purpose-built storage caverns have been filled and

maintained at higher pressures than in the 1970s. Pressurizing has mitigated salt creep and surface subsidence effects in land areas atop many of these domes (Thoms, 2000).

For example, the Bryan Mound Dome, located southeast of Houston on the Texas Gulf Coast, was one of the first domes to host SPR caverns. The SPR site's subsidence rate was 24.4-36.6 mm per year from 1982 to 1988; when subsequently pressurized from 1988 to 1994 the subsidence rate fell to 6.1-24.4 mm per year; and was 3.1-15.2 mm per year from 1994 to 1999. That is, the median subsidence rate atop Bryan Mound decreased by 70% following the increase in cavern pressure. Rates at the more recently constructed Big Hill SPR site ranged from 6.1-15.2 mm per year from 1989 to 1994; and from 6.1-9.1 mm per year from 1994 to 1999. By contrast, the subsidence rate at another SPR site, West Hackberry, was still high, approximately 76.2 mm per year after pressurization. The reason for the much lower rate at Big Hill is thought to reflect the very thick (300m+) brittle caprock covering the Big Hill salt stock (Linn and Culbert, 1999; Bauer, 1999).

Estimates of rates of acceptable bowl subsidence atop product cycling caverns can be calculated using influence functions based on linear elasticity, the same mathematics used by mining engineers. This works well if the displacements are small, continuity prevails, and if appropriate effective reaction moduli can be estimated for the various inhomogeneous overburden materials above the caverns. Assumptions of mathematical linearity are often incorporated into methods for fitting subsidence models to existing databases in order to predict future trends of subsidence over cavern fields. But different leaching rates and inhomogeneous distributions of subsurface features means predictions are often of limited use. More sophisticated three dimensional finite element computer programs have been used recently to analyse subsidence over brinefields incorporating closely spaced caverns with relatively complicated subsurface geometries (see Kunstman and Mazur, 2000).

Surface indicators of breached caverns

Measuring subsidence above an active storage cavity over a number of years is a useful tool to monitor the state of the cavern and the likelihood of any sinkholes appearing at the surface. Subsidence over breaching caverns, where the integrity of the roof span is finally lost, generally involves three stages (Figure 12.33; Thoms, 2000): 1) initial overburden collapse into breached cavern; 2) upward caving via "chimneying" through indurated strata (which engineers sometimes describe as "stiff soils"), and 3) transition to bowl subsidence in more plastic

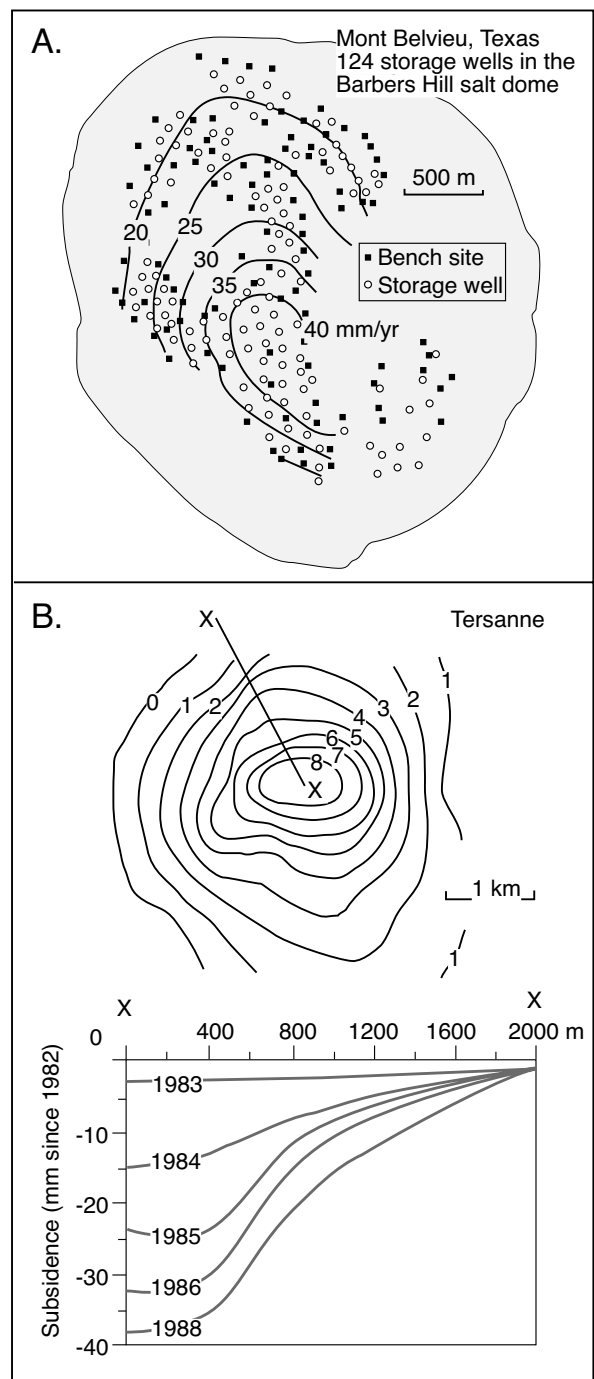

Figure 12.32. Landsurface subsidence above storage caverns. A) Subsidence contours in mm/year atop the Barbers Hill salt dome in the vicinity of Mont Belvieu, Texas (after Ratigan, 1991). B) Subsidence contours in mm/year atop the Tersanne storage cavern, France. Lower panel plots successive subsidence profiles from 1983 to 1988 along the line X-X' (after Bérest and Brouard, 2003; Durup, 1991).

soils near the surface. Following initial roof span collapse, local conditions determine whether caving or bowl subsidence will dominate. After an initial breach and collapse, Stage 2 caving stops vertically through indurated strata as an upward migrating cavity atop a growing chimney. The cavity diminishes in height as it rises because of the bulking of caved materials into the stopping chimney. In Stage 3 the caving mechanism transforms into bowl subsidence as more plastic horizons (weathered strata and soils) are encountered nearer the surface. Breached caverns typically manifest at the surface as relatively deep subsidence bowls, sometimes with sinkholes near their centres.

Stage 2 caving can be bypassed or be arrested if the breached cavern is overlain only by plastic overburden or the cavern is too small to contain all the bulking debris from the overlying strata. In the latter case, the bulking materials fill the cavity to where they can support the roof once more, so arresting further upward migration. Localized bowls of subsidence will usually be seen at the surface over the arrested cavity. With time, the bulked materials may consolidate and allow some additional upward migration of the cavity, and so drive additional subsidence.

Among the various subsidence features, sinkholes are of greatest concern as they are rapidly expressed surface features of typically downdropped plugs of surface material encircled by near vertical sides. They occur when Stage 2 caving dominates all the way to the surface. Concentric fissuring and collapse of the landsurface atop a sinkhole can form within hours of the structure first breaking through to the surface. Overburden

materials rapidly slip and fall into the growing water-saturated core with a huge potential for property damage and even loss of life (see case histories).

Monitoring and minimizing collapse

Subsidence effects, and even active sinkholing were once ignored by brinefield operators but changes in rates of subsidence, along with sonar monitoring of cavern shape, are now used as indicators of the state of the cavern. Responsible operators now conduct periodic or continuous subsidence surveys, and if anomalous effects are recognised, preventative action can be taken.

Routine monitoring of subsidence over storage cavern fields can be performed with conventional land surveying methods. A network of reference points or monuments is set up that effectively spans a brinefield or storage facility (Figures 12.32a). A tie-in is often made to an established reference point located some distance away from the influence of the field. Differences in elevations of points over time intervals between surveys can then be interpreted as velocities of vertical movement (Figures 12.25b, 12.32). It is important to perform surveys at about the same time each year to minimize effects of natural seasonal factors, e.g., soil temperature and rainfall. For some cavern fields it may be more efficient to make use of the Global Positioning System (GPS) for subsidence monitoring. Regulatory agencies often require that subsidence over storage caverns be routinely monitored and reported. Standard techniques for this

purpose are given in Swarts (1993), Watts (1991) and Wong (1982).

More sophisticated automated methods for monitoring subsidence are justified when there is a significant risk of environmental or property damage, as in an area where there is a high probability of sinkhole development in close proximity to residences or storage pipelines and other infrastructure. Such a system might consist of an array of strategically placed tiltmeters, geophones, and inclinometers, with remote read-out and telemetry components. This system should be capable of collecting and

Figure 12.33. Three stages of cavern collapse and sinkhole growth (after Thoms, 2000).

sending data to a comprehensive analysis station at selected time intervals or when activated by a precursor event. Significant events may consist of accelerating localized surface movements, microseisms, and fissures.

Monitoring ground subsidence and cavern shape allows a cavern operator to minimize the effects of subsidence by:

Minimising subsidence from salt creep - As noted earlier, salt creep into caverns causes longterm bowl subsidence at the surface. It follows that bowl subsidence can be mitigated by minimizing salt creep in caverns. The most direct method for minimizing salt creep in existing hydrocarbon storage caverns is to operate them at the highest practical pressures at all times. The determination of the highest practical cavern pressures and operating schedules will involve consideration of site-specific cavern rock mechanics, economic and regulatory factors, as well as the potential impact of subsidence (Rokahr, et al., 1998).

Maintaining adequate salt cover - In order to avoid possible collapse that might ultimately lead to sinkholes, an adequate salt cover must be maintained over salt caverns during solution mining and product cycling. Regulatory agencies generally now require that caverns be monitored to ensure that an adequate salt roof is maintained above caverns. Downhole "wireline" logging technology, e.g. sonar, is available to periodically check shapes and sizes of caverns and the location of the salt roof (Crossley, 1998).

So how stable is a storage cavern?

Sites that are most suitable for a storage cavern lie within relatively homogenous regions of salt located deep in a diapiric salt mass, typically more than a kilometre below the landsurface and hundred of metres below the upper surface of the salt. Even today, many salt caverns used for various types of storage were first used for the commercial production of brine or hydrocarbons, although the number of purpose-built facilities increases year by year. Some older caverns now have shapes and spans or are at shallower depths that make them marginally suitable for future storage or waste disposal. Likewise the access wells to these caverns were drilled some time ago and suffer the effects of corrosion and older cement technologies. These older non-purpose built caverns do however make excellent "in-situ" laboratories to test the strength and integrity of salt formations. For example one brine cavern in the Bryan Mound Dome in Texas now has a roof span of 335 metres, yet it has not collapsed (Thoms and Gehle, 2000a).

Natural gas storage caverns, with their inherent need for the deep cycling of internal pressures, place much greater demands on the integrity of the surrounding salt than caverns used for liquids storage. Salt cavities for natural gas storage were first designed with relatively small storage volumes but designs over the last three decades have increased in size. In Germany the maximum permitted volumes of gas for storage in salt caverns started at 350,000 m³, increased to 500,000 m³ and for the past ten years has been set at 700,000 m³. In the US cavern volumes for gas storage are not specifically regulated, but a design-specified cavern for natural gas storage with a volume of 15 mmbbl (6.5 Bcf) and a roof span of more than 100 metres is now underway in the Napoleonville Dome in south Louisiana (completion 2007).

Cavern Plugging

When a salt cavern used for hydrocarbon storage reaches the end of its life it must be plugged in a way that does not allow for any later environmental degradation. Wells can not be plugged using the same relatively straightforward methods used to seal an oil or gas well that has reached the end of its useful life. Oil and gas wells are usually sealed by simply installing a "plug" of alternating intervals of different grouts. Sealing and abandoning a brinewell or a salt cavern is not the same as plugging an oil and gas well for two main reasons (Ratigan 2000):

- 1) Brine wells are generally completed with much larger casings than oil and gas wells.
- 2) The fluid pressure in the abandoned salt cavern is still joined to the casing string and it rises after plugging.

The first is not a significant deterrent to plugging and abandoning a storage well, appropriate modern grouts and methods are offered by most service companies. Essentially all of the uncertainties associated with cavern sealing and abandonment are a direct result of the second factor, rising fluid pressure and its effects on the access well(s).

Once a cavern is sealed and abandoned, salt begins to flow or creep into the opening and continues to flow until pressure differences between the salt and the cavern interior vanish. Plugs in former access wells to abandoned caverns must be capable of holding back this pressure, otherwise brine or stored waste product may be squeezed back up the well bore. Fluid flow paths out of the cavern are schematically depicted

Figure 12.34. Factors influencing cavern integrity once a cavern has been plugged and abandoned (after Ratigan, 2000).

in Figure 12.34, while Table 12.5 summarizes the effects of the various processes contributing to fluid flow and pressure changes in a sealed salt cavern (Ratigan 2000).

It is not just salt creep that increases the fluid pressure in an abandoned cavern. Solution mining and product cycling results in a significant disruption of the thermal environment in the salt. Feed solvent injected into the formation to create the cavern is

almost always cooler than the salt formation, as is most stored product or waste. Continual leaching of a cavern to its final shape can result in a significant cooling of the salt surrounding the cavern, particularly near the cavern boundary. Unless a cavern has been inactive for a long period of time (tens of years), the fluid in the cavern will be at a lower temperature than the “pre-cavern” temperature of the rock salt. Thus, when the cavern is sealed, heat will flow from the salt mass to the cavern fluid and its temperature will rise in response. A rise in fluid temperature expands the fluid volume and, since the cavern is sealed, the cavern fluid pressure will rise.

Unless the cavern was idle for some years prior to its plugging, cavern fluid is not 100 percent saturated with sodium chloride. Salt dissolution may occur after a cavern is sealed and tends to lessen the effects of pressure rise. So, even after sealing, dissolution of the cavern wall continues until the enclosed fluid approaches halite saturation. This increases in the cavern volume and so tends to decrease the cavern fluid pressure. Salt dissolution is an endothermic chemical reaction, which further reduces the temperature of the fluid, and so further reduces fluid pressure in the cavern.

A number of other interactive processes can effect the stability of a storage cavern and its plugged entry hole, depending on the nature of any waste stored in a sealed cavern. Differential settling and compaction cause the various wastes pumped into the cavern to separate into layers. Various chemical reactions can then occur within or between layers of waste, or between the waste and the surrounding salt. All can cause unexpected pressure build-up and so drive fluid penetration of the plug seal. Gas can also be produced in a sealed storage cavern, either by bacterial degradation of waste materials or by natural degassing corrosion of the surrounding salt. This too leads to a buildup in fluid pressures and places increased stress on the cavity plug and the cavern walls.

Process	Influence on Fluid Pressure	Time Scale
Salt creep	Increases cavern fluid pressure at a monotonically decreasing rate	Majority of the pressure rise occurs years to tens of years after sealing
Fluid heat transfer between salt and cavern	Causes cavern fluid expansion and increases cavern fluid pressure at a decreasing rate	Majority of pressure rise within tens of years to many tens of years after sealing
Salt dissolution and cavern fluid saturation	Increases cavern volume and decreases fluid temperature, which in turn, causes a decrease in fluid pressure	Majority of pressure decrease within years after sealing
Cavern fluid escape into salt	Decrease in cavern fluid pressure	Continues indefinitely
Cavern fluid escapes via sealing plug/or casing cement	Decrease in cavern fluid pressure	Continues indefinitely

Table 12.5. Factors influencing fluid pressure in a plugged cavern (after Ratigan, 2000)

Even though salt has extremely low permeabilities, pressurised cavern fluid may slowly seep into the surrounding salt. This will reduce the volume of fluid in the cavern, and thus help ameliorate the pressure exerted on the salt by the cavern fluid. However, the entry of cavern fluids into the salt will also alter the salt matrix stresses, increase the rate of creep and the intrinsic permeability of the salt.

Before a cavern is sealed, the amount of cavern fluid that permeates the salt cavern walls is negligible. After the cavern is sealed and the cavern fluid pressure rises, the amount of cavern fluid that permeates the cavern wall must increase, both because the pressure gradient (driving the fluid transport) increases and because the salt permeability increases. If the cavern fluid pressure cannot be reduced sufficiently through the diffusional flow it is possible that fractures could develop in the salt. This would in turn reduce the cavern fluid pressure, but obviously increases the likelihood of a possible leak of cavern fluid into adjacent formations. Whether or not a fracture or fractures develop depends on the rate of cavern fluid pressurization. Low pressurization rates would not be expected to result in fracturing of the salt, rather the salt would flow and anneal. Very high rates of pressurization might well produce a brittle fracture.

But, as mentioned earlier, the salt itself is probably not the weakest link in terms of seal integrity. Pressurized cavern fluid will tend to first breach or fracture the sealing plug/casing shoe. Diffusional or fracture-induced flow could then occur through the sealing cement plug or the cement between the salt borehole wall and the deepest casing (Figure 12.34 inset).

As well as dissolution creating potential seal problems, there is also the longer term problem of ongoing local rise of smaller salt spines within a diapir (Figure 6.9c), which can shear casing and allow a breach to form in the well string. This was the situation in the at-surface well collar in well S-5 in the Sour Lake oilfield atop the Sour Lake diapir in Hardin County, Texas (Looff, 2001). In 1998 the well casing sheared, driven by a rising spine of salt in what was overall a degrading or dissolving diapir crest. The 13 5/8-inch casing string, set in salt caprock, was being pushed upward inside the 16 inch casing. This fractured the cement between the two strings and the 16-inch casing string, that had been welded to the wellhead, which was sheared off its foundation as it was displaced upward by several inches.

Storage in salt creates a complex situation with various processes and mechanisms driving cavern pressures in opposite

directions. A study of the stability of such systems is a study in multivariate rock mechanics, grout physics and pore fluid chemistry, well beyond the sedimentological emphasis of this book (see Munson, 1997; Lee and De Souza, 1998 for a discussion of some of the basic considerations). As yet, our models of salt and grout response of time frame of hundreds or even thousands of years do not allow us to reliably predict exact conditions under which pervasive fracturing or leakage will occur. Accordingly, most storage facilities are “over-engineered” to reduce the possibility of longterm failure (Ratigan 2000).

Summary

Solution mining with appropriate monitoring and timely plugging offers major advantages in generating chemical feedstock compared to room-and-pillar mining techniques. Drilling injection and production wells cost less than sinking deeper shafts and opening underground workings. It also provides safer operating conditions as underground miners are not needed.

In terms of problems with solution cavities and storage facilities it is important to note that a salt mass used for storage has never failed or leaked. The weak point in these systems is in the well, its casing and its grout. Even so, almost all the problems related to well failure are more a matter of human error, either by negligence, or a lack of understanding by on-the-ground personnel. There is a general rule of thumb when it comes to salt cavities salt mines and that is, “keep it in the salt!” Most failures and breaches occur when a leaching or a mining operation allows the cavity to contact the edge of the salt. There undersaturated water crossflows can exaggerate any uncontrolled dissolution problems.

The rapidly expanding technologies of deep purpose-built and monitored storage caverns located well within geologically suitable salt masses, will lead to future safer storage of hydrocarbons and hazardous wastes. Almost all the problems documented in the USA and elsewhere come from storage operations utilising caverns constructed by earlier less-defined solution methods. Even so, in all the incidents related to various storages in salt caverns the integrity of the cavern has never been threatened by any accident. All incidents to date can be traced back to poor management practises or utilisation of facilities that are not necessarily suitable. Salts caverns are probably one of the safest ways to store hydrocarbons and dispose of hazardous materials.

Evaporites
 climatic control on Quaternary deposits 59–67

Evaporite indicators
 attributes 531–559
 authigenic burial salts 559–564
 baryte 553–555
 calcitised evaporites 539–547
 celestite 548–553
 fluorite 553–555
 silicified evaporites 532–539
 controls on silica 537
 magadiite 261, 262–264, 537

Evaporite metal associations
 low temperature
 in Black Hills U 530
 in Cadjebut Pb-Zn 528–530

Evaporite solution breccias
 “chalky” dolomite 474, 506
 attributes 472–481
 basal anhydrite 498–500
 boxwork texture 477
 breccia geometries 478
 controls 478
 clasts
 description 473
 nature of movement 473
 origin 475
 diapiric 481–486
 dissolution residues
 attributes 472
 gypsum karst 494–500
 preferential solution 493
 evolution of texture 474–478
 focus for sulphide mineralisation 528–531
 hydrocarbon traps 786
 hydrological controls
 postinduration 480
 preferential solution breccias
 attributes 493
 effect on correlation 497
 speleothem textures 477
 stratiform breccia 472, 478–479
 typical vertical sequence 474
 uranium 530

Evaporitic carbonate
 algal mats 232
 attributes 5
 types
 boxwork limestone 228
 laminite 5, 226, 273
 stromatolites 6–57, 228
 tepee 16–18, 228
 travertine 9
 tufa 9, 223–224, 244–246

Evaporitic mudflat
 attributes 178–179, 296–297
 hydrological attributes 113
 Ewaso Ngiro River, Africa 257

F

“Fill and spill” cycles 351

 Great Salt Lake, USA 240
 Lake Lisan, Middle East 278
 Lake Urmia, Iran 255
 Lake Van, Turkey 249
 Mono Lake, USA 244
 Weakness of salt
 in salt flow modelling 381
 Weeks Island, Louisiana
 oil storage problems 930
 Wet interdune
 attributes 119–121
 Wilson cycle
 control on basinwide evaporites 331
 squeezed diapirs 425
 thin-skinned salt tectonics 419
 Woese, Carl
 domains of life 629

Y

Yotvata Sabkha, Israel
 attributes 181

Z

Zagros Foldbelt, Middle East
 compressional tectonics 420
 Zechstein evaporites, Europe
 authigenic magnesite 133
 brine evolution 84
 lack of kainite 84
 raft tectonics 397
 sequence stratigraphy 363–368
 Zeolite
 minerals and properties 882–887
 via brine alteration 85
