CONTENTS

1. INTRODUCTION

Significant progress has been made in the science of carbon nanotubes (CNTs) since the publication of Iijima's milestone paper in 1991 [1]. If there is one thing which has characterized fullerene and nanotube sciences, it is serendipity [2]. The discovery of buckminsterfullerene itself was a wonderful accident, and nanotubes were an unanticipated by-product of the bulk synthesis of C_{60}. CNTs have captured the imagination of physicists, chemists, and materials scientists alike. Their intriguing electronic, magnetic, optical, and mechanical properties, coupled with their unusual molecular shape and size, have made CNTs very promising as functional components for building molecular-based electronics, nanomachines, and nanoscale biomedical devices as well as composites as structural materials. Physicists have been attracted to their extraordinary electronic properties, chemists to their potential as "nanotest-tubes," and materials scientists to their amazing stiffness, strength, and resilience. Nanotechnologists, mostly from the three aforementioned areas, have discussed and explored possible nanotube-based nanodevices such as nanogears, nanobearings, single electron transistors, quantum computers, and so on. Many review articles [3–9], books [2, 10–14], and special issues of journals [15–17] have been devoted to this topic to collect the new developments and concepts in this rapidly developing interdisciplinary field.

Following the discovery of CNTs, single-walled carbon nanotubes (SWNTs) reported simultaneously by Iijima and Ichihashi [18] and Bethune et al. [19] in 1993, which are ideal models of one-dimensional materials with unique structural and electronic properties, have generated great interest for use in a broad range of potential nanodevices. Perhaps the largest volume of research into nanotubes has been devoted to the electronic properties, of which the field emission study was extensive, profound, and highly near to a practicable product. CNTs are known to be very good electron emitters. This is why since their discovery there has been a lot of speculation and experiments about the use of nanotubes in the construction of flat panel devices. The first study on CNT field emission (FE) properties was carried out by Rinzler et al. [20] from Rice University. They found that field emission of electrons from individually mounted CNTs has been dramatically enhanced when the nanotube tips are opened by laser evaporation or oxidative etching. A short time-hereafter, the field emission from a film of postsynthesized reduced CNT alignments was made by de Heer and co-workers [21]. However, a prerequisite for a major breakthrough in the area would be the perfect alignments of CNTs on a suitable surface.

This chapter is mainly focused on the synthesis and applications of aligned carbon nanotubes, including SWNTs and multiwalled carbon nanotubes (MWNTs). The organization of this chapter is as follows: Section 2 first considers three classical methods for synthesizing nanotubes, including arc discharge, laser ablation, and chemical vapor deposition (CVD), especially comparing the advantages and disadvantages of each synthesis method, and then presents the new preparation techniques developed in the last two years. In Section 3, the fabrications of various alignments and patterns are discussed in detail for MWNTs, and the emphasis in this section is on the controllable fabrication of nanotube alignments. Alignments of SWNTs are described in Section 4. Section 5 gives a discussion of properties and application of aligned CNTs, and the FE properties are of great concern. Finally, future research consideration and challenges are presented in Section 6.

2. CARBON NANOTUBES AND THEIR PREPARATION METHODS

A carbon nanotube consists of one or more seamless cylindrical shells of graphitic sheets. The nanotube is typically closed at each end, according to Euler's theorem [22], by the introduction of pentagons in the hexagonal network. A theoretical model of a CNT with two closed ends was simulated by Endo and Kroto [23]. However, an experimental observation of the tube with both ends closed has seldom been reported for two main reasons. One is that most CNTs, regardless of the synthesis methods (such as arc discharge, laser ablation, and catalyst decomposition of hydrocarbon), are attached by either open ends, or one closed carbon cap, or ends capped with metal particles. The other is that the large length/diameter ratio (>1000) prevents one from simultaneously observing two ends of the tubes in the same field of vision under a transmission electron microscope (TEM), though tubes with two caps exist in the product. In an earlier report [24], it was also noticed that nanotubes produced using the arc discharge technique can be fairly short, and these structures with two capped ends can be observed under high resolution transmission electron microscopy. However, the structure is so small and asymmetric, with a diameter of at most 40 nm, that it should be precisely defined as an elongated nanoparticle of graphitic carbon rather than a well-defined CNT with capped ends. We reported a perfect carbon nanotube with two graphitic caps observed in the products by pyrolysis of metal phthalocyanine [25]. Such a large CNT with capped ends is of great interest for the formation mechanism of nanotubes.

CNTs are most attractive because of their fascinating features. What makes nanotubes so special is the combination of dimension, structure, and topology that translates into a whole range of superior properties. The basic constitution of the nanotube lattice is the C–C covalent bond (as in graphite planes) which is one of the strongest in nature. The perfect alignment of the lattice along the tube axis and the closed topology endow nanotubes with in-plane properties of graphite such as high conductivity, excellent strength and stiffness, chemical specificity, and inertness together with some unusual properties such as the electronic structure, which is dependent on lattice helicity and elasticity. In addition, the nanodimensions provide a large surface area that could be useful in mechanical and chemical applications. The surface area of MWNTs has been determined by BET techniques and is $\sim$10–20 m^2/g, which is higher than that of graphite but small compared to activated porous carbons. This value for SWNT is expected to be an order of magnitude higher. Similarly, due to the relatively large hollow channels in the center of nanotubes, their density should be very low compared to graphite. Rough estimates suggest that SWNT density could be as small as 0.36 g/cm^3, and MWNT density could range between 1 and 2 g/cm^3 depending on the constitution of the samples [7].

2.1. Classical Synthesis Methods

Nanotubes are not always perfect seamless shells of graphite. Their quality depends on the method used to generate them and the exact conditions of the particular method. Making nanotubes is simple, but making good quality samples with high yields and highly graphitized shells is not trivial.

There are several methods to produce CNTs, but three classical methods including arc discharge, laser ablation, and a catalytic technique remain the most practical for scientific purposes and realistic applications. The arc method [26, 27] remains by far the best technique for the synthesis of high-quality nanotubes simply because the process has a very high temperature of 4000 K. However, this method suffers from a number of disadvantages [14]. First, it is labor intensive and requires some skill to achieve a satisfactory level of reproducibility. Second, the yield is rather low, since most of the evaporated carbon is deposited on the walls of the vessel rather than on the cathode, and the materials that are formed in the deposit contain substantial amounts of nanoparticle and other graphitic debris. Third, it is a batch rather than a continuous process, and it does not easily lend itself to scale-up. The amount of nanotubes that can be produced is limited. Progress in this direction has been hampered somewhat by a lack of understanding of the growth mechanism of tubes in the arc.

The laser evaporation technique developed by Smalley's group [28–30] appears to produce the highest yield and best quality materials, but the high powered lasers required for this method will obviously not be available in every laboratory. The synthesis of MWNTs in this way has been carried out by a pure graphite target [29]. In 1995, they reported the development of the laser synthesis technique which enabled them to prepare SWNTs with a target of a metal–graphite composite instead of pure graphite [28]. Subsequent refinements to this methd led to the production of SWNTs with unusually uniform diameter [30].

CVD of hydrocarbon over metal catalyst has been another classical method to produce carbon materials. Various forms of carbon fibers, filaments, and MWNTs have been synthesized by this technique in the past [31–34]. In general, metal catalytic particles are exposed to a medium containing hydrocarbon gaseous species, and the formation of nanotubes is catalyzed [35]. During growth, good uniformity in size of the tube is achieved by controlling the size of the seeded catalyst particles, and the process can be easily scaled up to produce large amounts of materials. In some cases, when the catalysts are prefabricated into patterned arrays, well-aligned nanotube assemblies are produced, which will be discussed in detail (Section 3). This seems a promising direction for further research. However, the quality of tubes produced in this way has been rather poor compared with the arc and laser methods. As shown in Figure 1, a nanotube prepared by a catalytic pyrolysis of iron phthalocyanines is a structure with lots of topological defects in a wall [36].

There is a further serious weakness of all these techniques for preparing nanotubes; they produce a wide range of the size and structures. This may not be a problem for some applications, but it could be a drawback in areas where specific tube structures with uniform properties are needed, such as in nanoelectronics. Progress in this direction has been hampered somewhat by a lack of understanding of the growth mechanism of tubes. Although a number of theories [37–40] have been put forward, none of which has gained universal acceptance, most questions remain unanswered and the uncertainty surrounding nanotube growth
Figure 1. A carbon nanotube with many topological defects synthesized by chemical vapor deposition. Reprinted with permission from [37], M. Endo and H. W. Kroto, *J. Phys. Chem*. 96, 6941 (1992). © 1992, Elsevier Science.

mechanisms has impeded progress in the development of more controlled synthesis techniques.

2.2. Preparation Methods of Nanotubes

In the last two years, a few new synthesis methods were developed to produce CNTs to solve one or more problems during the conventional preparation process. These ways take respective advantages over the conventional methods to a certain extent and were of important potential for basical research as a new route to produce CNTs. However, the samples of the nanotubes produced by all those new methods existed in lower quality and less perfect structures than the classical ones. A number of experimental conditions should be optimized before these synthesis methods are developed to produce nanotubes with high quantity and desirable structures to meet scientific research and practical applications.

2.2.1. Hydrothermal or Solvothermal Synthesis

The oxidative effect of hot water on amorphous carbon is currently used for purification of CNTs by hydrothermal treatment (immersion in water at moderate and high temperatures and pressures) [41, 42]. It was found that the hydrothermal processing method could be developed to synthesize nanostructural carbon [43, 44]. Recently, MWNTs have been synthesized in the absence of metal catalyst by hydrothermal treatment of amorphous carbon in pure water at 800 °C and 100 MPa [45]. The hydrothermal nanotubes are free of amorphous carbon after treatment. The homogeneity of hydrothermal processes and availability of amorphous carbon materials, without the need for catalyst, are

advantages favoring the scaling-up of this new method. However, this method suffers from harsh synthesis conditions (a high temperature of 800 °C, a high pressure of 100 MPa, and a long time of 48 h), and electron microscopy observations revealed that very short multiwalled tubes (hundreds of nanometers) exist together with the aggregates of needle-like and polygonal nanoparticles.

Compared with this method, a solvothermal route to MWNTs has been developed under a lower temperature (350 °C) and shorter time (8 h) [46]. This catalyst-assembly benzene-thermal route was carried out to produce CNTs using reduction of hexachlorobenzene by metallic potassium in the presence of Co/Ni catalyst. The synthesis temperature was low, but the quantity of the nanotubes was poor.

2.2.2. Supercritical CO_2 Technique

Carbon dioxide is nonflammable, essentially nontoxic, and environmentally benign [47]. Motiei et al. [48] reported the structures of graphitic concentric shells grown by supercritical CO_2. It is found that MWNTs and nested fullerenes could be prepared from dry ice in the presence of Mg by heating the precursors in a closed vessel at the autogenic pressure of the mixture. This method avoids the complexities of using a flowing gas at controlled pressures and high temperature and requires no technically complex equipment.

2.2.3. Solid-State Metathesis Reaction

The solid-state metathesis reaction has been developed over the past few years into a simple and effective route to materials that are difficult to synthesize by conventional methods [49–51]. These highly exothermic and self-propagating reactions initiated by a heated filament often use molecular precursors to produce crystalline products. An exchange reaction between carbon halides and lithium acetylide catalyzed by cobalt dichloride enables the rapid synthesis of CNTs by the following equation [52]: $C_2Cl_6 + 3 Li_2C_2 \rightarrow 8 C$ (nanotubes) $+ 6$ LiCl.

Without a catalyst, only graphitic and amorphous carbon forms. These reactions, once optimized, will likely require cheaper precursors, more preparation, and less expensive equipment than existing methods. However, along with multi- and single walled nanotubes, graphite-encapsulated cobalt nanoparticles, free carbons, and cobalt metals were found. These shortages should be overcome before the extensive application of this method.

2.2.4. Flame Synthesis

Combustion is widely used in industrial processes for large-scale materials synthesis, such as for carbon black and metal oxides [53, 54]. These flame processes are well known for their many desirable features including continuous processing and energy efficiency. Recent investigations have sought to take advantages of these advantages to synthesize SWNTs in aerosol form [55, 56]. It was found that SWNTs could be produced by a binary or ternary gas mixture of $CO/C_2H_2/H_2$ with a metal catalyst at 700 °C in a two-stage flame. This flame system afforded the advantage that the catalyst formation step could be separated from the nanotube growth steps, which allowed investigations of catalyst particle size

dependencies upon nanotube growth unlike methods that employ *in-situ* generation and concurrent growth.

Apart from the methods presented previously, there are many other methods such as a gas phase synthesis [57], a reduction catalysis route at a low temperature of 200 °C [58], and a solar approach [59], although these methods to produce nanotubes suffer from different drawbacks.

3. ALIGNMENTS AND PATTERNS OF MULTIWALLED CARBON NANOTUBES

CNTs are the most promising materials anticipated to impact future nanoscience and nanotechnology. Their unique structural and electronic properties have generated great interest for use in a broad range of potential nanodevices [60, 61]. Most of these applications will require a fabrication method capable of producing CNT alignments or patterns with uniform structures and periodic arrangements to meet device requirements. Therefore, the ability to controllably obtain ordered or pattering CNT architectures is important to both fundamental characterizations and potential applications [62]. Controlled synthesis involving CVD has been studied as an effective strategy to order or pattern CNTs on a variety of surfaces [63–67]. This has been stimulated by its simplicity, its ability to yield structures that are two- or three-dimensional (2D or 3D) periodic over large area, and its potential to be much less expensive than other synthesis methods such as an arc discharge and a laser ablation. In these early attempts, most of the works to date have focused on fabricating 2D CNT alignments or patterns over large areas because of their paramount importance for obtaining scale-up functional devices. However, in contrast to these efforts, little research on the preparation of 3D CNT alignments or patterns has been reported because of many technical difficulties, although the 3D structures show more unique and potential applications such as photonic devices [68, 69], data storage [70, 71], and ultrahydrophobic materials [72, 73]. In this section, various fabricating methods are discussed for alignments and patterns of MWNTs, including 2D or 3D structures.

3.1. Preparation of 2D Nanotube Alignments on Different Substrates

Alignments or patterns of CNTs are particularly important for fabricating functional devices such as field emitters and nanoelectronics. Earlier attempt to manipulate nanotubes for these application have been made by postgrowth methods such as cutting a polymer resin–nanotube composite [74] or drawing a nanotube–ethanol suspension through a ceramic filter [75]. In the past few years, a great quantity of research on the fabrication of 2D CNT alignments has been reported [63–67, 76–78]. Although all these 2D CNT alignments were synthesized by CVD, different technical routes were adopted by different research groups. The main differences of these synthesis methods may be summarized as the following factors: a substrate and a precursor. The substrates that are used to support the CNTs alignments may be put into two categories: porous templates (mesoporous

silica [63], nanochannel alumina [76], etc.) and plain plates (quartz glass [77], single crystal silicon plate [78], glass [65], etc.). As far as the precursor is concerned, there are two main materials: hydrocarbons [66, 76] and metal organic compounds [77]. When hydrocarbons are used as precursors, metal catalysts (such as Fe, Co, Ni) should be added to grow CNTs. However, as for metal organic compounds no additional metal catalyst is necessary since these precursors contain both the metal catalyst and carbon source required for CNT growth.

The following discussion is mainly focused on the substrates where the nanotube alignments grow.

3.1.1. Planar Substrate

Quartz glass is a good planar substrate for growing well-aligned nanotubes [64, 77, 79]. Terrones et al. [64] described a method for generating aligned nanotubes by pyrolysis of 2-amino-4, 6-dichloro-triazine over thin films of a cobalt catalyst patterned on a silica substrate by laser etching. We have grown well-aligned nanotubes with large diameters on quartz glass substrate by pyrolysis of a metal phthalocyanine under Ar/H$_2$ flow at a temperature of 950 °C [77]. We investigated the influence of the growth time and precursor level on the structures of MWNTs. It was found that both the outer diameter and length of aligned nanotubes increased with increasing growth time and precursor level. The outer diameters of well-aligned nanotubes range from 25 to 250 nm, and the length ranges from 1 to 500 μm. However, the microstructures of aligned naotubes are independent of the growth temperature and the Ar/H$_2$ flow rate in our case.

Figure 2a is a scanning electron microscopy (SEM) image showing a large area of well-aligned CNTs with uniform diameter and length. Figure 2b is a typical TEM image of the bamboo-shaped nanotubes [80] produced by pyrolysis of 0.5 g iron phthalocyanine in 12 min. The graphite sheath sliding out from the Fe particle surface accounts for the formation of the compartments of bamboolike CNTs. The driving force of the sliding was caused by the stress accumulated

Figure 2. A SEM micrograph showing large area well-aligned CNTs perpendicular to the surface of the substrate. (b) A typical TEM image of the CNTs produced by pyrolysis of 0.5 g FePc in 12 min. in the graphite sheath due to the segregation of carbon atoms from the inside of the sheath [80].

Apart from quartz glass, we can produce aligned nanotubes on various substrates made of other materials such as single crystalline silicon, iron plate, nickel plate, cobalt plate, and so on.

Glass is the most common material for panel display. The ability to prepare aligned nanotubes over a glass substrate makes them more suitable for electron emission applications. Recently, Ren et al. [65, 81] reported the growth of large scale well-aligned CNT arrays on nickel-coated glass at temperatures below 666 °C by plasma-enhanced hot filament CVD. Acetylene gas was used as the carbon source and ammonia gas was used as a catalyst and dilution gas. It was found that NH_3 plays a crucial catalytic role together with the nickel layer to promote the growth of the nanotubes, and nickel thickness plays a very important role in determining the diameters.

Nickel wafers were found to be another good substrate for producing nanotube alignments. Chen et al. have grown aligned graphitic nanofibers on single crystalline Ni (100) [82] and polycrystalline Ni substrate [83] via plasma assisted hot filament CVD using a gas mixture of nitrogen and methane. Small Ni particles on the substrate surface generated by the plasma acted as a catalyst for the growth of nanofibers.

3.1.2. Porous Template

Mesoporous silica containing iron nanoparticles was used as a substrate when well-aligned CNTs were first synthesized by Xie et al. [63]. The mesoporous silica was prepared by a sol–gel process from tetraethoxysilane hydrolysis in iron nitrate aqueous solution [84]. This method to produce large areas of highly ordered, isolate long nanotubes is based on CVD. The tubes are up to about 50 μm long and well graphitized. The growth direction of the nanotubes can be controlled by the pores from which the nanotubes grow.

Porous silicon, a light-emitting material [85, 86], is an ideal substrate for growing organized nanotubes. Fan et al. [60] have prepared porous silicon patterned with Fe film by electron beam evaporation through shadow masks and then on this substrate carried out the synthesis of self-oriented regular arrays of CNTs by catalyst decomposition of ethylene at 700 °C. Porous silicon substrate exhibits an important advantage over plain silicon for synthesizing nanotubes. The investigation showed that the nanotubes grew at a higher rate on porous silicon than on silicon. The well-ordered nanotubes can be used as electron FE arrays. Scaling-up of the synthesis process should be compatible with the existing semiconductor processes and allows the development of nanotubes devices integrated into silicon technology.

Highly ordered arrays of CNTs can be grown by pyrolysis of acetylene on cobalt within a hexagonal close-packed nanochannel alumina template at 650 °C [76]. The method is based on template growth. An illustration of a typical fabrication process flow is shown in Figure 3a. The process begins with the anodization of high purity (99.999%) alumina on a desired substrate. The next step is to deposit electrochemically a small amount of cobalt catalyst into the bottom of the template channels. The ordered arrays of nanotubes (Fig. 3b)
Figure 3. (a) Schematic of fabrication process. (b) SEM image of the resulting ordered arrays of CNTs synthesized using the nanochannel alumina template. Reprinted with permission from [76], J. Li et al., *Appl. Phys. Lett.* 75, 367 (1999). © 1999, American Institute of Physics.

are grown in a flow of a mixture of 10% acetylene in nitrogen. There are several features in this fabrication technique [87, 88]. First, each pore of the template is filled with one nanotube, which defines the tube diameter, and the tube diameter distribution throughout the arrays is narrow. Second, the controlled variation of the nanotube size, density, and array spacing depends on easily adjustable parameters such as the anodizing voltage, electrolyte composition, and temperature. Tube lengths of up to 100 μm can be obtained by varying the length of the pores in the alumina template, which can be achieved by varying the time of anodization. Finally, the method allows inexpensive production of large arrays of ordered nanotubes.

3.2. Controllable Fabrication of CNT Alignments

3.2.1. Selective Positioning Growth for Patterns

Selective positioning growth of CNT patterns is arousing a wide range of research interest [89–91]. In the past few years, several methods have been developed to site-selectively grow nanotubes.

Photolithographic Approach Wei et al. [89, 90] have used a CVD method with gas-phase catalyst delivery to direct the assembly of CNTs in a variety of predetermined orientations onto silicon/silica substrates, of which patterning was generated by photolithography followed by a combination of wet and/or dry etching. Figure 4 shows some striking examples of organized nanotube patterns grown on preselected substrate sites by the photolithographic approach. There is no nanotube grown on silicon, but the aligned nanotubes grow readily on silica in a direction that is normal to the substrate surface [90]. The preference of nanotubes to grow
Figure 4. SEM images of organized nanotube patterns grown on pre-selected substrate sites by a photolithographic approach. Scale bars, 100 μm. Reprinted with permission from [89], B. Q. Wei et al., *Nature* 416, 495 (2002). © 2002, Nature Publishing Group.

selectively on and normal to silica surfaces allows the sites of nucleation and the direction of growth to be controlled. Yang et al. [67] have also reported the fabrication of patterns of perpendicularly aligned nanotubes with resolution down to μm scale by pyrolysis of iron phthalocyanines onto a quartz substrate prepatterned with a photoresist film.

Electron Beam Lithographic Approach With a electron beam lithographic technique, patterned growth of freestanding nanotubes on nickel dots on silicon can be achieved by plasma-enhanced hot filament CVD [92]. The thin film nickel pattern as a catalyst for growing nanotubes was fabricated on a silicon wafer by a standard microlithographic method and metal evaporators. Well-separated, single MWNTs grew on each dot of an array of ∼100 nm nickel dots under an acetylene/ammonia mixture at below 660 °C. The diameter and height depend on the nickel dot size and growth time, respectively. Using this method, devices requiring freestanding vertical CNTs such as scanning probe microscopy, FE flat panel displays, etc. can be fabricated.

Soft Lithographic Approach Most microfabrication methods mentioned start with photolithography to form a pattern in a photoresist on the substrate. Although these techniques are very widely used, they are incompatible for solution such as gels, some polymers, some organic and organometallic species, and biological molecules. To pattern these materials successfully, the patterned photoresist must be impermeable to the reagents used and the deposited materials should not be compromised by solvents used for the liftoff. Methods other than photolithography

often involve a shadow mask formed from a rigid metal. The air gap between the mask and substrate makes the use of rigid shadow masks to pattern materials from solution impossible [60].

One micropatterning technique that circumvents some of these drawbacks is soft lithography [93–95], which uses a patterned elastomer fabricated from poly(dimethylsiloxane) as the mask, stamp, or mold. Because the elastomer can conform to and seal reversibly against the contours of a surface, it can be used as a mask or a stamp. Soft lithography has become a very promising technique for micro/nanostructuring a wide range of materials. Various strategies, including microcontact printing (μCP) [96–98] and micromolding [99], have been developed for nanoscale patterning.

Kind et al. [96] elucidated some important aspects of using μCP to pattern silicon substrate with catalysts followed by the growth of CNTs on the activated regions. In brief, a patterned and inked elastomeric stamp is used to print a catalyst as a pattern onto a substrate (Fig. 5). The growth of MWNTs follows from the catalytic decomposition of acetylene on the printed pattern of the catalyst. Changing the concentration of the catalyst in the ink solution allows one to tune the density of the nanotubes from single, randomly oriented nanotubes to densely packed arrays of nanotubes oriented normal to the substrate.

This approach relied on rigid solid-state substrates such as silicon and alumina to achieve aligned nanotubes, which
Figure 5. Procedure for the patterned growth of carbon nanotubes by microcontact printing a Fe(III)-based catalyst precursor onto silicon wafers. The stamp is inked with an ethanolic solution of Fe(III) and then printed onto the substrate. The growth of carbon nanotubes proceeds by the catalytic decomposition of acetylene. Reprinted with permission [96], H. Kind et al., *Langmuir* 16, 6877 (2000). © 2000, American Chemical Society.

may limit its wider scope of application. Hence, it would be interesting and challenging to investigate the possibility of performing *in-situ* selective growth on a novel substrate such as polymers and its direct integration with elastomeric polymers to fabricate practical devices. Ng et al. [98] have recently reported the combination of soft-lithography-mediated growth and surface wettability manipulation of an elastomeric polymer to achieve *in-situ* highly site-selective growth of multiwalled nanotubes arrays on elastomeric substrates patterned with catalyst precursors. The realization of this approach may provide new methodologies for flexible FE display, implantable sensors, etc.

Biasing Growth Approach   The investigations by Avigal and Kalish [100] showed that patterns of MWNTs could be obtained by positively biasing the substrate during growth. Growth was performed in a flowing mixture of 7% CH_4 in Ar onto Co covered Si held at 800 °C with and without the presence of an electric field. It was found that the tube alignment occurs only when a positive bias is applied to the substrate whereas no aligned growth occurs under negative bias and no tube growth is observed with no field. Therefore, selective area biasing may permit selected area growth of vertically aligned CNTs, a process that may find many applications.

Fabrication of micropatterned nanotubes remains both scientific and technically challenging. Many methods have been presented in preceding parts of this section to produce nanotube patterns. However, these synthetic methods suffer from complex pre- or postsynthesis manipulation. In 2000, we have developed a simple method [101] for large-scale synthesis of CNTs (up to several square centimeters) aligned in a direction normal to the substrate surface (typically, quartz glass plates). Unexpectedly, we found honeycomblike aligned CNTs by pyrolysis of nickel–cobalt phthalocyanine (designated as Ni–CoPc), which was synthesized by roasting the mixtures of metal salts, phthalanlione, urea, and ammonium molybdate.

A typical experimental procedure is as follows: a clean quartz glass plate ($4 \times 2 \times 0.1$ cm) was placed in a flow reactor consisting of a quartz glass tube and a furnace fitted with an independent temperature controller: A flow of Ar–H_2 (1:1, v/v, 20 cm^3 min^{-1}) was then introduced into the quartz tube during heating. After the central region of the furnace reached 950 °C, a quartz boat with 0.5 g Ni–CoPc was placed in the region where the temperature was about 500–600 °C. After 5 min heating, CNTs grew in a direction normal to the substrate surface.

Figure 6 is a set of SEM micrographs showing the honeycomblike shape of CNTs. As can be seen in Figure 6a, the honeycomblike CNTs are close together, and the diameters of the honeycombs range from 15 to 80 μm. Figure 6b is a higher magnification image of an area in Figure 6a and clearly shows the size and distribution uniformity of honeycombs. Figure 6c is a magnification image of a typical honeycomb shown in Figure 6a (square frame). The external diameter of the honeycomb is 80 μm, which contains a hollow inner cavity with diameter of 30 μm. The CNTs, forming the honeycombs, grow out from the inner cavity perpendicular uniformly to the substrate surface and then extend all around from the opening of the inner cavity, and finally twin with those of other honeycombs along its outside line.
Figure 6. (a) SEM micrograph of honeycomblike aligned CNTs. (b) A higher magnification image of honeycomblike aligned CNTs. (c) Magnification image of a typical honeycomb shown in Figure 2a. Reprinted with permission from [101], X. B. Wang et al., *Appl. Phys. A* 71, 347 (2000). © 2000, Springer-Verlag.

It is interesting that the same patterns of honeycomblike CNTs, two years later, were synthesized by prolysis of ferrocene and xylene on thermally oxidized silicon wafers [102].

3.2.2. Controllable Growth of Structures and Density of Aligned Nanotubes

Controllable Growth of Diameters and Lengths   Since nanotubes were first discovered in 1991, several advances in synthesis have led to the production of tubes in larger quanlities [63, 103] and higher purities [104–106]. Different diameter, length, and chairality of nanotubes give rise to diverse physical and mechanical properties [10, 107, 108]. However, controlling diameter, length, and charity has never been easy. Recently, several approaches for controlling diameters of SWNTs have been made. As far as the arc discharge method is concerned, the diameter of SWNTs can be changed by selecting metal catalysts [109] and ranging the pressure of helium gas [110]. For the laser ablation method, the diameters of SWNTs can be controlled by varying the furnace temperature [111] and laser pulse power [112]. However, the research on controlled growth of MWNTs, especially aligned CNTs, falls behind in contrast with that of SWNTs.

Choi et al. [113] have synthesized aligned CNTs on Ni-deposited Si substrate using microwave plasma-enhanced CVD. They found that the diameter, growth rate (length), and density of CNTs could be controlled systematically by the grain size of Ni thin films. With decreasing the gain size of Ni thin films, the diameter of the nanotubes decreased, whereas the growth rate and density increased. The gain size of Ni films varied with the radio frequency (rf) power density during the rf magnetron sputtering process.

As mentioned in Section 3.1.1, we can control the diameters and lengths of aligned CNTs by varying the growth time and the precursor level. Research results show that

the length of the aligned nanotubes increases with the increase of the growth time, and the mean diameters does sharply, too. The diameter distribution width (a difference of between the largest and smallest diameter of a sample) shifts systematically to larger region with increasing growth time, which indicates that the outer diameters of nanotubes become inhomogenous in longer growth time.

The template approach, shown in Section 3.1.2, can control effectively the diameter and length of aligned nanotubes by changing the nanochannel size and the thickness of template substrate, respectively. Recently, Jeong et al. [114] reported nanotube alignments with a narrow length distribution by etching the aluminum oxide template away. Sonication of aligned nanotubes on the template in an acetone solution cut the overgrown tubes effectively, resulting in short MWNTs.

Site Density Controlling of Aligned CNTs Although the diameter and the length of aligned nanotubes can be easily controlled by changing the catalyst particle size, the growth time, etc., control of the site density is still challenging. For well-aligned nanotubes, tuning of site density is very important for certain applications, such as FE, nano-electronic arrays, etc., because of the shielding effect of the dense arrays. Previous methods used to induce the site density include electron beam lithography [92], photolithography [115], microcontract printing [96], shadow mask [60], etc. However, all these methods either require expensive equipment and intensive labor or cannot control the site density in large area.

Recently, research efforts to control the site density have been successful. Pulse-current electrochemical deposition has been used to prepare Ni nanoparticles that are used as the catalysts for the growth of aligned CNTs [116]. The nucleation site density of the Ni nanoparticles was controlled by changing the magnitude and duration of the pulse current. The site density of the aligned nanotubes varied from 10^5 to 10^8 cm^{-2} (Fig. 7).

3.3. 3D Alignments and Patterns of CNTs

In the preceding part of this section, we gave a wide coverage on the fabrication of alignments and patterns of 2D nanotubes with selective positioning and controlled growth. However, in sharp contrast to the research enthusiasm for 2D aligned CNTs, the research on 3D alignment and patterns of nanotubes is sparse.

We have developed a simple method for the large-scale synthesis of 3D aligned CNT patterns on quartz glass substrate [62, 117]. A typical experimental procedure is as follows: a flow reactor, consisting of a quartz tube and a furnace fitted with an independent temperature controller, was heated to 950 °C under a flow of Ar/H$_2$ (1:1, v/v, 20 cm^3 min^{-1}). Almost immediately after the transfer of a quartz glass plate ($4 \times 2 \times 0.1$ cm) from acetone solution to the central region (950 °C) of the furnace, a quartz boat with 0.5 g of FePc was placed in the region where the temperature was 550 °C. After 5 min CNTs grew in a direction normal to the substrate surface.

Figure 8a shows an SEM image of 3D regular arrays of nanotubes aligned along the direction perpendicular to the
Figure 7. SEM images of aligned CNTs with site densities of (a) 7.5×10^5 (b) 2×10^6, (c) 6×10^6, (d) 2×10^7, and (e) 3×10^8 cm^{-2}, and (f) a single standing CNT. Reprinted with permission from [116], Y. Tu et al., *Appl. Phys. Lett.* 80, 4018 (2002). © 2002, American Institute of Physics.

substrate surface. A few pillar-shaped structures of CNTs grow out from the 2D alignments in a well-distributed mode, which characterizes the 3D CNT alignments. The CNT posts with a diameter of about 3.4 μm are 7.8 μm higher

Figure 8. (a) SEM images of 3D regular arrays of nanotubes aligned along the direction perpendecular to the substrate surface. SEM images of 3D nanotube patterns: (b) ringlike castles and (c) a 490-μm-long crucian carp without a tail and fins. Reprinted with permission from [117], X. B. Wang et al., *Chem. Commun.* 8, 751 (2001). © 2001, The Royal Society of Chemistry.

than the 2D nanotube alignments, whose height is mainly 6 μm from the quartz substrate. In addition to the pillar-shaped 3D nanotube alignments, most interesting patterns made of nanotubes arrays, such as ringlike castles (Fig. 8b) and a 490-μm-long crucian carp without a tail and fins (Fig. 8c), were observed under similar experimental conditions. Although the growth mechanism for these patterns is incomplete at present, we think that the substrate should be responsible for their formation. At the original stage, acetone soaked on the quartz glass substrate was rapidly carbonized at high temperature before volatilization to form the patterns. The resulting carbon, together with iron atom by pyrolysis of FePc, generates metal carbide, which is a more activated catalyst to grow CNTs than metal [80]. Thus, the CNTs in the pattern region formed by metal carbide grow more rapidly than those by metal. This accounts for the formation of alignments and patterns of 3D CNTs. Apart from this, both the strong van der Waals interactions between the tubes and the high surface density of the growing nanotubes serve as additional advantages for the constituent nanotube to be "uncoiled" and allow the aligned nanotubes to develop on the quartz substrate.

In spite of the interesting patterns of 3D nanotubes, the results were unexpected. On the basis of the previous experiments, we have recently realized the controllable fabrication of 3D nanotubes patterns with features of high resolution by a vacuum deposition technique through shadow masks [118]. Using SEM, we observed 3D aligned CNTs, consisting of two streaked ribbons with widths of 6.5 and 8.4 μm, respectively (Fig. 9), by pyrolysis of FePc for 5 min. The nanotubes in the ribbon area are about 1.4 μm higher than those of 2D alignments (beyond the ribbon region). The growth rates of the nanotubes in and beyond the ribbon region were about 25 and 20.3 nm/s, respectively. It is only the difference of growth rates that results in the formation of 3D nanotube alignment. These 3D micropatterns of well-aligned
Figure 9. SEM images of 3D nanotube alignments consisting of two ribbonlike structures (6.5 and 8.5 μm). The nanotubes in the ribbon region are 1.4 μm higher than those elsewhere. Reprinted with permission from [118], X. B. Wang et al., *Adv. Mater.* 14, 1557 (2002). © 2002, Wiley–VCH.

nanotubes were also prepared on photolithographically prepatterned substrates by the same method [119]. This opened the way for fabricating 3D nanotube micropatterns and thus developing novel nanoelectronic devices.

4. ALIGNMENTS OF SINGLE-WALLED CARBON NANOTUBES

Alignments of SWNTs have been envisioned to enhance performance of various technologically important devices such as sensors [120], field emitters, and organic light-emitting diodes [121]. Immobilizing the random SWNTs into a controlled orientation would be an extremely important step for these real device application of the nanotubes. However, the creation of SWNT alignments has fallen far behind MWNT arrays because of the technical difficulty in handling or aligning individual SWNTs to ideal locations.

4.1. Chemical Alignments

Chemical alignment is an effective method to order SWNTs perpendicular to the substrate by shortening SWNTs in an oxidizing environment, followed by chemical modification of the carboxyl end groups. Short and long SWNTs have exhibited considerable affinity for amine-functionalized substrates, although they tend to orient parallel to the substrate [122, 123]. Thiol functionalization of SWNTs resulted in better alignment on gold substrate; nevertheless, this system was plagued by low surface coverage and long adsorption time [124]. Recently, Wu et al. developed an alternative method for the assembly of oxidatively shortened SWNTs on silver surfaces [125]. This technique is based on the spontaneous adsorption (self-assembly) of the —COOH groups at the open ends of CNTs onto silver surfaces. Their studies revealed that most of the SWNTs (ca. 80%) assembled on silver surfaces have a bundle size of 6.5 ± 0.5 nm, possibly suggesting the selective adsorption of SWNTs on silver.

More recently, dense arrays of monolayer and multilayer assemblies of shortened SWNTs have been demonstrated using a metal assisted organization process from nonaqueous media [126]. The self-assembly, which was performed on a substrate such as glass, silicon (110) wafers with native oxide and quartz crystal microbalance resonator, consisted of sequential dipping in an aqueous solution of $FeCl_3$ followed by immersion in DMF dispersed shortened SWNTs and separated by intermedia washing in DMF. A monolayer of densely packed, needlelike domains was obtained after 30 min immersion in nonaqueous dispersions of shortened SWNTs. This geometry is believed to be the result of a high concentration of carboxy groups on the severed edges of shortened SWNTs, hydroxy functionalization of Fe^{3+}-decorated surfaces, and strong hydrophobic interactions between adjacent shortened SWNTs.

4.2. Alignments by an Electrical or Magnetic Field

Applying an electrical or magnetic field may be a simple and alternative method to align CNTs. Bubke et al. [127] reported that MWNTs dispersed in ethanol can be aligned by an electrical field. Due to the orientation of these elongated particles, the nanotube alignments exhibited optical

anisotropy. Thick films of aligned SWNTs and ropes have been produced by filtration/deposition from suspension in strong magnetic field [128, 129]. Recently, Chen et al. [130] aligned SWNTs on Si/SiO$_2$ substrate with an alternating current electrical field. Highly oriented SWNT samples were prepared when an electric field with a frequency of 5 MHz was applied. The alignment of the SWNTs demonstrated significant dependencies on the frequency and the magnitude of the electric field. The results suggested that the alignment degree of CNTs was reduced gradually with the decrease of the frequency of the electric field, and the concentration of the aligned SWNTs decreased with the decrease of magnitude. However, SWNT samples oriented by the dc electric field did not demonstrate the apparent orientation. Zhang et al. [131] also demonstrated electric field directed growth of SWNTs over the quartz substrate with prepatterned polysilicon films by CVD. Highly aligned suspended SWNTs can be fabricated along the electric field direction in the range of 0.5–2 V/μm.

4.3. *In-Situ* Self-Assembly of Aligned SWNTs

Both chemical alignment and alignment by an electrical/magnetic field were obtained by a postprocessing technique, which suffered from the difficulty of local position and complex postsynthesis manipulation. So *in-situ* preparation of aligned SWNTs is of paramount importance for basic research and many potential applications.

Schlitter et al. [132] reported the self-assembly of single crystal SWNTs using thermolysis of alternate layers of C$_{60}$ and Ni precursors. It is exciting that each crystal is composed of an ordered array of tubes with identical diameters and chirality, although these properties vary between crystals. The structures produced are almost perfect rodlike crystals of SWNTs preferentially oriented normal to the surface of a molybdenum substrate. The perfection of the crystals of SWNTs and the observation that they are all physically identical within any given crystal containing up to several thousand individual nanotubes are unexpected from the point of view of previous results and synthetic approaches in the field.

Zhu et al. [133] directly synthesized the long strands of ordered SWNTs by catalyst CVD with a floating catalyst method in a vertical furnace, where *n*-hexane in combination with thiophene, ferrocene, and hydrogen is catalytically pyrolyzed. The long nanotube strands up to several centimeters in length, consisting of aligned SWNTs, are an alternative to the fibers and filaments spun from nanotube slurries. The research on mechanical and electrical properties indicated that the aligned nanotube strand would be a candidate for practically useful nanotube-based macroscale cables.

However, well-defined alignments of SWNTs synthesized *in-situ* on a substrate were not fabricated until Botti et al. reported the latest results [134]. It was found that well-aligned SWNTs on heated Si substrates could be self-assembled from the carbon nanosized particles without a catalyst by a simple spraying technique. By increasing the substrate temperature, the density of the SWNTs increases and the nanotubes with a uniform length are oriented perpendicularly to the substrate. Although the aligned tubes are bundles of tightly interlaced SWNTs with different chirality

and mean diameter 1.1 ± 0.3 nm, this report opens a route to prepare aligned SWNTs.

5. PROPERTIES AND APPLICATIONS OF ALIGNED CARBON NANOTUBES

Carbon nanotubes are known for their superior mechanical strength and low weight [135], good heat conductance [136], varying electronic properties depending on their helicity and diameter [12], large surface area useful for adsorption of hydrogen or other gas [137], and their ability to emit a cold electron at relatively low voltages due to high aspect ratios and nanometer size tips [20]. Therefore, many future applications have been found in a wide range of fields for being used as field emitters for flat panel displays, vacuum microelectronic devices like microwave power amplifier tubes, nanofield effect transistors [138, 139], nanotube circuits [140], ultrasensitive electrometers [120, 141, 142], nanotweezers [143], nanothermometers [144], and so on.

For aligned CNTs, considerable attention is mainly focused on their excellent FE properties. In this section, apart from the FE properties, we will present other potential properties and applications such as the anisotropic electrical transport property, the superamphiphobic property, and energy storage.

5.1. Field Emission Properties

Earlier than FE, thermionic emission of electron guns had been a key concept in the electron-beam technique. In thermionic electron emission, the solid electron source (i.e., the cathode) is heated above 2000 °C to allow free electrons to escape from the surface [145]. The greatest advantage of this so-called "hot cathode," usually a heated tungsten (W) filament, is that it works even in non-ultra-high-vacuum (non-UHV) ambiences, which contain vast numbers of gaseous molecules. However, hot cathodes are prone to chemically react with residual water and oxygen to produce tungsten oxides and get thinner and thinner over a long duration through the sublimation of the oxides. In addition, hot cathodes require a power supply for heating, thus making it difficult to construct a compact electron-beam tool.

In the mid 1950s, these disadvantage of hot cathodes were be overcome by replacing them with a FE or "cold cathode" [146]. Unfortunately, the electron emission from a FE cathode is exponentially affected by the chemical and morphological states of the electron emitting area, resulting in instability of emitted currents in non-UHV ambiences. This is particularly true of metallic cathodes, which strongly interacted with residual gaseous molecules.

Chemically, carbon is far more stable, and hence more robust in non-UHV, than metals. Indeed, great effort has been made to develop field emitters based on carbon-containing materials such as diamond, diamondlike carbon, and tetrahedral-amorphous carbon [147, 148]. The high expectations and promise held by these materials, however, have not yet been matched by their performances.

CNTs have emerged as one of the most promising electron field emitters. The power of CNTs as electron sources for displays and lighting devices was amply demonstrated in

the last few years. The superior aspect ratio, good chemical stability, high thermal conductivity, and mechanical stiffness of CNTs are advantageous over conventional semiconductor and metal emitters [149–151]. The investigation of FE properties of individual CNTs and aligned CNT films was originally reported by Rinzler et al. [20] and de Heer et al. [21], respectively. From then on, many research techniques, including improving the method to fabricate CNT alignments, introducing gaseous adsorbates, and controlling the CNT density, have been developed to reduce the operating voltage, enhance the emission current, decrease the field-screening effect, lengthen the device lifetimes, increase the stability of electron emission, etc.

It is worth noticing that the Samsung CNT FE displays represent an impressive feat and an important milestone toward a fully functional device [152, 153]. They work up to now in diode configuration, which implies that the brightness of a pixel is controlled by varying the potential between emitter and phosphor screen, which is on the order of several kilovolts. Conversely, a triode configuration incorporates a control electrode located near the emitter, and the brightness of the pixel is then controlled by adjusting the potential between cathode and control electrode.

Many good FE properties of aligned CNTs have been obtained by different groups although they are still far from practical. Thong et al. [154] reported the emission current density up to 130 mA/cm^2 could be reached at an average field strength of 1.925 V/μm. This emission current was found to be very stable, with short-term fluctuations of no more than $\pm 1.5\%$, while the current drifted less than 1.5%. A turn-on field of 1.2 V/μm and emission currents of 1 mA/cm^2 at 3V/μm were achieved on well-aligned CNT emitters [115]. A test of cathode-ray tube lighting elements underway suggested a lifetime of exceeding 10,000 h.

5.1.1. Effect of Gas Adsorbates on FE Properties

The FE properties are correlated with the electronic structure of the CNTs, and intrinsic properties such as electrical resistivity, thermoelectric power, and thermal conductivity can be modified by adsorption and desorption of gas adsorbates [120, 142, 155]. Therefore, one way to achieve good emission properties is to introduce adsorbates that might effectively lower the ionization potential and facilitate the extraction of electrons.

Many studies have reported the effects of gases on the FE of CNTs [156–159]. Recent experiments done at Motorola [160] indicated that water molecules adsorbed on CNT tips significantly enhance FE current, while O$_2$ and H$_2$ not affect the FE behavior appreciably. The first principles density functional theory calculations [161] showed that the water–nanotube interaction under emission conditions at the tube tip can increase the binding energy appreciably, thereby stabilizing the adsorbate, and lower the ionization potential, thereby making it easier to extract electrons.

Wadhawan et al. [162] compared the effects of O$_2$, Ar, and H$_2$ gases on the FE properties of SWNTs and MWNTs. They found that H$_2$ and Ar gases do not significantly affect the FE properties of SWNTs or MWNTs. O$_2$ exposure temporarily increased the turn-on field of SWNTs by 22% and decreased

the FE current by two orders of magnitude. However, the FE properties completely recover after 40 h of FE operation in UHV. For MWNTs, the higher voltage O$_2$ exposure leads to a 43% increase of the turn-on field and reduction of FE current by three orders of magnitude. The recovery in UHV is only partial, indicating that the MWNTs suffer from permanent structural degradation [163]. Kung and Huang [164] demonstrated that the emission current of the CNT arrays treated by O$_2$ and O$_3$ was increased $\sim$800% along with a decrease of the onset FE voltage from 0.8 to 0.6 V/μm.

However, a contrary experimental result has been reported by Lee et al. [165] due to different measurement methods of FE properties. Their investigations showed that the turn-on voltages of O$_2$ and N$_2$ gases first decreased and saturated at large gas exposure times, whereas that of H$_2$ gas decreased initially and increased to saturation at large gas exposures. They considered this behavior to be being strongly correlated with the difference of electronegativity of the adsorbed gases. FE is a highly selective process and is extremely sensitive to small variations in the chemical nature and shape and or surroundings of the emitter [166, 167]. This makes a comparison of the results obtained by different groups delicate since the growth, purification, film preparation techniques, and experimental setups differ significantly.

5.1.2. Field-Screening Effect

It is known that the FE properties of the tubes could be affected by a field screening effect provoked by the proximity of neighboring tubes. The field screening affect is determined by various factors relative to the nanotube arrays, including the density, the height, and the diameter. According to the prediction of Nilsson et al. [168], the FE will become maximum when the height of the tubes is about one-half the intertube distance, and arrays with medium densities ($\sim 10^7$ emitters/cm^2) show the highest emitted current densities. The experiments by Suh et al. [169] suggested that the FE was optimal when the tube height was similar to the intertube distance. This is a little deviation from the prediction. Teo et al. [170] have demonstrated that the density of carbon nanofibers can be decreased to enhance the FE properties of vertically aligned carbon nanofiber emitters, and the arrays of individual, vertically standing nanofibers spaced twice their height apart had the most desirable FE characteristics and the highest apparent field enhancement factor. Therefore, we can tune the FE properties of CNT film emitters by varying the nanotube density [171]. The optimized field emitter can also be achieved by changing the tube diameter according to the result of the first principle calculations [172].

5.2. Anisotropic Electrical Transport Properties

The electrical resistivities of aligned CNTs are anisotropic, being smaller along the tubes than normal to them, because of corresponding differences in the electrical transport [173]. Chauvet et al. [174] observed magnetic anisotropies of the aligned CNTs as well. Recently, electrical, thermal, and structural anisotropies of magnetically aligned single wall CNT films have been obtained by Fischer's et al. [128, 129].

However, all of these aligned CNT films are not as-grown, either they were transferred to a Teflon surface [173, 174] or deposited on a nylon filter membrane [128, 129], which results in a deviation of experimental results. Moreover, these CNT films are imperfectly aligned with some entanglement or curvature of individual tubes (ropes). The disadvantageous factors make the observed results no real reflections of intrinsic properties of those partly aligned CNT films. However, to date the measurements of anisotropic electrical transport properties have not been carried out on as-grown aligned CNT films due to the difficulty in obtaining electrical resistance parallel to the tube axis.

Recently, we have developed a simple technique to measure anisotropic electrical transport properties of as-aligned carbon nanotube films [175]. The temperature dependence of relative electrical resistance suggests that most of the well-aligned carbon nanotubes are semiconductive in both directions parallel and perpendicular to the tube axis. The anisotropy ($R_\perp/R_\parallel$) of electrical resistance increases with decreasing temperature T, reflecting the difference in the longitudinal and transverse hopping rates. The differences of the electrical properties in both directions could be explained by a difference degree of localization of charge carries. The plot of the logarithm of relative resistance against powers of the reciprocal temperature $1/T$ is closely fitted by three-dimensional variable range conduction. After annealing and Br_2-doping treatments the resistivities of the aligned carbon nanotube films decreased by two orders of magnitude, resulting from the fewer defects and the greater carrier density, respectively.

5.3. Super-"amphiphobic" Properties

Wettability is an important factor for a material. Dujardin et al. have studied the wettability of CNTs in detail and found they could be wet and filled by different substances [176, 177]. In general, wettability of solid surfaces is controlled by the chemical composition and the geometrical structures of the surfaces, and it is usually enhanced by surface roughness [178], especially by fractal structures [181]. Recently, superhydrophobic or superlipophobic surfaces, that is, those with a contact angle of water or oil, respectively, that is higher than 150° [178, 179], have attracted much interest due to practical applications. These surfaces have been commonly prepared through the combination of surface roughening and lowering of the surface energy. However, few reports were concerned with super-"amphiphobic" surfaces [180], which appear to have both superhydrophobic and superlipophobic properties. As the structure of aligned CNT films is similar to that of these superhydrophobic surfaces, the films are expected to show special wettability features.

We reported that the aligned CNT films appear to have super-"amphiphobic" properties; namely, the contact angles for both water and oil are larger than 160° [72]. We demonstrated that the as-grown CNT films are superhydrophobic and superoileophilic. The contact angles for water and rapeseed oil are $158.5 \pm 1.5°$ and $0 \pm 1.0°$, respectively. However, the contact angle for water on a film of CNTs lying flat on a surface is $136.5 \pm 7.0°$, which shows that the aligned structure of the CNT films is responsible for the superhydrophobic properties.

A low free energy surface is required for a superoileophobic surface to be obtained, and this can be realized by modifying the aligned CNT films with fluorinated compounds. Since the surface of CNTs is rather inert, it is very difficult to modify the surface directly. The hot concentrated H_2SO_4 and HNO_3 mixture (1:1 v/v) was employed to oxidize the aligned CNTs for further chemical modification. The contact angle for water on the aligned CNT film was $128 \pm 3.0°$ after oxidation. It has been reported that some functional groups, such as hydroxyl and carboxyl, can be realized on the surface of CNTs through chemical oxidation treatments. Hence, the oxidized films were modified through immersion in a methanolic solution of hydrolyzed fluoroalkylsilane. After this modification the aligned CNT films contained fluoroalkylsilane groups, which repel both water and oil. The contact angles for water and rapeseed oil on the films were $171 \pm 0.5°$ and $161 \pm 1.0°$ respectively. Hence the film shows both superhydrophobic and superoileophobic properties; namely, it is a super-"amphiphobic" surface. The water droplets move spontaneously and do not come to rest, even when there is little or no apparent tilt of the surface ($<1°$), while the rapeseed droplets remain pinned in one place.

5.4. Hydrogen Storage

The use of CNTs for hydrogen storage has attracted more and more attention due to their high storage capability and potential applications in the next generation energy source. Different types of nanotubes, as well as nanofibers, have been studied for this purpose. In the experimental report published, high hydrogen pressure (up to 100 atm), [181] subambient temperature [183], and alkali–metal doping [184] are applied to achieve hydrogen adsorption. Recently, aligned CNTs were employed for hydrogen adsorption experiments in their as-prepared and pretreated states [185]. The hydrogen storage capacity of 5–7 wt% could be achieved reproducibly at room temperature under modest pressure (10 atm) for the as-prepared samples. Pretreatments, which include heating the samples to 300 °C and removing the catalyst tips, can increase the capacity up to 13 wt% and decrease the pressure required for storage. The release of the adsorbed hydrogen can be achieved by heating the samples up to 300 °C.

6. SUMMARY

In this account, we have given a brief survey of experimental work directed toward the synthesis and properties of aligned CNTs. In last few years, significant progress has been made for fabricating various alignments and patterns of CNTs, especially MWNTs. However, there still remain many fundamental and fascinating issues about their synthesis, for example, the formational mechanism of aligned CNTs, the controllable synthesis of CNT structures, and so on. The solution of these problems promises to be an exciting and challenging area of nanoscale physics and chemistry in the future. For the properties and applications of aligned CNTs, extensive research interest is only focused on the FE

although the properties of superamphiphobicity and hydrogen storage start to arouse research enthusiasm. There must be wide room, we believe, to explore the potential properties of aligned CNTs in future applications. We are still in the early days of the field, and many surprises undoubtedly lie ahead.

GLOSSARY

Aligned carbon nanotube　A film made of an alignment by carbon nanotubes.

Anisotropic electrical transport　The electrical resistivities of aligned carbon nanotubes are smaller along the tubes than normal to them.

Carbon nanotube　Carbon nanotubes can be thought of as graphitic sheets with a hexagonal lattice that have been wrapped up into a seamless cylinder.

Chemical vapor deposition (CVD)　CVD is a chemical reaction which transforms gaseous molecules, called precursor, into a solid material, in the form of thin film or power, on the surface on a substrate. The process is widely used to fabricate semiconductor devices.

Controllable fabrication of carbon nanotubes　Diameter, length, and position are controllable in preparation of carbon nanotubes.

Superamphiphobic　The contact angles between the surfaces of a material with water and oil are higher than 150 °C.

Alkanethiol Self-Assembled Monolayers

J. Justin Gooding

The University of New South Wales, Sydney, Australia

CONTENTS

1. INTRODUCTION

1.1. Self-Assembly in Nanotechnology

Nanotechnology involves making useful devices with nanometer control in at least one dimension. Nanometer control infers that nanotechnology involves fabrication from molecular components. Therefore, in nanotechnology different molecular components must be integrated into a functional device. Such integration requires the precise positioning of individual molecules. To create this molecular organization, the fabrication of nanostructures can be achieved with either the "top-down" or the "bottom-up" fabrication methods. The potential drawbacks of top-down methods, include the materials used, usually have little chemical diversity and the approach is limited in the number of nanodevices that can be fabricated at one time [1]. Therefore, bottom-up fabrication from molecular components possesses far more promise in enabling the nanotechnology revolution to be fully realized.

Bottom-up fabrication can be achieved either through the physical placement of individual atoms and molecules, or via self-assembly. The former invokes images of either molecular assemblers, which have been elegantly demonstrated by the iron corrals and molecular abacus assembled by the IBM research labs [2], or the single placement of phosphorous atoms on silicon surfaces as part of the development of silicon-based quantum computers [3]. In common with top-down fabrication, the physical placement of individual atoms, or molecules, has the disadvantage of low throughput of devices. Therefore, self-assembly appears to be the most likely strategy for developing a generic approach to the fabrication of functional nanodevices [1].

Self-assembly is how nature makes molecular machines. From linear sequences of amino acids, nanomachines like enzymes and ion channels form through spontaneous folding (sometimes with a little chaperoning) into functional conformations. The essence of self-assembly is that no external intervention is required once the process has started. That is, the rules for organization are encoded into the molecular structure and the conditions used [4]. The self-organization inevitably means the structures are thermodynamically stable, relative to other conformations, in conditions similar to those in which they were formed. Achieving such spontaneous assembly requires exquisite control over the noncovalent interactions involved as the nanomachines are formed. Frequently, different subunits of a protein or ion channel, derived from different linear chains of amino acids, will be combined to give the final functional device [5]. The combination of the subunits favors the production of a symmetrical molecule. The joining of subunits reflects two of the key features of self-assembly in natural systems. First, the molecules must have a strong affinity for each other. This affinity exploits molecular recognition to ensure that the binding of subunits is not only strong but also selective. This gives the second key feature, which is that predictable structures are formed when the subunits associate. These two features are demonstrated in the formation of a DNA duplex when two complementary single strands are self-assembled.

1.2. Self-Assembled Monolayers (SAMs)

Self-assembly directed by human hands is a long way removed from the complex nanomachines that nature produces, although impressive control has been demonstrated with self-assembled monolayers and other surfactant systems. Self-assembled monolayers (SAMs) are ordered monomolecular films, which are spontaneously formed from immersing a solid substrate into a solution containing amphifunctional molecules (see Fig. 1). The amphifunctional molecule has a head group, which usually has a high affinity for the solid surface, a tail—typically an alkyl chain—and a terminal group that can be used to control the surface properties of the resultant monolayer. The molecular
Figure 1. a) A self-assembling molecule with a surface active head group (in this case, a thiol group), an alkyl chain tail, and a terminal group. The terminal group is represented as an amine but could be any functional group; b) an alkanethiol SAM formed on an Au(111) surface with the characteristic 30° tilt from normal.

forces between the tails are chiefly responsible for the order of the monolayer. So SAMs have the two key features of self-assembly in biological systems, namely, that molecules have high affinity for each other and predictable structures are formed when the molecular units are associated. The ability to tailor both head groups and tail groups of the self-assembling molecules makes control over the self-assembly behavior possible. This control is important both for nanoscience and nanotechnology. With regards to nanoscience, SAMs provide an opportunity to increase the fundamental knowledge about self-organization, structure-function relationships, and interfacial phenomena [6]. From the perspective of nanotechnology, SAMs allow accessible molecular level control for bottom-up fabrication in at least two dimensions. Furthermore, because molecular level assembly frequently occurs on macroscopic surfaces, SAMs also provide a reasonably simple way of interfacing the nanodevices with the macroscopic human world.

The potential applications of SAMs in nanotechnology span a diverse range. From the simplest case of the assembly of a single component on a surface to give functional surface coatings (such as in corrosion or wear protection) [7–9] to complicated integrated molecular systems used in chemical and biosensing (where the biomimetic and biocompatible nature of SAMs is particularly attractive) [10–13] and in molecular electronics [14], where the addressing of functional molecules to each other and to the outside world is so important.

1.3. Organosulfur SAMs

The most extensively studied self-assembled monolayers are silanes, which are used to modify hydroxyl terminated surfaces, and organosulfur compounds, which exploit the affinity of sulfur for coinage metals (such as gold, platinum, and silver) [15]. The formation of SAMs of organosulfur compounds on metal surfaces was first described by Nuzzo and Allara [16] in 1983 with the adsorption of a di-*n*-alkyl disulfide onto gold surfaces. Since this time the research into organosulfur adsorbates has been exceedingly active. Apart from alkanethiols and di-*n*-alkyl disulfide [16–20] a number of other surface organosulfur compounds which form monolayers on gold have been reported including di-*n*-alkyl sulfides [19, 21–26], thiophenes [27–29] and alkyl xanthates [30–33] (see Fig. 2). Representative spectroscopic data and
Figure 2. The chemical structures of representative organosulfur compounds that can form self-assembled monolayers on coinage metal surfaces, a) *n*-decanethiol, b) di-dodecyl-*n*-disulfide, c) di-*n*-dodecyl sulfide, d) dodecyl xanthic acid.

physical properties for each class of organosulfur SAM are outlined in Table 1.

An alkanethiol has a thiol (-SH) head group and a tail that is usually an alkyl chain. At the end of the tail is the terminal group, which in a well-packed monolayer, determines the properties of the surface of the monolayer. *n*-Alkanethiols and di-*n*-alkyl disulfide self-assemble on coinage metals to form well-organized monolayers, where the formation of a bond between the thiolate head group and the metal surface anchors the organosulfur molecules to the surface and interactions between the alkyl chains give the monolayer its order (see Fig. 1). Both alkanethiols and di-*n*-alkyl disulfide give alkanethiolate surfaces. The other organosulfur compounds give different surface structures (see Fig. 2). (There has recently been debate as to whether carbon sulfur cleavage occurred in the self-assembly of the dialkylsulfides [19, 34–36], but it has been confirmed that both alkyl chains remain bonded to the sulfur [36, 37].). The vast majority of research has concentrated on alkanethiols and disulfides and hence are the focus of this chapter. As they produce the same surface

attached species—an alkanethiolate—throughout this chapter the term alkanethiol or alkanethiol SAMs will refer to SAMs formed from either, unless explicitly stated.

Alkanethiols and related compounds are popular for the formation of SAMs for a number of reasons. First, preparation of alkanethiol SAMs is relatively easy. Assembly does not require vacuum or anaerobic conditions and the solvent has minimal effect on the assembly process. Furthermore, the assembly process still occurs despite some surface impurity (although there will be an influence of the kinetics of SAM formation and the number of defects), as organic matter will be displaced by the alkanethiol as a consequence of the affinity of thiols for the metal. This affinity provides the second reason for the popularity of alkanethiol SAMs—namely, they are reasonably stable. The stability is demonstrated by the fact that alkanethiol SAMs survive prolonged exposure to vacuum used during many surface characterization experiments [15] and that the SAMs withstand a broad range of potentials applied to the underlying metal surface (typically between +1.0 and −1.0 V versus SCE) [38–40]. The third reason is that a variety of functional groups can be incorporated into the SAM without disrupting the self-assembly process. Finally, mixed SAMs can be prepared either through simultaneous deposition [41] or sequentially by a place-exchange reaction [42]. These final two reasons are a crucial feature in molecular level fabrication. Being able to direct the type and spacing of terminal groups of the SAM provides control over what is built upon a surface.

Applications of alkanethiolate modified surfaces include making surfaces biocompatible [43, 44], mimicking biological membranes [45], using SAMs to obtain fundamental information regarding electron transfer processes [46], in the fabrication of sensors [10, 11, 47], and as a "molecular glue" for fabricating nanostructures [48]. As coinage metals form good electrodes, the assembly of alkanethiol SAMs onto these surfaces has seen many of the applications involving alkanethiols being electrochemical [4, 10–12, 46, 49–51]. Typically, the SAM is used to alter the performance of the electrode, such as making it selective for an analyte [10–12], passivating it [46, 52, 53], or making the surface biocompatible [43, 44, 49, 54]. Synthesizing novel alkanethiols, which can act as molecular wires or conduits for electron transfer, allows SAMs to be used for fundamental research into electron transfer in nature [46, 55, 56] and for molecular electronics [57, 58]. The alkyl chains of the SAMs also allow bilayer structures to be formed so the interface mimics a biological membrane [45, 59, 60]. Self-assembled monolayers can also provide the base layer upon which a multilayer system with molecular level control is fabricated [61, 62]. The molecular level control of the modification of the interface provides a foundation which other nanoscale building blocks, such as nanoparticles [48, 63–65], nanotubes [66–68], and DNA [69–74], can be built upon.

There are a number of detailed reviews on SAMs, which the interested reader is referred to that address single issues in more detail. Reviews that are available address topics such as SAM formation and structure [6, 15], simulation of SAMs [15, 75, 76], their characterization using electrochemical [46], scanning tunneling microscopy [77], and atomic force microscopy [78, 79] techniques, their applications to

the fabrication of biosensors [11–13, 80], and electrochemical sensors [10, 47, 51], providing controlled surface properties [43, 44, 49, 54, 81, 82], patterning SAMs [81, 83–86], SAMs on nanoparticles [87, 88], and providing unique reaction environments [89]. The purpose of this chapter is to give an overall outline of the basic features of alkanethiol SAMs and then to review some applications of SAMs in sensing and nanofabrication.

2. PREPARATION AND PROPERTIES OF ALKANETHIOL SELF-ASSEMBLED MONOLAYERS

In this section, the formation of SAMs, their structure, and important variables in their preparation will be discussed. As there are many types of organosulfur molecules that self-assemble on a variety of metal surfaces (all of which can give subtle differences in SAM structure), SAM preparation procedures and so on, the discussion below will refer to long chain aliphatic alkanethiols (typically either dodecanethiol or hexadecanethiol) adsorbed onto gold surfaces unless otherwise stated.

2.1. Methods of Assembly

2.1.1. Solution Assembly

Alkanethiols adsorb spontaneously from solution onto the surface of coinage metals. Gold is the most frequently used. The thiol groups chemisorb onto the gold surface via the formation of a gold-thiol bond [6, 90] to produce a densely packed, highly ordered monolayer. Gold is the most popular metal surface for reasons of ease of handling. It is generally thought not to have a stable oxide under ambient conditions, and it can withstand harsh cleaning procedures that are often required in SAM preparation [91]. A stable oxide can, in fact, be formed on gold when exposed to ultraviolet (UV) light and in the presence of ozone to produce Au_2O_3 [92]. Ron et al. [93] have actually used the gold oxidation as a surface cleaning procedure, removing the gold oxide in ethanol, the most popular solvent for preparation of SAMs. The ethanol reduces the gold oxide to give a fresh gold surface for self-assembly. Soaking in pure ethanol for at least 10 min prior to adding alkanethiol is required to ensure all the oxide is removed [94]. Failure to completely remove the gold oxide will result in SAMs first assembling onto the bare gold and then onto the oxidized gold surfaces during the later stages of the self-assembly [94, 95]. Noncontact atomic force microscopy (AFM) shows that the SAMs formed on the oxide regions are less stable that the gold-thiol SAM [94].

As with the ozone treatment to clean gold surfaces, other cleaning procedures involve the oxidation of the gold surface and removal of this oxide. More common cleaning procedures for gold include etching the gold surface in dilute aqua regia [42], oxidizing organic contaminants using "piranha" (a 1:3 mixture of 30% hydrogen peroxide and concentrated sulfuric acid at 100 °C; *Warning a mixture that reacts violently with organic material and has been known to explode when stored in closed containers*) or electrochemical cleaning in 1 M sulfuric acid using cyclic voltammetry between

−0.3 and +1.5 V versus Ag/AgCl. Electrochemical cleaning involves oxidizing the gold surface during the positive potential sweep and reductively removing the oxide during the negative scan. As the area under the reduction peak allows the calculation of the number of gold atoms oxidized, the electrochemical cleaning procedure allows the simultaneous measurement of the active surface area of the gold [96, 97]. The importance of cleaning the gold surface is well recognized for bulk gold surfaces (either polycrystalline or single crystal), but frequently, thin film deposited gold surfaces are not cleaned prior to assembly of the SAM. The consequence of poorly cleaned surfaces with minor amounts of organic matter on the surface is a deleterious influence on the kinetics of SAM formation rather than the prevention of the assembly process altogether [46, 97]. More defects are expected on contaminated surfaces.

Typically alkanethiols are assembled onto gold surfaces from dilute solutions (millimolar concentrations). Common solvents are ethanol for shorter alkanethiols or hexane. Two distinct adsorption stages are observed in the assembly—a rapid stage within the first few minutes by which time the contact angle is close to its limiting value and the thickness is 80–90% of the maximum [98]. The length of this stage is dependant on the alkanethiol concentration, taking only a few minutes at a concentration of 1 mM but about 100 min at 1 μM [99, 100]. The second slow stage occurs over several hours as the contact angle and thickness reach their final value [98]. During the latter stage, the molecules in the SAM undergo a slow reorganization equivalent to surface crystallization [101]. The growth rate of the SAM is dependant on the number of vacant sites in agreement with simple first-order Langmurian kinetics [100, 102–104]. The kinetics of SAM formation was initially studied by *ex-situ* techniques such as external reflectance FTIR, optical ellipsometry [21, 98], contact angle measurements [21, 98], and radioisotope labeling [105], but more recently, *in-situ* quartz crystal microbalance measurements have been used [100, 104, 106]. Due to the slow reorganization of the SAM, many workers typically allow 12 to 24 hr for SAM formation prior to use.

2.1.2. Assembly by Printing

The process of microcontact printing, developed by Xia and Whitesides et al. [86, 107] for patterning surfaces, can also be used to form alkanethiol SAMs on metal surfaces in only a few seconds. A polydimethylsiloxane stamp is "inked" with a thiol solution. Typically, the solvent is evaporated and the inked stamp is contacted with the metal. The low surface energy and flexibility of the elastomeric stamp have advantages with regards to allowing the stamp to conform to the shape of the metal surface. Depending on the amount of alkanethiol placed on the stamp, the SAMs produced can be of equivalent integrity and structure as a solution-assembled SAM despite no time being allowed for the slow organization of the alkanethiols after deposition onto the surface [108–110]. Evaluation of the printed SAMs was performed using scanning tunnel microscopy (STM) [108] and electrochemistry [110]. To obtain equivalent SAMs to solution assembly requires the surface loading of the alkanethiol ink to exceed a threshold value (20 nmol mm^{-2} of

hexadecanethiol) [110]. The length of time the stamp is in contact with the surface does not, however, appear to be important [108]. Self-assembled monolayers of dialkylsulfides prepared by printing were also found to be of similar quality to decanethiol SAMs with regards to order and etch resistance [111].

2.1.3. Other Deposition Methods

A variety of other methods of preparing self-assembled monolayers have been less commonly employed. With volatile alkanethiols, deposition can be achieved from the vapor phase, both at ambient pressures [102, 112–117] and under vacuum [115, 118–120]. Alkanethiol monolayers have also been formed using the Langmuir–Blodgett film technique [121–123]. One technique, which is important for ensuring that the alkanethiol is deposited on a reduced metal surface, is to use potentially assisted deposition of the alkanethiol. At highly cathodic potentials, alkanethiols desorb from the underlying metal surface. As the potential is scanned back anodically, alkanethiols can readsorb onto the electrode [124]. Shifting the potential positively has also been shown to accelerate the rate of alkanethiol adsorption [125, 126].

2.2. Structure and Properties of Alkanethiol Monolayers

2.2.1. Monolayer Structure

The exact nature of the bond that forms between the gold and the sulfur is still not clear, but in the case of alkanethiols it can be considered as an oxidative addition of the S—H bond to the gold surface followed by a reductive elimination of hydrogen [6]

$$\text{R}-\text{S}-\text{H} + \text{Au}_n^0 \longrightarrow \text{R}-\text{S}^-\text{Au}^+ \cdot \text{Au}_n^0 + 1/2\text{H}_2$$
Evidence for H_2 leaving has been hard to come by, but the presence of a thiolate (RS^-) has been confirmed by XPS [17, 127–129], FTIR [130], electrochemistry [90], and other techniques [131–133]. A recent study by Hasan et al. [134], using NMR and gold nanoclusters, shows that the loss of hydrogen can be prevented if there is no easy reaction pathway for hydrogen removal. The Au—S bond strength is about 40 kcal mol^{-1} [131] and the free energy change for the adsorption of alkanethiolates on gold is approximately −5.5 kcal mol^{-1} [105]. The equivalent Au—S bond is also formed from a disulphide [6].

On an Au(111) surface, the alkanethiols form a ($\sqrt{3} \times \sqrt{3}$)$R30°$ hexagonal lattice with an average spacing of 5 Å between alkanethiol chains (see Fig. 2) [135, 136]. The alkane chains are in the all transconfiguration with very few gauche defects. The chains typically tilt between 20 and 30 degrees from normal to the surface (see Fig. 1). The tilt angle is dictated by the spacing of adsorption sites on the metal surface and is a consequence of the chains establishing van der Waals contact [6, 15].
Figure 3. Model of an alkanethiol SAM (large circles) on an Au(111) surface (small circles) where the SAM forms the $(\sqrt{3} \times \sqrt{3})R30°$ lattice.

2.2.2. Important Factors in Determining the Structure and Function of Organosulfur Monolayers

The structure discussed in Section 2.2.1 refers to the ideal structure observed with long chain aliphatic alkanethiols on an Au(111) surface. There are a number of factors that influence the SAM structure, and hence function, including the surface upon which the SAM is formed, the chain length, the terminal group of the alkanethiol, and having a mixture of components in the SAM. For example, attractive van der Waals forces between the alkyl chains affect the stability and level of defects within a SAM [98]. Defects in SAMs are important in determining a SAM. The consequence of a defect is either a pinhole (a hole in the SAM where there is direct access to the metal) in the SAM or a collapsed site. In both cases, the blocking ability of the SAM will be reduced. The decrease in blocking may be an advantage, such as in an electrochemical system where the underlying electrode is required to be electrochemically accessible [137–140], or may be a disadvantage if the function of the SAM is to block access to the metal [38, 86, 141, 142]. Therefore, any factor that increases or decreases the van der Waals forces will alter the order of the resultant SAM. Some of these variables will be discussed below.

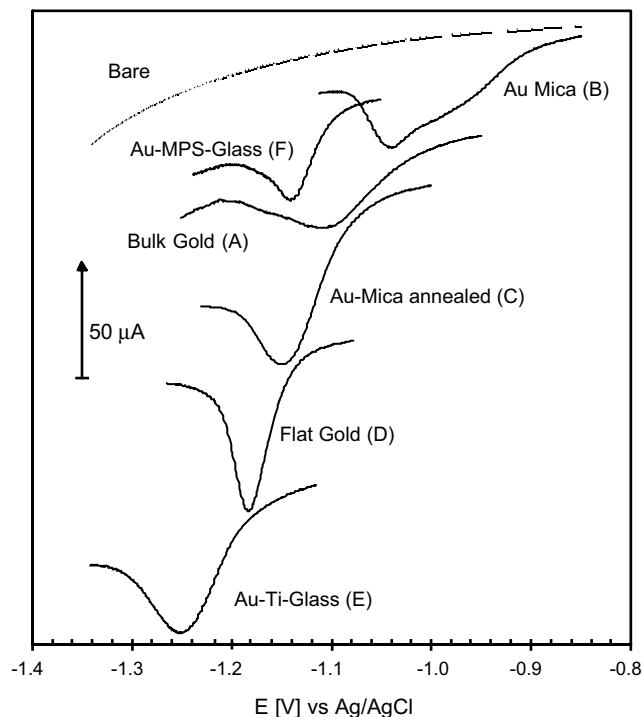
The Underlying Metal Surface Alkanethiol SAMs can be formed on a number of coinage metal surfaces apart from gold including platinum, silver, and copper, as well on different crystal faces of these metals. Turning our attention to gold first, the gold surface can be polycrystalline, single crystal, or thin film deposited. Single crystal surfaces are attractive for fundamental studies [143–145], as the surface is well defined, but are not compatible with the bulk manufacture of a large number of devices in the same way that deposited thin films are. Because of the influence of van der Waals forces on SAM integrity and stability, smoother surfaces produce more ordered and robust SAMs with higher integrity (i.e., less defects) than those with rougher surfaces [42, 109, 146–150]. The influence of the gold surface roughness on the energy required to remove a hexadecane SAM [109] is shown in Figure 4. Figure 4 shows the portion of a cyclic


Figure 4. Reductive desorption CV peaks for various gold substrates coated with SAM (first cycle). All recorded in 0.5 M KOH at scan speeds of 100 mV s^{-1}, except Au-MPS glass (F) which is recorded at 5 mV s^{-1}. Reprinted with permission from [109], D. Losic et al., *Langmuir* 17, 3307 (2001). © 2001, American Chemical Society.

voltammogram where the alkanethiol is reductively desorbed for six different gold surfaces. With the exception of one surface, the peak potential shifts to more cathodic (negative) potentials the smoother the surface. Higher potentials mean the SAM is more difficult to remove. The smoothness of the gold is even more important for microcontact printed SAMs than solution-assembled SAMs because the alkanethiol is only deposited where the stamp contacts the surface [109]. Of equal importance when preparing defect-free SAMs, however, is the purity of the gold [147].

In nanofabrication, it is important to recognize that often the variation in height of a gold surface is of a similar or greater scale than the size of the adsorbate. Therefore, schematics of molecular assembly frequently seen in the literature where molecules are arranged onto a perfectly flat surface only depict an idealized molecular assembly rather than reality. Methods of fabricating gold surfaces that are atomically flat over large regions have been developed using template stripping of the metal surface from mica [151–155]. Although such strategies have not been applied to other metals, there is no reason to assume such strategies would not also render molecularly smooth surfaces.

Different gold crystal faces have different metal atom spacing and, therefore, the resultant SAM has a different structure. For example, on a Au(100) face, the tilt angle is only 5° rather than the 30° seen on an Au(111) face [6]. The interest in Au(111) is a consequence of it being the most thermodynamically stable surface because it has the highest atomic surface density. Therefore, vacuum evaporation and

gold annealing typically give surfaces that are predominantly Au(111).

As stated above, apart from gold, SAMs can be formed on other metal surfaces, such as silver [7, 105, 156–159], copper [7, 8, 105, 160–164], nickel [165], platinum [21, 139, 166–168], and palladium [169–172] as well as on metal composite surfaces like gallium arsenide [173–176]. Schlenoff et al. [105] have shown that the surface coverage on a variety of surfaces decreases in the order Cu > Ag > Pt > Au > GaAs. The higher surface coverage on silver relative to gold is a consequence of the SAM structure. On Ag, the SAMs are very similar structurally to on Au(111) but with a lower tilt angle (12° compared to 30° for Au) and a smaller chain-chain distance (4.1 Å for Ag and 5.0 Å for Au) [177]. The SAMs on copper are structurally more complex and very sensitive to the surface preparation of the metal [177]. On platinum, in contrast to Au, Ag, and Cu, the SAM shows a number of gauche transformations which can reversibly be eliminated at both positive and negative potentials [166]. Surfaces where underpotential deposition is employed to deposit a monolayer of one metal onto a gold surface have also been modified with organosulfur SAMs [7, 178]. The underpotential deposition of silver onto gold has been shown to give a more stable SAM than on gold alone [7].

Chain Length The order and stability of alkanethiol monolayers are very sensitive to the length of the alkyl chain. Porter et al. [128] investigated the influence of alkyl chain length using electrochemistry, optical ellipsometry, and infrared spectroscopy. For carbon chains over 11 carbon atoms, the monolayer is densely packed and crystal-like [128]. As the chain length decreases, the structure becomes increasingly disordered with lower packing density and coverage. The transition between crystal-like and disordered occurs between 5 and 11 carbon atoms depending on the measurement technique and surface used. Electrochemical measurements, with the long-chain SAMs, show that the monolayers provide substantial barrier properties to electron transfer and are strongly resistant to ion penetration [128].

An additional influence of chain length on monolayer properties in highly ordered SAMs comes from the so-called "odd-even" effect where the orientation of the terminal group, and the structure of the SAM [179], depends on the number of carbons in the alkyl chain. The orientation of the terminal group has been shown to influence the electrochemical stability of biphenyl terminated SAMs [180], the reactivity of the SAM [181, 182], wetting [183, 184], and its tribological [184] properties.

As the densely packed monolayers of long-chain alkanethiols (10 or more alkyl carbons) passivate electrode surfaces, the choice of alkyl chain length is dictated by the application of the SAM. If the SAM is required to prevent access to the underlying gold, then a long-chain alkanethiol is required [185]. However, in many sensing applications, where electrochemistry must occur at the metal below the SAM, either short-chain alkanethiols are required [12] or the order of a long-chain SAM must be disrupted [139, 186, 187]. The consequence of a shorter chain SAM, however, is poorer electrochemical and thermal stability. Recently, Markovich and Mandler [188] have shown that

long-chain SAMs can be disrupted through the incorporation of amphiphilic molecules during deposition of the SAM.

The Influence of the Terminal Group If only one terminal group was available with alkanethiols, they would be of limited utility. Part of the power of alkanethiol chemistry is the ability to relatively easily tailor the chemistry of the self-assembly molecules to a particular application [189]. Altering the terminal group is perhaps the most important aspect of this ability as it allows the building onto the surface of additional components and controls the surface properties of the SAM-modified interface.

The influence of the terminal group on SAM structure depends very much on the size of the terminal group. Terminal groups such as $-CH_3$, $-OH$, $-CO_2H$, $-NH_2-CONH_2$, $-CO_2CH_3$, where the cross-sectional area is smaller than that of the alkyl chain (~20 Å) [98], do not interfere with the packing of the hydrocarbon chains. Hence, these monolayers present a single homogeneous functionality at the exposed surface. In contrast, SAMs with bulky terminal moieties, such as sulfonates and oligo(ethyleneoxides) [190], show significant deviation from the $(\sqrt{3} \times \sqrt{3})R30°$ hexagonal lattice due to disruption of the hydrocarbon packing [191, 192]. A consequence of disruption of the chain-chain packing is that no longer does the surface present homogeneous functionality. In the case of oligo(ethyleneoxide)-terminated surfaces their ability to be wetted is affected as a result [189].

Similarity of structure does not necessarily imply a similar function. An example of this relates to how the terminal influences the interactions of the terminal surface of the SAM with the surroundings. Methyl-terminated SAMs present low-surface free energy, hydrophobic surfaces while the high-surface free energy, alcohol-terminated surface is hydrophilic. Furthermore, the properties of the surface can be altered, depending on the terminal group, through changing solution conditions. The effect of solution conditions is demonstrated by a carboxylic acid-terminated SAM, which can be either negatively charged or neutral depending on the pH [193]. The change in the charge state of the interface will then greatly influence the blocking ability of the SAM on a surface. The variation in blocking ability with pH was used by Zhao et al. [194] to measure the surface pK_a of (3-mercaptopropionic acid). A pK_a titration was performed by electrochemically measuring the decreased ability of ferricyanide to penetrate the carboxylic acid-terminated SAM with increasing pH (as the surface changing from neutral to negatively charged). It is important to note that the surface pK_a can be significantly different than the pK_a of the molecule in bulk solution [195, 196]. Similar tailoring surface properties have been very important in using SAM-modified surfaces for tasks such as restricting protein adsorption [43, 197], orientating the approach of biomolecules [198, 199], controlled wetting [41, 200], controlling crystal growth [201], and influencing the surface friction [193, 202].

2.2.3. Stability of Alkanethiol Monolayers

The application of SAMs to anything other than fundamental studies requires the resultant modified surface to be stable. Self-assembled monolayers have good stability over a

wide range of conditions. Variation in stability between different SAMs is a function of the chain-chain interactions as the gold-thiolate bond is the same. Therefore, any factor that increases the integrity of the SAM will ultimately also improve the stability of the SAM.

Thermal stability of aliphatic alkanethiol SAMs has been the subject of several studies. The SAMs have been reported to begin desorbing from gold at temperatures from 75 °C for butanethiol [203] to above 100 °C for dodecanethiol [204]. There is some inconsistency in the reported desorption temperatures and rates for a given alkanethiol, because of the influence of parameters, such as the smoothness of the gold surface and the method of determining the loss of the alkanethiol. For example, Nuzzo et al. [17] have reported hexadecanethiol desorbs in a range between 170–230 °C using X-ray photoelectron spectroscopy and infrared spectroscopy, while Schlenoff et al. [105] use radiolabelling to show complete loss of the SAM at 210 °C which began at 100 °C. The greater the forces of interaction between the tails of the SAM-forming molecules, the greater the thermal stability of the SAM. Therefore, monolayers where there is hydrogen bonding [205] or π-π bonding [206] between the alkyl chains exhibit better thermal stability than aliphatic hydrocarbons. Similarly, repulsive forces between terminal groups such as carboxylic acids and sulfonates will result in a lower stability than the equivalent methyl-terminated SAM. The impact of these repulsive terminal interactions will again be influenced by the alkyl chain length, where the influence of the terminal group is diluted as the alkyl chain increases in length.

For many applications the electrochemical stability of alkanethiol SAMs is particularly important. Self-assembled monolayers have been shown to be stable to potentials between approximately +1.0 and −1.0 V versus SCE, although this potential window depends on chain length, terminal group, and the quality of the underlying gold surface [38, 40, 207]. Such a potential window is compatible with most electrochemical applications. Outside this range, the thiols are either oxidatively or reductively desorbed [33, 39, 124, 146, 150, 180, 208–210]. The instability at high potentials, however, can be used to control the order of the SAM during formation [124]. Self-assembled monolayers with high integrity and few defects are more stable, requiring more positive or negative potentials to desorb, because ordered regions, where there is a high level of bonding between alkyl chains, require whole sheets of the SAM to be removed at a time rather than individual alkanethiols [109, 150]. The influence of the gold surface on the stability of SAMs is demonstrated in Figure 5 with hexadecanethiol SAMs assembled on gold surfaces with different roughness [109]. The three gold surfaces are gold evaporated onto mica with no annealing (A), polycrystalline bulk gold (B), and atomically smooth gold prepared by template stripping (C) [155]. The roughness of the gold surfaces decreases from surface A to C. The higher the roughness of the surface, the poorer the packing between the alkyl chains and hence the greater the number of defect sites where pinholes, where bare gold is exposed to solution. Figure 5 shows the number of pinholes in the SAM formed on each surface. The pinhole fraction is measured by performing a cyclic voltammogram between −0.5 and 1.5 V versus Ag/AgCl in 0.1 M
Figure 5. The variation in the fraction of the SAM surface covered in pinholes as a function of the number of cycles in a cyclic voltammogram on three gold surfaces. The surfaces are (A) gold evaporated onto mica with no annealing, (B) polycrystalline bulk gold, and (C) atomically smooth gold prepared by template stripping. The roughness of the gold surfaces decreases from surface A to C. The number of pinholes in each SAM is measured by performing a cyclic voltammogram between −0.5 and 1.5 V versus Ag/AgCl in 0.1 M H$_2$SO$_4$. During this measurement there is a minor amount of further disruption of the SAM. The increase in pinhole fraction with the number of scans gives an indication of the SAM robustness with SAMs formed on smoother surfaces being more robust.

H$_2$SO$_4$, the same conditions used for the electrochemical cleaning of gold. In this experiment, as the potential is swept positive, any exposed gold from pinholes will be oxidized. Upon sweeping negative, this gold oxide is reduced and the area under the reduction peak allows the quantification of the amount of pinholes. During this measurement, there is a minor amount of further disruption of the SAM. This is evident in Figure 5 where the pinhole fraction increases as the number of scans increases. Note, however, with the smoother surfaces, where there are larger sheets of the SAM with more chain-chain interactions, the SAM is far more robust to this repeated cycling.

The long-term storage stability of SAMs is less well understood. Horn et al. [211] have used reflection-absorption IR spectroscopy (RAIRS) to monitor changes in structure of aliphatic alkanethiols over a 6-month period. Changes in the symmetric and asymmetric CH$_2$ stretching modes observed with the RAIRS are attributed to chemical oxidation of the thiolate species at the point of attachment to the gold. Upon oxidation of the thiolate to either sulfinates (—SO$_2^-$) or sulfonates (—SO$_3^-$), the SAM is less strongly bound to the gold as determined by their ability to desorb from the surface in solution [212]. The oxidative loss of alkanethiols is particularly problematic for applications that employ short chain alkanethiols, where oxygen and other oxidants can easily access the gold-thiolate bond [213]. The rate of oxidation of the thiol to a sulfonate has been shown to be dependent on the alkyl chain length [213, 214], as well as the terminal group of the SAM [214]. In the case of the terminal group, the rate constant for photo-oxidation has a ratio of 4:2:1 for CH$_3$:OH:COOH for both long and short chain SAMs [214].

In practice, the problem of oxidation can be reduced by storing devices in oxygen-free environments such as vacuum packs.

With the depiction of alkanethiol SAMs as ordered, stable, and static monolayers on surfaces, it is easy to forget that SAMs are dynamic systems in which the alkanethiols are capable of moving about on the surface, as is evident from the kinetic studies where after adsorption the SAM slowly reorganizes itself. The dynamic behavior of SAMs is demonstrated by two key observations. First, when a SAM modified gold surface is placed in a different alkanethiol solution, exchange occurs at the grain boundaries of the underlying metal surface [40, 42, 77, 105]. This is called a place exchange reaction. Second, the alkanethiol in a SAM have been shown to surface diffuse to heal gaps of exposed gold [210]. This healing process occurs over the time span of several hours [9, 215–217]. The rate to which defects are healed is independent of the chain length of the alkanethiol, which suggests the head group dominates the adsorption and desorption steps [215] and that the first layer of gold atoms are involved in the monolayer movement [9].

2.2.4. Mixed Monolayers

To use SAM surfaces as the base upon which nanofabrication can be performed requires more than one component to be incorporated within the SAM. The formation of homogeneous SAMs from mixtures of alkanethiols would allow the construction of integrated molecular systems where several components are incorporated within a single monolayer. For example, mixed monolayers can allow either large recognition elements or nanoscale building blocks to be spaced apart from each other if necessary. Furthermore, through varying the composition of a mixed SAM the density of attachment points, and hence the surface loading of added components, can be controlled.

Mixed monolayers have commonly been produced through the use of a mixture of alkanethiols in the solution to which the substrate is immersed, although place exchange reactions have also been used [40, 42, 105, 169, 218–226]. In a place exchange reaction the exchange is greater in SAMs with more defects [42].

A mixed SAM formed from two components in solution has been regarded as being a reasonably homogeneous mixture of the components [41, 227–229] rather than phase segregation into "islands" as has been observed in Langmuir–Blodgett films [15]. There is some controversy as to whether phase segregation occurs or not. Homogeneity was determined via wetting studies [41], which is supported by STM measurements that suggested no segregation occurs on the scale of greater than 50 nm [230]. However, on a smaller scale some phase segregation has been reported to occur [231]. Scanning tunneling microscopy studies indicate domain-rich regions of individual components of nanometer dimensions can be observed [232, 233]. This phase separation is believed to occur by adsorption/desorption followed by movement. Differences in length and chemical functionality certainly play a key role in any phase separation [231]. For example, Atre et al. [231] showed using wetting studies, FTIR and XPS, with a mixture of $HS(CH_2)_{15}CH_2OH$ and $HS(CH_2)_{(15+m)}CH_3$ with m increasing systematically from

-6 to $+6$, that the monolayer underwent structural change from randomly placed protruding —OH-terminated chains at low m to phase segregated at high m. However, in contrast to studies that show phase separation STM studies by Takami et al. [234] do not show phase separation even at the nanometer level for mixtures of azobenzene-terminated SAMs and dodecanethiol. This contradictory evidence highlights the many differences in SAM studies such as the surface upon which assembly occurs, the alkanethiol used, and the measurement technique, which play a role in the conclusions reached. With regards to phase separation in mixed SAMs, it appears that generally mixed SAMs form a 2-dimensional alloy, which can decompose into a heterogeneous distribution particularly when the two components are significantly different [118].

When forming mixed SAMs by solution assembly, the ratio of the components in the SAM can be adjusted by varying the ratio of the components in solution. Note, however, that the mole fraction of components in solution is not necessarily the same as the two components on the surface. In the two-component mixture, the more alike the two components the closer the mole fraction in the SAM will be to the mole fraction in solution. If the two components are quite different, the surface mole fraction can be very different to the solution mole fraction. For example, Offord et al. [18, 235] have looked at mixed SAM of octadecyl mercaptan **1** with either butyl mercaptan **2** or tert-butyl mercaptan **3** and a variety of different ratios in solution. Time-of-flight secondary ion mass spectrometry showed that the adsorption efficiency of **1**–**3** varied in the order $1 > 2 \gg 3$. In the case of a 1:1 mixture of butyl to octadecyl adsorbate in solution, there was a 3–4 fold excess of **1** to **2** and a 40–100 fold excess of **1** to **3** [18]. These excesses are dependent on the solvent used [235]. Therefore, it is clear that the relative solubility of the two adsorbates has an influence on the surface mole fractions. Similar results have also been observed with thermal desorption mass spectrometry [236].

A novel exploitation of the phase separation of mixed SAMs to control the surface loading of a recognition element has recently been developed by Satjapipat et al. [210] (see Fig. 6). They formed a mixed SAM of 3-mercaptopropionic acid (MPA) and mercaptohexanol (MCH). As the two alkanethiols are reasonably different chemically, they tended to separate into domains rich in each of the two components. As MPA desorbs at a lower potential than MCH, MPA was selectively removed through reductive desorption. The result was a surface that contained some bare regions. Before the remaining adsorbed MCH could diffuse across the surface to cover the bare regions, the substrate was placed in a solution of thiolated DNA which assembled onto these regions. This approach represents one method of fabricating interfaces with discrete domains of different components; in essence, this is patterning a SAM. More controlled methods of patterning SAMs are discussed in Section 2.3.

2.3. Patterning of SAMs

Many applications in nanotechnology require patterning of the surface chemistry, and hence the controlled positioning of the different components used to modify the surface.
Figure 6. Schematic representation of the procedure used by Satjapitat et al. [210] to fabricate a DNA recognition interface. A mixed SAM of MCH and MPA is formed. The electrode potential is scanned until the MPA is reductively desorbed to leave bare gold. The electrode is then placed in thiolated DNA which adsorbs onto the bare regions.

Applications include biosensors, microelectronics, and optical devices such as displays and waveguides. Many of these applications require the patterns to be as small as possible. Controlled positioning of different components can be achieved using a variety of techniques for patterning SAMs, which have recently begun being developed where resolution can vary from centimeters down to as low as 20 nm [237]. Approaches to patterning of SAMs can be divided into composition methods where the SAM is patterned during its assembly and decomposition methods, where parts of a complete SAM are removed to allow a second component to be added [238]. Decomposition methods, such as photolithography, electron beam writing, and micromachining, have traditionally been more popular for patterning SAMs. New decomposition methods like nanoshaving [237, 239] and a proximity printing technique using focused ion beams developed by Golzhauser et al. [240] have also been developed. However, in recent times with the advent of microcontact printing [43, 81, 83, 84, 86, 107–111, 171, 172, 197, 201, 241–254] and dip-pen lithography [73, 255–261], composition methods are moving to the fore.

2.3.1. Decomposition Methods

Photolithography   The wide applicability of photolithography in creating features and devices on the microscale has inevitably seen it also used for patterning SAMs. The photo-oxidation of alkanethiolate can be achieved directly upon exposure of the SAM to UV radiation in the presence of oxygen [262, 263]. Using a chrome mask patterned to allow selective exposure of the surface to UV radiation, patterning of the SAM can be achieved [264, 265]. The oxidized thiols can easily be desorbed from the surface and then a second alkanethiol can be assembled onto the bare surface. Alternatively, the remaining SAM can act as a chemical resist that blocks the access of etchants to the underlying surface: Therefore, exposure of the patterned surface to an etchant will result in the bare surface being etched away, with the SAM-covered regions remaining, to give a microstructure.

Patterns down to 100 nm have been achieved with photolithography by Behm et al. [266] using a microscope to focus the light in projection lithography. Although photolithography is an efficient method of patterning substrates to make microstructures, it has a number of limitations in nanofabrication, especially with regards to developing new nanodevices. First, it requires expensive specialist equipment and clean room facilities. Second, the shallow depth of field requires that only planar substrates can be patterned that limits the range of materials upon which nanostructures can be built. Finally, and perhaps most importantly, the ultimate resolution is dependent on the wavelength of light. This final limitation appears to restrict photolithographical patterning to defining regions on a surface where nanofabrication can occur rather than being involved in the precise positioning of molecular components in nanofabrication.

Beam Lithography   Beam lithography is a decomposition method that uses beams such as atoms, ions, or electrons to remove the alkanethiolates. Selectivity is again achieved with a mask. The best resolutions appear to be achieved using neutral beams [267, 268]. Berggren and Younkin et al. [267, 269] have patterned features smaller than 100 nm on gold and silicon using neutral cesium beams. Berggren et al. [268] have also shown nanometer resolution in patterning alkanethiols using argon beams. In common with photolithography, different alkanethiols show different susceptibility to the decomposition source, and therefore some tailoring of the technique is required for individual systems.

Nanoshaving   Truly nanometer-size features can be patterned onto SAMs using one of several scanning probe microscope (SPM) techniques [239, 255] collectively called scanning probe lithography. "Nanoshaving," developed by Xu and Liu et al. [237, 239] (Fig. 7) involves displacing the adsorbate on a SAM-modified surface using an AFM tip. The tip is scanned at a load higher than the displacement threshold. In this way, patterns of bare metal with feature sizes down to 20 nm can be produced. If the nanoshaving is performed in a solution containing a second alkanethiol, the exposed metal will be modified with the second component; this is called nanografting. An equivalent nanofabrication
Figure 7. The principles of nanoshaving where a) AFM tip is dragged across an alkanethiol modified surface with sufficient force to remove the alkanethiol from the surface. If this nanoshaving is performed in a solution containing a second alkanethiol, then a surface patterned with two alkanethiols can be produced. Feature sizes as small as 20 nm have been fabricate; b) shows a 50 nm wide island of octadecanethiol patterned into a decanethiol SAM. Reprinted with permission from [237], S. Xu and G. Y. Liu, *Langmuir* 13, 127 (1997). © 1997, American Chemical Society.

method using STM has also been developed, where the tip potential is sufficiently high to cause thiol desorption. Nanoshaving has also been used for fabricating semiconducting nanowires [270] and to characterize the thickness of novel alkanethiol SAMs [271].

2.3.2. Composition Methods of Patterning

Microcontact Printing Microcontact printing is one of a suite of soft-lithography methods for patterning surfaces developed by Xia and Whitesides [86]. The basic principles of microcontact printing are shown in Figure 8. A stamp with relief structure is prepared from a master. The master can be any structure with the appropriate relief. In fact, Deng et al. have shown how a master can simply be made using a normal computer printer and transparencies [253]. The stamp is coated with alkanethiol ink which is evaporated onto the stamp so the printing process is essentially dry. Upon contact of the inked stamp with the surface, a SAM formed at the points of contact. As the SAM only forms where the stamp contacts the surface, the pattern of the stamp is transferred to the solid substrate. In this way, features as small as 100 nm have been fabricated [245].

Placing the patterned surface into a solution containing a different alkanethiol allows a two-component system to be fabricated, which could be used to give either controlled wetting/dewetting [243] locations where the underlying electrode is passivated and others where access is maintained, provide specific sites for crystal nucleation [201] or allow the selective deposition of other materials such as polymers [247] and cells [107, 197]. Rather than deposit a second alkanethiol onto the exposed metal surface, it could be used either as a microelectrode array [252], or the printed SAM could be used as an ultra-thin chemical resist for selective etching to remove the exposed metal surface [244, 250].

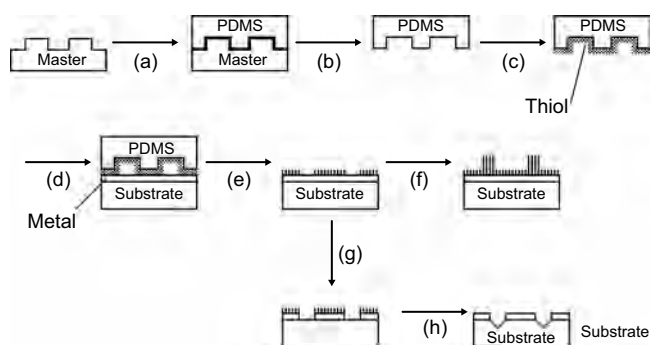
The essential advantages of microcontact printing are that it is cheap and easy to set up. Existing fabricated devices can be used as the masters for new stamps and, with some


Figure 8. Schematic of the process of microcontact printing where: (a) a master which contains a relief structure is coated with the elastomer PDMS, (b) the PDMS is removed from the master and becomes the stamp, (c) the stamp is inked with an alkanethiol, and (d) contacted with a the surface to be patterned, (e) the alkanethiol is transferred to the metal surface at the points of contact. The result is a patterned surface with exposed metal and metal covered in alkanethiol. Either (f) the patterned surface is placed in another alkanethiol solution to give a surface patterned with two different alkanethiols or alternatively in (g) the exposed metal is etched away, using the alkanethiol as a resist, followed by (h) the removal of the remaining alkanethiol.

creativity, quite sophisticated devices can be fabricated. The low cost is because no special clean room facilities or expensive masks are required. One of the reasons that clean room facilities are not required relates to the stamp itself. Typically, it is made of polydimethylsiloxane (PDMS) which is an elastomer with a low surface energy. If the surface to be patterned is contaminated by a speck of dust (which would be a big problem in photolithography), the stamp will conform around the dust particle and the mobility of the alkanethiols may even allow assembly onto the part of the surface covered by the dust particle.

Microcontact printing has been performed on nonplanar substrates [242] and even inside tubes [246]. With this emerging technique, issues that have been addressed include how to decrease the size of the pattern [245], what dimensions give a stable stamp that does not collapse upon itself [86, 248], the order of the printed SAM relative to solution assembled monolayers [108], methods of inking the stamp [251], how the ink is dispersed from the stamp to the substrate [249], the influence of the topography of the gold surface [109], and the amount of alkanethiol applied to the stamp [110] on the integrity of the printed SAM.

"Dip-Pen" Lithography "Dip-Pen" lithography is an ingenious approach to nanofabricating SAM-based structures with an AFM developed by Piner and Hong et al. (Fig. 9) [255, 272]. Dip-pen lithography exploits the water meniscus that travels with an AFM tip when contacting a surface under ambient conditions. By coating the tip in an alkanethiol, the water meniscus solubilizes some of the alkanethiol and transfers it to the solution substrate upon which it is traveling. In this way, line widths of 30 nm resolution have been achieved. Dip-pen generated templates of DNA have been used to orthogonally assemble nanoparticle building blocks, thus allowing nanofabrication in a third dimension [73]. This was achieved by patterning a gold surface with 16-MCH acid to which a sequence of DNA was attached. Gold nanoparticles were modified with thiolated complementary DNA. Exposure of the patterned surface to the complementary DNA allowed ordered arrays of nanoparticles to be fabricated onto the original gold surface. A similar approach has been used to pattern amine modified polystyrene spheres, which were bound to the MCH-patterned surface via electrostatic interactions [257]. Dip-pen lithography has now been extended beyond alkanethiols to sol–gel based inks [258].
Figure 9. Dip-pen lithography where an AFM tip coated in alkanethiol is scanning across a surface under ambient conditions. The meniscus of water that travels with the tip solubilizes the alkanethiol, transferring it to the metal surface to produce patterns.

An earlier variant of dip-pen lithography, which produced patterned features of size greater than 10 μm, is microwriting [273, 274]. In microwriting, neat alkanethiol is dispensed from the tip of a fine capillary directly onto the gold surface. Control over the distance between the tip and the surface gives some control over line widths that are achieved.

2.3.3. Controlled Positions of Alkanethiol Deposition

Controlling the location where a particular alkanethiolate SAM is deposited has also been achieved electrochemically. This is done using an electrode array where the elements of the array are held at different potentials, depending on whether they are to be modified by the SAM in solution or not. Such an approach is important in controlling the modification of different elements of an electrode array with different recognition species. The first demonstration of using electrode potential to control the deposition of alkanethiols was by Tender et al. [275], where interdigitated electrodes were first all coated with $HO(CH_2CH_2O)_6(CH_2)_{11}SH$. Sufficient potential was applied to one of the interdigitated electrodes to selectively desorb the SAM. The microelectrodes were then placed into 16-mercaptohexadecane (MHD) to coat the now bare electrode. The MHD-coated electrode allowed selective adsorption of proteins. The crucial aspect of this technology is that different elements in an electrode array can be selectively coated without requiring any alignment [276]. Wang et al. [125] have used the complete opposite approach to selectively coating individual electrodes in an array. By placing a negative potential on the electrode to be coated, the adsorption of the SAM from ethanolic solution onto that electrode is accelerated. The other electrodes, held at open-circuit potential, are modified much more slowly and therefore are only partially coated. Hsueh et al. [277] have also used potential to control which elements in an electrode array are modified with a SAM. The primary difference to the approach of Tender is, rather than use alkanethiols, the electrochemical oxidation of alkylthiosulfates (Bunte salts) to certain electrodes is used. The oxidation of the Bunte salts produces either a disulfide or an alkylsulfide radical at the electrode which is then trapped on the electrode surface to produce a gold-thiolate bond.

3. APPLICATIONS OF SELF-ASSEMBLED MONOLAYERS

As stated above there are a host of applications to which SAM modified surfaces have been applied including surface coatings, sensing, molecular electronics, and nanofabrication with nanoscale building blocks. We shall discuss each of these applications in turn.

3.1. Surface Coatings

The affinity of alkanethiols for coinage metal surfaces and their subsequent self-assembly onto the surface made use of alkanethiols as surface coatings for metal surfaces an obvious application. One of the attractive features of using alkanethiol chemistry is that the surface coating can be achieved with nanometer control. The alkanethiol surface coatings have been used to give metal surfaces corrosion resistance, changing the frictional properties of surfaces, making them hydrophobic or hydrophilic, giving controlled environments for crystal growth, making surfaces that resist fouling and preparing surfaces for controlled protein and cell growth. Many of these surface-coating technologies lead to further applications, such as surfaces for controlled protein adsorption can then be used for the development of biosensors.

3.1.1. Corrosion Resistance

Since metal surfaces can be passivated using close-packed alkanethiol monolayers, several workers have used these monolayers to protect copper [7, 8, 160, 161, 164, 278–284], iron [285–288], and gold [216, 242, 289] surfaces from species in solution. It is the ability of alkanethiol monolayers to protect an underlying metal surface, which is used in microcontact printing to allow etching of exposed gold and not gold coated by the SAM [86, 242, 244, 246]. Laibinis and Whitesides [290] first attempted to prevent the oxidation of copper surfaces coated with alkanethiols when in the presence of atmospheric oxygen. XPS measurements showed that the rate of oxidation was inversely proportional to the alkanethiol chain length. The resistance to corrosion was much greater with alkanethiols where the chain length was greater than 12 carbons due to more closely packed SAMs being formed [281]. In aqueous solutions of $NaSO_4$, however, even octadecanethiol did not prevent corrosion [291]. As a consequence, further modification of the alkanethiol was required to reduce the coatings permeability [160, 164, 207, 278–280, 283–285]. As example of this approach is by Itoh et al. [160], where copper surfaces were modified with 11-mercapto-1-undecanol. The alkanethiol was then reacted with an alkyltrichlorosilane to form an alkylsiloxane polymer. The formation of a polymer on the copper surface improved the corrosion resistance of the coating.

3.1.2. Surfaces for Controlled Crystal Growth

The terminal moiety of a SAM, and the ease to which this can be modified, provides a method of controlling the chemistry of a surface upon which crystallization occurs [201, 292–300]. The ability to easily pattern the SAM using microcontact printing allows the controlled position on a surface where nucleation of crystals occurs. This was elegantly demonstrated by Aizenberg et al. [201], where a SAM of an alkanethiol that promoted crystal growth (symbolized as $HS(CH_2)_{15}X$ and which was mercaptohexanoic acid X is COOH) was patterned into dots using microcontact printing onto a metal surface (gold, silver, or palladium). The rest of the surface was coated with MCH. Placing this patterned surface into a $CaCl_2$ solution exposed to carbon dioxide and ammonia vapor resulted in calcite crystals forming predominantly on the $HS(CH_2)_{15}X$ parts of the SAM. Not only can the position of crystal growth on a surface be dictated but also control over whether many or only a single crystal grew at each location was afforded by judicious choice of the feature size, as well as the density and concentration of the crystallization solution. Even more exciting was the demonstration that different X groups in $HS(CH_2)_{15}X$ resulted in crystal growth from different crystal faces. The ability to control the position of the growth of single crystals on a

surface, and also to be able to control the type of crystal, could be exceedingly useful for fabricating ordered arrays of nanoparticles. This concept has already been realized by Qin et al. [301] with arrays of a variety of crystals being grown including $CdCl_2$ and Nile red.

3.1.3. Biological Surfaces

Surfaces that interact with biological environments have enormous numbers of applications in a large number of fields ranging from biological implants, drug development, to biosensors. An important aspect of these applications is an understanding of how biological molecules and organisms interact with the man-made surfaces to which they are exposed. There is a huge amount of research in these fields which fills many volumes. In this section, the role alkanethiol SAMs have played in these fields will be discussed.

Proteins Adsorption   The adsorption to proteins to surfaces is exceedingly complex, and although there has been considerable research into the field there is yet to be a complete molecular level understanding [302–306]. Self-assembled monolayers are therefore important in understanding and using proteins adsorption, because they are model systems where the surface properties are well defined and can easily be altered in a known way [43, 49, 238, 307]. Furthermore, protein adsorption mediates subsequent cell adhesion which is important in implants [308, 309] and in controlled growth of cells on surfaces [49, 107, 307]. The adsorption of proteins while retaining the protein's configuration and activity is also important in the development of biosensors [11, 44, 81, 310]. As direct contact between a metal surface and proteins will cause denaturing of the protein, and hence in the fabrication of protein surfaces, SAMs play a role in not only allowing molecular level control over the immobilization of the protein but also insulate the protein from the metal. For controlled adsorption of proteins onto surfaces, however, nonspecific adsorption needs to be eliminated. Nonspecific adsorption of proteins occurs on many different SAM end groups [190, 238, 309, 311–314] and appears to correlate with the hydrophobicity of the surface [311, 314]. Some end groups, however, have been shown to resist nonspecific adsorption of proteins onto surfaces [190]. The most widely used [107, 197, 315–320] and successful terminal group that resists protein adsorption has been poly(ethylene glycol) with between two and seven ethylene glycol units (see Fig. 10). The polyethylene glycol head group has been shown to resist nonspecific adsorption of a number of proteins with a range of molecular weights and isoelectric points under a wide range of solution conditions [321, 322]. Self-assembled monolayers that resist protein adsorption then allow specific adsorption of a protein of interest, as well as patterning a surface so that the protein adsorbs at well-defined locations.

Specific adsorption of a protein for the development of biosensors has most commonly been performed via covalent attachment where either the protein is first derivatized with an alkanethiol and attached to the surface, or alternatively, the surface is modified with a SAM and covalently linking the protein to the SAM (see Section 3.2.1 and Figure 14 for an example of this strategy). An alternative approach is to use biospecific recognition of the protein for a ligand.
Figure 10. Structure of an ethylene glycol-terminated alkanethiol that resists protein adsorption. The number of ethylene glycol repeat units typically ranges from 2 to 7.

To achieve the biospecific recognition requires the substrate to restrict nonspecific binding to the surface so that the ligand can interact with the desired protein. The classic example of such an approach in nature is the biotin-avidin affinity reaction. There have been, however, some elegant examples developed in recent years. The Whitesides group prepared a mixed SAM of ethylene glycol end groups and a benzosulfonamide ligand for the specific adsorption of carbonic anhydrase. In a similar strategy, Sigal et al. [315] prepared a mixed SAM terminated with ethylene glycols and nitrilotriacetic acid (NTA). The NTA chelates with Ni(II) to form a complex with two vacant sites on the Ni(II) center. This surface can now selectively bind proteins prepared with a histidine tag as confirmed via surface plasmon resonance. Schlereth et al. [323] have also used a biospecific binding to immobilize the enzyme lactate dehydrogenase onto electrodes where the ligand is a triazine dye. One of the attractive features of the specific adsorption of proteins using biospecific ligands is that the protein is immobilized with control over its orientation. The specific adsorption of proteins onto surfaces not only opens up the opportunity for well-controlled immobilization for biosensors but also provides a surface upon which cell adhesion can occur.

Cell Adhesion   The analysis of individual cultured cells, and how they interact with target molecules, is important in screening target drugs in genetic engineering and in assessing the toxicological effects of compounds. To use individual cells for any of these applications requires the isolation of large numbers of cells, controlling their distribution, and position in space. The obvious way of achieving ordered arrays of individual cells is to immobilize them on the surface. The adhesion of cells onto surfaces is mediated by proteins of the extracellular matrix (ECM) such as fibronectin, laminin, heparin, vitronectin, and collagen. Therefore, to

promote controlled cell adhesion, one approach is to first adsorb one or more of these proteins to the surface [81]. Both hydrophilic [324, 325] and ionic [326] SAMs have been used for this purpose; they afford poor control over the adsorption process.

A more nanotechnological approach to controlled cell adhesion is to exploit the fact that the attachment of the cells to the extracellular matrix is controlled by specific interactions between the integrin receptors on the cell membranes and peptide sequences of the ECM proteins [327]. As specific peptide motifs are involved in the cell adhesion, surfaces terminated with the appropriate motif, such as Arg-Gly-Asp, can be used to promote adhesion. Forming a mixed SAM with an ethylene glycol-terminated component and a peptide-terminated component can promote cell adhesion while limiting nonspecific adsorption [316, 328].

Achieving the desired outcome of arrays of individual cells of defined shape, size, and distribution has been achieved using patterned SAMs [329] (see Fig. 11). The substrates, upon which individual cells of a defined shape were cultured, were prepared using microcontact printing. The metal surface was stamped with hexadecanethiol ($HS(CH_2)CH_3$) to form the islands upon which the cells were grown. The rest of the gold surface was coated with $HS(CH_2)_{11}(OCH_2)_3OH$
Figure 11. Demonstration of the ability to grow ordered arrays of individual cells of a defined size and shape by forming islands upon which cells will adhere using microcontacting printing. Initially, the surface is patterned with a —CH₃-terminated SAM with the rest of the surface coated in an ethylene glycol-terminated SAM. As extracellular matrix proteins will only adsorb to the —CH₃ surface, these are the only locations to which the cells will adhere. The size of the cell islands was shown to influence whether the cells proliferated or underwent apoptosis. Adapted with permission from [329], C. S. Chen et al., *Science* 276, 1425 (1997). © 1997, American Association for the Advancement of Science.

to prevent protein adsorption. The islands were coated with appropriate ECM proteins. Cells cultured on the surfaces spread to the size and shape of the island. The size of the islands were shown to influence cell life or death with apoptosis increasing with decreasing island size.

3.2. Sensors

The vast majority of the applications of SAMs, which involve nanofabrication, have been in diagnostic devices [10, 11, 44, 51, 81, 87, 310, 330], in particular electrochemical sensors, where a number of elegant nanostructures or integrated molecular systems have been fabricated. The focus on electrochemical sensing is partly related to organosulfur SAMs being formed on an electrode material—gold. Typically, a sensor requires a recognition molecule integrated with a signal transducer. Usually the recognition molecule, which gives the sensor its selectivity, is immobilized over the signal transducer. This arrangement is depicted in Figure 12. The signal transducer determines the extent of the recognition reaction and outputs the signal to an end user. Examples of recognition species include macrocyclic or other types of ligands, enzymes, antibodies, DNA, and even whole cells or tissues. An array of approaches to transduction have been employed including electrochemical [10, 47, 331], acoustic wave [332], optical [333], calorimetric [334], changes in surface force [335–338] or stress [330, 339, 340].

The immobilization of the recognition molecule is the critical step in the fabrication of a sensor. The most common immobilization strategy is to either entrap or covalently attach the recognition molecule within a polymer membrane. Although highly versatile as an approach, the control over the location and density of recognition molecules is poor [331].

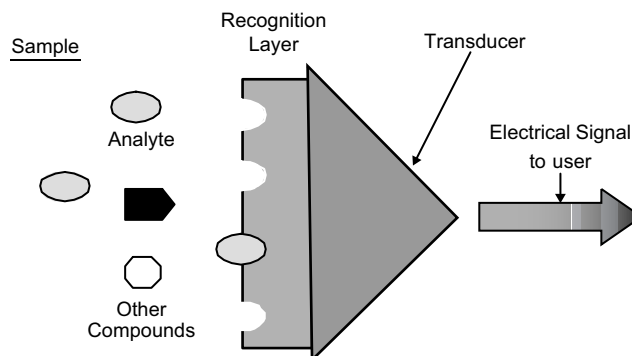
Furthermore, if the analyte to be detected is large, then only recognition molecules at the surface of the polymer will interact with the analyte. In contrast, the modification of gold with a SAM can be achieved with molecule level control over the interface, and hence the position of the recognition molecules in space can also be controlled with molecular level precision. That is, the sensing interface can be fabricated using the bottom-up principle of nanotechnology.


Figure 12. Schematic of a sensor showing the recognition layer that gives the sensor its selectivity for the target analyte despite the presence of other molecules in the sample. The transducer determines the extent of the reaction between the recognition component and the analyte and converts this to an electronic signal which can be outputted to the end user.

The simplest sensors based on alkanethiols are monolayers that either provide selective access to the underlying transducer surface [341, 342] or incorporate a recognition molecule attached to the SAM-modified transducer [10–13]. Slightly more complicated examples include controlling the spacing of the recognition molecule on the surface [343, 344] or using mixed monolayers to control the micro-environment of the recognition molecule [343]. Controlling the micro-environment may serve the purpose of orientating the recognition molecule [70], preventing adsorption of electrode fouling species [43, 201, 345], or providing a charge exclusion layer to prevent interferences interacting with the electrode [52, 216, 252, 346, 347]. Using the initial monolayer as the base for layer-upon-layer fabrication allows this molecular level control to be extended into a third dimension. This extension into the third dimension may be with a single recognition element [61, 62, 348–357] or with more than one type of recognition molecule that operate cooperatively [348, 358]. The number of roles that the SAM can play in the development of a sensing interface, in many ways represents the level of control afforded by SAMs in nanofabrication as several molecular components are integrated in a controlled way to fulfill a variety of functions. The sophistication to which nanofabrication, using SAMs, is perhaps best demonstrated by enzyme biosensors.

3.2.1. Catalytic (Enzyme) Biosensors

Basics of Enzyme Electrodes   Enzyme biosensors employ an enzyme as the recognition element. Typically, the enzyme is a redox enzyme, which either oxidize or reduce its substrate. As the enzyme reaction is a catalytic reaction, enzyme biosensors are often classed as *catalytic sensors*. In an enzyme biosensor, the substrate is the analyte of interest. The analyte reacts with the enzyme and produces a product. Transduction is achieved by monitoring either a molecule consumed in the enzyme reaction or one that is produced. The classic example is a glucose biosensor which uses the enzyme glucose oxidase (GOD) to oxidize glucose in the presence of a mediator to produce gluconolactone and a reduced form of the mediator (see Fig. 13).

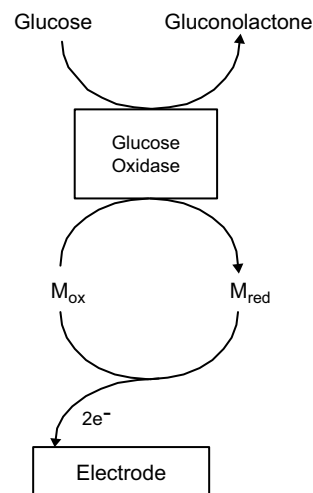
The role of the mediating species is to complete the catalytic cycle. The enzyme in its oxidized form is reduced as the glucose is oxidized. Therefore, the mediator oxidizes the reduced form of the enzyme and in the process is itself reduced. In nature, the mediator is oxygen with hydrogen peroxide being produced while many of the commercial glucose biosensors use redox species such as ferrocene or ferricyanide [359]. As there are changes in oxidation state in the recognition reaction, it is common for the transduction of enzyme reactions to be electrochemical. In a conventional enzyme biosensor, the reduced form of the mediator is detected amperometrically at the electrode with the current being proportional to the amount of glucose in the sample. These principles can be extended to many other enzymes, where all that is required is an enzyme specific for the analyte and a product of the enzyme reaction that can be transducer. The commercial glucose meters that arise from these ideas usually immobilize the enzyme in a polymer layer over the electrode [360]. Immobilization of enzymes in polymers, however, gives poor control over where the enzyme


Figure 13. Schematic of an electrochemical glucose biosensor, where glucose is oxidized by the enzyme glucose oxidase to produce gluconolactone. In the process, the enzyme is reduced. The reduced enzyme is reoxidized by a mediator. In nature, this mediator is oxygen with hydrogen peroxide being produced as the reduced form of the mediator. The reduced form of the mediator is oxidized at the electrode to give a current proportional to the amount of glucose in the sample.

is in space, which is partly responsible for reproducibility problems associated with enzyme electrodes [361].

Fabricating the Biorecognition Interface   Enzyme electrodes fabricated using SAMs have been studied extensively with a view to providing more controlled enzyme immobilization [12, 13, 62, 70, 140, 155, 348–350, 354, 358, 361–379]. The simplest enzyme electrodes fabricated using SAMs involve the covalent attachment of a single enzyme on a SAM as represented schematically in Figure 14. In this case, the SAM is prepared from 3-MPA and the enzyme is GOD [361, 376]. The reasons for using MPA are two-fold. First, the short chain alkanethiol produces a disordered SAM, which makes the underlying gold electrode electrochemically accessible. Second, the carboxylic acid functionality allows covalent attachment of the enzyme via the formation of a peptide bond after activation. In Figure 14, the activation is achieved using 1-ethyl-3(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) and N-hydroxysuccinimide (NHS), which yields a succinimide ester intermediate that
Figure 14. Reaction scheme for the immobilization of enzymes and other biomolecules onto a carboxylic acid-terminated SAM. In this case, the SAM is composed of 3-mercaptopropionic acid. The carboxylic acid terminated-SAM is activated using EDC and NHS. The succinimide ester-terminated SAM is now susceptible to nucleophilic attack from amines such as found on the surface of biomolecules. The result of the nucleophilic attack is a peptide bond.

is susceptible to nucleophilic attack from amines such as those found on proteins. This is perhaps the most common method of attaching enzymes, although other methods of immobilizing enzymes onto SAMs include other methods of covalent attachment [380, 381], electrostatic adsorption [62], using biotinylated enzymes bound to streptavidin [350, 382–384], using antibody-antigen binding [349, 363–368] and cross-linking [139, 351, 385–391]. Apart from the glutaraldehyde approach, which results in the uncontrolled formation of multilayers of enzyme and hence loses the advantage of controlled immobilization using SAMs, the other methods give a monolayer of enzyme immobilized on the SAM surface that exhibit good reproducibility [376, 378]. Many of the important issues in molecular level fabrication of enzyme electrodes have been reviewed elsewhere [12, 13, 376, 377]. Importantly, for this work on simple SAM-based enzyme electrodes are that the SAM provides a generic base upon which many different enzymes, and other biomolecules, can be immobilized.

Examples of SAM-Based Enzyme Electrodes That Employ Nanofabrication From the platform of a single enzyme-modified SAM, quite complicated molecular constructs have been fabricated with multiple functionality integrated into a single layer or multilayer. Multilayers of enzyme systems can be fabricated using a variety of strategies with molecular level control [61, 62, 348, 349, 382]. Riklin and Willner [348] have shown that multiple enzymes can be incorporated into an enzyme electrode with a layer-by-layer approach. Importantly, however, Gooding et al. [358] have shown that in a bienzyme amplification system, using glucose oxidase and glucose dehydrogenase, the response of the final enzyme electrode is sensitive to the relative spatial organization of the two enzymes (see Fig. 15). In this bienzyme system, the glucose is converted into gluconolactone by the glucose oxidase, and the glucose dehydrogenase reduces the gluconolactone back to glucose to create an amplification cycle. In each cycle where the glucose is oxidized to gluconolactone, the mediator a *p*-benzoquinone is reduced to hydroquinone. The hydroquinone is then detected at the electrode. When the enzyme electrode was made in two layers, one containing glucose oxidase and the other gluconolactone, a different linear range and gain was observed depending on whether GOD was in the inner layer directly adjacent to the electrode or on the outer layer.

Improving and/or controlling the transduction of the biorecognition reaction has been the objective of considerable attention with SAM-modified enzyme electrodes [140, 370, 372, 373, 388, 392, 393]. In many examples of SAM-based enzyme electrodes, a redox mediator in used either in the sample solution or attached to the enzyme [12]. Blonder and Willner et al. [372, 388] modulated the access of the mediator to the enzyme interface using nitrospiropyran. Reversible photoisomerism of nitrospiropyran to the cationic nitromerocyanine can be achieved by irradiating with UV light, switching back to nitrospiropyran using light of wavelengths greater than 475 nm. By covalently attaching nitrospiropyran to the enzyme, the access of the charged mediator—ferrocene monocarboxylic acid—can be modulated through charge exclusion by switching between the
Figure 15. The bienzyme electrode fabricated by Gooding et al. [358], which employs the two enzymes GOD and glucose dehydrogenase (GDH) to create an enzyme amplification cycle as shown in a) where the analyte glucose (G) is oxidized to gluconolactone (Gl) by GOD in the presence of the mediator benzoquinone (Q). During the oxidation, the B is reduced to hydroquinone (H$_2$Q). The Gl is reduced back to G by GDH, in the presence of the enzyme cofactor, reduced nicotinamide adenine dinucleotide (NADH), to complete the amplification cycle; b) shows the influence of the enzyme electrode geometry on the amplification gain where (i) is an enzyme electrode fabricated with glucose alone, (ii) contains both enzymes in the same layer, (iii) the GOD is in the inner layer and the GDH is immobilized in a second layer over the GOD, and (iv) GDH is in the inner layer and GOD in the outer layer. Reprinted with permission from [358], J. J. Gooding et al., *Electrochem. Commun.* 2, 217 (2000). © 2000, Elsevier Science.

two photoisomers [388]. Improved exclusion of the mediator, and hence improved switching, was achieved by attaching the nitrospiropyran directly to the redox active center of GOD—flavin adenine dinucleotide (FAD) [372].

As the enzyme reaction involves a change in oxidation state, the ultimate goal of enzyme electrode research is to obviate the need for a mediator by oxidizing and reducing the enzyme directly at the electrode. The attractiveness of SAM technology for achieving direct electron transfer is that the enzymes can be immobilized close to the electrode in a highly controlled manner. Furthermore, with judicious choices of self-assembling molecules, the SAM-forming molecule can be used to facilitate the electron transfer [55, 56, 394–397].

Direct electron transfer has been achieved with SAM-based enzyme electrodes where peroxidase enzymes are used [198, 373, 393, 398]. Lötzbeyer et al. [371, 373] have investigated the distance dependence of long-range electron transfer by using hydrogen peroxide-reducing enzymes of different size which are a covalent attachment to short chain alkanethiol SAM-modified electrodes. The focus on peroxidase enzymes is a consequence of their redox active sites being located close to the enzyme surface [398]. With most enzymes, however, the redox active centers are located a sufficient distance from the surface of the glycoprotein to prevent direct electron transfer [399]. For example, in the case of glucose oxidase, the closest approach of the redox active center—FAD—to the enzyme surface is 13 Å

[400]. Willner et al. [392] have spanned this 13 Å gap with an electrically wired enzyme electrode where a mediator—pyrroloquinoline quinone (PQQ)—was covalently attached to a cystamine-modified gold electrode using EDC. The PQQ-terminated SAM was then bonded to a derivatized version of the FAD cofactor for GOD, N^6-(2-aminoethyl)-FAD, to form a diad. The PQQ/FAD diad was treated with *apo*-glucose oxidase to provide a glucose enzyme electrode mediated by PQQ. This enzyme electrode had an extremely large linear range—up to 80 mM—consistent with efficient turnover of enzyme [358, 361], and an exceedingly high sensitivity of 300 ± 100 μA cm^{-2}.

The elegant-wired enzyme electrode of Willner et al. still represents a mediated enzyme electrode where the ultimate intimate relationship between the enzyme and the mediator is achieved via molecule level fabrication. The transport of electrons between the enzyme and the electrode is still achieved via hopping from the FAD to the PQQ and then to the electrode. Liu et al. [401] are extending this principle to achieve electron tunneling directly to the electrode from the FAD (see Fig. 16). This electrode construct requires the synthesis of norbornylogous bridge-based SAMs as the connector between the electrode and the FAD. Norbornylogous bridges have been shown to allow efficient electron transfer over long distances via the super-exchange mechanism [55, 402, 403]. N^6-(2-aminoethyl)-FAD is attached to the end of the bridge and the *apo*-GOD reconstituted over FAD to give active enzyme. In this case, despite the enzyme active on the FAD being embedded within the protein, and being 108° from the electrode, direct electron transfer between the FAD and the electrode is still observed.

3.2.2. Affinity Biosensors

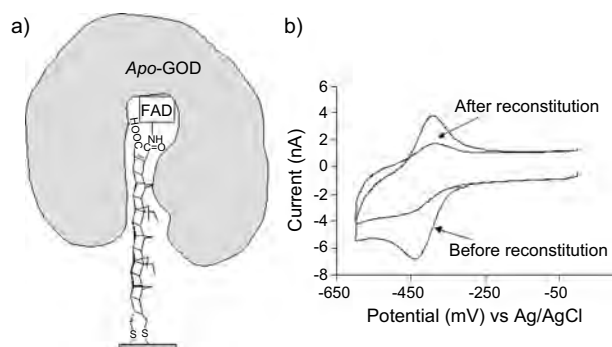
Basics of Affinity Biosensors Affinity biosensors rely on a binding reaction between the biorecognition molecule and the analyte. Typical biorecognition molecules used


Figure 16. Electrode construct designed to achieve direct electron transfer to enzymes such as glucose oxidase. In a) an 18 Å long norbornylogous bridge SAM is formed with the redox active center of glucose oxidase FAD, attached to the end of the bridge, which serves as a conduit for electron transfer between the electrode and the redox active center of the enzyme. Subsequently, the *apo*-glucose oxidase (*apo*-GOD) is reconstituted over the FAD to form the active enzyme; b) shows the electrochemistry of the FAD before and after reconstitution. The characteristic FAD electrochemistry shows that FAD 18 Å from the electrode can still be interrogated before and after the active enzyme is reconstituted. This illustrates direct electron transfer to the redox active center of glucose oxidase.

in affinity biosensors are antibodies, sequences of DNA (oligonucleotides) or peptides. Frequently, the analyte to be bound is also a protein or sequence of DNA, although the molecule to be bound can also be a small molecule. Once the binding reaction has occurred, there is still the need to transduce the biorecognition event. Unlike catalytic biosensors, where the biorecognition event produces a molecule that can then be detected, in affinity sensors the analyte simply binds. To transduce such biorecognition events either requires labels, so familiar in the myriad of immunoassay formats, or a transduction method that can detect the change that occurs at the interface. The two most popular methods that allow label-free transduction of affinity biosensors are evanescent wave techniques such as surface plasmon resonance (SPR) [81, 220, 315, 318, 404–425] and piezoelectric acoustic wave devices such as the quartz crystal microbalance (QCM) [31, 320, 332, 422, 425–451], although a variety of other transduction methods that may involve labels have been employed including electrochemical [433, 452–468], and microcantilever [330, 340, 469, 470].

Surface plasmon resonance is an optical method where a thin film of gold or silver (∼50 nm thick) is deposited over one face of a prism. It is this metal film that forms the sensing surface and will be modified with a SAM. When light is launched into the film, such that it is reflected off the prism face coated with the metal layer, the light is coupled into the surface plasmon-polaritons. The surface plasmon-polaritons occur at the outer surface of the metal. The adsorption of molecules onto this surface causes a change in the refractive index of the interface, which affects the amount of light coupled into the surface plasmon mode, and hence a change in the intensity of light reflected into the detector. To use this phenomenon for affinity sensing, the metal surface is modified with the biorecognition molecule. The binding of the analyte causes a change in the surface plasmons and hence transduction is achieved without any labels [359, 471]. Examples of simple SPR transduction for monitoring bioaffinity reactions include peptides for recognizing antibodies [407–409] or lipoproteins [318, 410, 411], DNA to detect specific sequences of DNA [220, 412, 413, 415, 416, 419–421], and proteins to detect other proteins and small molecules as in immunosensors [315, 320, 406, 408, 409, 414, 422, 424, 425, 450, 451, 472].

Transduction using a QCM is achieved using an oscillating piezoelectric AT cut quartz crystal. The deposition of electrodes, gold in most cases, onto both faces of the quartz slice allows an alternating current to be applied to the crystal. The alternating current causes the crystal to oscillate at a frequency characteristic of the thickness of the crystal slice. Adsorption or desorption of molecules from the crystal surface cause a change in the frequency of oscillation with picogram sensitivity. Thus, by immobilizing the biorecognition molecule onto the surface of one of the gold electrodes, the bioaffinity reaction is transduced by a decrease in the frequency of the QCM [11, 332]. In a similar manner to SPR, affinity biosensors employing QCM transduction have been developed for DNA recognition [426–428, 430, 431, 435–439, 442] and for monitoring antibody-antigen binding [422, 425, 429, 432, 433, 440, 441, 443–449].

Fabricating the Biorecognition Interface In a bioaffinity sensor, the recognition molecule must be free to bind with the analyte. Therefore, immobilizing the biorecognition molecule such that it is accessible for binding is exceedingly important. The molecular level control afforded over, not only the immobilization of biomolecules but also the environment in which they are immobilized, makes SAMs very attractive for fabricating bioaffinity interfaces. An example of the control afforded over biomolecule immobilization is the SAM interface used for the immobilization of DNA by Levicky and Steel et al. [70, 473–475] (see Fig. 17).

In a DNA sensor, typically a single strand of DNA (ss-DNA) is immobilized onto the transducer surface. This immobilized ss-DNA is referred to as the probe strand and is the biorecognition molecule. Hybridization of the immobilized probe DNA with the complementary sequence in solution (the target strand) is the binding reaction that is to be transduced. Levicky et al. [70] synthesized probe DNA with a mercaptohexyl linker at the 5′ end of the DNA. With the thiol linker only located at one end, end point immobilization of the probe DNA is achieved via self-assembly onto a gold surface. The idea of the end-point immobilization was to minimize the decrease in configurational freedom caused by the hybridization. Such minimization is particularly important in DNA biosensors, as the probe and target must be free to rotate around each other for hybridization to
Figure 17. Steps involved in the fabrication of the DNA recognition interface prepared by Levicky et al. [70], which allows efficient hybridization of DNA where one of the strands is immobilized onto a gold surface using alkanethiol chemistry. Efficient hybridization is achieved by having endpoint immobilization of the DNA and preventing nonspecific binding of the DNA to the gold electrode by using a diluent layer of 6-MCH.

occur. Neutron reflectivity studies, however, indicated that the ss-DNA was lying flat on the gold surface with multiple adsorption points due to the DNA bases complexing with the gold [70, 210, 476, 477]. The resultant hybridization efficiency was low—10% or less. Hybridization efficiency was improved to almost 100% by preventing the nonspecific adsorption of the DNA bases. This was achieved by exposing the DNA-modified surface to 6-mercoptohexanol (MCH). The MCH not only lifted the nonspecifically adsorbed DNA off the surface but the net negative dipole of the alcohol terminus repelled the negatively charged DNA backbone, thus helping to project the probe strand out into solution.

Synthesizing a biorecognition molecule with a thiol linker is not always the simplest strategy for immobilizing biorecognition molecules. However, there are a number of reasonably generic methods of fabricating recognition interfaces for affinity sensors which provide favorable conditions for the recognition reaction to occur. One is to use a similar strategy to that used for enzyme biosensors (Fig. 14), where the gold surface is modified with a carboxylic acid-terminated SAM and carbodiimide coupling is used to attach the biorecognition molecule. Such an approach has been used for oligonucleotides [379, 478, 479], antibodies [405, 440], and peptides [480–482].

An alternative generic interfacial structure first developed by Häussling, Schmitt, and Spinke et al. [483–485] involves using a biotin-terminated SAM. Biotin has an exceedingly high affinity for avidins, such as strepavidin ($K_{aff} = 10^{15}$ M), making the binding virtually irreversible. As each avidin has four binding sites, the 'plug-and-socket' aspect of the avidin-biotin system makes it a very important molecular building block for nanofabrication. The usefulness of the avidin-biotin system is enhanced further by the ease of modifying other molecules with biotin. In the case of SAM-based affinity sensors the avidin is bound to the biotinylated monolayer and subsequently biotinylated biorecognition molecules are bound. Such a strategy has been used for the immobilization of antibodies [319, 485], DNA [319, 413, 430], peptides [319, 486] and even enzymes [382–384]. The accessibility of the biorecognition molecule can be controlled by forming mixed SAMs, where a long-chain alkanethiol acts as a spacer to keep the biotin group away from the monolayer surface, and the shorter alkanethiol spaces the biotin coupling points apart [485].

Examples of Affinity Biosensors Relevant to Nanotechnology There have been many examples where SAMs have been employed to make affinity biosensors, primarily because of the ability to control the accessibility for binding of the biorecognition molecule and the compatibility with the SPR and QCM transduction systems. Among these examples are some of the most exquisite examples of nanofabrication that have thus far been realized. We shall discuss a few of these examples in turn.

The first example is the fabrication of a simple immunosensor for *Salmonella paratyphi*, where transduction is achieved using a quartz crystal microbalance [447]. The biorecognition interface is fabricated as in Figure 14 by modifying the gold electrodes on the 10 MHz quartz crystal with 3-MPA followed by activation with EDC and NHS to allow by covalent attachment of antibodies specific for the

S. paratyphi bacteria. After immobilization of the antibody, the rest of the crystal was coated in bovine serum albumin to prevent nonspecific binding to the crystal surface. The resultant sensor could differentiate between *S. paratyphi* and other bacteria, including *E. coli* and other serogroups of *Salmonella* with a detection limit of 1.7×10^2 cells/mL.

A sensor for low-density lipoproteins (LDLs) by Gaus and Hall et al. [318, 410, 411] provides an example where multiple molecule components are incorporated in the one interface to allow differentiation between LDLs and oxidized LDLs. Initial work used a heparin-modified surface to detect LDL adsorption to the interface via surface plasmon resonance, but this lacked the specificity to differentiate between LDLs and the more harmful oxidized LDLs. To improve the ability to differentiate between LDLs and oxidized LDLs, the fifth ligand repeat unit (LR5) of the LDL receptor was genetically engineered and attached to a mercaptoundecanoic acid SAM using EDC/NHS chemistry [410]. Unfolded LR5 was ineffective as an affinity ligand, but refolded LR5 showed a high affinity for native LDLs but little affinity for oxidized LDLs (see Fig. 18). This study showed the potential for using small peptide sequences— 40 amino acids in this case—as highly selective affinity ligands. The one drawback was the instability of the refolded LR5 ligand. To overcome the instability of the affinity ligand, Gaus and Hall investigated a library of short peptide ligands (three to five amino acids long) related to conserved peptide sequences of the LR5 receptor [318, 411]. A more sophisticated recognition interface was used comprised of a mixed SAM of mercaptoundecanoic acid for coupling the amino acids and 1-mercapto-octyl-hexa(ethylene glycol) to resist nonspecific adsorption. Amino acids were coupled
to the SAM on the SPR chip one amino acid at a time to enable *in-situ* synthesis of peptide sequences by step-wise elongation. Using this combinatorial approach, a library of peptides was assessed for their affinity to LDLs and oxidized LDLs. The short peptide sequences GlyCystineSerAspGlu and GlyLysLys-OH were found to be the most effective for the selective binding of LDLs and oxidized LDLs, respectively, although detection limits were not quite as low as the LR5 ligand. The variation in LDL binding with oxidation levels of the peptide sequences provides a powerful approach to detecting the LDL oxidation levels in an unknown sample which could provide a sensing system to assess a patient's atheriosclerosis risk [411].

The above example illustrates a recognition interface involving combinatorial synthesis of the recognition element and multiple functionalities incorporated within the recognition interface. The DNA sensor developed by clinical microsensors (CMS) [345], which is illustrated in Figure 19, shows a recognition interface where nanofabrication using SAMs enables the recognition interface to also fulfill several functions. The SAM recognition interface contains two other components apart from thiolated DNA. The majority of the SAM is composed of polyethylene glycol terminated alkanethiol, designed not only to resist nonspecific binding of DNA and proteins, but also to insulate the electrode [107, 190, 316]. Oligophenylethynyl thiols are also present in the SAM. The function of the oligophenylethynyl thiols is to allow communication with the electrode, as these molecules are efficient molecular wires. Upon hybridization between a target nucleic acid and the capture probe, transduction is achieved by also hybridizing a reporter sequence of DNA with the target. The reporter sequence is modified with ferrocene labels. The molecular wires allow oxidation of the

Figure 19. Schematic of the DNA biosensor of Umek et al. [345]. The SAM is composed of polyethylene glycol-terminated alkanethiol, which resist nonspecific binding of DNA and insulates the electrode, oligophenylethynyl thiols, which act as molecular wires to allow communication with the electrode and thiolated probe DNA molecules. Upon hybridization between a target nucleic acid and the capture probe, transduction is achieved by also hybridizing a reporter sequence of DNA with the target. The reporter sequence is modified with ferrocene labels. The molecular wires allow oxidation of the ferrocene labels. Therefore, recognition of the target strand is transduced by the occurrence of a current signal.

ferrocene labels. Therefore, recognition of the target strand is transduced by the occurrence of a current signal.

The final example is the ion-channel biosensor currently being commercialized by AMBRI [45, 317, 487–493]. The ion-channel biosensor can arguably be claimed to be the first real nanomachine with moving components. The recognition interface is comprised of a lipid bilayer which is anchored to an underlying gold electrode using alkanethiol chemistry (see Fig. 20). The lipid bilayer contains 10 or more components including gramicidin ion channels. The ion channels in the lower layer of the bilayer are fixed to the electrode while those in the upper layer float free. The ion channels in the upper layer are derivatized to allow transduction of a biorecognition event. In one variant of the biosensor, the upper ion channel is modified with antibody Fab' fragments. The other half of the antibody-binding site is locked into its position in the bilayer using a thiol-terminated membrane-spanning lipid. When there is no analyte present, the floating gramicidin channel moves through the top layer of the bilayer allowing a complete ion channel to form. Opening of the ion channel results in a flow of ions through the bilayer and there is a large increase in conductivity. When analyte is present, the two halves of the Fab-binding site bind to the analyte. This binding event locks the ion channel in a closed position; thus the conductivity decreases. The particularly elegant aspects of this design we first, utilize not only biological molecules for detecting but mimic cellular approaches to transduction and second, the transduction method can be applied to a wide variety of different types of analytes. The system has been used to detect small molecules such as digoxin, hormones, bacteria, and even sequences of DNA [45, 494].

3.2.3. Chemical Sensors

The differentiation between a biosensor and a chemical sensor can be made according to the recognition element. In a chemical sensor, the recognition element is of nonbiological origin and therefore refers to a ligand of some sort. There have been many SAM-based chemical sensors and in this section only a few that are interesting examples of nanofabrication will be discussed.

Hickman et al. [137] developed the first electrochemical SAM-based pH sensor that contained two terminals: a quinone was used as the pH indicator (having pH sensitive electrochemistry) and pH insensitive ferrocene as a reference electrode. The two redox species were coimmobilized onto a SAM. The oxidation and reduction peaks of the quinone shifted linearly with pH, which allowed accurate measurement of pH between pH 1–11. Beulen et al. [495] elegantly extended this principle to where the different components of a SAM act cooperatively. Rather than form a mixed SAM, a carboxylic acid-ferrocene sulfide was synthesized to give a bifunctional monolayer adsorbate. The normally pH independent electrochemistry of the ferrocene unit became pH dependent due to through space interactions with the adjacent carboxylic acid. Deprotonation of the adjacent carboxylic acid stabilized the oxidized state of the ferrocene resulting in a pH sensitive cathodic shift.

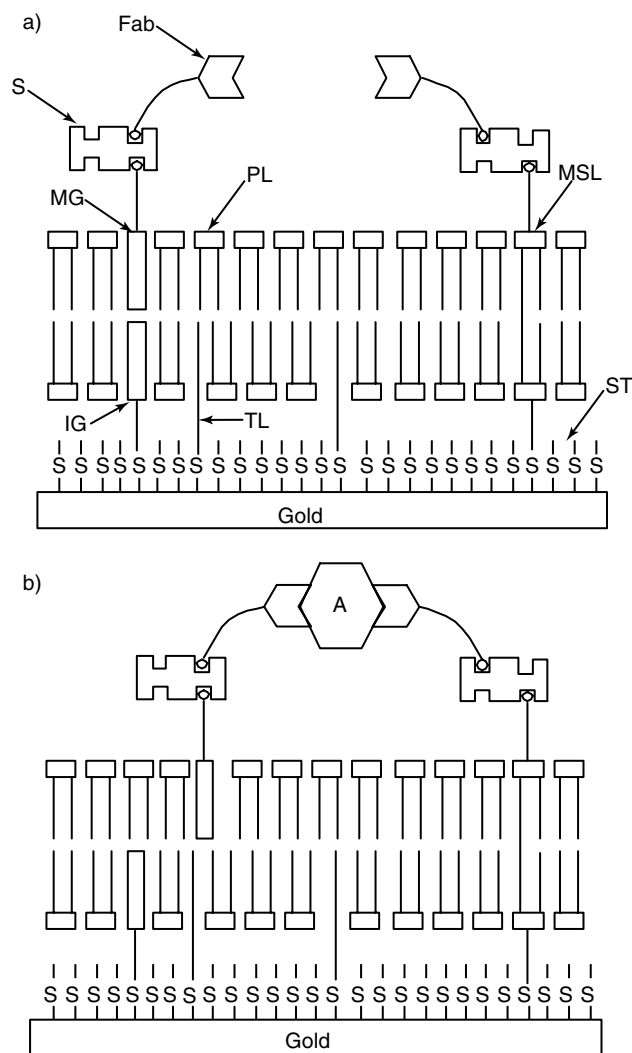
Electrochemical sensors for metal ions have been the subject of considerable interest. A sophisticated example involving SAMs is reported by Rubinstein et al. [186], where SAMs


Figure 20. The ion-channel biosensor based on a suspended lipid bilayer developed by AMBRI. The self-assembled monolayer consists of spacer thiols (ST), which define an ionic reservoir under the bilayer composed of phospholipids (PL). The bilayer is anchored to the gold electrode using tethered lipids (TL), which span into the lower half of the bilayer. Incorporated within the lower part of the bilayer are immobilized gramicidins (IG), which are immobilized to the electrode with a thiol. In the open state, the IG are associated with mobile gramicidins with pendant biotin groups (MG) in the top part of the bilayer. Membrane spanning lipids (MSL), also with pendant biotin, span across both halves of the bilayer. Biotinylated antibody fragments are attached to both the MG and the MSL using streptavidin (S) as a molecular building block. When there is no analyte (A) present, the MG can move across the bilayer. a) When the MG and IG coincide, there is a large increase in conductivity as ions can pass across the bilayer. b) When the analyte binds to the two Fab antibody fragments, the gramicidins can no longer diffuse freely through the bilayer and the ion channels are closed. The result is a low conductivity.

were used to selectively detect Cu^{2+} in the presence of Fe^{3+}. This was achieved using the ligand 2,2'-thiobisethyl acetoacetate (TBEA). The thiol group allows the assembly onto a gold electrode while the tetradentate ligand satisfied the four coordinate complexation preference of Cu(II). The metal ion sensors were prepared with a mixed SAM of

octadecylmercaptan (OM) and TBEA. The OM passivated the electrode, while the TBEA provided defect sites where the Cu^{2+} was bound and amperometrically detected. As the Fe^{3+} did not effectively bind to the TBEA and the OM prevented direct access to the electrode, Cu^{2+} could effectively be detected despite the presence of the other metal species.

Many other metal ion sensors have been developed where ligands such as crown ethers [496–499], oligoethylene glycols [500–502], and calixarenes [503] are attached to an electrode using SAMs. Calixarenes have also been reported as selective recognition elements for organic molecules such as steroids [404, 456, 504]. The key drawback of using selective ligands is the need to design and synthesize a new ligand for each analyte. Therefore, a simple generic synthetic strategy is required if arrays of sensors are to be developed. Yang and Gooding et al. [481, 482, 505, 506] have addressed this issue using amino acids [505], oligopeptides [482], and polypeptides [481] as the selective ligands for metal ions. A high degree of selectivity for Cu^{2+} with very low detection limits has been achieved. An attractive feature of this approach is that similar, simple synthetic protocols can be used for most peptide sequences desired. Thus, the amino acids act as the alphabet from which a library of receptor ligands with varying selectivity can be synthesized.

An interesting approach to the fabrication of chemical sensors for organic molecules using SAMs has recently been developed, which is analogous to molecular imprinting [507–510]. In molecular imprinting, an artificial receptor is prepared by forming a polymer or sol–gel in the presence of the analyte of interest. The analyte is then removed to produce a three-dimensional porous structure where the cavities match the molecular structure of the analyte. With SAMs of alkanethiols, the same principle can be applied to give two-dimensional receptor sites (Fig. 21) [51, 511–516]. Typically, the binding of the analyte into the receptor site was transduced by a change in capacitance of the interface [513] or the restricted access of an electroactive species to the underlying electrode [512]. One of the difficulties that must be overcome with imprinting receptor sites in SAMs is the mobility of the alkanethiols [216, 217]. Initial attempts to imprint receptor sites resulted in the loss of the receptor property after a single adsorption/desorption cycle [513]. To overcome this problem, a templating molecule with the same shape as the analyte was adsorbed to the surface with a long-chain alkanethiol. The templating molecule was maintained on the surface with pores defined by the long-chain alkanethiols available for binding the analyte. The binding of the analyte is transduced by a decrease in the interfacial capacitance of the electrode. The molecular imprinting approach has been demonstrated for cholesterol [511, 512, 515], barbiturates [513], quinines [516], phenothiazines [511], and adenine triphosphate (ATP) [51].

3.3. Electron Transfer and Molecular Electronics

Electron transfer through alkanethiol SAMs, or even individual molecules, has potential applications in improving our fundamental understanding of electron transfer processes [46], molecular electronics [517], and in sensing [458]. Alkanethiol SAMs have a number of advantages that make
Figure 21. The alkanethiol SAM-based artificial chemoreceptor. The binding sites are formed by adsorbing the template thiobarbituric acid **1** onto a gold surface in the presence of the matrix molecule **2** which was dodecanethiol. The template must be a similar shape to the analyte and must be able to bind strongly to the gold surface so that it is not displaced by the matrix molecule. When the analyte barbituric acid **3** is exposed to the surface, it can bind in the clefts in the SAM formed by the templating molecule. Reproduced, with permission from [513], V. M. Mirsky et al., *Angew. Chem.-Int. Edit.* 38, 1108 (1999). © 1999, Wiley-VCH.

them suitable for studying and exploiting long-range electron transfer. These advantages include those that have already been discussed, such as densely packed SAMs giving well-defined distance relationships, the formation of mixed SAMs allowing the spacing of redox centers, the low number of defects or pinholes in well-prepared SAMs ensuring that tunneling processes are probed, and the ease of altering their chemical structure allowing simple exploration of structure-function relationships. A further advantage is that the thiol functionality is ideal for connecting "molecular wires" to bulk materials and hence allowing a connection to the surroundings. Thus, the organosulfur molecules act as the "glue" between electronic materials in molecular devices. Such electronic materials could be bulk surfaces or quantum particles. The alkyl chain or unsaturated conjugated system acts as the conduit for electron transfer.

Thus, the electron movement can be through σ-bonding systems, which are the most frequently investigated systems so far. In the case of σ-bonding systems, the electron transfer occurs through a superexchange mechanism [403]. Alternatively, electron movement can be through a π-bonding system via a typical electron transport mechanism. The actual nature of the chemical connection is exceedingly important and a subject of considerable interest. If the influence of the actual contact can be understood, then the potential to tailor the connection in organic-conductor/semiconductor hybrid systems is greatly expanded and the behavior of the devices will be better controlled.

Our understanding of the influence of the contact is poor at this stage but improving rapidly through a number of elegant experiments involving alkanethiol molecules. Cui et al. [518] demonstrated the importance of an alkanethiol having a bond to both electronic materials. A gold surface was modified with either an octadecanedithiol or an octadecanethiol SAM. To the other end of the SAM was bound gold nanoparticles. So in the case of the dithiol, a gold-thiol bond formed with the nanoparticle while in the monothiol case the nanoparticle simply adsorbed onto the methyl terminal of the SAM. The current-voltage (I-V) properties of these molecular constructs were measured using a conduction probe AFM. There was increase in current of up to four orders of magnitude for a given tip bias when the dithiol was used relative to the monothiol. A similar increase in conductivity was also observed by Selzer et al. [519] with the addition of a bond, in this case between a mercury and a semiconductor surface. The influence of different types of bonds on the conductivity was investigated by Holmlin et al. [520]. A gold surface modified with one alkanethiol SAM and a mercury electrode modified with a second SAM are brought into contact and the I-V behavior measured. With judicious choice of the monolayers, they compare electron transfer across bilayers that form either covalent, hydrogen, or van der Waals bonds. The conclusion was that tunneling rates increased in the order van der Waals < hydrogen bonds < covalent bonds. It is clear from these studies using alkanethiols how important the junction between the organic molecule and the electronic material is. The actual contact resistance of a gold-thiol bond has been estimated at $10^4\,\Omega$ by Wold et al. [521] using a similar conducting AFM-type experiment to Cui et al. [518] but without the gold colloid.

The research into tunneling through alkanethiol SAMs has been dominated, not by measuring the influence of the link between the organic molecule and the electronic material, but by the distance dependence of the rate of electron transfer through the organic molecules. Distance dependence has typically been measured using redox monolayers, where a redox active group attached to the terminus of a SAM is probed electrochemically. This approach is well covered in a review by Finklea [46] and in a number of excellent papers since (see, for example, [56, 142, 522, 523]). A wide variety of electroactive groups and redox proteins have been investigated [46]. A number of electrochemical methods allow the measurement of rates in the range of 10^{-2}–$10^5\,\text{s}^{-1}$ including cyclic voltammetry [524], AC impedance spectroscopy [525] or voltammetry [526], square wave voltammetry [527], and chronoamperometry [528].

The distance dependence of the rate of electron transfer can be described using Marcus theory [529], which relies on the overlap of donor and acceptor energy levels in the redox molecule and the electrode. The important parameters in the theory include the reorganization energy (λ), the energy needed to change the redox center's structure and solvation sphere during the change in oxidation state, and tunneling parameter β. The tunneling parameter is a structure dependent constant, which describes how the electronic coupling decays, as seen in the equation describing the electron transfer rate constant, k_{ET},

$$k_{ET} = k_0 \exp[-\beta d]$$

where k_0 is the rate constant at zero overpotential and d is the distance between the donor and acceptor in this case (the redox species and the electrode). A remarkable consistency in the dependence of the electron transfer with rate is beginning to emerge for aliphatic hydrocarbons. Despite the different redox active species that have been investigated, the value of β is found to be between 0.8–1.1 Å^{-1}. Similar values for β are also found when the I-V characteristic of alkanethiol SAMs are measured using conducting AFM [521, 530] or the bilayer approach of Holmlin et al. [520, 531]. Although the presence of different coupling chemistry to a redox active species does not appear to significantly alter the value of β [523], large structural rearrangements in the molecule during the electron transfer, such as found with azobenzenes, do cause increases [532]. Conjugation on the other hand definitely causes a decrease in the value of β, indicating less decay in the electron transfer rate with distance. Values for β that have been quoted for conjugated systems include for oligo(phenylethynyl) "molecular wire" bridges β of 0.36 Å^{-1}, around 0.4 Å^{-1} for oligophenylenevinylene bridges [394], 0.41 Å^{-1} [521] or 0.61 Å^{-1} [520] for oligophenylenes, and 0.67 Å^{-1} [520] for benzyl derivatives of oligophenylene. These lower decay constants indicate useful molecular wires could be developed with conjugated systems.

3.4. Nanofabrication with Other Nanobuilding Blocks

In recent times, SAMs have been used as the foundation upon which nanofabrication into the third dimension is achieved using nanoscale building (nanobuilding) blocks such as nanoparticles, nanotubes, and dendrimers.

3.4.1. Nanoparticles

Monolayer-protected gold nanoparticles have received considerable attention since a simple synthetic strategy for their production was described by Brust et al. [63]. The gold nanoparticles are typically of the order of 1 to 3 nm (which represents 50 to a few hundred gold atoms) with an alkanethiol coating that serves to stabilize the colloidal solution. The quality of the SAM on the nanoclusters appears to be very similar to SAMs formed on planar surfaces with a similar number of gauche defects [533, 534]. Self-assembled monolayers on nanoclusters are important from a nanoscience perspective as they can be regarded as three-dimensional

SAMs. As these three-dimensional SAMs can be investigated in bulk solution, the SAMs can now be investigated using a range of analytical techniques not available to the two-dimensional variety.

The alkanethiol coating, however, also provides the opportunity to add specific chemical functionality to the clusters. The first example of functionalized monolayer-protected clusters (MPCs) used a place exchange reaction to substitute ω-ferrocenyl groups for simple aliphatic alkanethiols [535, 536]. Each cluster contains multiple redox sites which were not strongly electronically coupled with each other. If the clusters are probed electrochemically, under hydrodynamic control with a rotating disk electrode, the voltammograms indicate that nanoclusters are electronically charged in solution so as to equilibrate the potential of the metal-like Au cores of the clusters with the electrode. This double layer charging of the clusters means they are, in fact, nanoelectrodes. As the size of the nanoelectrodes decreases, their double layer charging behavior undergoes a transition from metal-electrolyte interfaces to exhibiting redox chemical behavior [537], which means the cluster capacitance changes from being dominated by electrostatic processes to one dominated by binding interactions.

Nanoparticles certainly have the potential to be used as structural components in the fabrication of three-dimensional nanostructures. Gold and silver nanoclusters have been used to produce surfaces with well-defined nanostructure and roughness [536], as well as to produce electrodes using an entirely wet process [64]. Connecting nanoclusters together in a well-defined way has been demonstrated by Mirkin et al. [69], where two batches of gold colloidal particles were modified with noncomplementary DNA. Upon addition of an oligonucleotide duplex, with ends complementary to the two sequences attached to the nanoparticles, the nanoparticles self-assemble into aggregates. An attractive feature of this assembly technique is that denaturing of the duplexes allows the aggregates to be redispersed. Oligonucleotide modified gold colloids have also been used by Alivisatos and Loweth et al. [538, 539] where with judicious choices of oligonucleotide sequence, DNA-based assembly of the colloids can be used to produce highly ordered linear assemblies of colloids (Fig. 22). Alternative approaches to nanoparticle assembly have used biotin-modified colloids connected using avidin [540] while Murray's group have also assembled clusters using Cu^{2+} to connect gold colloids, which are modified with ω-carboxylate alkanethiols [65, 541]. These aggregates are surface bound using a carboxylate or thiol-terminated surface. Thermal decomposition of the surface bound MPCs produces films of the core metal.

Nanoparticles are beginning to find utility in a variety of applications in sensing, either as the sensors or as labels. An example where the nanoparticle is used as the label is in the detection of DNA hybridization by the Mirkin group, using nanoparticle modified oligonucleotides in the transduction of hybridization [535, 536], and by the Willner group [71]. A recent development by the Mirkin group [74] employed oligonucleotide-modified gold nanoparticles and nanofabrication to transduce DNA hybridization by forming a connection between two gold electrodes. This is achieved using two types of capture probes.
Figure 22. Schematic illustrations and representative transmission electron microscopy images of DNA/gold nanoparticle structures [539]. Image (a) shows a 10-nm homodimer; (b) shows a 10-nm/5 nm heterodimer; (c) shows a 10-nm homotrimer; and (d) shows a 5-nm homotrimer. Reproduced with permission from [539], C. J. Loweth et al., *Angew. Chem. Int. Ed.* 38, 1808 (1999). © 1999, Wiley-VCH.

One set of capture probes is immobilized in a line in the gap between two microelectrodes. The second set of capture probes is attached to the surface of the gold nanoparticles in solution. A longer target strand is introduced in solution which is complementary to both capture probes. Therefore, hybridization of the target to the surface immobilized probes allows the oligonucleotide-tethered gold colloids to align in the gap between the two microelectrodes, thus increasing the conductivity between the two electrodes. The increase in conductivity can be amplified markedly by the addition of Ag(I) and hydroquinone to give a sensor that can detect concentrations of as low as 0.5 pM.

The application of nanoparticles as the platform upon which nanosensors are developed has been demonstrated for fluorescence-based nanosensors, which are capable of detecting metal ions and molecular oxygen within mammalian cells [542–545]. Such sensors use polymer nanoparticles rather than exploit alkanethiol SAMs but they do highlight an application in which three-dimensional monolayers could be employed. A recent example of nanoparticle-based sensors that rely on alkanethiol chemistry is by Maxwell et al. [546]. In this biosensor, single strands of DNA are attached to gold nanoparticles using an alkanethiol linker. To the other end of the DNA is attached a fluorophore, which is attracted to the gold surface. The adsorption of the fluorophore onto the gold quenches the fluorescence. Hybridization with the complementary sequence forces the fluorophore away from the gold

nanoparticle with a concomitant increase in fluorescence. Alkanethiol-modified gold nanoparticles are also used by Storhoff et al. [547] in a DNA assay where hybridization causes the aggregation of oligonucleotide-modified gold nanoparticles. With the aggregation, there is a color change from the ruby red of individual nanoparticles to the blue to purple of the aggregated particles.

3.4.2. Carbon Nanotubes

The discovery of buckminsterfullerene in 1985 [548] was the first example of the third form of carbon. The equally serendipitous discovery of carbon nanotubes by Ijima [549] followed in 1991. The two discoveries have lead to whole research fields focused on nanocarbon [550]. Nanocarbon structure, and in particular carbon nanotubes, serve as important building blocks in nanofabrication and possibly the fabrication of nanocircuits. Carbon nanotubes can be thought of as graphene sheets rolled up into cylinders. They can be classified into multi-walled nanotubes (MWNT) or single-walled nanotubes (SWNT) depending on the number of graphene sheets that make up the cylinder. Diameters range from 1 nm to tens of nanometers. The MWNT are generally perceived as concentric SWNT of different diameters arranged inside each other [550], although there is electron microscopy evidence that some tubes have a scroll-like structure [551]. The interest in carbon nanotubes from many diverse fields is stimulated by their unique properties, those being that they are relatively defect-free, highly conductive, and the strongest materials known. Because of their relatively structural simplicity, SWNT have been the subject of most attention with regards to an understanding and prediction of nanotube properties, although MWNT are simpler to manufacture [550]. With regards to the electrical properties, which are the source of much interest in molecule electronics, SWNT can be metallic or semiconducting depending on the helices index. The helices index refers to the way the graphene sheet is rolled up [552].

So what of the integration of carbon nanotubes with SAMs? Liu et al. [553] have controlled the deposition of individual nanotubes which is important in the fabrication of molecule circuit components such as the nanotube field effect transistor developed by Huang et al. [554, 555]. To achieve this, silicon surfaces were modified with a tetramethylsilane (TMS) SAM. The TMS is selectively removed using e-beam or AFM lithography and replaced with an amine-terminated SAM. Nanotubes are shown to selectively adsorb onto the amino-functionalized surface. This technique has been used to demonstrate a single nanotube connecting two gold electrodes.

The integration of carbon nanotubes with alkanethiol SAMs is at its very beginning. Liu et al. [66–68, 556] have developed a number of methods for organizing SWNT normal to a surface. All these methods involve the shortening of the tubes in a combination of nitric and sulfuric acids. These oxidizing acids attack defects in the walls of SWNT causing a breakage. The now open end of the tube contains carboxylic acid moieties. These ends have then been modified with an alkanethiol, and self-assembled onto a gold surface [66], or aligned directly onto silver surfaces using the affinity of carboxylic acids for Ag^+ [67].

More recently, aligned nanotubes have been covalently attached to a cysteamine-modified gold surface using carbodiimide coupling to form a peptide bond between the amine-terminated SAM and the carboxylic acid terminated tubes [68, 556]. Yang et al. [557] have formed the same molecular construct, but to the free ends of the nanotubes they have attached microperoxidase MP-11 and shown that direct electron transfer to the enzyme can be achieved. These represent initial experiments into using carbon nanotubes as molecular wires for sensing applications.

3.4.3. Dendrimers

Dendrimers are regularly branched, monodispersed macromolecules that have attracted extensive scientific interest of late because of their unusual architecture and properties [558–561]. An example of a dendrimer is the poly(amidoamine) (PAMAM) dendrimer shown in Figure 23. The globular structures have three distinct regions. There is a central core, then a repetitive branching region and finally the terminal moieties [562]. The structure can be precisely controlled at the molecule level and the dendrimer properties can easily be altered by changing the type of core, the amount of branching, and the functionality at the termini. Furthermore, the dendrimers have a low mass density in the interior and are highly permeable to small molecules [562]. It is therefore clear that dendrimers have enormous promise as nanoscale building blocks in supramolecular devices. Applications proposed for dendrimers include catalysis [563], encapsulation and controlled release of drugs [564], chemical sensors [565, 566], and biomimetic materials [567].

Integrating dendrimers with SAMs to give three-dimensional structures projecting from a surface has recently attracted some interest. An early example by Tokuhisa and Zhao et al. involved using the molecular gating capabilities of PAMAM dendrimers [562, 568]. The dendrimers were

Figure 23. Chemical structure of a second generation the PAMAM dendrimer.

adsorbed directly onto a gold surface where they tended to spread out. If a SAM of hexadecanethiol was adsorbed onto the dendrimer-modified surface, the dendrimers were confined into a more compact structure. Apart from confining the dendrimers, the hexadecanethiol SAM had a second function of passivating the electrode not covered by the dendrimers. The dendrimers were used to prevent access of positively charged ruthenium (III) hexamine complex to the electrode at neutral pH, at which the dendrimer is positively charged. At the same pH, the access of negatively charged ferricyanide was barely impeded by the dendrimer. Altering the pH to 11.0 made the dendrimers neutral and allowed the $Ru(NH_3)_6^{3+}$ to pass through the dendrimer and react at the underlying electrode. To confirm that the gating was through the dendrimer rather than defects in the SAM, the terminal amine functionality of the PAMAM dendrimer was converted to 4-(trifluoromethyl)benzamido groups. With these modified dendrimers, the ferricyanide was now prevented from accessing to electrode but the ruthenium hexamine could pass through the dendrimers. Dendrimers have also been coated onto gold nanoparticles by converting some of the amine terminals of the PAMAM into thiols [569]. Dendrimers have been used to assemble nanoparticles onto a planar surfaces in a controlled way [570] and have been patterned onto SAM surfaces using microcontact printing [254]. Dendritic SAMs have also been synthesized and assembled on gold electrodes where the organothiol is the focal point of the dendrimer [571–573].

Early examples of the application of dendrimer-modified surfaces are again beginning to emerge in the field of sensing. Yoon et al. [457] have developed an affinity sensor for the detection of avidin using PAMAM dendrimers, which are modified with biotin as the recognition element for avidin and ferrocene for transduction of the affinity reaction. The amine-terminated dendrimers were covalently attached to a gold electrode modified with 3,3-dithiopropionic acid bis-*N*-hydroxysuccinimide ester. Glucose oxidase in solution is used as a diffusional tracer. The ferrocene-labeled dendrimer mediates the glucose oxidase reaction with glucose, thus providing a current. Binding of the avidin onto the electrode surface reduces the ability of the glucose oxidase to access the dendrimer, and therefore a reduction in current is observed. The purpose of using dendrimers to fabricate sensors is that they provide a spatially ordered and compact sensing surface. In the example by Yoon et al. [457], the enzyme layer had a surface coverage of 2.5 pmol cm^{-2}. This enzyme loading is 2.5 times higher than that achieved with enzyme attached directly to a SAM [375], which suggests that attaching enzymes to a dendrimer may allow more sensitive monolayer enzyme electrodes to be developed.

4. CONCLUDING REMARKS

The application of SAMs of alkanethiols on surfaces has seen some exquisite and complicated examples of integrated molecule systems developed in pursuit of novel surface coatings, sensors, and molecular electronics. Many of these elegant examples represent the very edge of what has been achieved thus far in nanotechnology with bottom-up fabrication. What has been achieved so far clearly demonstrates that alkanethiol SAMs have the potential to enable

the fabrication of many useful nanodevices by self-assembly in sufficiently large volume and with sufficient control to be commercially viable. In fact, two of the most complicated affinity sensors discussed in this review, which are perhaps some of the best examples of molecular level fabrication of useful devices, namely, the AMBRI biosensor and the CMS DNA sensor, are close to or have already been commercialized.

Regardless of the success of the AMBRI and CMS sensors, SAMs have enabled a considerable amount of fundamental nanoscience to be conducted which drives much of the current nanotechnological developments and enables many other nanotechnological dreams to be realized. Furthermore, what we learn about self-assembly and how to control molecular level fabrication from alkanethiol monolayers will be exceedingly valuable in developing other self-assembly systems. This brings us to the future. The author believes the research into SAMs will follow two key directions. First, more advanced integration of nanoscale building blocks such as the nanoparticles, nanotubes, and dendrimers, with SAMs will certainly be developed. Second, alternative self-assembly systems will be developed that have the many attractive features of alkanethiol chemistry outlined throughout this article but which solve the long-term stability problems that alkanethiol chemistry have. Certainly, some researchers are already directing their attention to the problem of stability through new alkanethiols which increase the forces of attraction between the alkyl chains [205–207] or through self-assembly systems which form more robust bonds with the underlying substrate using more attachment points [499] or different chemistry [574]. So the application of SAMs is expected to grow in the future.

GLOSSARY

Alkanethiol The family of compounds of the general formula HS—$(CH_2)_n$—X where the thiol headgroup self-assembles onto coinage metal surfaces to form self-assembled monolayers, the aliphatic chain contributes to the order of the monolayer, and the X terminal group defines the surface properties of the monolayer.

Biosensor A portable analytical device that integrates a biorecognition molecule, such as an enzyme, an antibody, or DNA, with a signal transducer. The biorecognition molecule gives the biosensor the selectivity for the analyte while the transducer determines the extent of the biorecognition reaction and converts this to an electronic signal which is outputted to the user.

Microcontact printing A method of patterning self-assembled monolayers where a stamp that is patterned with the desired relief is inked with self-assembling molecules and contacted with a substrate to give a patterned self-assembled monolayer on the substrate surface.

Scanning probe lithography The suite of techniques for patterning self-assembled monolayers using atomic force microscopy, scanning tunneling microscopy or associated techniques.

Self-assembled monolayer (SAM) Ordered monomolecular film that is spontaneously formed upon immersion of a solid into a solution of an amphifunctional molecule.

Analytical Characterization
of Single Wall Carbon Nanotubes

Sivaram Arepalli, Pasha Nikolaev, Olga Gorelik

G. B. Tech./NASA-Johnson Space Center, Houston, Texas, USA

CONTENTS

1. INTRODUCTION

During the last few years, interest in the study of single wall carbon nanotubes (SWCNTs or SWNTs) has grown exponentially because of their extraordinary properties [1, 2]. Some of the possible applications include flat panel displays, superstrong fibers and panels, multifunctional materials, nanoelectronics and sensors, supercapacitors, and fuel cells [3–5]. The large aspect ratio (nanometer diameter and several micrometer length) adds tremendous appeal to the SWCNTs as reinforcing materials for composites. Also, the large surface areas available from individual tubes provide possible means for energy storage. The anisotropic nature allows enhanced properties along the length of the tube such as directed thermal energy transfer. The applications depend heavily on the diameter, length, chirality, and bundle size as well as on the amount and extent of impurities existing in the nanotube material. These impurities are inherent to the production process and change in character with the processing and purification steps used.

The carbon nanotubes can be produced by a variety of techniques including carbon arc, laser ablation, chemical vapor deposition, and carbon monoxide disproportionation [6–9] using metal catalysts. In addition to SWCNTs, the produced product may contain multiwall tubes with inferior properties. The as-produced material is known to be inhomogeneous and contain a variety of impurities including graphite coated metal clusters, amorphous carbon, and other carbon compounds including fullerenes. The type and extent of these impurities change with the production method used. The production process also influences the length, diameter,

chirality, and surface moiety of the nanotubes (and nanotube bundles). It is indeed a challenge to determine all these impurity levels and characterize this material to a reasonable extent using the available analytical techniques. Also, the purification processes used to improve the percentage of SWCNTs in the material tend to alter the nanotubes by adding functional groups, damaging and cutting the tubes [10–13]. For some applications, it is indeed necessary to add functional groups at specific locations and therefore requires additional sophisticated analytical tools for characterization.

The SWCNT material seems to behave similar to carbon soot and may require additional precautions while handling because of its submicrometer size dimensions. It is therefore necessary to assess all possible hazards involved in handling and address the toxicological effects of the nanotubes [14].

This chapter addresses the analytical tools and techniques used to characterize the SWCNT material. Most of the aforementioned aspects are covered in general and the reader may like to follow the cited references for further detailed information. Some of these techniques which are qualitative in nature can be used for quantitative estimates by using calibrated standards and procedures. Each technique is described briefly and its application to SWCNTs is shown by providing one or two measurements as examples.

2. ANALYTICAL TECHNIQUES

The analytical techniques are divided into subgroups based on general operating principles. The first group is based on electron microscopy and encompasses techniques such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), scanning tunneling microscopy (STM), and atomic force microscopy (AFM). The second group is related to spectrophotometry (absorption and emission) in the ultraviolet-visible-infrared (UV-VIS-IR) regions and includes Raman methods. The third group is focused on mass spectrometry [gas chromatography (GC) and time-of-flight (TOF) mass spectrometry (MS)] and chromatography [high pressure liquid chromatography (HPLC)] that use size-selection processes to characterize the material. The fourth

group is based on X-ray excitations such as X-ray diffraction (XRD), X-ray photoelectron spectroscoy (XPS), and extended X-ray absorption fine structure (EPXAFS). Magnetic resonance methods such as electron paramagnetic resonance (EPR) and nuclear magnetic resonance (NMR) constitute the fifth group. The sixth group covers the thermal methods such as thermogravimetric analysis (TGA), temperature programmed oxidation (TPO), and differential scanning calorimetry (DSC).

2.1. Electron Microscopy

2.1.1. TEM

Transmission electron microscopy remains one of the best tools to characterize nanotubes and related nanostructures. Historically, both multiwall [15] and single-wall [16] carbon nanotubes were discovered on the TEM micrographs of the cathode deposit and soot formed in the arc-discharge fullerene generator. Figures 1 and 2 show high resolution TEM images of single wall carbon nanotubes produced by two different processes. A number of other nanostructured carbons, like bucky peapods [17] and carbon nanohorns [18], were also discovered and studied in TEM.

TEM works on the same principle as optical microscope, except photons (typical wavelength 200–800 nm) are replaced with electrons (typical wavelength 0.0025 nm at 200 kV accelerating voltage). Numerical aperture of TEM is much smaller than that in the optical microscope (35′ compared to ~70°). Electron beam optics is essentially free of chromatic aberrations, while spherical aberrations are severe. Theoretical resolution is determined by electron wavelength and numerical aperture and is very high, while in practice it does not exceed ~0.3 nm and is limited by spherical and diffraction aberrations.

Imaging in TEM is strongly dependent on the type of the electron source. There are three common types: tungsten filament, lanthanum hexaboride (LaB_6) crystal, and field-emission gun (FEG). Tungsten filament creates a source of relatively large size, low brightness, and low coherence and is hardly used anymore. A LaB_6 source is the most common
Figure 1. High-resolution TEM image of a SWCNT produced by the HiPco process.
Figure 2. High-resolution TEM image of single wall carbon nanotubes produced from carbon monoxide feedstock using Fe–Mo catalyst supported on silica particles.

these days and provides much better coherence, brightness, and size while still being a relatively inexpensive option. There are few field-emission-type TEMs available, which are significantly more expensive than other options. Source size and beam coherence in FEG systems are excellent, which significantly improves resolution. But brightness of the FEG source exceeds that of LaB_6 by 1–2 orders of magnitude, which creates much higher fluence of the electron beam illuminating the sample. Therefore a TEM equipped with a FEG source quickly produces significant e-beam damage of the nanotube samples. The authors have observed nanotubes literally falling apart in a matter of minutes. FEG TEM has to be used with the understanding that nanotubes can be damaged very quickly.

Another important factor in TEM imaging is the accelerating voltage. The common range is 100–200 kV, but modern TEMs can achieve up to 800 kV–1 MV. In theory higher accelerating voltage allows one to achieve higher resolution, since electron wavelength is smaller. In practice, however, TEM imaging is always a trade-off between resolution and contrast. Carbon atoms are relatively light and do not scatter high-energy electrons well. Scattering cross-section decreases quickly at higher accelerating voltages, and image contrast becomes very small. Defocusing can be used to increase contrast, but then resolution suffers. It is believed that accelerating voltage in the range of 100–160 kV is optimal for imaging nanotube samples.

The most common way to prepare TEM specimens is to disperse nanotubes in organic solvent (alcohol, acetone, etc.) and then place a droplet of suspension on the TEM grid lying on tissue paper. The solvent is adsorbed by the tissue, and the nanotubes lay flat on the grid and coat it more or less uniformly. The thickness of the carbon film on the commercially available grids is around 50–100 nm. This means that individual nanotubes and small bundles (1–10 nm in

thickness) cannot be imaged effectively sitting directly on the support film. It is necessary to use "holey" or "lacey" grids, with plenty of holes in the support film, in order to image nanotubes bridging the holes.

There are more exotic ways to prepare TEM specimens. For example, TEM can be used to measure nanotube diameters. But nanotubes exist almost exclusively as bundles, which makes it nearly impossible to distinguish walls of each nanotube in the bundle lying flat on the support film in order to measure the diameter of each nanotube. Moreover, if a triangular lattice of a well-ordered nanorope is positioned a certain way with respect to the electron beam, line spacing observed on the TEM image represent either $\frac{\sqrt{3}}{2}(d + a)$ or $\frac{1}{2}(d + a)$, where d is nanotube diameter and a is van der Waals interwall spacing in the nanorope [19]. Figure 3 shows the same nanorope rotated 0 and 60 degrees around its axis, and interline spacing follows this expression. However, if the bundle loops through the focal plane of the TEM so that nanotubes are parallel to the electron beam, one can image the cross-section of the bundle with nanotubes represented as circles (Fig. 4). It is easy to determine the diameters of a large number of nanotubes on such an image. There is a simple technique to prepare a specimen with a large number of cross-sectional views of SWNT bundles, which works well on dry and fluffy as-made nanotubes. One can place a small chunk of dry nanotube material on a TEM grid and wet it with a droplet of alcohol. The nanotube chunk becomes compressed by capillary forces and sticks to the support film. In the process SWNT bundles at the chunk extremities fold onto themselves and create loops, most of which are in-plane or at some angle to the e-beam. A small fraction of the loops, however, is parallel to the e-beam, which creates the aforementioned cross-sectional images. To make measurements of the diameters of a large number of circles easier, Nikoalev has written a simple program [20] which allows one to superimpose a circle over a nanotube image, adjust its size and position to achieve the best fit, and then record its diameter. About 200–300 circles can be accurately measured in an hour (Fig. 5).
Figure 3. TEM images of crystalline SWCNT nanorope rotated around its axis by 0° and 60°. Interline spacing changes according to the particular view of the triangular lattice of the nanorope. Amorphous carbon is a major impurity in the SWNT. It is not well understood, and there is no single analytical technique which can reliably discriminate between nanotubes and other forms of carbon. TEM observations are often used to estimate the purity of SWNT materials, although such estimates are very subjective. TEM is also frequently used to determine dimensions of various nanostructures.

2.1.2. SEM

Scanning electron microscopy is another common tool used to study nanotubes and related nanostructures (Fig. 6). Modern SEMs utilize the same electron sources as TEMs, tungsten, LaB_6, and field emission guns, FEG providing the
Figure 5. Diameter distribution of SWCNT shown in Figure 4, measured from TEM micrographs. Reprinted with permission from [63], A. G. Rinzler et al., *Appl. Phys. A* 67, 29 (1998). © 1998, Springer-Verlag.
Figure 6. SEM image of unpurified dry SWCNT.

best brightness and coherence. SEMs detect either backscattered or secondary electrons. There are no reports on using backscattered electron detectors in nanotube imaging, so all discussion will concentrate on secondary electrons (although backscattered electrons can be used to image nanocomposites, i.e., nanotubes embedded in polymers). Resolution of SEM depends on the beam diameter, which is usually 3–5 nm, but is not determined by it. This happens because electrons penetrate into the surface of the specimen, and observed secondary electrons are emitted from the pear-shaped volume within the sample which can extend up to a micrometer below the surface. This means that generally SEM cannot detect individual nanotubes, but only bundles of at least 3–5 nm in diameter. Sample preparation for SEM is fairly simple—a small piece of nanotube material is mounted on the double-sided carbon tape or glued to the substrate with silver paint, in order to assure good electrical contact. Nanotube samples are generally conductive enough to prevent charge buildup, but in rare cases it is necessary to coat samples with a thin layer of platinum to improve conductivity. The most common use of SEM is to estimate the purity of nanotube samples, although, just like in TEM, such estimates are very subjective.

2.1.3. Energy-Dispersive Spectroscopy

EDS stands for energy-dispersive spectroscopy. TEMs and SEMs are frequently equipped with EDS detectors, which are able to detect characteristic X-rays generated by various elements when irradiated with high-energy electrons. The EDS spectra indicate the relative amounts of metals and other noncarbon elements in SWCNT material (Figs. 7 and 8). While EDS is good in determining relative amounts of heavy elements, it is notoriously unreliable in determining carbon concentration because of hydrocarbon contamination present in all SEMs and TEMs, and poor sensitivity of EDS detectors in the low-energy end of spectrum, where the carbon peak is found. In addition, EDS spectra taken in TEM usually show large copper peaks coming from copper TEM grids and apertures in the column, and TEM grids are frequently contaminated with silicone grease during manufacturing, producing a weak silicon signal. While the former
Figure 7. EDS spectrum of purified HiPco SWCNT obtained in TEM. Iron particles have been removed. The large Cu signal comes from the TEM grid and apertures. A small Si peak can appear due to impurities in SWCNTs as well as silicone grease contaminating the TEM grid.

is largely irrelevant since nanotubes do not normally have any copper in them, the latter is a problem, since silicon is frequently present in nanotube samples. EDS utilizes the same samples as TEM and SEM; therefore we refer reader to Sections 2.1.1 and 2.1.2 for sample preparation.

2.1.4. Microprobe

An electron beam microprobe operates on the same principle as EDS, except the beam current is much higher and X-ray detectors are different. Microprobe instruments are
Figure 8. EDS spectrum of the same purified HipCO SWCNT as in Figure 7, obtained in SEM.

better equipped to produce elemental maps with larger lateral span and better resolution. Sample preparation for microprobe measurements is similar to SEM sample preparation, described in the relevant section. The microprobe is usually calibrated before each use using standard samples. Accuracy of the microprobe measurements is sensitive to the precise focusing of the electron beam. Therefore, the sample surface has to be very smooth and level in order to produce meaningful elemental maps, which is rarely achieved with buckypaper-type samples. Concentration measurements performed with a stationary beam are therefore more accurate, but sample composition in one spot may not be representative of the whole specimen due to inhomogeneity of nanotube material. Figure 9 shows the elemental maps of a target material (graphite with 1% Co and Ni) used for production of nanotubes by laser ablation. The microprobe suffers from the same hydrocarbon contamination problems as EDS, and measured carbon concentration is prone to overestimation. The microprobe has been used in the past to measure the amount of fluorine in fluorinated nanotubes [21], but for the reasons mentioned and in the absence of independent verification, the accuracy of such measurements remains questionable.

2.1.5. AFM

Atomic force microscopy is used to determine the topography of flat samples. A sharp tip is scanned over the sample surface, and either tip deflection or change in the amplitude of the tip oscillation serves as feedback in the vertical direction. Accuracy of the height measurement is tremendous, approaching 0.01 nm. Lateral resolution, on the other hand, is determined by the tip diameter and is typically 15–30 nm. Nanotubes have to be deposited onto a suitable smooth substrate for AFM imaging (Fig. 10). The easiest way is

Figure 10. Tapping mode AFM image of a SWCNT wrapped in PVP (polyvinyl pyrrolidone) and deposited on amine-functionalized silicon oxide surface.

to disperse nanotubes in organic solvent or in water with surfactant, and spin-coat or dry on silicon, mica, graphite (HOPG, or highly oriented pyrolitic graphite), or even glass coverslip. AFM is often used to assess how well nanotubes are dispersed in the solvent, so it could be important to preserve the state of dispersion as nanotubes are transferred to the substrate and dried. For example, nanotubes can be electrodeposited onto a HOPG surface in the DMF suspension [22]. Another approach is to coat silicon surface with a positively charged amine-terminated self-assembled monolayer and dip such substrate in nanotubes dispersed in water in the presence of sodium dodecyl sulphate (SDS), an anionic surfactant giving nanotubes a net negative charge [23]. Other surfactants or polymers [24] can also be used. Arepalli et al. have reported nanotubes being deposited onto polished fused silica substrates directly in the laser oven, as they are produced, bypassing the solvents altogether [25]. Figure 11 shows tapping mode AFM image of nanotubes deposited onto quartz substrate this way. AFM is often used to measure diameters and lengths of nanotubes and nanoropes (nanotube bundles). It is important to mention that because of the poor lateral resolution AFM can only measure height, rather than diameter, of a nanostructure. Therefore it is impossible to distinguish one individual nanotube

Figure 9. E-beam microprobe elemental maps and secondary electron image of a polished surface of carbon/Co/Ni target used for SWCNT production in a laser oven.
Figure 11. Tapping mode AFM image of a SWCNT deposited on a fused silica substrate directly in the laser oven. Reprinted with permission from [25], S. Arepalli et al., *Appl. Phys. Lett.* 78, 1610 (2001). © 2001, American Institute of Physics.

and a small bundle of nanotubes lying flat on the substrate, having the same height. Nanotube length measurement is straightforward for short tubes not exceeding a few micrometer in length. But if nanotubes are longer and exist in bundles, it becomes impossible to find both ends of a particular nanotube, and one can only estimate nanotube lengths.

2.1.6. STM

Scanning tunneling microscopy is similar to AFM, except that tunneling current between the sample and the sharp metal tip is utilized as a feedback signal. Therefore STM samples have to conduct electric current, which limits substrates to HOPG, heavily doped silicon, and metals. Otherwise the sample preparation is similar to that of AFM samples. The tunneling current is limited to a few atoms on the tip closest to the sample, since its intensity drops exponentially with the distance from the sample. Because of that, lateral resolution of STM is much higher than in AFM and allows one to achieve atomic resolution, which usually calls for measurements in high vacuum and at low temperatures. While AFM probes actual topography of the specimen, STM probes local density of electronic states in the sample, which varies with the distance from the Fermi level. Therefore SEM images taken with different bias between sample and tip are different. STM also allows scanning tunneling spectroscopy measurements, in which the tip is kept stationary above the sample, and bias is varied in order to probe the density of states above and below the Fermi level. Such measurements, combined with helicity measurements from the atomically resolved images [26], have provided the first proof of the relationship between nanotube geometry (helicity and diameter) and electronic structure (Fig. 12).

2.2. Spectroscopy

2.2.1. UV-VIS-NIR Absorption and Emission

The age-old spectrophotometry is used to measure absorption and transmission of SWCNT samples in the solution phase as well as thin films. The measurements are done a double beam apparatus by comparing the transmission with a reference solvent [27–29] in the wavelength range of 200 to 2000 nm. Figure 13 shows changes of the optical spectra with oxidation and annealing of single wall carbon nanotubes. Recently, excitation spectra and fluorescence of individual SWCNTs (Fig. 14) were also recorded [30]. This measurement is used to identify the chirality and the "n, m" designation of the semiconducting tubes in the raw HiPco material (Fig. 15). The procedure involves extensive sonication of the material in a surfactant (SDS) followed by very high level centrifuging (200,000 g) which yields very short (couple of hundred nm long) individual tubes wrapped with surfactant. The energy levels responsible for the sharp absorption and fluorescence features arise from "van Hove" singularities in the electronic density of states [31]. Metallic tubes can be monitored in the absorption spectrum only and no fluorescence can be observed because the conduction band provides a way for rapid nonradiative relaxation. The features from the semiconducting tubes can be used to determine the primary (S11), secondary (S22), as well as tertiary (S33) transitions. Fluorescence is only observed from individual
Figure 12. (A) Typical atomically resolved STM image of a (15, 0) SWCNT. The image was recorded in the constant-current mode with bias voltage of 0.65 V and current 0.15 nA. Scale bar, 1 nm. (B) Tunneling conductance data, dI/dV, for different zigzag SWCNTs, with corresponding calculated densities of state shown below each experimental curve. Reprinted with permission from [81], M. Ouyang et al., *Science* 292, 702 (2001). © 2001, American Association for Advancement of Science.

tubes and disappears when bundling takes place [30]. However, absorption can still be noticed and it may be possible to determine the bundle size from the width of the spectral features.

The absorption spectra of the SWCNTs can also be used to determine the stability of nanotube suspensions. If the nanotubes tend to bundle up, floculate, and fall out of the solution, the absorption decreases and this change in the absorptivity as function of time is used to assess the dispersion stability [32].

Atomic Absorption and Inductively Coupled Plasma

These two techniques are used for qualitative as well as quantitative estimation of metals in materials. Atomic absorption (AA) uses selective absorption of "fingerprint" spectral lines either from a broadband source or from sharp hollow-cathode lamp sources that provide very sharp atomic
Figure 13. UV-visible-near IR absorption spectra of SWCNT: (a) raw HiPco tubes, (b) after 225 °C oxidation step, (c) after 325 °C oxidation step, (d) after 425 °C oxidation step. Each oxidation step is completed by HCl sonication, vacuum-drying, and annealing at 800 °C in Ar for 1 hour. Spectra have been normalized at 925 nm and scale bar shows adjusted tube diameter. line radiation emission. Hollow cathode lamps and multi-detector arrays are used with spectrometers operating in "echelle" modes to provide simultaneous detection of several elements with high sensitivity [33]. High temperature furnaces are used to vaporize the material with a short heat pulse and thereby provide gas phase atoms for AA study. Current AA methods extend from VUV to IR wavelength regions and use laser sources to provide atomic radiations. This is especially true in the IR where solid state diode lasers are used with very high resolution and increased sensitivity.
Figure 14. Emission spectrum (red) of individual fullerene nanotubes suspended in SDS micelles in D_2O excited by 8 ns, 532 nm laser pulses, overlaid with the absorption spectrum (blue) of the sample in this region of first van Hove bandgap transitions. The detailed correspondence of absorption and emission features indicates that the emission is band gap photoluminescence from a variety of semiconducting nanotube structures. Bachilo et al., *Science* 298, 2361 (2002). © 2002, American Association for Advancement of Science.

The inductively coupled plasma (ICP) technique involves injecting the material as a spray into a plasma torch which vaporizes the material. This process pumps the atoms to excited states which emit "fingerprint" spectral lines and can be used for quantitative elemental analysis of the material. This technique coupled with a mass spectrometer is useful for a complete elemental analysis for even organic compounds including polymers.

Both of these techniques have been used to monitor the metal contents in SWCNT material [34]. It is to be understood that metals encapsulated in graphite may be difficult to detect by ICP and the quantification of the metal content determined by this method may be underestimated.

2.2.2. IR Absorption and Emission

The absorption and emission in the infrared region (2 to 20 micrometer) arise from vibrational modes of the molecules constituting the material. The spectra arising from vibrational energy of the molecular bonds such as C—C, C=C, C—H, C—H_2, CH_3, C—F, C—N, O—H, N—H, etc. are commonly used as "fingerprints" of the material. In principle, the Kramer–Kronig relationship can be used to deduce the dielectric function of the material from the IR spectrum [35]. Data collection in the IR region normally done in double beam spectrometers can be done faster with fourier transform spectrometers and the capabilities are easily extended to very small solid samples using accessories. The IR region of the SWCNT is very very weak because of the low absorption cross-section of the carbon nanotubes (Fig. 16). In the recent work on SWCNT films and suspensions IR is used to monitor the functional groups attached to the SWCNTs (Fig. 17) as well as the effect of surfactants [35–38]. The IR spectrum is also used to analyze the condensable gases that are released when the material is heated (for example in conjunction with TGA [39]).

2.2.3. Raman

Raman spectroscopy is a powerful spectroscopic tool in providing "fingerprint" spectra of the molecular vibrational modes of the material [40]. The Raman spectra can be obtained in any wavelength region using different laser
Figure 16. ATR-IR spectra of the SWCNT. (A) SWCNT fluorinated to $\sim C_5F$ stoichiometry. (B) Cut SWCNT. Reprinted with permission from [39b], Z. Gu et al., *Nano Lett.* 2, 1009 (2002). © 2002, American Chemical Society.

wavelengths. The recent advances that include FT Raman and confocal micro-Raman provide rapid data acquisition of even micrometer size materials in addition to the normal solid, liquid, and gas phase studies. The Raman spectra of SWCNTs can be separated as three distinctive regions (Fig. 18), one in the small wavenumber region called radial breathing mode (RBM), the second in the intermediate wavenumber region called transverse mode (TM), and the third at higher wavenumber regions emanating from harmonics and combinations of these two fundamental modes [41, 42]. The RBM modes are resonantly enhanced because of van Hove singularities and can be used to monitor the changes in the diameter distribution of SWCNTs [43]. The TM (G-Mode) region also shows spectral features that can be attributed to amorphous carbon (D-mode). The intensity ratio of the D-band and G-band ("D/G" ratio) is used by many researchers to determine the relative purity of the SWCNT material [44, 45]. However, it is noted that the
Figure 17. Mid-IR spectrum of functionalized SWCNT (thin film on quartz substrate). s-SWCNT-CONH(CH$_2$)$_{17}$CH$_3$ showed peaks at 2918 and 2845 [ν(C—H) stretch modes of the alkyl chain], 1660 [ν(C═O) stretch of the amide], 1583 [ν (C═C) stretch of the SWCNTs], and 1471 cm^{-1} [δ(C—H) bend of the alkyl chain]. Figure 18. Room-temperature Raman spectra of purified SWCNTs excited at five different laser frequencies. The laser frequency and power density for each spectrum are indicated, as are the vibrational frequencies. Reprinted with permission from [41b], A. M. Rao et al., *Science* 275, 187 (1997). © 1997, American Association for Advancement of Science.

broad "D-band" becomes sharper with increasing "purification" and may therefore contain a SWCNT signature. This also occurs when the nanotubes are functionalized. Recent Raman work is focused on monitoring isolated SWCNTs (Fig. 19) and their chiralities [46]. Polarized Raman studies are used to assess the alignment of SWCNT fibers by changing the polarization of the laser with respect to the fiber axis [47, 48]. There is a preferential enhancement when the polarization axis is parallel to the nanotube axis and this "parallel to perpendicular" ratio is used to estimate the extent of alignment. Raman is also used to monitor strain (Fig. 20) in the SWCNT fibers and their load transfer to the composite matrices [49]. Temperature variation studies of Raman spectra are also used to assess the intrinsic nature and their dependence of the vibrational modes [50].

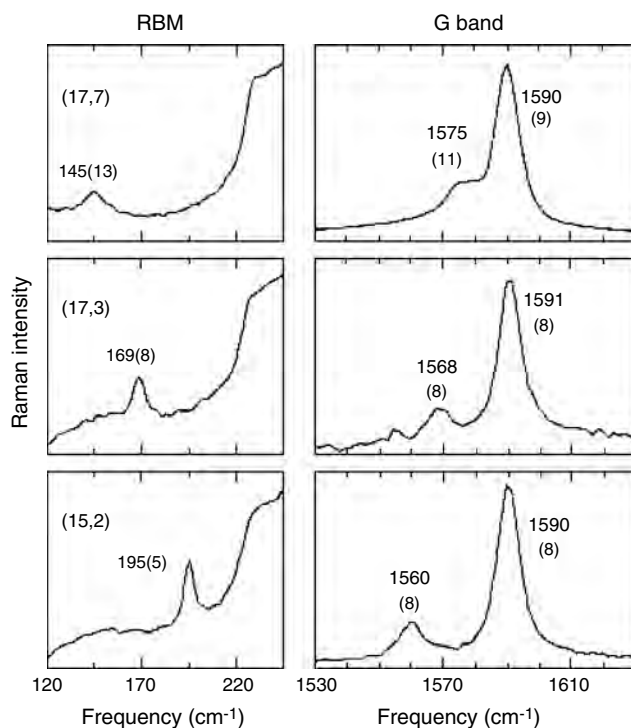
RBM   G band


Figure 19. The RBM and *G*-band Raman spectra for three isolated semiconducting SWCNTs resonant with E_{laser}; that is, $E_{\text{laser}} = 2.41$ eV for the spectrum in the top, labeled (17, 7), and $E_{\text{laser}} = 2.54$ eV for the other two spectra, labeled (17, 3) and (15, 2). The spectra are taken at three different spots on the substrate. The frequencies (linewidths) of the principal peaks for the RBM, ω_G^- and ω_G^+ features, are displayed in cm^{-1}. The shoulder observed to the right side of the RBM spectral feature comes from the Si substrate. Reprinted with permission from [83], A. Jorio et al., *Phys. Rev. B* 65, 155412 (2002). © 2001, American Physical Society.

2.2.4. Surface Characterization Tools

A variety of techniques are available [XPS, electron energy loss spectroscopy (EELS), etc.] to monitor the surface characterization of thin films consisting of SWCNTs. The techniques are all based on monitoring electrons or photons emitted from the material when excited with high energy electrons or X-rays. Photoelectron spectroscopy utilizes photoionization and energy-dispersive analysis of the emitted photoelectrons [51]. This is useful for the study of the composition as well as the electronic state of the surfaces. In X-ray photoelectron spectroscopy, the photon is absorbed by an atom in a molecule or solid, leading to ionization and the emission of a core (inner shell) electron. By contrast, ultraviolet photons can be used to probe valence levels.

The kinetic energy (KE) distribution of the emitted photoelectrons is measured using an electron energy analyzer and allows one to deduce the binding energy (BE) of the electron:

$$A + h\nu \longrightarrow A^+ + e^-$$

$$KE = h\nu - BE$$

The exact binding energy of an electron varies with the oxidation state as well as chemical environments giving rise to

"chemical shifts." An XPS spectrum of a nanotube film is shown in Figure 21.

Another technique that can be used to determine the atomic neighbors is extended X-ray absorption fine structure. The modulations noticed in the X-ray absorption spectrum arise from interference of the outgoing photon with the reflections from the neighboring atoms. This spectrum can then be used to determine the size and distances of the neighboring atoms from the atom of interest. Herrera et al. used EXAFS and X-ray absorption near edge structures

Figure 20. Raman spectra (782 nm excitation) of composite sample (1% SWCNT embedded in epoxy). *G*-mode frequency increases proportionally to the applied compressive stress (ε_s).

(XANES) to monitor the production of SWCNTs under varying catalyst concentrations [52]. The XANES spectra are shown in Figure 22. The EELS technique has also been used to assess the valence state of carbon atoms [53].

2.3. Chromatography

Chromatographic based techniques are used for solubilized SWCNTs to separate different components and constituents of SWCNT material. Different mass fractions can be identified with mass spectrometry in conjunction with gas chromatography and matrix desorption. This information in turn can be utilized to establish the nature and extent of the derivatization of the SWCNT materials and matrices with SWCNTs. Early successes are achieved in "purification" of the SWCNT material by using HPLC columns [54]. Recently, HPLC has been used to separate the SWCNT tubes and ropes by their lengths [55].

2.3.1. GC MS and TOF MS

The identification and quantification of trace organic constituents of the SWCNT material extractable by water or any organic solvent are done by gas chromatographic methods. In gas chromatography, a mobile phase (a carrier gas such as nitrogen or helium) and a stationary phase (capillary column coating) are used to separate individual compounds. When the sample solution is introduced into the column, the organic compounds are vaporized and moved through the column by the carrier gas. They travel through the column at different rates, depending on differences in partition coefficients between the mobile and stationary phases. The electrolytic conductivity detector is used to monitor halocarbons and nitrogen containing compounds. The electron

capture detector usually is used for the analysis of compounds that have high electron affinities such as halogens, peroxides, quinines, and nitro groups. The flame ionization detector is also widely used because of its high sensitivity to organic carbon-containing compounds. Mass analysis of the large fullerenes found in the SWCNT material is carried out using a time-of-flight mass spectrometric detector connected to a matrix assisted laser desorption/ionization (MALDI) system as shown in Figure 23 [56].

2.3.2. HPLC

This method is used for identification and quantification of trace organic constituents and soluble fullerenes extractable by organic solvents like toluene, dichlorobenzene, carbon disulfide, and others. High performance liquid chromatography is an analytical technique in which a liquid mobile phase transports a sample through a column containing a stationary phase. Selection of a suitable column is very crucial and the researchers used columns including Styragel HMW7, C_{18}, and Plgel Mixed-A columns. The interaction of the sample with the stationary phase selectively retains individual compounds and permits separation of sample components. Of special concern for HPLC is the masking of the absorbance region of the HPLC mobile phase and its additives. This may reduce the range and sensitivity of the detector to sample components. This test method is applied for the determination of monoaromatic, diaromatic, and polyaromatic hydrocarbon contents in toluene extracted solutions from raw nanotube material produced by arc, laser, or HiPco methods [57]. The total aromatic content in % m/m is calculated from the sum of the individual aromatic hydrocarbon types (Fig. 24). This test method is calibrated for distillates containing from 4 to 40% (m/m) monoaromatic hydrocarbons, 0 to 20% (m/m) diaromatic

Figure 22. Near edge spectra XANES obtained at the *K* edge of Co ($E_0 = 7.709$ eV) on a fresh Co : Mo/SiO catalyst (Co : Mo = 1 : 2), pretreated in H_2 (500 °C) /He(700 °C), and after the growth of carbon nanotubes by decomposition of 50% CO/He at 700 °C for reaction periods of 10 and 30 min. The XANES of a Co foil is included for comparison. Reprinted with permission from [66], W. E. Alvarez et al., *Carbon* 39, 547 (2001). © 2001, Elsevier.
Figure 23. LDI-TOF mass spectral patterns recorded under identical conditions on HiPco raw samples soft baked for varying times. The raw sample showed a mass spectral span of 1800–4500 amu with the maximal intensity at 2600 amu. The masses were evenly separated at a spacing of 24 amu. Note that the mass number for maximal intensity has shifted to higher mass numbers in the oxidized samples indicating a lower threshold for low-molecular weight carbonaceous species. Figure 24. HPLC chromatogram of toluene extract of SWCNTs produced in a laser oven. The *Y*-axis is absorption at 316 nm wavelength. This sample has ~4% by weight of C_{60} and C_{70}, plus a small amount of higher soluble fullerenes (C_{76}, C_{78}, and C_{84}).

hydrocarbons, 0 to 6% (m/m) polycyclic aromatic hydrocarbons, and 4 to 65% (m/m) total aromatic hydrocarbons. The precision of this test method has been established for an extract of soluble fullerenes and their blending components, containing from 4 to 40% (m/m) monoaromatic hydrocarbons, 0 to 20% (m/m) diaromatic hydrocarbons, 0 to 6% (m/m) polycyclic aromatic hydrocarbons, and 4 to 65% (m/m) total aromatic hydrocarbons.

2.4. Magnetic Resonance

Two of the prominent magnetic resonance techniques are electron spin resonance (ESR) and nuclear magnetic resonance. In the case of ESR, one monitors the precession of the valence electron in a strong magnetic filed. The ESR spectrum can be used to study the effect of ligands and chemical environments by monitoring the shape, symmetry, width, and splitting of the ESR lines. Figure 25 shows that ESR spectral features change during purification. Petit et al. [58] reported microwave resistivity and ESR of laser grown SWCNTs and observed that the system remained metallic even at low temperatures. Theoretical work by DeMartino et al. [59] successfully explained the double-peak nature of the ESR spectrum to spin-charge separation.

The nuclear magnetic resonance methods are used to measure the hydrogen content (from ^{1}H NMR) and carbon content (by the ^{13}C NMR). Kleinhammes et al. [60] studied the hydrogen adsorption in carbon nanotubes by following the kinetics of adsorption and desorption as a function of temperature and pressure. The electronic structures of the SWCNTs are also determined by relaxation times of ^{13}C NMR signals [61]. The fast relaxing component is attributed to metallic tubes. Figure 26 shows the effect of spinning (MAS stands for magic angle spinning) on the NMR spectra of SWCNT samples. It was found to account for one-third of the sample which is consistent with random chirality of the SWCNTs. It is also noted that exposure to small amounts of oxygen can drastically change the relaxation behavior of the
Figure 25. Electron spin resonance signal of unpurified and purified SWCNTs recorded at 9 GHz and at 300 K as a function of the static magnetic field. The former shows the huge ferromagnetic resonance line coming from the catalytic particles, while this signal is almost absent on the latter. NMR signals. The proximity of paramagnetic or ferromagnetic impurities (catalysts used in SWCNT production) may cause broadening of the NMR linewidths [62].

2.5. Thermal Methods

The following thermal methods rely on monitoring the weight, heat content, and reactivity of the SWCNTs as a function of elevated temperatures. These constitute one set of analytical techniques where the sampled material is destroyed or altered permanently. However, these can be used for quantitative estimation of purity of SWCNT samples and also yield very crucial information on thermal stability of these materials. The change in heat content is monitored by DSC where the phase transformations from crystalline to amorphous and/or glassy states are recorded.

2.5.1. TGA and TPO

Thermogravimetric analysis is used to monitor the changes in weight of the sample with increasing temperature [63]. Normally, this is done in air and at a ramp rate of 5 to 10 degrees per minute. The effects of compacting, ramp rate of the furnace, and type of gas used for TGA are discussed
Figure 26. The static and MAS (spun at 11.7 kHz) ^{13}C spectra of SWCNT. The isotropic shift is 124 ppm based on the MAS spectrum. The fit is the powder pattern of a chemical shift tensor with $\sigma_{11} = 195$ ppm, $\sigma_{22} = 160$ ppm, and $\sigma_{33} = 17$ ppm. Reprinted with permission from [61], X.-P. Tang et al., *Science* 288, 492 (2000). © 2000, American Association for Advancement of Science.

in a recent presentation [64]. A faster ramp rate is observed to result in premature combustion and excessive compacting reduces the extent of oxidation (Figs. 27, 28). The peak of the derivative (dm/dT) plotted in Figure 27 is now regarded as indicative of the temperature of oxidation. For SWCNTs, this will shift to lower temperatures for small diameter tubes and derivatized tubes (which can burn easily). At temperatures beyond 1073 K, the ash content can be attributed to metal oxides and therefore can be used to estimate the metal content of the SWCNT material. This technique is one of the few quantitative techniques that can be used to compare different purification methods (by comparing the metal contents of the samples).
Figure 27. TGA traces of unpurified HipCO nanotubes (100 sccm air, 2.5 °C/min ramp rate; the same sample was measured three times). Small differences in the TGA traces are attributed to the inhomogeneity of the sample.
Figure 28. Burning temperature (T_0, defined as a maximum in the weight loss rate) and its standard deviation dependence on the ramp rate in TGA. Run parameters and samples are similar to those in Figure 28. T_0 increases by $\sim$70 °C as heating rate goes from 1 to 30 °C/min. Standard deviation of T_0 also increases, due to uncontrolled combustion above 5 °C/min.

Also, the shape and size of the derivative signals used are indicative of the "temperature of oxidation." The oxidation temperature is noted to decrease with smaller diameter tubes and also when the nanotubes have extensive derivatization and/or defects [65].

In the temperature programmed oxidation technique, the material is submitted to a programmed temperature increase in an oxidizing mixture of gas (small percentage of oxygen in inert gas) and the reduction or oxidation rates are continuously measured by monitoring the change in composition by chemical means or by weight. In general, TPO studies are carried out under low partial pressure of the reactive gas. In this way it is possible to observe the intermediate reactions, depending on analytical conditions such as temperature rate, flow rate, and concentration of reactive gas. Alvarez et al. used this to separate out the peaks in the TGA data (Fig. 29)
Figure 29. TPO traces of SWCNTs produced by decomposition of CO on Co:Mo catalyst of varying composition. A continuous flow of 5% O_2 in He is passed over the material while the temperature is linearly increased at 11 °C/min ramp rate. The evolution of CO_2 produced by the oxidation of the carbon species is monitored by a mass spectrometer. The arrow indicates the center of the peak corresponding to the oxidation of the SWCNT. Reprinted with permission from [87], B. Kitiyanan et al., *Chem. Phys. Lett.* 317, 497 (2000). © 2000, Elsevier Science.

and could identify and estimate the different types of carbon in the SWCNT sample [66].

2.5.2. DSC

Differential scanning calorimetry uses an indirect method of estimating the heat content of the sample as a function of temperature. The DSC spectrum can be used to monitor exothermic and endothermic reactions, and transition temperatures between different phases. This becomes especially useful when nanotubes are used to make composite materials for strength or conductivity enhancements. Also, peaks in the derivative signals of DSC can be used to determine curing temperatures, glass transition temperatures, and crystallization temperatures [67].

2.6. Miscellaneous Methods

2.6.1. XRD

One of the early methods used to monitor the extent of crystallinity was X-ray diffraction of SWCNT material [68]. The sharpness of the peaks at low angles increases with increased purity and crystallinity (Fig. 30). The broad background in the XRD spectrum at larger angles is attributed to the extent of amorphous content. This technique has also been used for estimating the diameter distribution [69] and the phonon density of states of SWCNTs [70].

2.6.2. Optical Microscopy

Resolution of the optical microscope is limited by numerical aperture and wavelength of light and does not exceed 400–500 nm. So it is not useful for imaging nanotubes and even large bundles. But optical microscopy has been utilized to assess nanotube dispersion in polymer films [71]. Nanotubes were dispersed in polyimide, and optical transmission micrographs of the resulting films were used to compare the degree of nanotube dispersion (Fig. 31). Dispersion of purified nanotube material in DMF is studied by drying a

Figure 31. Optical transmission images of a SWCNT (0.05%) dispersed relatively well (A) and worse (B) in polyimide film.

drop of nanotubes suspended in DMF on a glass slide. For a quantitative comparison, one can resort to algorithms that can count the size and number of aggregates in the image. It is to be noted that the drying process may alter the state of aggregation of nanotube material. Optical microscopy is more useful for dispersability study when higher concentrations of nanotubes (>0.1 mg/mL) are used. For low concentrations (0.01 mg/mL), normal transmission study may be sufficient for this evaluation (see Section 2.2.1).

2.6.3. Surface Area and Surface Energy Measurements

A variety of applications including supercapacitors and rechargeable batteries depend on the availability of the large surface area of the SWCNTs. It is to be noted that the available surface area varies with the functional groups attached to the nanotubes as well as the number of dangling bonds. This in turn determines the surface energy of the nanotube material that affects the extent of adhesion of the SWCNTs to the surrounding matrix material. The BET surface area analyzer estimates the specific external surface of a solid by determining the volume of a specific gas that is absorbed

Figure 30. X-ray diffraction pattern of laser oven SWCNTs annealed in vacuum at 1000 °C. Reprinted with permission from [7], A. Thess et al., *Science* 273, 483 (1996). © 1996, American Association for Advancement of Science.
Figure 32. N_2 adsorption isotherms (77.6 K) for the raw SWCNTs and a sample purified using the complete two-step process. Isotherm for a sample which skipped Step 1 (DMF/EDA treatment) and was subjected only to the HCl treatment/wet oxidation (Step 2) is also shown for comparison. Reprinted with permission from [77], M. Cinke et al., *Chem. Phys. Lett.* 365, 69 (2002). © 2002, Elsevier Science.

under controlled conditions [72]. Surface area and pore volume can be determined using a commercial instrument such as a BET COULTER SA 3100. The method consists of one-hour gas evacuation at 393 K and of determination of the pore volume introducing helium gas, followed by adsorption of nitrogen at the temperature of liquid nitrogen (77 K). The system performs automatic single-point and multipoint BET surface area, full adsorption and desorption isotherms, and pore volume distributions. One can use other gases such as krypton, hydrogen, carbon dioxide, and saturated hydrocarbons. A typical single-point surface area analysis takes a few hours, while a full adsorption/desorption isotherm can take up to 3 days to complete (Fig. 32).

The surface areas of SWCNTs are reported to be in the range of 300 to 3000 m²/g. Early work on the surface area determination of SWCNTs was prompted by the possibility of high hydrogen adsorption [73–75]. Other applications such as supercapacitors and catalysts required precise surface area and pore size measurements [76, 77]. Improved performance of supercapacitors using single walled CNT electrodes was reported by Young Hee Lee of Sung Kyun Kwan University, Korea. The heat treatment at high temperature was necessary to increase the capacitance and reduce the CNT-electrode resistance. The increased capacitance was well explained by the enhancement of the specific surface area and the abundant pore distributions at lower pore sizes of 30 to 50 angstroms estimated from the BET (N_2) measurements [78].

Direct measurement of surface energy can use inverse gas chromatography (Hans Darmstadt, Univ. Laval [79]). Surface energy of the SWCNTs can also be estimated by measuring the contact angle with different solvents and surfaces. Initial experiments seem to indicate low contact angle with water and other common solvents [80].

GLOSSARY

Bucky peapods   Nanoscale material consisting of string of buckyballs (cage-like carbon clusters) enclosed inside carbon nanotube.

Chemical vapor deposition   Chemical process based on catalytically assisted decomposition of gas-phase precursor molecules.

Chirality   Property of an object that is not superimposable on its mirror image.

Chromatic aberrations   Wavelength-dependent artifacts in imaging that occur because the refractive index of the lens material varies with wavelength.

Field emission electron gun (FEG)   Electron source based on extremely sharp tip. Electric field in the tip vicinity is high enough to allow electron emission without thermal assistance (or with very low thermal assistance).

Nanohorns   Nanoscale material made of graphene sheets rolled into capped cones.

Nanorope   Term used to describe a bundle of nanotubes held together by Van der Waals forces. Nanoropes are not twisted, unlike real ropes.

Numerical aperture   The sine of the vertex angle of the largest cone of meridional rays that can enter or leave an optical system or element, multiplied by the refractive index of the medium in which the vertex of the cone is located.

Spherical aberrations   Imaging artifact caused because a spherical lens does not focus parallel rays to a point, but along a line.

Analytical Ultracentrifugation of Nanoparticles

Helmut Cölfen

Max-Planck-Institute of Colloids and Interfaces, Golm, Germany

CONTENTS

1. INTRODUCTION

Analytical ultracentrifugation (AUC) is a powerful fractionating technique for polymer and particle characterization and has played a significant part in the understanding of colloidal but especially macromolecular systems starting with the pioneering work of Svedberg and co-workers [1, 2] who initially invented this technique for the characterization of particle sizes [1, 3]. However, it soon turned out that the technique was also well suited to the study of macromolecules, especially biopolymers, so that interest shifted almost exclusively to the study of macromolecules. One important result of the early work was the proof that macromolecules truly exist and that they are not aggregates of small molecules as was heavily debated at the time. Since that time, analytical ultracentrifugation has gained importance and become one of the most important characterization techniques for polymers mainly in biophysics/biochemistry. By 1970, there were about 1500 analytical ultracentrifuges in operation throughout the world. However, evaluation of the experimental results was tedious and time consuming in many cases because the results had to be derived from photographic records. With the advent of faster, cheaper, and more convenient techniques such as light scattering (LS), the importance

of the analytical ultracentrifuge decreased so that, by the end of the 1980s, only a few old instruments were still in use. The use of this technique for nanoparticle characterization appeared forgotten and only a few specialized, mainly industrial laboratories, still applied AUC for particle characterization.

However, in the beginning of the 1990s, Beckman Instruments released a new analytical ultracentrifuge—the Optima XL-A—equipped with a scanning absorption optical system [4]. This modern and fully computer controlled instrument led to a resurrection of analytical ultracentrifugation as the data acquisition was much simplified so that, nowadays, modern computer technology and powerful software can be applied for fast and rigorous evaluation (e.g., fitting experimental data to a model, handling of multiple data sets, etc.).

Analytical ultracentrifugation is an absolute method requiring no standards and covering a broad application range of molar masses between 200 and 10^{14} g/mol and particle sizes between less than 1 and 5000 nm. The power of the technique lies in the fractionation of the sample into its components either according to their molar masses/particle sizes or to their structure/density without the need for any stationary phase as required in many chromatographic methods. The fractionation enables the measurement of distributions of molar masses, particle sizes, and densities, and different types of basic experiments with the same instrument can yield complementary physicochemical information. Also, sedimentation equilibrium analysis is based on solid thermodynamics. Often, analytical ultracentrifugation is the only applicable technique if complex mixtures are to be investigated. For example, a unique feature of the technique is that interactions between molecules and/or particles can be investigated over a wide range of concentrations without perturbing the chemical equilibrium [5]. This is important for the study of biologically relevant relatively weak interactions ($K \approx 10$–100 M^{-1}) but can, in analogy, be adapted to any kind of interaction such as macromolecule–particle.

The range of samples that can be investigated by analytical ultracentrifugation is extremely wide and includes all systems that consist of a solvent and a dispersed or dissolved

substance spanning from gels to microgels and dispersions and emulsions to solutions. Also, there are no limitations on the choice of solvent even at extreme pH. This results in a whole variety of applications, and although the technique has already existed for about 80 years, there are still new methods and applications coming up. This review will give the basics of the technique but will also discuss the modern applications and recent trends of the last few years. Here, the methods that have been developed for polymer analysis but are, in principle, adaptable to nanoparticle analysis are also mentioned to give the reader the full array of available experimental or evaluation methods.

2. INSTRUMENTATION

An analytical ultracentrifuge is an ultracentrifuge with one or several optical detection systems that allow for the observation of a sedimenting sample in a centrifugal field of up to 290,000-fold the gravitational force (see Fig. 1). The sample is placed in a single- or double-sector cell (see Fig. 1) where the sector shape prevents convection during sedimentation due to the radially sedimenting sample. In addition to the two optical systems that modern machines are equipped with (see Fig. 1) and that detect the radially changing concentration in the cell, the Schlieren optical system, which detects the refractive index/concentration gradient, can also be applied. It delivers the first derivative of the radial concentration gradient and is thus well suited to watch sedimenting boundaries during sedimentation velocity experiments. The typical Schlieren peak is probably the most well known experimental output of an analytical ultracentrifuge. All three optical systems have their special advantages. The UV-absorption optics combines sensitivity with selectivity due to the variable detection wavelength, whereas the Rayleigh interference optics yields accurate experimental data due to the acquisition of a number of interference fringes, which are then evaluated via a fast Fourier transformation. However, the interference optics can only determine relative concentration changes with respect to a fixed point, which is usually the meniscus air/solution. The Schlieren optics is well suited for high concentration or density gradient work and all kinds of experiments where a derivative of the concentration gradient is needed for the evaluation (e.g., the determination of the z-average molar mass from sedimentation equilibrium). The Schlieren optics is similar to the setup of the Rayleigh interferometer in Figure 1 but has a phase plate or knife edge in the focus of the condenser lens as an additional element.

The Schlieren optics was widely considered to be the least sensitive of the three detection systems, but it was shown that the sensitivity equals that of the Rayleigh interferometer [7]. An ultrasensitive Schlieren optical system has also been described [8]. However, despite the equipment of many ultracentrifuges with video cameras to save the photographic evaluation of the experimental traces, fully automated evaluation of the images was very difficult and only reported in one case [9] until the recent introduction of an on-line Schlieren optical system [10].

The typical optical patterns derived by the three detection systems are shown in Figure 2. For an extensive description of these optical systems, see [11]. For modern ultracentrifuges, only the Rayleigh interferometer (as an on-line detector) and the absorption optics are still available although the Schlieren optics was recently adapted for use in the Beckman Optima XL/XL-I [12]. Other detection systems include a fluorescence detector [13] and a turbidity detector specially designed for particle size analysis mainly of latexes [14–17].

The fluorescence optical system is extremely sensitive and allows for the selective investigation of components with concentrations as low as 10 ng/mL even in mixtures with a much larger amount of other components. A prototype

fluorescence detector for the Optima XL-I ultracentrifuge has recently been constructed [18] so that now a third detector is commercially available, which can be simultaneously used in a modern analytical ultracentrifuge. The turbidity optics, on the other hand, proves its virtues for the analysis of particle size distributions, even if they span the entire colloidal range; as with the appropriate correction of the particle concentration for MIE scattering, even weakly scattering small particles can be precisely characterized in the presence of strongly scattering large particles.

It is generally advantageous to combine several optical systems. In particular, the combination of the Rayleigh interference optics and the ultraviolet/visible (UV/vis) absorption optics can yield important information about complex systems where, for example, an absorbing component is selectively detected with the absorption optics, whereas the Rayleigh interferometer detects all components. For examples, see [20] or Figure 18.

3. BASIC EXPERIMENTS

There are four basic types of experiments that can be performed with an analytical ultracentrifuge. Each of them can deliver its own range of physicochemical information on the sample. The different experimental approaches will be treated in the following section. Table 1 outlines the characteristics of each experiment type and the most important accessible parameters.

3.1. Sedimentation Velocity Experiment

A sedimentation velocity experiment is carried out at high centrifugal fields and is the most important AUC technique for nanoparticle characterization. Here, the molecules/particles sediment according to their mass/size, density, and shape without significant back diffusion according to the generated concentration gradient. Under such conditions, a separation of mixture components takes place and one can detect a steplike concentration profile in the ultracentrifuge cell usually exhibiting an upper and a lower plateau (see Fig. 2, lower trace). Each step corresponds to one species. If one detects the radial concentration gradient in certain time intervals, the sedimentation of the

molecules/particles can be monitored. This is demonstrated in Figure 3a.

From the velocity of the sedimenting boundary, one can determine the sedimentation coefficient s according to

$$s = \frac{\ln(r/r_\mathrm{m})}{\omega^2 t} \tag{1}$$

where r is the position of the midpoint or second-moment point of the moving boundary, r_m the radial distance of the meniscus, t the time, and ω the angular velocity of the rotor. The sedimentation coefficient is a concentration- and pressure-dependent quantity that can be taken into account by appropriate correction or by extrapolation of a concentration series to zero concentration. A plot of $\ln(r/r_\mathrm{m})$ vs. $\omega^2 t$ is a line in which the slope s is equal to the sedimentation coefficient (see Fig. 3b). The sedimentation coefficient is measured in svedbergs (S) where $1\,\mathrm{S} = 10^{-13}\,\mathrm{s}$. If the diffusion coefficient D is known from other experiments (light scattering, ultracentrifugation, etc.), one can calculate the molar mass of the sample according to the Svedberg equation:

$$M = \frac{sRT}{D(1 - \bar{v}\rho)} \tag{2}$$

where M is the molar mass of the sample, R the gas constant, T the thermodynamic temperature, $\bar{v}$ the partial specific volume, and ρ the solvent density. The partial specific volume is a critical value, but it can be determined with good precision in a density oscillation tube if enough sample material is available. For hybrid particles in mixtures with different compositions, $\bar{v}$ cannot be measured as only the average over all particles in the mixture is obtained. Here, the workaround of reasonable assumptions must be applied or quantitative density gradient experiments can yield the average density from the density distribution.

In general, sedimentation velocity experiments offer a good possibility for the rapid determination of particle size distributions and molar mass but also of equilibrium constants of interacting systems, which is especially advantageous for unstable systems that cannot be subjected to sedimentation equilibrium experiments due to possible sample degradation during the experiment [22].

Table 1. Basic experiment types in analytical ultracentrifugation and their characteristics and basic accessible parameters.

Experiment	Operative term in the Lamm equation (8)	Characteristics of experiment	Main accessible physicochemical parameter
Sedimentation velocity (3.1)	Sedimentation term prevails over diffusion term	High rotational speed	Sedimentation coefficient
Synthetic boundary experiment (3.4)	Only diffusion term operative	Low rotational speed, synthetic boundary cell	Diffusion coefficient
Sedimentation equilibrium (3.2)	Both terms operative, equilibrium between sedimentation and diffusion	Low to moderate rotational speed	Molar mass, equilibrium constants, and stoichiometries of interacting systems
Density gradient (3.3)	Both terms operative, equilibrium between sedimentation and diffusion	Moderate to high rotational speed, establishment of a radial solvent density gradient	Density

3.1.1. Moving-Boundary Method

Many procedures for the determination of s from sedimentation velocity data are available which cannot all be named here. Some of them like the moving-boundary method [23] allow an evaluation of the diffusion coefficient from the spreading of the boundary during the proceeding experiment [24] and thus a calculation of M. However, the calculation of D from the boundary spreading suffers from the requirement of reasonably monodisperse or at least reasonably separated samples because polydispersity leads to a boundary spreading proportional to time whereas diffusion goes only with the square root of time. If the whole boundary

spreading is only attributed to the diffusion spreading for polydisperse samples, the determined diffusion coefficient can be found to be significantly too high. Whereas polydispersity is often not an issue for biopolymers, it can be serious in nanoparticle analysis in that it can lead to erroneous results if the diffusion coefficient is determined by this method. Therefore, in nanoparticle analysis, the diffusion coefficient should be determined by other methods such as dynamic light scattering or flow–field–flow fractionation.

3.1.2. van Holde–Weischet Method

A problem arising from the diffusion broadening of boundaries is that the boundaries of several components can be smeared so that the overall boundary appears to be that of a single component. An approach to removing the effects of boundary spreading by diffusion and thus enabling calculation of the integral diffusion-corrected s distribution $G(s)$ was introduced by van Holde and Weischet [25]. This is done by selecting a fixed number of data points from one experimental scan that are evenly spaced between the baseline and the plateau. Then, an apparent sedimentation coefficient $s*$ is calculated for each of the data points and plotted versus the inverse root of the run time, yielding the typical van Holde–Weischet plot (see Fig. 4).

If a linear fit of the corresponding $s*$ (one slice) is performed, the integral diffusion-corrected sedimentation coefficient distribution $G(s)$ can be obtained from the y values at infinite time in the van Holde–Weischet plot. In the case of a single monodisperse component, the lines intersect in one point (see Fig. 4). For multiple components, the corresponding number of intersects is obtained whereas the intersection point is shifted to times less than infinity in the case of nonideality. Therefore, the van Holde–Weischet analysis is a rigorous test for sample homogeneity or nonideality [25–31].

3.1.3. Time Derivative Method

In many cases, particles are polydisperse or one detects a multimodal distribution. In such cases, it is of interest to determine the sedimentation coefficient distribution $G(s)$ or the differential form thereof $g(s)$. Although this is, in principle, possible by the van Holde–Weischet method, a
Figure 4. Typical van Holde–Weischet plot of a sedimentation velocity experiment with a monodisperse system. Reprinted with permission from [26], K. Schilling, Ph.D. thesis, Potsdam (1999).

better suited method for the determination of $g(s)$ is the time derivative method [21, 32, 33], which determines the time derivative of the radial scans acquired at different times according to

$$g(s^*)_t = \left(\frac{\partial\{c(r,t)/c_0\}}{\partial t}\right)\left(\frac{\omega^2 t^2}{\ln(r_{\mathrm{m}}/r)}\right)\left(\frac{r}{r_{\mathrm{m}}}\right)^2 \quad (3)$$

where $g(s^*)$ equals the true distribution $g(s)$ in cases where diffusion can be ignored. An example for bovine serum albumin is given in Figure 3c. An important advantage of this procedure is significant improvement in the signal-to-noise ratio of the experimental data because two scans are subtracted from each other so that systematic errors in the optical patterns cancel out and the random noise decreases. This approach takes advantage of the rapid data acquisition of modern analytical ultracentrifuges (Rayleigh interference optics) where 100 or more scans per velocity experiment are no longer an experimental problem. Hence, even scans for very diluted solutions where the sedimenting boundary can hardly be seen in the raw scans can be evaluated with the time derivative method. By that means, concentrations as low as 10 μg/mL can be investigated so that interacting macromolecules and particles can be addressed in a concentration range previously not accessible with the analytical ultracentrifuge. However, a drawback of the time derivative method is that only scans from a relatively narrow time interval can be used for a single evaluation so that, in fact, no full advantage is taken of the possibility to scan several hundreds of experimental scans throughout an experiment.

If diffusion is significant, extrapolation of the $g(s^*)$ curves calculated for different times to infinite time yields the true distribution. The diffusion coefficient can also be derived from the $g(s^*)$ distribution using the maximum of the $g(s^*)$ curve [21]:

$$g(s^*)_{\max} = \left(\frac{s}{2\pi D}\right)^{1/2}(\omega^3 r_{\mathrm{m}})\left(\frac{t}{\sqrt{1-e^{-2\omega^2 st}}}\right) \quad (4)$$

and thus a plot of $g(s^*)_{\max}$ vs. $t/\sqrt{1-e^{-2\omega^2 st}}$ yields a line with a slope proportional to the square root of s/D so that the Svedberg equation can be applied to derive the molar mass

$$M = \frac{2\pi RT}{(1-\bar{v}\rho)\omega^6 r_{\mathrm{m}}^2}(\mathrm{slope})^2 \quad (5)$$

However, for heterogeneous systems, the molar mass can be underestimated by 10–20%.

Another way of determining D from $g(s^*)$ is to look at the standard deviation σ of a Gaussian distribution fitted to $g(s^*)$:

$$D = \frac{(\sigma\omega^2 t r_{\mathrm{m}})^2}{2t} \quad (6)$$

If a solution is analyzed where just different conformations of the same molecule or different particle shapes with the same molar mass or small amounts of aggregates are present, M and thus s/D can be fixed in the Svedberg equation for each component [Eq. (2)] to give the basis for a

very sensitive analysis—the so-called conformational spectra (CON-SPEC) [34]. Combining (2) and (6) with the equation for the Gaussian distribution function yields

$$g(s^*) = \frac{A}{\sqrt{2\,g(s^*)_{\max}\pi J}}\exp\left(\frac{-(s^*-g(s^*)_{\max})^2}{2(g(s^*)_{\max}J)^2}\right) \quad (7)$$

where A is the amount of the considered species and

$$J = \frac{2RTt}{(\omega^2 t r_{\mathrm{m}})^2(1-\bar{v}\rho)M}$$

is the collection of all known terms in the analysis. As M has to be known, J can be calculated so that only A and s can vary in (7). When σ in the Gaussian distribution function is replaced with the value of the standard error of the determination of $g(s^*)_{\max}$, a sort of mass spectrum is obtained where broad sedimentation coefficient distributions are replaced by sharp error-related distributions. This gives a very sensitive analysis for marginal differences in s even in the second digit for different components (see Fig. 5).

The determination of $g(s^*)$ can yield a lot of important information besides the sample homogeneity and number of components. In the case of interacting systems, for example, interaction constants can be derived [35–37]. If multiple Gauss curves with a maximum at fixed s are fitted to $g(s)$, then each of them corresponds to one component [38]. By that means, the aggregation state as well as the corresponding concentration of the different aggregates can be determined for aggregating systems so that the equilibrium constant and thus the free enthalpy of the association steps is accessible. An example of the advantageous application of this technique was reported for the precrystallization aggregation of lysozyme, which yielded the smallest oligomer capable of forming a crystal [39].

3.1.4. Fitting to Approximate or Finite-Element Solutions of the Lamm Equation

One new and recently much investigated approach has proved useful for the determination of s and D and thus M as well as the concentrations of individual components from sedimentation velocity data as in Figure 3a. This is the fit
Figure 5. CON-SPEC ($s_{20,w}$) for α-actinin showing a modest conformational change upon an increase in salt concentration from 50 to 150 mM KCl. That the change is only marginally significant can be seen from the slight overlap of the two functions. Reprinted with permission from [34], N. Errington, et al., *Biophys. Chem.* 80, 189 (1999). © 1999,

of a series of radial concentration profiles to approximate solutions of the Lamm [40] differential equation of the ultracentrifuge [41–46] or finite-element solutions of the Lamm equation [47–50]:

$$\frac{\partial c}{\partial t} = \underbrace{D\left(\frac{\partial^2 c}{\partial r^2} + \frac{1}{r}\frac{\partial c}{\partial r}\right)}_{\text{Diffusion term}} - \underbrace{\omega^2 s\left(r\frac{\partial c}{\partial r} + 2c\right)}_{\text{Sedimentation term}} \qquad (8)$$

As the Lamm equation (8) is the fundamental equation in analytical ultracentrifugation capable of describing all types of ultracentrifuge experiments, fitting of experimental data to this equation is a potentially very powerful approach. However, a drawback is that this method is clearly model dependent. Nevertheless, it is widely applicable and can quite accurately determine the sedimentation and diffusion coefficients even in mixtures of up to three components as long as the proper fitting function is used, the individual components are reasonably monodisperse (see the discussion about boundary broadening), and the individual components have differences in s of a factor of 1.5 or more. For smaller s differences, the van Holde–Weischet method is better suited. In the case of unknown samples, the van Holde–Weischet method can be used first to determine the type of system under investigation so that the correct model can be used for fitting the Lamm equation.

If mixtures of more than three components have to be analyzed, the s and D values of some components have to be known in order to get reliable fitting results. The fitting of experimental data to solutions of the Lamm equation has its special merits for small macromolecules or nanoparticles that sediment so slowly ($s < 1$ S) that they do not clear the meniscus. Furthermore, such approaches permit the rapid determination of molar masses with an accuracy of 10% within 15–30 min after the start of a sedimentation equilibrium experiment using a modified Archibald approach [50]. This is especially important for unstable samples that have to be characterized rapidly.

Very recently, the requirement of monodisperse samples for fitting of the Lamm equation was overcome so that now even the sedimentation coefficients and molar mass distributions of polydisperse samples can be investigated [51]. However, this approach suffers from the necessary prior knowledge of $\bar{v}$ (no serious problem) and the frictional ratio f/f_0 of the sample (f is the frictional coefficient and f_0 is the frictional coefficient of the spherical particle having the same mass and $\bar{v}$ as the sample under consideration). If the frictional ratio is not known, it can also be fitted, which, in turn, allows conclusions about the particle shape.

The most significant advantage of this approach for nanoparticle analysis is the possibility to correct for the effects of diffusion on the broadening of the sedimenting boundary so that diffusion-corrected sedimentation coefficient distributions can be obtained reflecting the true sample polydispersity. The method was recently shown to yield reliable results for different model systems [52].

3.2. Sedimentation Equilibrium Experiment

In contrast to the sedimentation velocity run, a sedimentation equilibrium experiment is carried out at moderate centrifugal fields. Here, the sedimentation of the sample is balanced by a back diffusion according to Fick's law caused by the established concentration gradient. After the equilibrium between these two transport processes is achieved, an exponential concentration gradient has formed in the ultracentrifuge cell (see Fig. 6a, which represents a true thermodynamic equilibrium). Therefore, the sedimentation equilibrium analysis is based on solid thermodynamics. The time of equilibrium attainment considerably depends on the column height of the solution [53] so that short column techniques with solution columns of about 1 mm are common practice nowadays where even a rapid equilibrium within 1–2 h or less is desired [54].

The concentration gradient contains information about the molar mass of the sample, the second osmotic virial coefficient, or the interaction constants in the case of interacting systems independently of the particle shape. An advantage is that the detection of the concentration gradient is possible without disturbing the chemical equilibrium even of weak interactions. Sedimentation equilibrium is of more value for polymeric systems, because the molar mass of particles can already be too high to allow a significant diffusion counteracting the particle sedimentation. Nevertheless, for smaller down to the smallest nanoparticles, or even subcritical clusters and complexes, it can also be applied successfully as shown for the example of complexes of Zr(IV) and Hf(IV) formed by hydrolytic polymerization in an acidic medium [55, 56]. Various procedures exist for the evaluation of

Figure 6. Sedimentation equilibrium experiment on bovine serum albumin in 0.5 N NaCl at 20 °C and 10,000 rpm. (a) Experimental raw data acquired with scanning absorption optics. (b) Plot of ln(absorbance A) vs. r^2 to evaluate $M_{w,\,app}$ from the slope.

sedimentation equilibrium experiments which are discussed in the following.

3.2.1. Classical Approaches

The classical approach to the evaluation of sedimentation equilibrium concentration gradients is to plot $\ln c$ vs. r^2 to obtain the weighted-average molar mass M_w from the slope according to the following equation (see Fig. 6b):

$$M_{w,\,app} = \frac{2RT}{(1-\bar{v}\rho)\omega^2}\frac{d(\ln c)}{dr^2} \qquad (9)$$

It must be noted that these M_w values have apparent character because they are calculated for finite sample concentrations. Consequently, they are denoted $M_{w,\,app}$. The true M_w can be obtained by an extrapolation of a concentration series to infinite dilution. The evaluation according to (9) works well for monodisperse ideal samples because, in such cases, the $\ln(c)$ vs. r^2 plot is linear. However, in many cases, this plot is curved, which yields erroneous $M_{w,\,app}$ values from linear regression. Nevertheless, the curvature indicates whether the sample is nonideal (downward curvature) or heterogeneous or self-associating (upward curvature). One advantage of (9) is that it allows for the computation of local $M_{w,\,app}(r)$ values for every acquired data point. $1/M_{w,\,app}(r)$ can be plotted against the corresponding concentrations to yield M_w and the second osmotic virial coefficient A_2 due to

$$\frac{1}{M_{w,\,app}(r)} = \frac{1}{M_w} + 2A_2 c(r) \qquad (10)$$

From the radial concentration gradient (Fig. 6a) and the local $M_{w,\,app}(r)$ values, the apparent z-average molar mass $M_{z,\,app}(r)$ can also be obtained according to (11) if the data set is of good quality (double differentiation of the experimental raw data) [57]:

$$M_{z,\,app}(r) = M_{w,\,app}(r) + \frac{2RT}{(1-\bar{v}\rho)\omega^2}\left[\frac{d\ln M_{w,\,app}(r)}{d(r^2)}\right]$$
$$= \frac{2RT}{(1-\bar{v}\rho)\omega^2}\frac{d}{d(r^2)}\ln\left(\frac{1}{r}\frac{dc(r)}{dr}\right) \qquad (11)$$

An alternative evaluation procedure was described by Lansing and Kraemer [58]:

$$M_{w,\,app} = \frac{2RT}{(1-\bar{v}\rho)\omega^2}\frac{c_b - c_m}{c_0(r_b^2 - r_m^2)} \qquad (12)$$

where the indices b and m denote bottom and meniscus, respectively. This procedure also allows for the calculation of $M_{z,\,app}$ [59, 60]:

$$M_{z,\,app} = \frac{RT}{(1-\bar{v}\rho)\omega^2}\frac{1}{(c_b - c_m)}$$
$$\times \left[\frac{1}{r_b}\left(\frac{dc(r)}{dr}\right)_b - \frac{1}{r_m}\left(\frac{dc(r)}{dr}\right)_m\right] \qquad (13)$$

Equations (12) and (13) yield average molar masses for the whole cell and no local values. A significant disadvantage of this evaluation is that it completely relies on the correct determination of the concentration at the meniscus and the cell bottom where there might be considerable uncertainty. Furthermore, the obtained molar masses can be strongly influenced by impurities being much smaller (c_m influenced) or larger (c_b influenced) than the sample due to the evaluation of a whole-cell average molar mass.

3.2.2. Fitting Concentration Gradients to a Model

An approach for the analysis of sedimentation equilibrium data greatly facilitated by cheap and commonly available computers is the fit of the radial equilibrium concentration gradient to a theoretical model using nonlinear least squares analysis [61, 62]. This approach is highly popular today, and a whole variety of programs is available for this purpose, commercial as well as public-domain software [61, 63]. Furthermore, such fitting routines can easily be set up on commercial software platforms, offering freely definable functions for the curve-fitting process. In general, the radial equilibrium concentration gradient in the ultracentrifuge is described as the exponential form of (9) for a single-ideal component, as a modified exponential equation in the case of nonideality [see Eq. (14)], or as a sum of exponentials for different components in a mixture or in an interacting system [see Eq. (15)]. For a nonideal one-component system, the radial concentration gradient $c(r)$ can be described by

$$c(r) = c(r_{ref})\exp\left(\frac{\omega^2}{2RT}M(1-\bar{v}\rho)(r^2 - r_{ref}^2)\right.$$
$$\left. - A_2 M(c(r) - c(r_{ref}))\right) \qquad (14)$$

where r_{ref} is the chosen reference radius.

$$c(r) = c_{mon}(r_{ref})\exp\left(\frac{\omega^2}{2RT}M_{mon}(1-\bar{v}\rho)(r^2 - r_{ref}^2)\right)$$
$$+ c_{mon}(r_{ref})^{n_2}K_2\exp\left(\frac{\omega^2}{2RT}n_2 M_{mon}(1-\bar{v}\rho)(r^2 - r_{ref}^2)\right)$$
$$+ \cdots + c_{mon}(r_{ref})^{n_i}$$
$$\times K_i\exp\left(\frac{\omega^2}{2RT}n_i M_{mon}(1-\bar{v}\rho)(r^2 - r_{ref}^2)\right) \qquad (15)$$

For an ideal self-associating system of the type n monomer $\rightarrow$ n-mer with $K = c(n\text{-mer})/c(\text{monomer})^n$, the first two exponentials in (15) can be used as a fitting function, whereas for a more complicated self-associating system with several n-mers, the sum of the exponentials in the form of (15) can be applied. By such an approach, the quantitative determination of the association constant(s), stoichiometries, and second virial coefficients for self-associating systems is possible [64–69].

One can think of many more models for a system that can be used to fit the experimentally detected radial concentration gradient. However, the case of a polydisperse and often highly nonideal system—colloid chemists are very often confronted with—is not yet covered by a model in the commonly available programs. Therefore, in this case, the models for a monodisperse system must be applied knowing

that the obtained values for the polydisperse system are only averages.

Very often, a baseline absorbance that originates from nonsedimenting but light-absorbing material is used as a fitting parameter for data derived from absorption optics just by adding a variable to the right-hand side of (14) and (15). This can have an enormous influence on the results and extreme care has to be taken when allowing the baseline absorbance to be a fitting variable. Wherever possible, one should determine the baseline absorbance using the so-called overspeeding technique where the sample is sedimented to the cell base, leaving only the nonsedimenting material behind. If the Rayleigh interference optics is applied, which yields interference fringe shifts relative to the meniscus, it is recommended to apply synthetic boundary experiments in order to determine the fringe shifts at the meniscus for low-speed equilibrium experiments [70]. Another possibility is to use the so-called high-speed equilibrium technique, which applies such high speeds that the meniscus is cleared of the sample, leaving an exponential radial concentration gradient. Whereas this technique works well for relatively monodisperse samples, in highly polydisperse systems the high-molecular-weight material has sedimented to the cell bottom already and is thus lost for detection, resulting in a molar mass that is found to be too low.

The advantage of fitting the radial equilibrium concentration gradient to a model is that the experimental data can directly be analyzed without differentiation, an operation that amplifies experimental noise. Furthermore, multiple data sets can be fitted to one model, allowing for an analysis with better statistical significance. On the other hand, a possible danger of every fitting process that the least squares fit just corresponds to a side minimum can become serious even if the fitted curve well describes the experimental data. The fact that sums of exponentials have to be used for the analysis of the equilibrium concentration gradient limits the analysis of multicomponent systems considerably to three or four components [71] because the fitting parameters of the exponentials are badly determined by the data. A further serious disadvantage is that a model has to be known prior to the fitting process; that is, one must already have information about the system from other sources. However, one does not often know anything about the sample under investigation. In such cases, several models can lead to answers of similar accuracy from the statistical viewpoint. This requires either other independent techniques to seek more information or applying model-independent approaches such as the M^* function (see below) or an evaluation using a classical approach to learn something about the system of interest prior to fitting.

3.2.3. Model-Independent Approaches

There are two main model-independent approaches to evaluate sedimentation equilibrium data. The first one is the so called M^* function [72] defined as

$$M^*(r) = \frac{c(r) - c_{\mathrm{m}}}{\Phi c_{\mathrm{m}}(r^2 - r_{\mathrm{m}}^2) + 2\Phi \int_{r_{\mathrm{m}}}^r r[c(r) - c_{\mathrm{m}}]\, dr} \quad \text{with}$$

$$\Phi = \frac{(1 - \bar{v}\rho)\omega^2}{2RT} \tag{16}$$

The most useful property of the M^* function is that it equals $M_{\mathrm{w, app}}$ at the cell bottom. This means that one can get a cell average molar mass by extrapolating $M^*(r)$ to r_{b}. The M^* function has been combined with the classical evaluation according to (9) in evaluation algorithms [73, 74] to yield the whole-cell average $M_{\mathrm{w, app}}$ via $M^*(r)$ as well as the local $M_{\mathrm{w, app}}(r)$ via (9) to allow detailed insight into the kind of system under investigation besides the evaluation of $M_{\mathrm{w, app}}$. Afterwards, the selection of a model for fitting the radial concentration gradient should lead to realistic results in coincidence with those already derived for $M_{\mathrm{w, app}}$, allowing more detailed insight into the system under consideration (e.g., concentration of different components in a mixture, equilibrium constants of interacting systems, etc.).

The second model-independent approach—the Ω function [75, 76] or (in a recently derived form) ψ function [77]—is particularly well suited for interacting systems. The Ω function is a transformed type of the concentration distribution at sedimentation equilibrium:

$$\Omega_i(r) = \frac{c(r)}{c(r_{\mathrm{ref}})} \exp\left[\frac{(1 - \bar{v}_i\rho)\omega^2}{2RT} M_i(r_{\mathrm{ref}}^2 - r^2) \right]$$

$$= \frac{a_i(r_{\mathrm{ref}})c(r)}{a_i(r)c(r_{\mathrm{ref}})} \tag{17}$$

where M_i is the molar mass of the smallest sedimenting species i (1 in the beginning of the evaluation). M_i usually has to be determined in a separate experiment using routines like MSTAR [74]. a_i is the thermodynamic activity of the smallest sedimenting species i equal to the concentration in the ideal case. If $\Omega_i(r)$ is plotted vs. $c(r)$, the intercept (or, realistically, the extrapolated intercept) equals the ratio of $a_i(r_{\mathrm{ref}})/c(r_{\mathrm{ref}})$, where $c(r_{\mathrm{ref}})$ is known from the experimental data. The activity/concentration at the reference radius then allows for the calculation of the concentration gradient using the integrated form of (9) [see also (14) or (15) in the form for an ideal noninteracting one-component species]. Then, a revised radial concentration gradient $[c(r) - c_i(r)]$ can be calculated, and the analysis is repeated for the next smaller sedimenting component. This unraveling of the total concentration gradient into those of the individual components is illustrated in Figure 7.

From the concentration gradients of the individual species, one can calculate the equilibrium constants. The elegance of this model-independent approach is that it avoids any differentiation/integration, the former being especially sensitive to the amplification of experimental noise. Furthermore, it allows for the calculation of activity distributions, giving a rigorous thermodynamic treatment of nonideal systems. However, one difficulty is still the curvature in the $\Omega(r)$ vs. $c(r)$ plots, especially for low $c(r)$, which are important for the extrapolation to infinite dilution to give the correct intercept (see Fig. 7a). Therefore, the Ω function was modified giving the ψ function [77], which shows a much better linearity when plotted as $c(r)/\psi_i(r)$ (y axis) versus ψ_{i+1}/ψ_i on the x axis and thus allows a safer determination of the intercept and $c_i(r_{\mathrm{ref}})$, where $\psi_i(r)$ is defined as

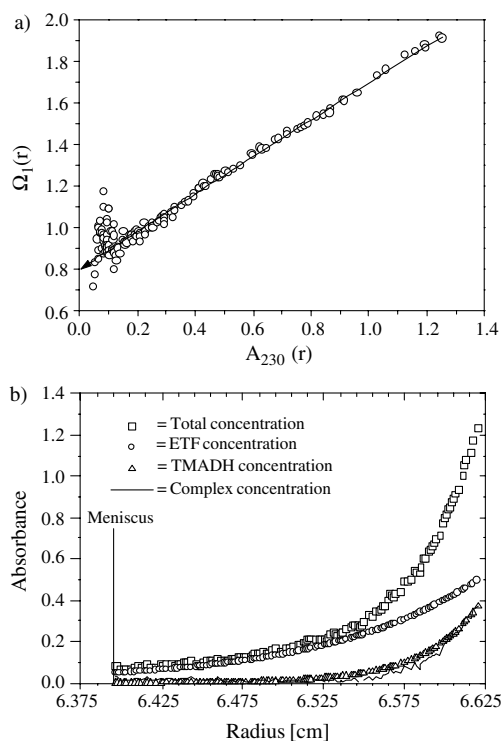
$$\psi_i(r) = \exp\left[\frac{(1 - \bar{v}_i\rho)\omega^2}{2RT} M_i(r^2 - r_{\mathrm{ref}}^2) \right] \tag{18}$$


Figure 7. Interacting system between trimethylamine dehydrogenase (TMADH) and the corresponding electron transfer flavoprotein (ETF): (a) shows the Ω function for ETF in relation to the concentration in absorbance units to demonstrate a typical example; (b) shows the individual concentration gradients of all components in the mixture which allow the calculation of interaction constants for each set of corresponding data points.

Then, the calculation of the concentration distribution of i can be performed using $c_i(r) = c_i(r_{ref})\psi_i(r)$ and the analysis is repeated for the next smaller sedimenting species. This evaluation was recently implemented in a computer program [78]. Such analysis is especially useful if nothing is known about the kind of interaction taking place in a complicated mixture (homogeneous or heterogeneous interaction) and in which several components are involved [79]. If the interaction is found to be homogeneous, the total concentration gradient $c(r)$ can be fitted to simple polynomials of $c_1(r)$ of the form

$$c(r) = c_1(r) + K_2[c_1(r)]^2 + K_3[c_1(r)]^3 + \cdots \quad \text{or}$$

$$c(r) = c_1(r) + K_n[c_1(r)]^n \quad \text{for monomer} \rightarrow \text{n-mer} \quad (19)$$

This allows for the analysis of complicated self-associations with a general polynomial fit or of monomer $\rightarrow$ n-mer interactions using the second part of (19).

The Ω resp. ψ function has several other useful features. One is a sensitive diagnostic test for the discrimination between polydispersity and self-association. If $\Omega(r)$ is plotted for different cell-loading concentrations but a common $c(r_{ref})$, the plots will be superimposed in the case of self-associating systems, whereas they will not be superimposed in the case of a polydisperse or impure system. This test is more sensitive than the commonly applied plot of $M_{w, app}(r)$ vs. $c(r)$ for different cell-loading concentrations [80].

3.3. Density Gradient Experiment

The second principal possibility of separation in an analytical ultracentrifuge is the separation due to the chemical structure expressed in different solute densities in a density gradient. To generate a continuous density gradient in the ultracentrifuge cell, either a high-density salt (CsCl, etc.) or a substance like sucrose is dissolved in water or a mixture of two organic solvents with very different densities is applied. Under the action of the centrifugal field, the salt or the more dense solvent sediments toward the cell bottom and thus changes the density of the solution continuously toward the cell bottom. If a sample is placed into the density gradient, it will sediment/float to a position where its density matches that of the gradient. In the case of a mixture, this leads to a banding of the components due to their chemical structure/density. The range of densities that can be covered using density gradients is limited (0.8–2.0 g/mL) [14] but sufficient for the separation of purely polymeric substances. However, inorganic or organic–inorganic hybrid colloids have a density that is, in most cases, too high for the successful application of a density gradient. Also, the high salt concentrations in aqueous density gradients may be a problem for the analysis of electrostatically stabilized colloids. Furthermore, these so-called static density gradient experiments take a long time, usually on the order of several days (see Fig. 8), due to the slow banding of the sample. Also, potential solvent binding of the sample in a density gradient may be a problem. Nevertheless, density gradients are an excellent tool for the investigation of structural differences in mixtures and have especially proven to be an invaluable tool for the analysis of polymer latexes [14].

The separation capabilities of a static density gradient are demonstrated in Figure 8 for the separation of a mixture of an acrylonitrile–vinylacetate copolymer in a DMF/CHBr$_3$
Figure 8. Static analytical density gradient. (a) Banding of a sample in a density gradient observed with Schlieren optics (upper) or absorption/Rayleigh interference optics (lower) at different times. (b) Acrylonitrile-vinylacetate copolymer in a DMF/CHBr$_3$ (136 g/L) density gradient after 35 h at 33,450 rpm. Fractions 1 and 2 are separated already. (c) After 108 h at 33,450 rpm (equilibrium). Figure adapted with permission from [81], R. Buchdahl et al., *J. Polym. Sci.*, Part C 1, 143 (1963). © 1963, John Wiley.

density gradient. The sample consists of three fractions that could be successfully separated: (1) linear polymer (0.5×10^6 g/mol, $\rho = 1.0347$ g/mL), (2) highly branched polymer (25×10^6 g/mol, $\rho = 1.0365$ g/mL), and (3) weakly cross-linked polymer (75×10^6 g/moL, $\rho = 1.0371$ g/mL). If one looks at the densities of the separated components, one sees that the resolution of the separation is in the fourth digit of the density.

Much of the theory for the analysis of analytical density gradient experiments was established in the classical papers of Meselson, Hermans and Ende [82–85]. However, the Hermans–Ende equation was restricted to ideal systems, which can result in serious errors in the calculation of the radial density profile. Therefore, it was recently improved for real systems [86–88]. The basic equations that allow for the calculation of the density of the gradient at every point in the ultracentrifuge cell can be found in these references. From the width σ of the Gaussian concentration profile of the sample, the molar mass can be calculated [82]. The accuracy is much smaller, however, than that of the molar mass derived by sedimentation equilibrium experiments so that it can realistically only serve as an estimate.

The disadvantage of the prolonged experimental times for static density gradient experiments can be overcome by using the so-called dynamic density gradients [89, 90]. Here, a layer of H_2O is usually layered upon D_2O in a synthetic boundary experiment (see the corresponding section for details of this technique) establishing the fast formation of a dynamic H_2O/D_2O density gradient within a few minutes. Although the density range of this type of gradient is rather limited (1.0–1.1 g/mL), it is well suited for the fast characterization of latexes—especially polystyrene—and can be extended to 0.85–1.25 g/mL under certain circumstances [89]. An example is given in Figure 9 where an 11-component latex mixture with different densities is subjected to an H_2O/D_2O density gradient. As five latexes have a density in the density range between H_2O and D_2O, the gradient selectively separates these components, whereas the other six components are not detected although their density is partly quite close to the solvent. This example illustrates how fast information on the structural composition of a mixture can be derived. After only 2 min of centrifugation, four of the five latexes are already separated; after 4 min, all

five components are separated; and the separation is further improved within the next 12 min. Therefore, dynamic density gradients are the fastest technique to learn about the structural heterogeneity of mixtures as long as the particles have densities in the limited range for this type of density gradient.

3.4. Synthetic Boundary Experiment

In a synthetic boundary experiment, changes of a boundary between solution and solvent with time are observed at low centrifugal fields where no sedimentation of the sample occurs. Such experiments require special cells where the solvent is layered upon the solution column under the action of a certain centrifugal field. This is achieved by capillaries that connect the solvent compartment with the solution compartment and that allow a flow at a certain hydrostatic pressure. At $t = 0$, a sharp boundary comparable

Figure 9. Formation of a dynamic H_2O/D_2O density gradient with a mixture of 11 different ethyl hexylacrylate/methylacrylate (EHA/MA) copolymer lattices that have been polymerized separately (w[MA] = 0/10/20/30/40/50/60/70/80/90/100 wt%). All particles had approximately the same diameter of 200 nm and exhibit the following densities: 0.980/1.000/1.021/1.043/1.066/1.089/1.114/1.167/1.196/1.225/1.140 g/mL. Just five of these are in the density range between 0.997 (pure H_2O) and 1.095 g/mL (pure D_2O). Run conditions: 40,000 rpm, 25 °C. (a) 2 min, (b) 4 min, and (c) 16 min. to the meniscus is obtained (see Fig. 10b). Within seconds, this boundary spreads by diffusion according to Fick's law due to the high concentration gradient at the boundary. The spreading of the boundary with time is monitored (see Fig. 10b and c). Now the plateau concentration of the upper plateau c_P as well as (dc/dr) at the boundary position can be determined. A plot of $(c_P/(dc/dr))^2$ vs. time yields a line with a slope equal to $4\pi D$. It is also possible to derive the dependence of D on the polymer concentration in a single synthetic boundary experiment [92]. A pseudo synthetic boundary experiment can be constructed from a normal sedimentation velocity experiment if $G(s)$ is obtained by the van Holde–Weischet method and subtracted from the experimental scans at various times [93]. This has the advantage that any layering imperfections that can occur in a conventional synthetic boundary experiment are avoided and, furthermore, samples that sediment at even the low speeds of a conventional synthetic boundary experiment can be investigated. However, compared to dynamic light scattering, a synthetic boundary experiment is more tedious and time consuming for the determination of the particle diffusion coefficient, so that, here, dynamic light scattering is the method of choice. Nevertheless, if aggregates are present in a sample, the light-scattering results can be seriously obstructed, whereas the synthetic boundary experiment will be unaffected as the aggregates will sediment even at the low applied speeds.

4. ANALYSIS OF NANOPARTICLES

There are numerous examples of information derived by one of the four basic experiments or combinations thereof using an ultracentrifuge. They cannot be treated completely here, but the selected applications will show that analytical ultracentrifugation is a universal absolute technique for the characterization of polymers or colloids, especially in mixtures. The examples given here have been chosen in such a way that the range of information obtained by AUC is as broad as possible and the emphasis of the selected examples is more on the methods of how to derive information on a nanoparticle system by AUC rather than on how precisely this information can be obtained for a specific nanoparticle system. At the end of this section, a table is presented which will give the reader an overview of the primary literature for specific systems.

4.1. Particle Size Distributions

The application of analytical ultracentrifugation for the determination of particle sizes and their distributions to address problems of colloid analysis was already realized by the pioneers of this technique because sedimentation velocity experiments provide a sensitive fractionation due to particle sizes/molar masses [3, 94–96]. Nevertheless, it appears that the potential of this application is still not yet commonly recognized. It is relatively straightforward to convert a sedimentation coefficient distribution, which can be calculated using (1) for every data point (a) r_i (if a radial scan has been acquired at a specified time) or (b) t_i (if a concentration detection at a specified radius has been performed in dependence of time), to a particle size distribution. Assuming the

validity of Stokes' law (e.g., the sample is spherical), the following derivative of the Svedberg equation (2) is obtained

$$d_i = \sqrt{\frac{18\eta s_i}{\rho_2 - \rho}} \tag{20}$$

where d_i is the particle diameter corresponding to s_i, ρ_2 is the density of the *sedimenting* particle (including solvent/polymer, etc., adhering to the sample), and η is the solvent viscosity. If the particles are not spherical, only the hydrodynamically equivalent diameter is obtained unless form factors are applied if the axial ratio of the particles is known from other sources such as transmission electron microscopy (TEM).

The conversion of a sedimentation coefficient distribution to a particle size distribution highly relies on the knowledge of the density of the sedimenting particle. For hybrid particles or very small nanoparticles less than 5 nm, this issue can be a severe problem, especially in the case of mixtures, as the density of the particles is usually not known. Measurements of the average particle density in the mixture can lead to erroneous results so that in such cases the correlation of the sedimentation coefficient distribution with a distribution obtained from a density-insensitive method such as flow–field–flow fractionation or dynamic light scattering is meaningful. This can, in turn, yield the particle density, which can give information about the relative amount of materials building up the hybrid particle [97]. But even an apparent particle size distribution that is calculated within the limits of reasonable particle densities can already yield very valuable information [98].

However, in the case of industrially important latexes, the particle density is usually exactly known from the chemistry of particle formation/polymerization. Thus, the determination of particle size distributions with the analytical ultracentrifuge is a rapid technique providing a high statistical accuracy (e.g., every sedimenting particle is detected) in contrast to transmission electron microscopy (TEM), which delivers information about the particle shape but often suffers from drying artifacts. Determination of a particle size distribution from TEM images requires counting hundreds/thousands of particles. This problem has only partly been diminished by the advent of commercially available picture evaluation algorithms. A recent test dedicated to particle size analysis by the Bayer group in 17 laboratories, confirmed the view that TEM and/or analytical ultracentrifugation are the best techniques for the determination of particle size distributions [99] as discussed above. A combination of TEM, AUC, and X-ray diffraction techniques can provide a complete insight into a colloidal system [100]. Analytical ultracentrifugation in combination with electron microscopy in its various forms can be considered the most powerful characterization approach for particle size distributions and particle morphologies known to date. The following examples illustrate the fractionation power of the analytical ultracentrifuge for latexes [14, 101, 102] (see Fig. 11a) and especially for inorganic colloids [103].

In the case of latexes, the accessible size range is between 10 and 5000 nm with a baseline resolution for monodisperse components differing just by 10% in diameter [105], whereas for inorganic colloids, analytical ultracentrifugation separates dispersions with an almost atomar resolution. The

smallest reported species that could be detected was a ZrO_2 precursor just 0.4 nm in diameter [98], which shows the potential of the analytical ultracentrifuge for the analysis of the smallest nanoparticles or subcritical complexes. This means that particle size distributions derived by ultracentrifugation can well be used to investigate particle growth mechanisms [98, 103] from its initial stages/the critical crystal nucleus, especially if the growth is slow enough to detect time-dependent particle growth as in the example of ZnO (see Fig. 11c) [103, 104].

For very small particles, diffusion becomes significant so that it must be corrected. This is possible by extrapolation to infinite time, but, recently, another method was suggested which is based on the calculation of the diffusion coefficient from the particle size [106]. From this, the diffusion broadening of the sedimenting boundary can be calculated and subtracted from the measured concentration distribution, giving the diffusion-corrected particle size distribution. This procedure works best for monomodal and relatively narrow distributions, whereas it becomes less accurate for broad and/or multimodal distributions. An alternative is the diffusion correction of the sedimentation coefficient distribution by fitting the experimental concentration profiles to approximate solutions of the Lamm equation [51].

Another substance class rapidly gaining importance is the hybrid colloids between polymers and inorganic matter. Here, analytical ultracentrifugation shows all its merits for the investigation of transformations, aggregation processes, and so on. For example, the encapsulation of a molybdenum cluster with a surfactant could be characterized as well as the aggregation of the primary clusters in different solvents with high resolution [107]. An example of monitoring a restructuring process of a complex hybrid colloid in solution is given in Figure 12. Here, calcium phosphate was synthesized within functional polymeric aggregates so that a very unusual neuron-like crystal morphology was obtained within the polymeric aggregates. This neuron-like morphology is slowly transformed into a more compact spherical structure (see photos from left to right), which could be monitored by analytical ultracentrifugation so that the relative proportions of each species could be determined [108]. Since the
Figure 12. Transformation of "neuron-like" calcium phosphate into a more compact spherical form and the time-resolved observation of this process by analytical ultracentrifugation. particle density is not known, only the consideration of the sedimentation coefficient distributions makes sense.

From the sedimentation coefficient distributions, the whisker structure is evident in the species with the lower sedimentation coefficient, whereas the dense spherical structure can be identified by its high sedimentation coefficients. The formation of the dense species has a clear maximum before its amount decreases again due to macroscopic precipitation. The observation of such transformation in solution enhances the visual information from TEM and shows the potential of ultracentrifuge experiments combined with a TEM investigation.

A combined particle size and density gradient analysis is a powerful tool for the analysis of very complex mixtures where the particle sizes as well as the densities of the components are different. This is illustrated in Figure 13. Here, a mixture of four different polybutylacrylate (PBA) latexes was grafted with a styrene/acrylonitrile (SAN) copolymer which has a higher density than PBA [14].

In the density gradient, the four grafted particles are clearly resolved, indicating that the degree of grafting is different for every particle size. From the particle size distributions of the ungrafted and grafted PBA particles, it becomes obvious that the mass fraction of the smaller particles increases after grafting. This allows the conclusion that the amount of grafting is proportional to the particle surface.

Another possibility for obtaining the density of unknown particles is to run two velocity experiments in chemically similar solvents with different densities (e.g., H_2O/D_2O) [101, 109]. This allows us to simultaneously determine particle sizes and density distributions. The method works best for particles with densities less than 1.5 g/mL but requires

rather good data quality. Recently, a diffusion correction has been implemented into this method, which is especially important for small particles/molecules so that even complex mixtures become accessible by this method [110].

4.2. Characterization of Emulsions

In analogy to dispersions, emulsions, respectively mini- or microemulsions, can be characterized by the particle size distribution of the dispersed phase if flat centerpieces are used which permit the passage of light to the detector through the turbid emulsion as the emulsion cannot be diluted in contrast to a dispersion. One such example was reported for water/AOT/heptane water in oil microemulsions [111]. Furthermore, it is possible to force the coalescence of the emulsion by the ultracentrifugal field which can easily be detected as the formation of a new phase by any optical detection system of the ultracentrifuge. This is a fast and effective measure to look at the stability of emulsions in a qualitative way by determining either the centrifugal field necessary for spontaneous coalescence or the time until coalescence occurs at a given centrifugal field [112–114]. From experimental parameters such as the rotational speed and density, a coalescence pressure can be calculated as a more quantitative measure [112].

4.3. Characterization of Microgels

The analytical ultracentrifuge has proved to be very useful for characterization of the thermodynamic and elastic properties of gels and microgels as reviewed in [115, 116]. In the case of microgels in a thermodynamically good solvent, the degree of swelling Q can be determined from sedimentation velocity experiments [117]. If the microgel contains un-cross-linked polymer, two components are resolved in the sedimentation coefficient distribution calculated via (1). From $G(s)$ (see Fig. 14), the amount of each component can be

Figure 13. Particle size distribution and density gradient of a four-modal ungrafted and a SAN-grafted PBA dispersion (40 : 30 : 20 : 10 wt% mixture). D refers to the particle diameter; the index $0i$ to ungrafted and i to the grafted latex. Reprinted with permission from [17], W. Mächtle, "Analytical Ultracentrifugation in Biochemistry and Polymer Science," p. 147, Royal Society of Chemistry, Cambridge, UK, 1992. © 1992, Royal Society of Chemistry.

Figure 14. Sedimentation coefficient distributions for lattices with different degrees of cross-linking. Reprinted with permission from [117], H. G. Müller et al., *Prog. Colloid Polym. Sci.* 86, 70 (1991). © 1991, Springer-Verlag.

derived. The swelling degree Q can then be calculated using

$$Q = \frac{bd^2}{s} - \frac{\rho_2 - \rho}{18\eta} \quad (21)$$

where d is the diameter of the compact, unswollen particle, ρ_2 is the density of the compact, unswollen particle, ρ is the density of the dispersion medium, and η is the viscosity of the diluted dispersion. b is a factor according to $m_r = b \cdot m$ where the mass of the particle m_r reduced by the soluble part is related to the mass m of the particle consisting of soluble and insoluble components. It can be derived from interference optical traces.

The particle diameter of the unswollen sample has to be determined in a nonsolvent in a separate experiment. The swelling degree can be related to the molar mass of the elastically effective network chains and thus to the elastic properties of the microgel applying the Flory–Rehner theory. Such experiments not only allow the characterization of microgels but can furthermore be used to investigate the efficiency of cross-linking reactions by specifying the amount and physicochemical properties of the un-cross-linked polymer [118]. Figure 14 shows the sedimentation coefficient distributions that are derived for different cross-linking degrees of latexes. One can now easily compare samples from different cross-linking reactions.

4.4. Observation of Chemical Reactions

It is possible to perform chemical reactions in the analytical ultracentrifuge with a synthetic boundary experiment using a special cell (see Fig. 15a). In biochemistry, this kind of centrifugation is called "active enzyme centrifugation" [119], but the principle can be applied to every chemical reaction. In the synthetic boundary cell (Fig. 15a), a small amount
of a reactant (usually 10–15 μL) is layered onto a column of the second reactant while the centrifuge is speeded up to about 3000 rpm. Thus, a reaction boundary is established. The detection wavelength of the absorption optics is set to a wavelength where the reaction product (here the enzyme–substrate complex) absorbs. One can then observe the product formation and sedimentation as visualized in Figure 15b. The absorbance increases with the time of sedimentation, indicating that the sedimenting enzyme is reacting continuously. Such experiments can yield sedimentation and diffusion coefficients of the enzyme in its catalytically active state which enables detection of differences in polymerization state, hydration, or conformation with the nonreacting enzyme. If the extinction coefficient of the reaction product is known, the product concentration in relation to time can be calculated. Figure 15c shows that a slight change in pH can turn the enzyme to its inactive state. An advantage of the application of synthetic boundary cells of the type shown in Figure 15a is that only a few microliters corresponding to a few micrograms/nanograms of reactant are required.

This type of synthetic boundary experiment was recently adapted to carry out crystallization reactions inside the spinning cell of the ultracentrifuge and was named "synthetic boundary crystallization ultracentrifugation" [120, 121]. Here, a small amount of Na_2S was layered upon a solution of $CdCl_2$ containing a stabilizer. A fast reaction to CdS with subsequent stabilization of the small nanoparticles takes place according to the scheme shown in Figure 16. [121].

The advantages of this technique lie in the fast chemical reaction within the very small reaction zone and the quenching of additional particle growth in lack of the second reaction partner as soon as the particles move out of the reaction zone by sedimentation or diffusion processes. These particles are then fractionated according to their size and density and a particle size distribution can be determined as discussed above. However, as the formed nanoparticles are very small, they show significant diffusion so that they can diffuse back into the reaction boundary and grow further, thus forming the second growth generation of particles. This process is repeated until the reaction partner in the reaction zone is used up (which usually occurs within a few minutes), so that the particles only sediment due to their size/density with the usual diffusion broadening of the boundary. By this technique, different growth stages of nanoparticles can be

Figure 15. (a) Synthetic boundary cell with small sample compartments. (b) Sedimentation velocity profile of a glutamate dehydrogenase mutant enzyme which reacts with its substrate. (c) Sedimentation velocity profile of the same enzyme at a different pH. The enzyme is now inactive and no chemical reaction takes place.
Figure 16. Schematic representation of synthetic boundary crystallization ultracentrifugation.

investigated. However, due to the extensive diffusion of the particles, the individual particle size distributions become extensively smeared so that they are only detected as a continuous distribution. Nevertheless, even such data can show the different stabilizer capabilities with a resolution in the Angström range as shown for CdS in Figure 17 [120, 121].

Another elegant way to observe reactions with a synthetic boundary technique was introduced by Wandrey and Bartkowiak [122]. They were able to observe the formation of polyelectrolyte complex membranes between two oppositely charged polyelectrolytes and the influence of parameters such as pH, ionic strength, component ratio, and temperature. Also, the membrane formation kinetics could be detected as overlaying of the two polymer solutions resulted in the formation of a thin membrane at the solution interface which could be precisely detected and its thickness measured.

4.5. Determination of Sample Homogeneity, Efficiency of Chemical Reactions, and Determination of Extinction Coefficients

In many fields of polymer or colloid chemistry, complicated complexes or hybrid colloids are synthesized. It is often desirable to have a quick and convenient check for the efficiency of the reaction as well as a check of sample homogeneity. Sedimentation velocity experiments can be used very advantageously here due to the fractionation without any stationary phase as is demonstrated for the case of iron oxyhydroxide particles partly stabilized in a self-assembling microgel of κ-carrageenan (Fig. 18) [123]. If one component selectively absorbs light (FeOOH) and the second does not (κ-carrageenan), one can selectively detect the absorption of the iron oxide in the polymeric superstructures with absorption optics, whereas all components together are detected by the simultaneously used Rayleigh interference optics. Here it must be stated that most colored inorganic compounds have a high extinction coefficient and are thus almost exclusively detected in the UV/vis absorption optics, whereas
Figure 18. Iron oxyhydroxide in κ-carrageenan microgels. Detection of the different species by combination of UV/vis and refractive index detection. Reprinted with permission from [123], F. Jones et al., *Colloid Polym. Sci.* 278, 491 (2000). © 2000, Springer-Verlag.

the simultaneously applied interference optics almost exclusively represents the local polymer concentrations which can be converted to the real concentrations via the refractive index increment and the known refractive index of the solvent. From Figure 18, three species are clearly quantitatively detected: free unbound κ-carrageenan, κ-carrageenan + iron oxyhydroxide microgels, and larger cross-linked aggregates. The control of efficiencies of chemical reactions was also reported for complicated complexes between oppositely charged polyelectrolytes [124].

If the change in the refractive index of a sample (Rayleigh interference optics) is simultaneously detected with its absorption at a specified wavelength, extinction coefficients can be determined [125]. This is not particularly interesting if a single component is considered, but for mixtures the analytical ultracentrifuge is often the only method capable of determining the extinction coefficient of a specified component in a complicated mixture. The extinction coefficient can be calculated from a concentration reading in the Rayleigh interference scan which must be converted to the concentration unit of desire using the refractive index increment and the corresponding absorption. Figure 19 demonstrates this for ZnO prepared in polystyrene–polymethacrylic acid (PS–PMAA) micelles.

An extinction coefficient based on an absorption reading taken in a spectrophotometer under the assumption that all Zn^{2+} have reacted to ZnO delivers a low extinction coefficient of less than 1000 L mol^{-1} cm^{-1} due to the majority of UV/vis inactive species. Therefore, it is of interest to detect which amount of the sample is the spectroscopically active ZnO. Figure 19a shows the results and confirms that only a minor amount of the mixture is responsible for the detected light absorption. From the interference scans in Figure 19a, it can be seen that the component with a similar sedimentation velocity as the ZnO-filled micelles detected by the corresponding UV-absorption scans has only a concentration of 0.18 fringes. The major part is a considerably slower sedimenting component (micelles with unreacted Zn^{2+}). A third component (polymer or empty micelles) is also detected.

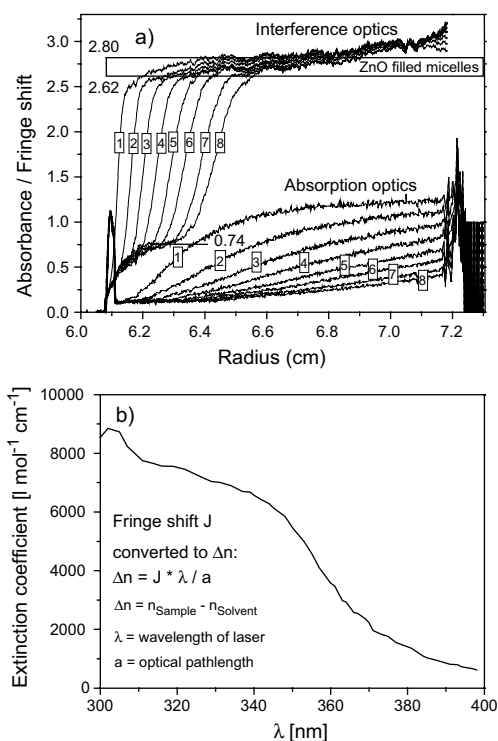

Figure 19. Determination of the extinction coefficient of ZnO in PS–PMAA micelles [104]. (a) Sedimentation velocity profiles acquired simultaneously with Rayleigh interference and absorption optics (315 nm). Run parameters: 20,000 rpm, scan interval 2 min. The numbers represent the corresponding interference and absorption scans. (b) Wavelength dependence of the extinction coefficient for ZnO prepared in PS–PMAA micelles. The particle diameter of the ZnO (from TEM) is 3.2–6.7 nm. The diameter of the micelles (from light scattering) is 64.4 ± 33.9 nm. Reprinted with permission from [104], H. Cölfen et al., *Prog. Colloid Polym. Sci.* 107, 136 (1997). © 1997, Springer-Verlag.

The interference fringe shift of the ZnO-filled micelles can be converted to a concentration and this can be related to a spectrum of the ZnO in the ultracentrifuge cell, giving the wavelength dependence of the ZnO extinction coefficient (Fig. 19b). The extinction coefficient is found to reach about 9000 L mol^{-1} cm^{-1}. This illustrates how important the separation is to determine the spectral properties of the optically active component in a complicated mixture. Many more variations of such experiments are possible, showing that the separation capability of the AUC can be used not only to determine the concentrations of the individual compounds but also to elicit their spectral properties if they absorb light.

4.6. Analytical Ultracentrifugation of Nanoparticles Sorted by Systems

Table 2 gives some examples of nanoparticle systems that have been investigated by AUC with references to the original literature. The table is by no means exhaustive or representative and is just meant to guide the reader to the original literature if solutions for a particular nanoparticulate system are sought.

5. CURRENT TRENDS IN ANALYTICAL ULTRACENTRIFUGATION

The current trends in analytical ultracentrifugation can be divided into three subcategories: (a) improvement of data evaluation methodologies, (b) new detection systems, and (c) application of analytical ultracentrifugation to novel systems apart from the classical biomolecules.

5.1. Improvement of Data Evaluation Methodologies

Progress in computer and electronic technology has greatly facilitated the analysis capabilities of analytical ultracentrifugation and catalyzed the rebirth of this technique. Nowadays, it is relatively simple to apply fitting functions for all kinds of experimental output and, furthermore, it is possible to acquire data fast and conveniently even when simultaneously using several different methods of detection. Therefore, a major current trend in analytical ultracentrifugation is the development of better evaluation methodologies and algorithms. One example is the simultaneous radial and wavelength analysis of sedimentation equilibrium experiments possible with the Optima XL-I ultracentrifuge [153]. A complicated interacting system exhibiting three different chromophores and consisting of the Band3 membrane protein, a small ligand, oxyhemoglobin, and the complexes between these components—an 11-component system overall—could be successfully analyzed. These investigations are also applicable to complicated colloid mixtures. This amounts to seven more components than possible before when analyzing a concentration profile acquired at a single wavelength. The increase in components that can be resolved is achieved by the acquisition of as much experimental information as possible—in this case wavelength scans at different radii as well as radial scans at different wavelengths. From this information, it is possible to create a two-dimensional data surface in a radius–wavelength–absorption space which allows a proper analysis by fitting procedures. Therefore, it is not surprising that more and more scientists are using the capability of scanning at multiple wavelengths [154, 155]. A further enhancement of the data space is achieved by the application of several rotational speeds in the experiments. As this increases the experimental time, so-called short-column techniques [156, 157], which considerably decrease the time to reach the sedimentation equilibrium by the application of a shorter solution column in the ultracentrifuge cell, are becoming popular as long as the resolution of the optical system is still sufficient for the short solution column. However, for the mainly polydisperse nanoparticles, such an approach is restricted.

Significant effort has also been put into other efficient analyses of ultracentrifuge data which generally increases the sensitivity of ultracentrifuge experiments. Nowadays, components can be identified, which are almost not visible in the experimental raw data and thus could not be recognized in the old days of analytical ultracentrifugation. As the Rayleigh interference system of the XL-I ultracentrifuge allows a rapid acquisition of large data sets, the confidence intervals of fitting procedures in general can be

Table 2. Application of AUC to different nanoparticulate systems.

System	Experiment type/quantity	Ref.
Latex dispersions	Sedimentation velocity/particle size distribution; static and dynamic density gradient/particle density	Polystyrene [14]; polystyrene, polybutylacrylatestyrene, polybutadiene, polyethylacrylate [15]; polystyrene [16]; polystyrene, polybutylacrylate (also styrene and acrylonitrile grafted), polybutadiene, acrylic homopolymer and copolymer dispersions [17]; polychloropropene [96]; polystyrene, polystyrene/polybutadiene, polystyrene-co-butadiene, polychloropropene [99]; polystyrene, polystyrene-co-butadiene, styrene, and acrylonitrile grafted polybutadiene [101]; polystyrene [102]; polyurethane [105]; polystyrene [106]; polystyrene, polybutadiene, Polybutylacrylate-co-butadiene [109]
Inorganic nanoparticles	Sedimentation velocity/particle size distribution	Au [3]; Au [94]; ZrO_2 [98]; Au_{55} cluster [100]; Pt, ZnO [103]; ZnO, Au, CdS, Pt [104]; CdS [105]; silica [106]; β-FeOOH [109]; CdS [120]; CdS [121]; iron oxide [126]; surfactant-encapsulated $(NH_4)[H_3Mo_{57}V_6(NO)(6)O-183\ H_2O(18)]$ [127]
Inorganic complexes	Sedimentation equilibrium/molar mass	Zr complexes [55]; Zr complexes [56]
Magnetic fluids	Sedimentation velocity	Fe_3O_4 [128]; Fe_3O_4 [129]
Microgels	Sedimentation velocity/composition and density	Styrene-butadiene [117]; acrylic acid [118]; polystyrene-poly-4-vinylpyridine microgels [130]
Gels	Sedimentation velocity and equilibrium/ swelling degree and pressure, amount of soluble compounds	Gelatin, κ-carrageenan, agar, casein [116]; gelatin, κ-carrageenan, agar, casein [131]; other systems (reviews)
Emulsions	Sedimentation equilibrium	SDS-stabilized n-decane in water [112]; food emulsions [113]; Legumin-stabilized n-decane in water [114]; legumin-stabilized n-decane in water [132]
Supramolecular assemblies and polymers	Sedimentation equilibrium/molar mass, sedimentation velocity/particle size	Co-coordination arrays [133]; Co-coordination arrays [134]; Fe-coordination polymers [135]; Co-coordination arrays [136]
Polyelectrolyte complexes	Sedimentation velocity/particle size and composition, sedimentation equilibrium/ molar mass and interaction and membrane characteristics; synthetic boundary/ membrane formation	Alginate/chitosan [122]; polysyrenesulfonate/ polydiallyldimethylaminchlorid acrylamide [124]
Micelles	Sedimentation velocity/composition; dynamic density gradient/composition	Polymampholyte/fluorinated and hydrogenated dodecanoic acid [137]; lipid and detergent micelles [138]; review, different systems [139]; polystyrene-b-polyisoprene, polystyrene-b-poly(ethylene-co-propylene) [140]; polylactide-co-polyethyleneglycol [141]; enzymes in reverse micelles [142]
Dendrimers	Sedimentation velocity and sedimentation equilibrium/hydrodynamics	Carbohydrate-coated polypropyleneimine dendrimers [143]; lactosylated polyamidoamine dendrimers [144]
Hybrid colloids	Sedimentation velocity/composition/ particle size	Au/polystyrenesulfonate microgels, CdS or Au in polystyrene-b-poly-4-vinylpyridin micelles, Pt in polyethyleneoxide-polymethacrylic acid [104]; Calcium phosphates in alkylated polyethyleneoxide-b-polymethacrylic acid [108]; FeOOH, NiOOH, and CoOOH in κ-carrageenan microgels [123]; review of various systems [145]; CdS in reverse micelles [146]; Pt and Pd in polystyrene-b-polyethyleneoxide/ cetylpyridiniumchloride mixed micelles [147]; Au, Pt, and Pd in poly-2-vinylpyridine-b-polyethyleneoxide micelles [148]; Pt, Pd, Rh, and Cu in polyethyleneoxide-b-polyethyleneimine [149]
Organic colloids	Sedimentation equilibrium; sedimentation velocity/composition, molar mass	Cu-phtalocyanine [102]; κ-casein particles [150]; κ-casein particles [151]
Nanocapsules	Sedimentation velocity, density gradient/composition	Oil-filled polybutylcyanoacrylate nanocapsules [152]

significantly improved. However, the interference data contain time-invariant and radial-invariant noise components in addition to the random noise so that an efficient algebraic method was developed for the elimination of the time- and radial-invariant noise [158]. This leads to a high sensitivity of Rayleigh interference data even for such experiments where the sedimentation boundary can only barely be traced due to the noise components. The so-improved data sets can then be used for fitting to approximate analytical and numerical solutions of the Lamm equation. It is also possible to eliminate systematic noise components in the interference data of sedimentation equilibrium profiles by extraction of the time-invariant noise during the approach to equilibrium [159]. It turned out by this approach that the sensitivity of the Rayleigh interference optics for sedimentation equilibrium experiments can be improved by an order of magnitude so that equilibrium experiments with concentrations as low as 50 μg/mL are no problem for Rayleigh interference detection. Very recently, the described systematic noise decomposition method [158] has been applied for linear least squares modeling of the sedimenting boundary by a superposition of $g(s)$ of ideal nondiffusing components [160]. This approach turned out to be especially advantageous for data acquired during a large time interval so that, in such cases, an improved resolution could be achieved especially for heterogeneous mixtures. A very recent advance is the determination of molar mass distributions from the fitting of finite-element solutions of the Lamm equation (8) paired with regularization algorithms as discussed before [51]. However, the range of successful application still needs to be explored.

5.2. New Detection Systems for the XL-I Ultracentrifuge

Computer-based picture evaluation allows the on-line capture of Schlieren patterns, enabling the fast and efficient evaluation of these records, which previously had to be photographed [9, 10, 161, 162]. The on-line digitization and picture evaluation of these optical records rely on the proper detection of the zeroth-order Fresnel fringe, which is the detected Schlieren curve in Figure 2a. Either by means of picture manipulation performed in order to facilitate a proper detection of the Schlieren curve even with a nonuniformly illuminated picture or by additional consideration of higher order Fresnel fringes, the concentration gradient curve can be properly detected automatically. Especially with the system built at the University of Leicester/ Nottingham [10], high rates of data acquisition can be achieved with good data quality so that the on-line Schlieren system proves its virtues. This system is currently being adapted to the XL-I ultracentrifuge. Also, the Schlieren optics was set up on a preparative ultracentrifuge [12]. A potentially interesting optical system that should also be adaptable to XL ultracentrifuges is the Lebedev interferometer, which gives an interference pattern but with a Schlieren peak for a sedimenting boundary [163]. Therefore, the fast evaluation algorithms developed for the Rayleigh interferometer should be applicable here as well, resulting in high-quality Schlieren images.

Another system that is currently commercially available on the XL-I ultracentrifuge is the fluorescence detector developed by Schmidt and Riesner [13] and adapted to the XL-I by MacGregor and Laue [18]. These systems are designed to be simultaneously applicable with the present absorption and Rayleigh interference optics with the exception of the Schlieren optics, which uses the optical path of the interference optics. Further current approaches toward the faster detection of UV/vis data are under way in the laboratories of Laue and Cölfen [164].

5.3. Application of Analytical Ultracentrifugation to Novel Systems

Apart from biological systems, analytical ultracentrifugation is more and more being applied to complicated synthetic systems, for example, supramolecular assemblies and polymers [133–136], colloidal clusters [127], smallest colloids and their interactions with stabilizers [100, 120, 121, 127], synthetic polyelectrolytes [165–169] and complexes thereof [124], micelles [139–141], components inside micelles [142], dendrimers [143, 144], and hybrid colloids between organic and inorganic matter [108, 148, 149]. In most of these applications, advantage is taken of the simultaneous acquisition of Rayleigh interference and UV/vis absorption data. Insofar, it can be speculated how much a simultaneous application of additional detectors could yield further information and thus would open further applications. A visionary paper about future requirements in ultracentrifuge methodology and detection systems was published by Mächtle [170] more than 10 years ago, and it can at least be stated that the simultaneous application of as many detectors as possible as already realized in size exclusion chromatography is advantageous and will open up new applications for AUC.

6. AVAILABILITY OF FREE EVALUATION SOFTWARE

In general, most of the best evaluation software for analytical ultracentrifugation experiments is still free and shared among different user groups.

To download free evaluation software, one can use several offers: ftp://bbri.harvard.edu/dka200/anonymous/rasmb/spin/ at the Boston Biomedical Research Institute or http://www.cauma.uthscsa.edu/software at the University of Texas Center for Analytical Ultracentrifugation of Macromolecular Assemblies. At both sites, one can find a comprehensive collection of the freely available evaluation software.

Furthermore, there is a user group called RASMB (Reversible Associations in Structural and Molecular Biology), which is a discussion platform for the study of interacting systems and analytical ultracentrifugation. However, do not hesitate to be included on this list if you are not directly working in the field of biochemistry/biophysics as many general aspects of analytical ultracentrifugation are adressed on this discussion platform. To be included on the e-mail list, check out http://rasmb-email.bbri.org/mailman/ listinfo/rasmb. On the RASMB, there are further links to all relevant Internet sites related to AUC.

7. CONCLUSION

Analytical ultracentrifugation is one of the most universally applicable and variable physicochemical techniques for characterization of colloidal or polymeric systems in solution, dispersion, or emulsion. The power of analytical ultracentrifugation lies in the fractionation of the sample due to either the molar mass/size (sedimentation velocity/ sedimentation equilibrium) or the chemical structure (density gradient) in the solvent and therefore the possibility to measure distributions without the interaction with any stationary phase or solvent flows as occurs in current chromatographic techniques. Wherever information is sought for the individual components in a mixture, analytical ultracentrifugation is among the first techniques of choice. On the other hand, the sedimentation equilibrium is an equilibrium well described by thermodynamics. Thus, it is possible to derive information even on complicated or interacting systems on an absolute basis and without disturbing this equilibrium. There are many different physicochemical quantities that can be determined. However, simple investigations such as those of sample homogeneity can provide much information on a system. But a complete physicochemical characterization is also possible, often with information that cannot be obtained by other techniques. Similar to other analytical techniques, the rapid computer and electronics development of the past years was of benefit for analytical ultracentrifugation. This development provides many new applications, improved sensitivity of the experiments, and even the realization of evaluation approaches not possible so far. Briefly stated, not only has the amount of experimental data from an ultracentrifuge experiment been increased but also the amount of information. This has led to a resurgence of interest in this technique. Especially if multidetection systems can be realized on ultracentrifuge platforms, new dimensions of analytical information will be available from a single sedimentation velocity experiment. Therefore, a synergy between ultracentrifuge hardware and methodology development can be expected which will lead to an increasing number of applications.

In biochemistry/biophysics, analytical ultracentrifugation is once again gaining importance after a slowdown in the 1980s. The same trend is not unlikely for the field of polymer or colloid chemistry although so far many chemists are not yet aware of the potential of analytical ultracentrifugation.

GLOSSARY

Analytical ultracentrifugation Analytical observation of sedimentation processes at speeds up to 60000 RPM.

Density gradient Separation of a binary mixture to a continuous concentration and thus density gradient in the ultracentrifugal field.

Lamm equation The basic equation of analytical Ultracentrifugation which describes the transport process by sedimentation and diffusion in the centrifugal field.

Partial specific volume The volume change in ml if one gram of pure sample is added to an infinite amount of solvent.

Sedimentation coefficient Detected Sedimentation velocity normalized to gravitational force.

Sedimentation equilibrium experiment Particle sedimentation at moderate speed where sedimentation is balanced by counter diffusion to yield the absolute molar mass.

Sedimentation velocity experiment Particle sedimentation at very high speeds to determine the sedimentation coefficient.

Synthetic boundary experiment Overlaying of a solvent onto a solution to create a liquid interface.

RELATED LITERATURE

Although the primary literature cited above will give the reader an appropriate insight into the AUC analysis of nanoparticle systems, a selection of related literature follows which contains textbooks and books about recent AUC developments together with a short description. This is mainly for the reader who wants to learn more about AUC.

GENERAL TEXTBOOKS

There are several general books in the English language on analytical ultracentrifugation. All of them are quite out of date, but are nevertheless still useful both for the beginner and for the more experienced user if they are still available.

171. T. Svedberg and K. O. Pedersen, "The Ultracentrifuge." Clarendon, Oxford, 1940. The classical textbook about analytical ultracentrifugation still with much impact today.

172. H. K. Schachman, "Ultracentrifugation in Biochemistry." Academic Press, New York, 1959. A compact and useful book covering experimental and theoretical aspects.

172. C. H. Chervenka, "A Manual of Methods for the Analytical Ultracentrifuge." Spinco Division, Beckman Instruments, Palo Alto, CA, 1969. A very useful compilation of classical evaluation methods with examples.

173. T. J. Bowen and A. J. Rowe, "An Introduction to Ultracentrifugation." Wiley, London, 1970. An introduction for the beginner.

174. J. W. Williams, "Ultracentrifugation of Macromolecules." Academic Press, New York, 1972. A compilation of seminars covering polydisperse solute and self-associating systems in more detail.

175. H. Fujita, "Foundations of Ultracentrifugal Analysis." Wiley, New York, 1975. An exhaustive description of the mathematical theory behind analytical ultracentrifugation, not recommended for the beginner.

NEW BOOKS WITH RECENT DEVELOPMENTS

176. S. E. Harding, A. J. Rowe, and J. C. Horton, Eds., "Analytical Ultracentrifugation in Biochemistry and Polymer Science." Royal Society of Chemistry, Cambridge, UK, 1992. The most comprehensive modern book about analytical ultracentrifugation. A very good overview about methods and techniques of analytical ultracentrifugation and a valuable source of modern applications.

177. T. M. Schuster and T. M. Laue, Eds., "Modern Analytical Ultracentrifugation." Birkhäuser, Boston, 1994. A compilation of some modern trends in analytical ultracentrifugation.

CONTENTS

1. INTRODUCTION

The concept of a new class of materials with an ultrafine grain structure possessing unique properties was first introduced by Gleiter [1] about two decades ago. Originally referred to as "interfacial materials," the main characteristic of these materials is the enhanced volume fraction of their interface component (i.e., grain boundaries, triple junctions, quadruple nodes [2, 3]) compared with their polycrystalline counterpart as a consequence of the ultrafine grain structure. With the large proportion of atoms located at interfacial regions, it was suggested that the atomic and electronic structures of such a material might be different from the structures found in compositionally equivalent material in the amorphous or polycrystalline states. Today these materials are referred to as nanocrystalline or nanostructured materials and are generally defined as materials with a characteristic length scale (e.g., grain size, particle size, film thickness, structure size) less than 100 nm. In the case of bulk nanostructured materials this length scale is the grain size. In recent years, bulk nanostructured materials have generated much excitement in the scientific community due to the many enhanced properties associated with the nanoscale grain structure, which have led to many new industrial applications.

Many synthesis techniques have been developed over the past 20 years to produce bulk nanostructured materials, including: physical and chemical vapor phase processing, mechanical attrition, consolidation of nanophase powders, crystallization of amorphous precursors, as well as chemical and electrochemical methods (e.g., [4, 5]). A common feature of most synthesis techniques is that they operate far from equilibrium conditions to favor nucleation of new grains and reduce growth of existing grains, thus promoting a nanocrystalline grain structure. Unlike many other synthesis techniques, electrodeposition is a single-step process that produces fully dense material without the need for secondary consolidation of powders or annealing of amorphous precursors. The focus of this chapter presented here is on electrodeposited nanostructures.

Over the past decade, electrodeposited nanostructures have advanced rapidly to commercial application because of the following factors: (1) an established industrial infrastructure (i.e., electroplating and electroforming industries), (2) a relatively low cost of application whereby nanomaterials can be produced by simple modification of bath chemistries and electrical parameters used in current plating and electroforming operations, (3) the capability in a single-step process to produce metals, alloys, and metal–matrix composites in various forms (i.e., coatings, freestanding complex shapes), and most importantly (4) the ability to produce *fully dense* nanostructures free of extraneous porosity. From the outset, the fully dense nanomaterials have displayed *predictable* material properties based upon their increased content of intercrystalline defects. This "predictability" in ultimate material performance has accelerated the adoption of electrodeposited nanomaterials by industry, whereby such

extreme grain refinement simply represents another metallurgical tool for microstructural optimization.

The development of a thorough understanding of the structure–property relationships of electrodeposited nanostructured materials over the years has enabled the "optimization" (rather than simple minimization) of the grain size of various nanostructured materials for specific industrial applications. In this chapter, current and emerging practical applications for electrodeposited nanostructured materials are presented and discussed in light of the enhanced properties relevant to the specific application.

2. SYNTHESIS AND STRUCTURE OF ELECTRODEPOSITED NANOSTRUCTURES

Electrodeposition is likely the simplest method of producing nanostructured materials. However, the earliest systematic studies on the use of electrodeposition to produce nanocrystalline materials were only published in the late 1980s [6, 7]. Potentially, any metal or alloy can be modified to yield nanocrystalline deposits during the electrodeposition procedure. Important processing parameters include bath composition, pH, temperature, overpotential, bath additives, etc. To date, a large number of systems (pure metals, alloys, composites, and ceramics) have been electrodeposited with average grain sizes less than 100 nm. For example, the literature contains numerous examples giving electrochemical processing windows for the synthesis of nanocrystalline pure metals (e.g., Ni [8–11], Co [12], Pd [13], Cu [12]), binary alloys (e.g., Ni–P [6, 7], Ni–Fe [14, 15], Zn–Ni [16, 17], Pd–Fe [18], Co–W [19]) and ternary alloys (e.g., Ni–Fe–Cr [20–22], Co–Fe–P [23]). Even multilayered structures or compositionally modulated alloys (e.g., Cu–Pb [24], Cu–Ni [25, 26], Ag–Pd [27], Ni–P [28]), metal–matrix composites (e.g., Ni–SiC [10, 23, 29], Ni–Al$_2$O$_3$, Ni–MoS$_2$ [23]), ceramics (e.g., ZrO$_2$ [30]), and ceramic nanocomposites (e.g., Tl$_a$Pb$_b$O$_c$ [31]) have been successfully produced by electrodeposition methods.

Electrodeposited bulk nanostructures, in the as-deposited condition, are fully dense materials, with negligible porosity (as determined by density [32] and position annihilation [33] measurements), unless deliberately produced in powder form. High-resolution electron microscopy has demonstrated that grain boundary structures in electrodeposited bulk nanostructures are similar to structures found in conventional polycrystalline materials [34]. Grain size measurements commonly show log normal grain size distributions [8] when the materials are deposited with an equiaxed grain structure. Average grain size and crystallographic texture can be controlled by various plating parameters, including but not limited to bath pH, current density, pulse parameters, and bath additions. Cross-sectional examination of thin (<3 μm) and thick (>1 mm) coatings has shown that the nanocrystalline structure is fully established right at the interface with the substrate and that the grain size is independent of coating thickness [35], in contrast to conventionally produced electrodeposits which often show considerable grain coarsening with increasing coating thickness [36]. Binary and ternary alloys typically show extended

solid solubility ranges, compared to materials produced under thermodynamic equilibrium conditions (for example, in Ni–P [6, 7] Zn–Ni [16], Co–W [19]).

Various coatings with thicknesses up to ∼100 μm electroplated onto substrates to modify specific surface properties are probably the most widely known applications of electrodeposition technologies. It should be noted, however, that several other methods (e.g., brush plating, electrowinning, and electroforming) are used to produce bulk nanostructured materials as thick coatings (several mm thick) or as freestanding material in the form of sheet, foil, tubes, wire, mesh, plate, and foam. Table 1 lists examples of shapes and the corresponding applications of commonly produced electrodeposited and electroformed products.

3. PROPERTIES OF ELECTRODEPOSITED NANOSTRUCTURES

Many detailed investigations have focused on identifying the important structure–property relationships of nanocrystalline materials, attempting to correlate the distinct structure of these materials with various physical, chemical, mechanical, electrical, and magnetic properties. For example, extensive studies of fully dense nanocrystalline nickel produced by electrodeposition have indicated that the structure–property relationships can be categorized into two basic groups: (i) those that exhibit a strong dependence on grain size and (ii) those with weak grain size dependence. A summary of the various grain size dependent and independent properties is given in Table 2 [37]. Detailed descriptions

Table 1. Various shapes and applications of electrodeposited and electroformed products.

Shapes	Applications
Thin coatings (on substrates)	surface modification for wear and corrosion resistance; catalytic surfaces
Thick coatings (on substrates)	electrosleeve™; repair of worn components
Sheet, foil (freestanding)	gaskets; pressure control membranes; hydrogen purification membranes; thermal barriers; solar energy absorbers; microfoils; soft magnets
Tubes, wire (freestanding)	surgical tools; missile guidance systems; miniature gamma radiation sources
Mesh (freestanding)	filters; precision sieve screens; razor foils; printing screens; centrifuge screens
Plate (freestanding)	structural applications
Foam (freestanding)	filters; electromagnetic shielding; battery electrodes; catalyst carriers
Molds (freestanding)	CD stampers; embossing tools for holograms; compression, injection and pattern molds
Free forms	precision bellows; erosion shields for helicopters; trust chambers for rocket engines; components for micromagnetic motors, micro-optics, microactuators and microfiltration; shaped charge liners; precision reflectors and mirrors; nozzles
Powder	catalysts; reinforcements

Table 2. Grain size dependent and independent properties of electrodeposited nanocrystalline nickel.

Grain size dependent properties	
Property	Observation
Solid solubility	greatly enhanced
Hydrogen solubility	greatly enhanced
Localized corrosion	nearly eliminated
Corrosion potential	shifted to more noble potential
Defect structure in passive layer	higher defect density
Thermal stability	greatly reduced
Hydrogen diffusivity	greatly enhanced
Coefficient of friction	reduced by a factor of 2
Wear resistance	greatly enhanced
Strength	increased by a factor of 3 to 10
Ductility	greatly reduced
Hardness	increased by a factor of 5
Electrical resistivity	increased by a factor of 3

Grain size independent properties	
Property	Observation
Bulk density	reduced by <1%
Thermal expansion	unchanged
Young's modulus	unchanged
Adhesion to substrate (for coatings)	unchanged
Thickness of passive layer	same as polycrystalline (1.3 nm)
Resistance to salt spray environment	unchanged
Saturation magnetization	reduced by ∼5%

of the enhanced properties associated with electrodeposited bulk nanostructured materials, relevant to specific industrial applications, will be given in the following section.

4. APPLICATIONS OF ELECTRODEPOSITED NANOSTRUCTURES

The starting point for the development of a particular application of electrodeposited bulk nanostructured materials is the realization that different properties scale differently with grain size. In this context material design and selection involves the optimization of all important property requirements, which then dictates the final grain size for a particular application. Other microstructural parameters, such as grain shape, crystallographic texture, grain boundary character distribution, alloying additions, and second phase particles, can also be further modified (if necessary) to design the final material. The development of a thorough understanding of the various material properties as a function of grain size over the years has led to the successful implementation of various electrodeposited bulk nanostructured materials for specific industrial applications. In the subsequent sections, several structural and functional applications

are discussed along with the relevant material properties integral for the application.

4.1. Structural Applications

As would be expected from Hall–Petch considerations, numerous practical applications for nanocrystalline materials are based upon opportunities for high strength structural components. Table 3 displays mechanical properties of nanocrystalline nickel (99.99%) with grain sizes of 10 and 100 nm, in comparison to conventional polycrystalline (10 μm) nickel. Remarkable increases in hardness, yield strength, and ultimate tensile strength are observed with decreasing grain size. It is also interesting to note that the work hardening coefficient decreases with decreasing grain size, to a negligible value at a grain size of 10 nm [38]. The ductility of the material decreases with decreasing grain size from 50% elongation to failure in tension for conventional material to 15% at 100 nm grain size and approximately 1% at 10 nm grain size. Ductility in bending was generally observed to be somewhat greater than in uniaxial tension. As is also shown in this table, the fatigue performance of the 100 nm material is fully consistent with that of the conventional Ni. Compared to conventional polycrystalline Ni, nanocrystalline Ni electrodeposits exhibit drastically reduced wear rates and lower coefficient of friction as determined in dry air pin-on-disk tests [37].

In a recent study on the tensile properties of electrodeposited nanocrystalline cobalt [39], the yield (0.2%) and ultimate tensile strengths for materials with an average grain size of approximately 12 nm were reported to be 1000–1100 and 1750–1950 MPa, respectively, while maintaining considerable ductility with elongation values ranging between 4 and 8%. For direct comparison, the yield (0.2%) and ultimate tensile strength for a coarse-grained polycrystalline cobalt counterpart with an average grain size larger than 1 μm were reported to be 370–400 and 760–860 MPa, respectively, with elongation values between 7 and 18%.

Table 3. Mechanical properties of conventional and nanocrystalline nickel.

	Conventional[a]	Nano-Ni	
Property	10 μm	100 nm	10 nm
Yield strength, MPa (25 °C)	103	690	>900
Ultimate tensile strength, MPa (25 °C)	403	1100	>2000
Tensile elongation, % (25 °C)	50	>15	1
Elongation in bending, % (25 °C)	—	>40	—
Modulus of elasticity, GPa (25 °C)	207	214	204
Vickers hardness, kg/-mm^2	140	300	650
Work hardening coefficient	0.4	0.15	0.0
Fatigue strength, MPa (10^8 cycles/air/25 °C)	241	275	—
Wear rate (dry air pin on disk), μm$^3/\mu$m	1330	—	7.9
Coefficient of friction (dry air pin on disk)	0.9	—	0.5

4.1.1. Steam Generator Repair

One of the first large-scale structural applications of a bulk nanostructured material is the use of an electrodeposited nanocrystalline nickel microalloy as an *in-situ* repair technique for nuclear steam generator tubing [40, 41]. This so-called electrosleeve process [42] has been successfully implemented in both Canadian and U.S. pressurized water reactors and has been incorporated as a standard procedure for pressure tubing repair [43], wherein a thick coating (0.5–1.0 mm) of nanostructured Ni microalloy (80–100 nm grain size) is electrodeposited on the inside surface of steam generator tubes to form a complete structural repair at sites where the structural integrity of the original tube has been compromised (e.g., corrosion, stress corrosion cracking, etc.). Figure 1 shows a cutaway of an alloy 600 nuclear steam generator tube repaired with the electrosleeve process. The high strength and good ductility of the 100 nm grain size microalloy allows for an appropriate thickness (0.5–1 mm) for which the impact on fluid flow and heat transfer in the steam generator tube is minimized.

4.1.2. Wear and Corrosion Resistant Coatings

Also as a result of Hall–Petch strengthening, nanocrystalline materials display significant increases in hardness and strength relative to their coarser grained counterparts. Hardness increases on the order of 500% to 700% are typically observed [6, 44–49]. Deviations from Hall–Petch behavior have been noted at extremely fine grain sizes (i.e., <20 nm) and were attributed to the breakdown of dislocation pileup mechanisms [49] and the potential for alternative "softening" mechanisms such as room temperature Coble creep [45] and triple line disclination processes [44, 50]. Table 4 summarizes the nanocrystalline grain sizes and corresponding hardness values for several nanocrystalline metals and alloys synthesized by electrodeposition.

The general relationship between wear performance and material hardness is often expressed by Archard's law [51], which demonstrates that the volume loss due to wear should

Table 4. Typical hardness values achieved with electrodeposited bulk nanostructured materials.

Coating composition	Average grain size (nm)	Hardness (VHN)
Ni	11	660
Ni–7 wt% Mo	14	620
Ni–0.5 wt% P	<5	>1100
Ni–20 wt% Fe	15	690
Ni–15 wt% Cr–10 wt% Fe	12	890
Co	13	650
Co–1 wt% P	<10	680
Co–5 wt% P	<10	745
Co–30 wt% Fe–3 wt% P	15	890
Co–45 wt% Fe–10 wt% Zn	10	650
Co–12 wt% W	<100 nm	550
Zn–13 wt% Ni	60	425
Zn–20 wt% Ni	<100 nm	540

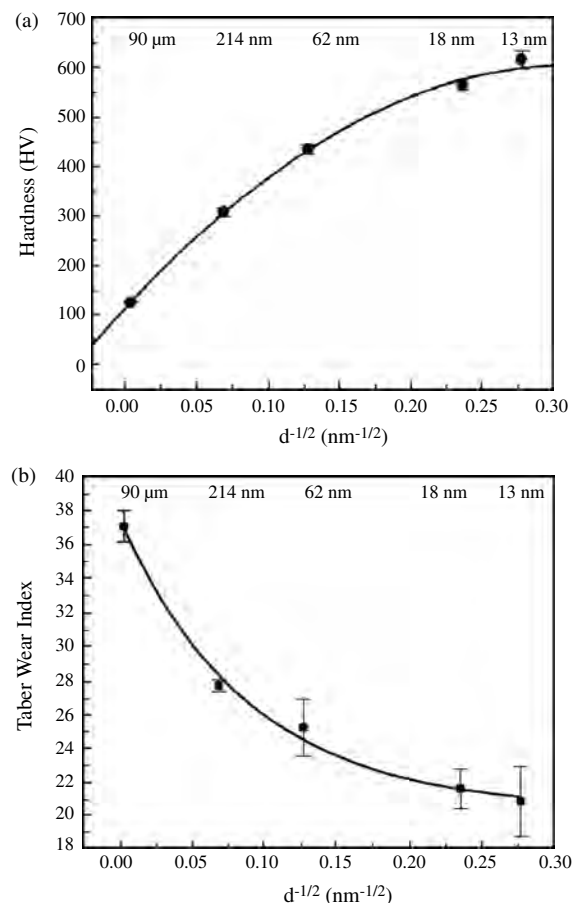
be inversely proportional to the hardness of the material. The applicability of this law to nanocrystalline materials has recently been demonstrated [52] where the grain size dependence of abrasive wear performance was examined using the commonly used Taber wear technique [53].
Figure 1. Cutaway view of an alloy 600 nuclear steam generator tube repaired with the electrosleeve process.


Figure 2. (a) Hardness as function of grain size for Ni. (b) Taber wear index as function of grain size for Ni. Adapted with permission from [52], D. H. Jeong et al., *Scripta Mater.* 44, 493 (2001). © 2001, Elsevier Science.

Figure 2 shows the effect of average grain size on both the hardness and Taber wear index (a measure of volume loss due to wear) for nickel. As shown, decreasing the grain size of Ni from 90 μm to 13 nm results in hardness increases from 125 to 625 VHN; commensurately, the Taber wear index is reduced from approximately 37 to 21.

Figure 3 shows the pin-on-disk (POD) volume wear loss for various nanocrystalline Co alloys relative to those obtained with mild steel, tool steel, and hard chrome. As noted in this figure, the wear resistance is no longer a simple function of the material hardness. When tested under identical conditions, the wear resistance of most of the nanocrystalline deposits exceeded that of hard chrome, even though their hardness values were lower. The POD volume wear loss values for nanocrystalline cobalt decreased with the addition of phosphorus (Co–4% P) and with precipitation hardening (Co–4% P, HT). The addition of iron results in a further decrease in the wear loss.

4.1.3. Environmentally Benign Replacements for Hard Chrome Electroplating

Electrodeposited hard chromium coatings (0.25 to 10 mil thick) are commonly used in both industrial and military applications [54–57] for imparting wear and erosion resistance to components. This is because of their intrinsic high hardness (600–1000 VHN) and low friction coefficient (<0.2) [58]. The most common (and most practical) means of depositing such hard chromium deposits has been through the use of chromic acid baths. However, health risks associated with the use of hexavalent chromium baths have been recognized since the early 1930s [59], wherein skin irritation and inflammation, particularly in the nasal passages, were identified. More recently, such hexavalent Cr baths have been shown to enhance the risk of cancer of the lung and nose [60]. Although significant progress has been made in
the development of less harmful "trivalent Cr" plating processes (e.g., [61]), a reliable industrial process has yet to emerge.

In addition to the health risks associated with Cr plating, there are several other technical drawbacks to this technology. As a result of the relatively low electrolytic efficiency of Cr plating processes, deposition (or build) rates are relatively low compared to the plating of other metals and alloys (e.g., 20–50 μm per hour for Cr versus >200 μm per hour for nickel) [62]. As a further consequence of this low Cr-plating efficiency, high rates of hydrogen co-generation occur and precautions must be taken to prevent hydrogen embrittlement of susceptible substrate materials (e.g., high strength steels) [56]. Moreover, the intrinsic brittleness of hard chromium deposits (i.e., <0.1% tensile elongation [63]) invariably leads to micro- or macrocracked deposits. These "cracks," which do not compromise wear and erosion resistance, are wholly unsuitable for applications where corrosion resistance is required. In these applications, an electrodeposited underlayer of more ductile and corrosion resistant material (usually Ni) must be applied [63].

Electrodeposited bulk nanostructured nickel and cobalt alloys have been recently developed as environmentally benign replacements of hard chrome electroplating [23, 64, 65]. It is important to note that although the wear performance of some of these single phase nanocrystalline coatings currently only approaches that of hard chrome, there exist significant benefits for many of these nanocrystalline coatings, which already render them a superior alternative for specific applications. For example, the significant ductility of nanocrystalline materials relative to hard chromium, and the absence of microcracking, provides significant advantages in fatigue and corrosion performance. Also, the high current efficiencies associated with the deposition of these nanocrystalline materials mitigates problems associated with hydrogen embrittlement. Furthermore, as will be outlined, these nanocrystalline single-phase systems can provide a hard but still relatively ductile matrix for incorporation of second phase particles, which can impart even greater hardfacing improvements.

Further increases in hardness and wear resistance may be achievable through the incorporation of second phase particulates in the nanocrystalline metal/alloy matrix. Two approaches can be used to accomplish this. The first is alloy deposition followed by heat treatment to precipitate a finely dispersed second phase, and the second is to co-deposit particulate during the deposition process. Significant increases in hardness have been achieved by precipitation of phosphates in electrodeposited Co–P [64, 65], Co–Fe–P [23], and Ni–P [66] to values exceeding those commonly found for hard chromium coatings (800–1200 VHN). Figure 4 shows precipitation hardening in the nanocrystalline cobalt–iron–phosphorus alloy, whereby hardness is plotted as a function of annealing time at 300, 400, and 500 °C for up to 100 hours. The Co–Fe–P deposits show an increase in hardness with annealing time at all temperatures, passing through a maximum after approximately 1 hour, followed by a slow decrease with increasing time. The subsequent decrease in hardness is believed to be due to the overripening of the precipitates. The additional loss in hardness during annealing at 500 °C to values below that of the

Figure 3. POD wear loss values for various nanocrystalline materials along with mild steel, tool steel, and hard chromium. The Vicker's microhardness value is given on top of the bar for each material on the chart.
Figure 4. Effect of annealing time at 300, 400, and 500 °C on the hardness of a nanocrystalline Co–Fe–P alloy.

as-deposited material is due to the onset of grain growth, resulting in a loss of the Hall–Petch strengthening.

Nanocomposite coatings can also be produced by co-deposition during the electroplating process, whereby the second phase particulate is kept in suspension in the plating bath. In this manner, insoluble second phases of metals, alloys, ceramics, or polymers can be uniformly distributed in the host nanocrystalline metal or alloy matrix. Figure 5a shows an example of nanocrystalline nickel (13 nm avg. grain size) containing a uniform dispersion of aluminum oxide particles, produced by electrodeposition. Figure 5b presents a bright field transmission electron microscope (TEM) image of two Al_2O_3 particles and the surrounding nanocrystalline nickel showing that the nanocrystalline matrix structure continues up to the particle/matrix interface.

The benefits of utilizing nanocrystalline metal–ceramic composites is shown in Figure 6 for Ni–SiC [67]. Significant increases in hardness, yield strength, and ultimate tensile strength are achieved by utilizing a nanocrystalline rather than a conventional nickel matrix. In this work [67], it was also noted that, for low concentrations of SiC, the nanocrystalline composite possessed significantly improved ductility compared with nanocrystalline nickel of the same grain size but without SiC particles.

In addition to the potential for co-depositing hard second phase particles, there exists the opportunity to also incorporate second phases with functional properties. For example, hard-facing coatings with self-lubricating properties are highly desirable in certain applications. These properties can be achieved through the use of dry lubricant particles such as graphite, polytetrafluoroethylene, etc. Such co-deposited systems are already commercially available with a conventional grain size matrix (e.g., Ni). However, a hard nanocrystalline matrix extends the usage of these coatings to more severe industrial conditions, since by application of the rule of mixtures, the relatively "soft" lubricating second phase can be incorporated to larger volume fractions without significant compromise of the overall hardness of the coating.

Figure 7a and b shows parallel and through-thickness scanning electron microscope (SEM) micrographs, respectively, of a nanocrystalline Ni–P matrix containing hexagonal
Figure 5. (a) Scanning electron micrograph (backscattered electron image) of nanocrystalline nickel (13 nm average grain size) matrix containing Al_2O_3 particulate (black). boron nitride (BN) particles (mean particle size ∼10 μm). The presence of the BN particles in the material results in a coating that "self-lubricates" during wear. Figure 8 shows a photograph of hydraulic expansion mandrels, coated with a nanocrystalline Ni–MoS_2 composite, which utilize the self-lubricating mechanism in order to extend their service life.

4.1.4. Microelectromechanical Devices

Rapid growth in the demand for microelectromechanical structures (MEMS) has resulted in the development of suitable fabrication techniques for micrometer-scale
Figure 6. Summary of mechanical properties for Ni–SiC composites produced by electrodeposition. Adapted with permission from [67], A. Zimmerman et al., *Mater. Sci. Eng. A* 328, 137 (2002). IOP Publishing Ltd. © 2002,

components. One of the most commonly used fabrication techniques for metallic MEMS components is molding by electrodeposition (through-mask electroplating or LIGA, originally developed in Germany). The LIGA technique makes use of photoresist technology to allow for the fabrication of high aspect ratio structures (e.g., [68]). Conventionally produced LIGA and other electrodeposits, however, have been shown to suffer from severe reliability problems in terms of unpredictable properties (e.g., [69, 70]). Properties such as Young's modulus, yield strength, ultimate tensile strength, fatigue strength, and creep behavior have been shown to be extremely sensitive to processing parameters. Using conventional electroplating, columnar grain structure with varying crystallographic texture and large grains (in the micrometer range) are typically found in LIGA Ni, which is the main cause of the unreliability issue, as not all material properties are isotropic. Another critical factor in these devices is the fact that the grain size of conventionally electroformed MEMS structures approaches the length scale of the actual structure compromising the overall strength of the components. Initial studies have shown that the concerns with current LIGA structures can be alleviated by adopting electrodeposition parameters that yield nanocrystalline deposits [8, 9] with controllable and reproducible grain shape and crystallographic texture.

4.1.5. Other Applications

The exceptional specific strengths displayed by electrodeposited nanocrystalline metals and alloys have led to the development of a cost-effective, corrosion resistant, multilayer nanocomposite which can form the basic building unit for armor laminate panels or complex laminate components for lightweight armor applications. By providing specific strengths >850 kpsi/(lb/cu.in.), intrinsic energy absorption and dissipation capability, and multiple round projectile blunting capability a broad range of threats can be defeated. Table 5 summarizes the specific strengths of electrodeposited nanocrystalline nickel, cobalt, and iron. As shown in this table, cobalt and iron, which can be produced in a cost-effective manner, already exhibit the lightweight structural

Table 5. Summary of specific strength properties of nanocrystalline metals produced by electrodeposition (NanoPlate™).

Material	Grain size (by XRD)	Crystal structure	Density (lb/cu. in.)	Tensile strength (kpsi)	Specific strength
NanoPlate™ Ni	17 nm	fcc	0.32	175	**547**
NanoPlate™ Co	12 nm	hcp	0.32	283	**884**
NanoPlate™ Fe	10 nm	bcc	0.28	484	**1729**

properties desired for the lightweight armor applications. Further increases in the specific strength can be achieved by incorporating lightweight ceramic phases.

Recent geometric models and experimental findings [71, 72] have shown that nanostructured materials can possess a high resistance to intergranular cracking processes, including creep cracking. Several emerging applications for nanocrystalline materials possessing high intergranular cracking resistance include lead-acid battery (positive) grids and shape charge liners (Cu, Pb, Ni) for military and industrial applications (e.g., demolition, oil well penetrators, etc.). In these applications, durability and performance of conventional polycrystalline materials are frequently compromised by premature intergranular failure.

4.2. Functional Applications

4.2.1. Soft Magnetic Films and Foils

The magnetic properties of ferromagnetic materials are strongly dependent upon parameters such as composition, crystallographic texture, internal stress, grain shape anisotropy, and the grain size distribution [73–75]. The magnetic properties of interest for nearly all applications can be divided into two categories: intrinsic and extrinsic magnetic properties. The fundamental intrinsic properties are generally independent of structure, such as the saturation magnetization (M_S) and the Curie temperature (T_C). The extrinsic magnetic properties are those that depend in some way on microstructure, such as permeability (μ), coercivity (H_C), and remnant magnetization (M_R).

Over the years, tailoring the chemistry and optimizing microstructure have resulted in significant improvements in the intrinsic and extrinsic magnetic properties of ferromagnetic materials. For soft magnetic applications, ranging from electromagnetic shielding, transformer materials, read–write heads, high efficiency motors, or emerging microelectromechanical system components, magnetic materials that exhibit small hysteresis losses per cycle are required. More specifically, materials with: (i) high permeability (the parameter which describes the flux density in very small fields), (ii) low coercivity, (iii) high saturation and remnant magnetization, (iv) high electrical resistivity (to minimize losses due to eddy current formation), and (v) high Curie temperatures are required. High strength is also of concern in particular for very thin foils or wires as is high corrosion and wear resistance, if these materials are used as a coating on softer substrates.

In nanocrystalline materials, the grain size approaches or decreases below the critical magnetic length scales found in conventional materials such as the domain (Bloch) wall

thickness or the ferromagnetic exchange length. As a result, considerable changes in the magnetic behavior can occur. In conventional polycrystalline materials (grain sizes >100 nm), the coercivity is found to be inversely proportional to the grain size. In this case, the grain size exceeds the domain wall thickness and the grain boundaries effectively act to pin magnetic domain wall motion, resulting in magnetically harder materials with decreasing grain size.

However, when the crystal size is reduced to the extent that the domain wall thickness is comparable to the average grain diameter the magnetic structure in relation to the microstructure is not well understood. For a series of nanostructured materials produced by crystallization from amorphous precursors it was found that the coercivity decreased by several orders of magnitude for grain sizes less than about 50 nm, following a D^6 relationship, where D is the grain size of nanocrystals (e.g., [76]). This observation was explained in terms of a random anisotropy model. Although this effect is not observed for all nanocrystalline materials, recent results have demonstrated that materials prepared by electrodeposition [77] show similar trends.

Early studies on the saturation magnetization of ultrafine particles and nanocrystalline materials made by gas condensed nanocrystalline powders found the M_S to be reduced, by as much as 40%, when compared to their compositionally equivalent polycrystalline counterparts [78–81]. Studies on the M_S of electrodeposited nanocrystalline materials, however, showed a decrease in M_S by no more than 5% [82–85]. Initially the reduced M_S in consolidated nanocrystalline powders was explained in terms of the structural disorder of the interfaces, in which atoms located at the interfaces were estimated to possess only half the magnetic moment of the atoms located within the grains [81]. However, in later work involving higher purity material [86], the previously reported reduction in M_S was attributed to oxygen contamination. Recent detailed calculations on the magnetic properties of grain boundaries [87, 88] revealed that the local magnetic moment in nickel is rather insensitive to the amount of disorder present in the structure, varying at most by 20%, for only certain sites in the boundary, thereby agreeing with the measured M_S values from nanocrystalline materials made by electrodeposition [82–85].

The Curie temperature of nanocrystalline materials has also been the subject of debate over the years. While a considerably reduced Curie temperature has been reported for nanocrystalline nickel made by consolidated nanocrystalline powders [89], no major reduction has been observed for nanocrystalline nickel produced by electrodeposition [90].

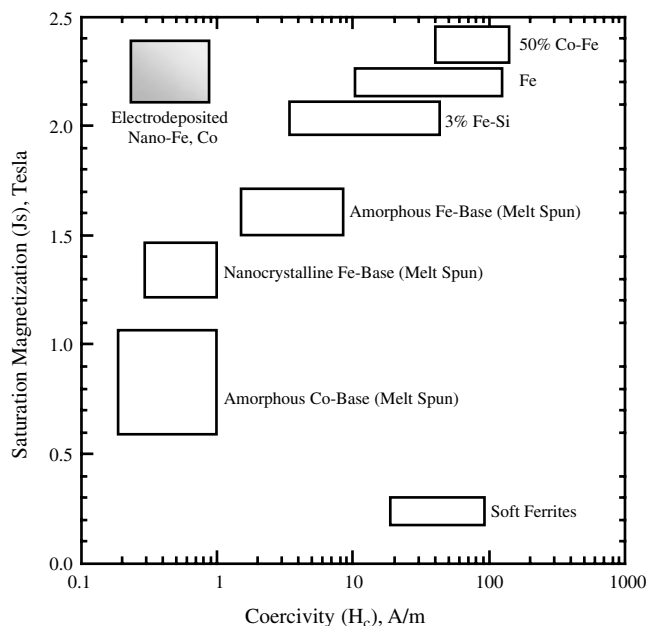
Nanocrystalline Fe- and Co-based soft magnetic materials made from devitrified amorphous alloys are currently being used in industry. The rapid solidification production technique of the amorphous precursor alloys, however, requires substantial alloying with metalloids such as boron and/or phosphorus. Therefore improvement in some of the soft magnetic properties, such as coercivity and permeability as a result of the ultrafine grain size, comes at the expense of the saturation magnetization of the base material (Fe or Co). In the case of electrodeposited nanocrystalline materials, the ultrafine grain size is accomplished without the need for alloying, such that saturation magnetization is not sacrificed, as shown in Figure 9.


Figure 9. Saturation magnetization as a function of coercivity for targeted electrodeposited materials (white boxes) along with various commercial materials (grey box).

The industrial use of these high performance ferromagnetic materials in motor, transformer, and shielding applications was accelerated by the development of a drum plating process (shown in Fig. 10) for cost-effectively producing large quantities of sheet, foil, and wire in nanocrystalline form.

4.2.2. Copper Foil for Printed Circuit Boards

Line etchability of copper foil for printed circuit board applications is strongly dependent on the crystallographic orientation of the crystals in the foil [91]. Nonuniform line etching has become a severe issue as the linewidth continues to decrease to dimensions close to the grain size in conventional polycrystalline copper foils produced by electrodeposition. In an effort to improve the line etchability, a nanocrystalline Cu foil was recently developed [92]
Figure 10. Prototype drum-plater for producing nanocrystalline sheet, foil, and wire products.
Figure 11. Field emission scanning electron micrograph of electrodeposited nanocrystalline Cu foil having an average grain size of 50 nm.

with grain sizes in the 50–100 nm range. Although further grain size reduction would be beneficial in terms of strength advantage and etchability, the associated increase in electrical resistivity would be unacceptable for this particular application [93]. Figure 11 shows a cross-sectional field emission scanning electron micrograph of nanocrystalline Cu foil produced for this application.

4.2.3. Catalytic and Energy Storage Applications

The high density of intercrystalline defects present within the bulk and intersecting the free surface of nanostructured materials provides considerable opportunity in catalytic and hydrogen storage applications. Hydrogen transport rates and storage capacity in nanocrystalline Ni have been shown to be significantly enhanced over that observed in conventional material [94, 95]; 6- to 10-fold increases in hydrogen diffusivity and 60-fold increases in hydrogen storage capacity have been determined at room temperature. In addition, higher electrocatalytic behavior has been noted with regard to the hydrogen evolution reaction for alkaline water electrolysis at room temperature [95]. Several applications are being developed for the use of these materials in nickel metal hydride battery systems and as alkaline fuel cell electrodes.

5. SUMMARY

Bulk nanostructured materials produced by electrodeposition exhibit excellent mechanical, wear, corrosion, catalytic, and magnetic properties. Several economically viable electrodeposition technologies are already available to produce large quantities of various pure metals, alloys, and composites in many different forms and shapes including thin and thick coatings, freestanding foil, sheet, tubes, and wires as well as complex geometries. Based on the outstanding properties and the established industrial infrastructure a number of advanced applications for electrodeposited nanostructures have been developed over the past decade, which have herein been presented.

GLOSSARY

Co-deposition   The deposition of more than one species during electrodeposition. For example, if two metals are co-deposited at the same time the resulting material is an alloy. Metal matrix composites can be produced by co-depositing a second phase particle (e.g., ceramic, polymer, or intermetallic particles) with a metallic matrix.

Electrodeposition   The deposition of a metal, ceramic, semiconductor, or polymer from an aqueous, or organic solution, or a molten salt.

Interfacial material   A fully dense polyerystalline material such as a metal, alloy, ceramic or semiconductor with crystal sizes less than 100 nm. These materials have large volume fractions of interfaces (i.e., grain boundaries or phase boundaries) and, therefore, their properties quite different from those observed for their amorphous or conventional polycrystalline counterparts.

Nanocomposite   A composite material in which at least one of the phases is nanocrystalline with a crystal size less than 100 nm.

CONTENTS

1. INTRODUCTION

Focused ion beam (FIB) systems and technology were developed about 20 years ago in the early 1980s. As the applications increased and demand for commercial equipment increased, commercial instruments became available on the market [1]. Today FIB systems are being widely used in semiconductor research and processing, failure analysis, and chip design. The technology makes it possible to carry out localized milling and deposition of conductors and insulators with high precision. Because of this FIB application has become possible in device modification, mask repair, process control, and failure analysis [2–6]. The possibility to image at high magnification and milling at a very specific site has made possible preparation of specimens for transmission electron microscopy (TEM). The FIB technique is also being used in production processes like trimming of thin-film magnetoresistive heads (for magnetic storage disks) [7]. Recently a number of reports have appeared in the literature about the use of FIB in micromachining applications

for microelectromechanical structures [8–10]. This powerful tool shows a promising future in nanotechnology and nanofabrication. The FIB is based on the interactions of an ion beam with surfaces and molecules. It is therefore important to cover how ions interact with matter.

2. INTERACTION OF IONS WITH MATTER

Ion implantation for integrated circuit manufacture is a well established technique. It has been widely studied and there is a considerable amount of literature available in this area. Typical energies used in ion implantation are in the 10 to 200 keV range, while typically the commercially available FIB systems use around 30–50 keV. The incident ion loses its energy when it strikes the surface of the specimen. This energy is partially lost to the electrons and partially to the atoms itself. Due to Coulomb interaction the ion excites the electrons in the solid to bound states or to continuum states. This is a predictable process. The loss of energy to the atom is more complicated. This is because of the finite number of random collisions with significant energy loss. The development of the theory of an ion slowing in a solid has been difficult because the problem of describing both the ion and the target is complex. Once the ion penetrates a solid, it is quickly stripped of some of its electrons, and its charge state becomes a function of the target. The target feels the ion coming, and its electrons polarize around the moving ion. The charge state of the ion is modified by the polarized target, which then further affects the target. Some of the target atoms penetrate through the ion's electron cloud causing quantum exclusions of available states. Finally, all of these effects depend on the constantly changing ion velocity. When a ion strikes the surface of a solid, the ion is deflected from its path and the atom is displaced from its original

position. The ions penetrate the solid to a depth R_p called penetration depth or range. If a Gaussian curve is fitted to the distribution of ions at a depth Z it has the form exp $[-(Z - R_p)^2/2(\Delta R_p)^2]$ where ΔR_p is called range straggle. In addition to this the collisions also produce uncertainly in the transverse position of the ion in the solid. This is described as ΔR_t or transverse straggle. Plots of R_p, ΔR_p, and ΔR_t for silicon are available in the literature [11].

More recently computer simulations are available on the internet called the stopping and range of ions in matter. The simulation has used a vast number of data points available in the literature. The software claims to be accurate to about 10% of the available data.

The ion causes various effects when it is incident on the specimen surface. A schematic diagram of the interactions can be seen in Figure 1.

1. The ions produce radiation damage. This is a result of displacement of atoms from their lattice sites due to collisions with ions. The cumulative effect of the damage can result in formation of an amorphous layer. For example, after an implantation dose of 10^{14} As^+ ions/cm^2 such an amorphous layer is formed in silicon. Light ions such as B^+ do not form such a layer. The depth and distribution of the damage follows the distribution of the ions.
2. The ions striking the surface can cause sputtering. This is removal of atoms from the substrate. This occurs at low energies of 50–1000 eV. The removal of atoms from the substrate is dependent on the energy of the incident ions. The yield or the number of atoms removed increases with energy up to about 100 keV and then decreases. Typical yield is about 1 to 10 atoms per ion. The sputtered ions leave the surface with a few eV of energy.
3. When the ion strikes the surface, electrons are emitted. About 1–10 electrons are emitted per ion with typical energies of a few eV. In a FIB system these electrons called secondary electrons are used to image the surface.

ION BEAM

Sputtered atoms

Embedded
Ga Atom
Figure 1. Interaction of ion beam with specimen.

4. Chemical effects are also produced by ions. These are because of the ion–electron interactions as well as ion–atom interaction. When a photoresist is exposed to the ions, the molecules are changed because of the ions. They can either make the resist soluble or insoluble in developer. Ions can also break molecules into parts. A typical example is an organic gas molecule carrying a metal atom. The ions can break the molecule causing deposition of the metal on the surface. Another example is ion assisted etching where a gas is used in combination with the ion source.

3. PRINCIPLES OF FOCUSED ION BEAM

A modern dual beam FIB system has two separate columns, one for the electron beam and the other for the ion beam. The ion beam interacts with the specimen and has two important functions, namely milling of material and deposition of material. Interaction of the ion beam with the sample surface can also used for imaging. The principal components and functions of FIB are the following:

1. ion source
2. ion column
3. imaging
4. milling
5. deposition

3.1. Ion Source

Focused ion beam machines make use of a liquid metal ion source or LMIS. This consists of a blunt field emitter with an end radius of around 10 μm which is coated with a metal film that has a high surface tension and a low vapor pressure at its melting point. The field emitter is heated to the melting point of the metal so that the metal forms a liquid film on the emitter. A high electric potential is applied to the field emitter relative to an electrode in its proximity called an extractor electrode. The positive voltage is in the range of 2–10 kV. The magnitude of the voltage is dependent on the distance between the field emitter and the extractor electrode. The liquid film experiences two kids of forces: the surface tension of the liquid and the electrostatic field. Depending on the balance between these forces the liquid film is drawn into a conical shape. The radius of the tip of the cone is about 5 nm. The small radius and high electric field cause the formation of ions by field evaporation. Because of the high field the potential barrier against evaporation is lowered and the atoms can evaporate. The evaporated atoms then ionize in the electric field. At low ion currents this is the dominating mechanism. At high ion currents ions are formed by field ionization of metal atoms which are in the vapor state. Several elements have been used as ion sources. These are Al, As, Au, B, Be, Cs, Cu, Ga, Ge, Fe, In, Pb, P, Pd, Si, Sn, U, and Zn. The LMIS is more complicated to describe mathematically than a solid source, because unlike the solid source, the liquid tip is the emitter. The shape of the tip is determined by the forces acting on the liquid. As mentioned, these are the surface tension and the electrostatic force. The balance of these forces

maintains the liquid in a conical form. It is therefore necessary to have an accurate description of the electric field that maintains the liquid in a conical form in the presence of the space charge. The space charge is highly dependent on the field because of the field evaporation process. The situation is further complicated by the fact that the pressure in the interior of the cone is altered because of flow of liquid through it to replace the evaporated atoms. The flow is dependent on the rate of evaporation, which is dependent on the current. A LMIS source is a device where sufficiently high electric field can be applied to the liquid metal so that it forms the conical shape when the surface tension just balances the stress caused by the electric field. This is known as the Taylor cone.

Some of the most important properties of the LMIS sources are the highly nonlinear current–voltage characteristics. The LMIS source also displays variation in the energy distribution of the beam and composition of the ions dependent on the current.

3.2. Ion Column

The ion column is quite similar to the electron column of a scanning electron microscope (SEM). However, in a SEM an electron beam is manipulated using electromagnetic lenses, while in an FIB ion column, the ion beam is manipulated using electrostatic lenses. A typical ion column can be seen in Figure 2. The LMIS functions in vacuum and the entire column is maintained at about 1×10^{-7} mbar. The ion beam from the LMIS is in the form of a cone and first a spray aperture limits the shape of the beam. The first electrostatic lens then condenses the beam. The beam stigmatism is adjusted by the first octopole. The ion beam has energy of about 10–50 kV. The beam currents vary between 1 and 10,000 pA. The beam current is controlled by introducing variable apertures. Small currents are used for imaging while large currents are used for milling. Typical beam currents in FEI FIB equipment are 1, 4, 11, 70, 150, 350, 1000, 2500, 6000, and 11,000 pA. There is another octopole below the apertures. This is used to scan the surface of the sample as in a SEM. The beam also can be blanked using a blanking mechanism. A second electrostatic lense focuses the beam to a fine spot. This can give a resolution of up to 5 nm.

3.3. Imaging

As described previously, when energetic ions hit the surface of a solid sample, they lose their energy to the electrons of the solid as well as the atoms. The electrons in the solid leave the surface of the sample and are called secondary electrons. These electrons are collected on a multichannel plate (MCP) detector. This detector can be positively biased to collect the secondary electrons. When the ion beam rasters the surface of the sample, the secondary electrons produce the image of the surface of the sample. The energetic ions can also cause the atoms on the surface of the sample to leave the surface as ions. These are called secondary ions. These ions can be collected by the MCP when it is negatively biased. These can also be used to image the sample surface. Nonconducting samples pose a problem.
Figure 2. Typical ion column.

The surface builds up positive charge because of the ions. This interferes with the imaging of the sample surface. This problem is overcome using a separate electron source to flood the surface with electrons. In a dual beam machine it is possible to use the electron column for this purpose.

The traditional single-beam ion system has some limitations. The imaging process in a FIB system results in the ion beam continuously removing material from the sample. If the feature or defect being imaged is small, under 0.1 mm, the feature will be damaged or altered in the time needed to collect a high-resolution image. This has led to the development of a dual-column FIB system. A well-designed dual-column system is able to integrate the ion beam's milling and deposition capabilities with the electron beam's high-resolution, nondestructive imaging, without compromise to either column's performance. A system that provides these qualities can be used like a dedicated SEM for defect inspection and, when needed, provide three-dimensional (3D) inspection of particles, buried defects, or metrology.

The best resolution achieved by FIB machines using an ion beam is dependent on the spot size of the beam. This is typically of the order of 5 nm in modern equipment. In a dual beam machine of course the resolution is same as that of a SEM.

There is another effect of the ions when they strike a material like aluminum and copper. The ions penetrate to some depth in these materials. The depth of penetration varies because of channelling along the open columns in the lattice structure. The penetration depth therefore depends on the orientation of the crystal with respect to the incident beam. Since secondary electron emission is dependent on the depth of penetration, the image reveals differences in orientation of the crystals [12]. When the specimen is tilted, it is possible to see changes in brightness of the grains due to changes in channeling conditions as the angle between the grains and the incident ion beam changes.

3.4. Milling

The main purpose of FIB equipment is milling of materials. The energetic ions striking the surface of the specimen eject the atoms on the surface. This results in milling of the specimen surface. As mentioned, removal of atoms from the substrate is dependent on the energy of the incident ions. The yield or the number of atoms removed increases slowly with energy, flattens out, and then decreases at about 50 keV [13]. With Focused ion beams, the characteristics of milling, such as yield, are geometry dependent. When an ion beam is scanned on the surface as a line, a trench develops which has a Gaussian shape as expected from the beam profile. However, when the dose is increased, the trench becomes sharp, narrowly V shaped, and deep [14, 15]. In addition, the shape of a milled feature is also dependent on whether it is obtained with a single scan or repetitive scans even though the total dose is kept the same [15, 16]. The yield has to be defined in such a way that the geometric effects are avoided such as repetitive scanning over an area where the lateral dimensions are much larger than the depth milled. Thus if the material has a density ρ (atoms/cm^3) and an ion dose Δ (ions/cm^2) mills the material to a depth d (cm), then the yield can be defined as

$$Y = (\rho \, d/\Delta) \quad \text{(atoms/ion)}$$

Since in focused ion beams milling ions can be buried in the material, and other phenomena such as redeposition can also take place, the actual yield may not correspond exactly to the atoms removed per ion. Typical implantation depth and sputtering yield for Ga$^+$ ions in silicon dioxide (SiO$_2$) and aluminum (Al) at normal incidence is given in Table 1 [12]. The sputtering yield is also dependent on the angle of incidence. It roughly increases with $1/\cos(\theta)$, with θ the angle between the surface normal and the ion beam direction.

In order to speed up the milling process, or to increase the selectivity toward different materials, an etching gas can be introduced into the work chamber during milling. It will increase the etching rate and the selectivity toward different materials by chemically facilitating the removal of reaction products. This technique is called gas assisted etching

Table 1. Typical implantation depth and sputtering yield for Ga$^+$ ions in silicon dioxide (SiO$_2$) and aluminum (Al).

Ga ion energy	Implantation depth			Sputtering yield		
	Si	SiO$_2$	Al	Si	SiO$_2$	Al
10 keV	13 ± 5	12 ± 4	11 ± 4	1.46	Si: 0.62; O: 2.23	2.59
20 keV	20 ± 7	19 ± 6	17 ± 6	1.87	Si: 0.64; O: 2.34	2.98
30 keV	27 ± 9	25 ± 8	23 ± 8	1.98	Si: 0.67; O: 2.25	2.91
40 keV	33 ± 11	31 ± 10	29 ± 10	2.04	Si: 0.77; O: 2.54	3.54
50 keV	39 ± 14	38 ± 11	35 ± 12	2.01	Si: 0.67; O: 2.39	3.48

(GAE). Typical etching gases and their milling rate enhancement factors are shown in Table 2 [12]. One of the advantages of GAE is that the reaction products are volatile and this prevents redeposition and permits high aspect ratio structures to be fabricated [17–19]. With increasing use of copper, GAE of copper is gaining importance. Recently several studies on GAE of copper have been reported using SiCl$_4$ and BCl$_3$ [20–23]. A 12-fold increase in milling rates has been reported [17]. More recently water has been added to the arsenal of gases for FIB chemical etching. FIB water etching is especially rapid with polymers (including photoresist). The enhancement factor for poly(methyl methacrylate), for example, can exceed 10x, which may have value for resist lithography purposes. Presently FIB water etching has been employed to cross-section photoresist for SEM analysis [24]. Recently, selective etching has made progress. New machines offer up to four etching chemistries:

- enhanced etch: milling rate enhancement for materials such as silicon, aluminum, and gallium arsenide
- selective carbon mill: removes photoresist and other polymers
- insulator enhanced etch: removes insulating materials used in the IC manufacturing process
- delineation etch: enables the imaging of various materials and oxide layers exposed in a FIB cross-section

3.5. Deposition

For many years people have used FIB systems for beam induced deposition of metals and insulators onto device surfaces. As can be seen in Figure 3, the deposition of materials is accomplished by introducing metal or insulating atoms as a part of a carrier molecule, very close to the sample surface where they collide with gallium ions from the primary ion beam and are forced onto the sample surface. The principle is chemical vapor deposition (CVD). As the ion beam can be focused to a very small spot size, the deposition is

Table 2. Typical GAE gases and their etch rate enhancement factors on various materials.

	Al	W	Si	SiO$_2$, Si$_3$N$_4$	Photoresist; polyimide
Cl$_2$	10–20	—	10	—	—
Br$_2$	10–20	—	6–10	—	—

Figure 3. Schematic diagram showing metal deposition.

very localized. The beam can be made to follow a preprogrammed pattern and this results in deposition of the metal in the desired form. The carrier molecule is in vapor form and is introduced through a needle which is brought in close proximity to the sample surface. The gas is adsorbed on the surface of the specimen. The ion beam dissociates the carrier molecule as it collides with it. The dissociated products are volatile and are removed by the vacuum system while the desired reaction products carrying the metal atoms remain attached to the surface. The deposited metal is not pure as it also contains Ga and parts of the carrier organic molecule. The most common metals deposited in commercially available machines are Pt and W. In case of W the orgonometallic gas is $W(CO)_6$. Insulating material like SiO_2 can also be deposited. In this case 1,3,5,7-tetramethylcyclotetrasiloxane and oxygen or water vapor is used as a precursor. A wide range of metals have also been deposited for research purposes such as Ta [25], Au [26, 27], C [28], Fe, and Al [29]. The smallest feature that can be deposited by conventional FIB is of the order of <100 nm. Traditionally these depositions are mainly used to connect or isolate wires when doing device edit operations.

A new application for metal deposition is to deposit a layer of metal in order to protect the features of small particle defects during ion beam cross-sectioning. If the particle is exceedingly small (>0.20 μm) the ions used for depositing the protective metal layer can still damage the particle during initial exposure. In a dual-column system the electron beam can be used to do the initial deposition of metal, generally a thin layer less than 0.1 μm thick. Once this initial layer is deposited, the ion beam can be used to finish the deposition without affecting the particle. The slow milling rate of the metal also gives a clean face to the cross-section while preserving the particle's important physical and compositional characteristics.

4. FOCUSED ION BEAM EQUIPMENT

A modern two-beam FIB workstation like the one marketed by made by the FEI Corporation is typically used for research, design modification, defect characterization, process control, and site specific TEM specimen preparation.

A schematic diagram showing the configuration of a two-beam FIB is shown in Figure 4. With a dual beam, the sample can be viewed by SEM while it is being processed by the ion beam. This makes it possible to make slice-by-slice, 3D images of features of interest. The samples that are processed by FIBs are mounted on a motorized five-axis stage, mounted inside the specimen chamber. There are two types of specimen stages. For highly accurate navigation the specimen stage has laser interferometers. The stage is much more rigid. This, however, limits freedom of movement in tilt. Accuracy of such a stage is about 5 nm. The specimen stage with five-axis freedom has less accuracy. Under normal operating conditions, 10^{-7} mbar vacuum is maintained. A system of vacuum pumps is needed to maintain the vacuum inside the specimen chamber. A fore pump is used in combination with a turbo pump for pumping the specimen chamber. The ion column and the electron column are provided with additional ion pumps. Loading of samples in FEI machines is done by opening the whole front of the specimen chamber. This enables large samples to be loaded so that the maximum size of the specimen chamber can be exploited.

As discussed, gas assisted milling and deposition of various metals requires that there is a possibility to introduce these gases in the specimen chamber. The gas containers are outside the specimen chamber. The gas sources are connected with appropriate piping to the specimen chamber. The gases have to be delivered very close to the specimen itself. This is achieved by retractable needles which can be lowered to the specimen surface when required. This is necessary so that the specimen can first be manipulated without the hindrance of the needle.

A computer system governs all the operations. Imaging is also digital and displayed on a computer monitor. The new machines have powerful navigation software. A specimen can be positioned to within 5 nm of the desired location. The system can read CAD files for positioning which are the same files used for preparation of masks.

5. APPLICATIONS OF FOCUSED ION BEAM IN NANOTECHNOLOGY

There is a very large number of applications of FIBs reported in the literature in this area. The most successful application of FIBs in semiconductor technology is in failure analysis. In addition a lot of information can be obtained
Figure 4. Dual beam configuration.

for process control. Furthermore, the capability of cross-sectioning makes the FIB a powerful tool to make site specific TEM samples. Now with the considerable activity in the nanotechnology FIB has found new role in nanofabrication.

5.1. Making Site Specific Cross-Sections

A FIB system has the ability to image a specimen and then to select a specific feature of interest on the surface. This feature can be milled with the ion beam. After the milling operation, the specimen can be tilted to view the cross-section. This gives a unique opportunity to make and examine site specific cross-sections. A FIB milled cross-section of a "surface defect" is shown in Figure 5. The cross-section reveals that the surface defect is in fact an underlying defect.

5.2. Milling of Optical Fibers

A new emerging field is near field optical microscopy. The light field at the surface of an object actually contains more information—higher spatial frequencies—than we can image by using a "far-field" lens system. Only the spatial frequencies that reach the imaging lens (pass through the numerical aperture) are "seen." These are the propagating, low frequencies. Higher spatial frequencies exist at the sample surface but decay exponentially within a distance less than the wavelength, so they never reach the detector. These high spatial frequencies are the "near field" (NF; the detector must be very near to see them). These are detected using a very small aperture to illuminate the object in the NF. An optical fiber is drawn to a sharp point. This is then coated with Al. The end is trimmed and an aperture is made by FIB milling. Figure 6 shows such probes fabricated using a FIB.

5.3. Trimming and Shaping of Magnetic Disk Heads

An industrial use of FIB micromachining is trimming and shaping of thin-film magnetic disk heads [7]. FIB milling is used to to reduce the pole width of giant magnetoresistive heads to 100 nm. Such narrow gaps increase the the magnetic resolution of the heads up to areal densities of 100 Gb in^{-2}. Manufacturers now offer dedicated machines for this purpose. The main advantage is that the existing production facilities can be used while greatly reducing the critical
Figure 6. Near-field optical microscopy probes trimmed with FIB. The diameter of the tip is about 450 nm and the aperture is about 50 nm. Images courtesy of F. B. Segerink, MESA+, University of Twente.

dimensions. The process is fully automated using pattern recognition software. The magnetic heads can be trimmed on wafers and lapped rowbars. Typical cycle times are of the order of 2 to 5 sec/head.

5.4. Nanofabrication with Wet Etching

It has been reported in the literature that Ga$^+$ ions in silicon act as an etch stop [30]. This is particularly effective in an etchant like KOH. This phenomenon can be used to fabricate micro- and nanomechanical elements in silicon. FIB ions have relatively low energy compared to the ion implantation process. As a result only a very thin layer is implanted with Ga$^+$ ions. This layer is thinner than 50 nm. It is found that the critical dose for the etch stop to be effective is about 1×10^{15} ions cm^{-2}. This dose is easily obtained using a current of 100 pA in a few seconds of exposure. The implanted regions are amorphous. Using this method cantilevers of nanometer sizes can be fabricated. Sidewall doping can also be used to fabricate nanostructures in combination with wet etching.

5.5. Mask Repair

One of the first uses of FIB technology was photomask repair. To repair opaque defects, the undesired metal, for example, Cr, can simply be milled away [31]. The milling ions do embed themselves in the glass. This can lead to some loss in transmission of light. Clear defects can be repaired by milling a light scattering structure in the material. A grating or a prism, for example, acts to scatter light and appears opaque when viewed in transmission. The new technology uses extreme ultraviolet photolithography for nanoscale devices. Based on 70 nm node, the minimum space between features on a 4X mask is 280 nm. The minimum mask feature size is 180 nm (corresponding to a 45 nm gate length on wafer). The minimum printable defect size is 55 nm. For such a mask the repair process has the following requirements: etching dimension <280 nm, deposition dimension <180 nm, resolution required to repair small defects <55 nm, edge placement precision 35 nm, and the repair must not damage multilayer. FIB has been shown to be successfully applied to meet all the requirements [32].

Figure 5. Cross-sectioning of a "surface defect" revealing that it is in fact below the surface.

5.6. Site Specific TEM Specimen Preparation

The FIB is ideally suited for making site specific TEM specimens. These are of great importance in the semiconductor industry for defect characterization and process control. FIB specimen preparation has been used to investigate several failure mechanisms, for instance of gate oxide defects, overalloyed contacts, various kinds of particles, notches in metal lines, electromigration failures, implant damage, and other site specific problems [33]. There is considerable literature about application of FIB for making TEM specimens [34–36]. TEM specimen preparation can be seen in Figure 7. Now FIB has also found applications in nano technology. The FIB specimen preparation technique has been used to investigate carbon nanotube/metal junctions [37].

5.7. Fabrication and Trimming of Nanotips

Atomic force microscopes (AFMs) are fabricated using a Si or Si_3N_4 tip with a metallic or a well conducting film. AFM measurements of semiconductors with conventional pyramid shaped tips can lead to problems. The feature of interest may be in proximity to a large step and the region next to the step cannot be reached. To overcome this, tips with high aspect ratios are of importance. A FIB is used to trim the pyramid shaped all diamond tips to obtain high aspect ratio tips. Tips with a height of 700 nm, a tip radius of 30 nm, and an aspect ratio of 1:7 have been reported. Still higher values of aspect ratios can be obtained [38]. The field ion microscope (FIM) is a powerful tool for analysis and imaging at atomic scale. However, the material to be observed

Figure 8. Nanofabrication for measuring electrical properties of carbon nanotubes using CVD deposition.

has to be in the form of a sharp needle with a tip radius of around 30 nm. The FIB has been successfully used to make FIM specimens from various materials like TiAl alloy, Cu–Co alloy, and even multilayer film devices [39].

5.8. Nanofabrication

Electron beam (EB) equipment and FIBs have both been successfully used to fabricate nanoscale devices. These include single electron transistors and metal-oxide semiconductor transistors with nanometer gate length. Commercially available FIB workstations can form 10 nm structures with beam diameters of 5–10 nm and a high resolution photoresist. The deposition of FIB CVD is much higher than EB CVD because of the difference in the mass of the ions compared to electrons. The penetration depth of the ions is smaller than electrons allowing fabrication of nanostructures [40]. Examples of such devices are shown in Figure 8. The facility of milling patterns in FIB has made it possible to use this technique to fabricate photonic devices. Examples of such structures milled in a chromium film can be seen in Figures 9 and 10. The shape of the holes and the pitch can

Figure 10. Hexagonal holes milled in a Cr layer on Si.

be varied freely. Typical milling current is 70 pA and milling time is 7 min.

5.9. Device Modification and Prototyping

The ability to mill any material and to deposit conductors as well as insulators can be used to carry out device modification and prototyping. In many cases a part of the circuit needs to be modified and tested. This can be achieved by cutting through the connects then milling through the via. The circuit can be reconfigured by laying new connects. In a modern machine it can also be tested using probes present inside the specimen chamber. An example of the modification is shown in Figures 11–14.

Figure 14. Modified device viewed by tilting.

6. SUMMARY

We have seen that the FIB has evolved from an implantation device to a flexible and versatile equipment. There are ever increasing applications of FIBs in the semiconductor industry, materials science, and nanotechnology. The developments have led to smaller beam diameters, better positioning hardware and software, and a greater number of materials that can be deposited. A greater number of gases for GAE and selective etching are also being made available. Over the years the FIB has become a powerful tool in mask repair, defect analysis, and TEM specimen preparations. The FIB remains the only tool that can be used for device modification and prototyping. Further developments in detectors has made it possible to use FIB also as an analytical tool. In the field of nanotechnology the FIB has very important applications in making near-field optical probes, sensors, photonic devices, and nanostructures by deposition of material. The FIB is now also used in production specially of magnetic heads. It is not, however, suitable for mass throughput fabrications. It remains a relatively slow process. Despite the drawbacks the applications show a great promise in path breaking technologies in nanotechnology. It is clear that FIB technology will play a central role in the coming years.

GLOSSARY

Amorphous layer   Layer which does not display a regular ordered structure seen in crystals.

Coulomb interactions   Electrical interactions in charged particles.

Failure analysis   When a semiconductor device or any component fails, the causes of failure are investigated. The factors leading to the failure are analyzed.

Ion implantation   Ions directed at a surface of a material, with high energy embed themselves in the material. This is used to change the properties of the material by adding another species to the material.

Magnetoresistive heads   The magnetoresistive heads used for information storage are made from a ferromagnetic alloy whose resistance changes as a function of an applied magnetic field. This phenomenon was discovered by Lord Kelvin in 1857 and today is called the anisotropic magnetoresistance effect.

Mask repair   Photolithography depends on masks which are used to expose a photoresist to light. The pattern of the mask is thus transferred to the photoresist.

Raster   Scan.

Sputtering   Removal of atoms from the surface of a material due to impact of incident atoms.

CONTENTS

1. INTRODUCTION

The scanning tunneling microscope (STM) was initially intended for imaging surfaces and has proven its unique abilities in producing images down to atomic resolution. Soon it was realized that, due to its close proximity to the surface atoms, the STM tip often influences and modifies the surface due to tip-induced migration of surface particles. This obvious disadvantage for imaging was, however, readily turned into a positive prospect by realizing that the tip–substrate interactions as well as electrical field and current can be used to induce modifications of the surface. Pertinent studies proved that the STM tip–surface forces indeed offer startling possibilities to move single atoms and molecules in a desired way

on the atomic scale [1–6]. Thus, the longstanding dream of building man-designed functional nanostructures and creating new material combinations or even new materials in an atom-by-atom manner appears to have come into realistic reach.

To modify a surface by means of a STM tip, one can use three different parameters: the electrical field between tip and substrate, the tunneling current, and the forces between tip and surface (Fig. 1) [1,2,5]. Although field and current effects can be used for surface modifications, these parameters yield mainly gross changes like attraction or repulsion of charged particles or particles carrying a dipole moment from a region under the tip by applying corresponding tip biases [7–11] or electron current induced desorption due to local heating [4]. Reliable atomic scale precision for manipulation is achieved mainly by soft manipulation, where only the tip–substrate forces are employed. These forces can be tuned by changing the distance between the tip and the manipulated particle (Fig. 1). On working with single atoms and molecules, lateral and vertical manipulation modes are distinguished. In the former mode, a particle on the surface is moved along the surface to the desired place without losing contact with the substrate (Fig. 2), while in the latter mode a particle is deliberately picked up to the tip and then released back to the surface (Fig. 2).

2. SCANNING TUNNELING MICROSCOPY

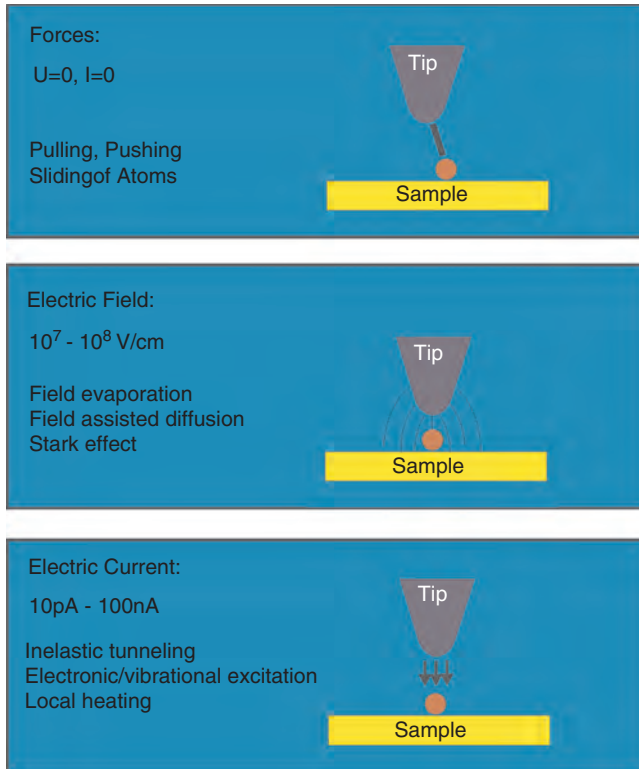
The controlled manipulation of single atoms and molecules demands a higher stability and lower thermal drift of the microscope than necessary for imaging surfaces. Most experiments up to now have been performed at low temperatures since instrumental effects like piezo creep, hysteresis, and thermal drift are then negligible. STMs cooled by liquid helium show usually a drift of less than a few Å within 24 hours, making it possible, for example, to manipulate single atoms from hexagonal close packed (hcp) to face-centered cubic (fcc) sites—a distance of only 1.6 Å. Furthermore, at low temperatures the sample surface can be


Figure 1. Schematic image of the basic tip–sample interaction mechanism for atomic scale modification of surfaces.

kept clean for many days since the surrounding radiation shieldings act as cryogenic pumps and create ideal vacuum conditions—a necessary condition for the time consuming creation of larger artificial structures. Descriptions of instruments capable of operating at low temperature can be found in [12–21].

For the lateral manipulation the control unit is required to be able to (1) position the tip over the adparticle, (2) switch the feedback loop to the manipulation parameters, (3) move the tip (with the adparticle) to the final position, and (4) retract the tip back to the initial imaging height (Fig. 2). Alternatively the feedback loop can be switched off during
Figure 2. Schematic sketch of the lateral manipulation procedure of single atoms or molecules on a surface.

the manipulation to work in the constant height modus [22]. Recording simultaneously the feedback loop signal or the tunneling current gives information about the manipulation process itself. Software lacking these possibilities can be used for tip induced migration only. Automatized software for the lateral manipulation including the determination of the initial position has been used in [23]. For the vertical processes the tip needs to be positioned over the adparticle and the voltage and/or distance is then varied with the feedback loop on or off. For tunneling spectroscopy the first or second derivative measured with a lock-in technique is recorded together with the current. For extended datasets or in case of low signals repeated measurements have been acquired using an automatized tracking procedure to keep the tip over the adparticle [24].

Adparticle-surface systems suitable for lateral manipulation experiments should not exhibit thermally activated diffusion of the adparticles but need to have binding energies low enough that the counterforces acting on the tip do not alter the tip apex instead. As substrates for the manipulation experiments mainly low index noble metal surfaces like Cu(111), Ag(111), Ag(110), Cu(100), and Cu(211) were widely employed, the latter being a regularly stepped surface consisting of (111) nanofacets separated by (100) steps of monoatomic height. The crystal surfaces have to be cleaned in ultrahigh vacuum by several cycles of sputtering with noble gas ions and annealing at elevated temperatures. Desired very small coverages of gaseous adsorbates are dosed at low temperature either through very fine holes to the sample located in the STM or in separate preparation chambers. Metals and heavier molecules are evaporated from Knudsen cells in analogous ways.

Due to the aforementioned requirements attempts to do lateral manipulation at room temperature achieved a much lower precision in the experiments than at low temperatures. Nevertheless vertical manipulation can be done with atomic precision at room temperature too.

3. LATERAL MANIPULATION

Figures 3 and 4 prove the ability to create artificial structures by lateral manipulation. Figure 3 shows the first structures by the first two groups who have succeeded in showing manipulation on atomic scale. In the upper part, the name of their company was written by Eigler and Schweitzer using 35 Xe atoms with a 4K-STM [25]. In the lower part, the Berlin group of Meyer et al. formed at 25 K the two letters F and U with a total of 20 CO molecules, which designate the abbreviation of their university [26]. Notice that at this elevated temperature the CO molecules were still so mobile that it was impossible to keep them in the desired places due to irregular thermally induced jumps. In contrast to this, at temperatures of 15 K structures can be built with CO with atomic precision, as proven in Figure 4, where the Brandenburg Gate of Berlin is reproduced on the nanometer scale. The structure was built by manipulating 47 CO molecules laterally on Cu(211). At 15 K, the molecules are frozen to a sufficient degree that precise working is possible with a rather large number of particles and the artificial structure remains stable for a long time. An impression concerning different stages of the buildup work of an artificial
Figure 3. The first successful works of artificial atomic structures created by manipulation with a STM. Upper: The IBM logo written with single Xe atoms on Ni(110). structure is given in Figures 4, 5, 8, and 41. Although all experiments presented here are performed at low temperature, tip-induced diffusion at room temperature of Br atoms strongly bound on Cu(001) (Fig. 6) has already been demonstrated [27]. The construction of atomically perfect structures with many atoms or molecules is, however, to date bound to low temperatures.

As demonstrated, the first successful manipulation experiments were performed with Xe atoms [1] and small molecules like CO and C_2H_4 [26]; manipulations of metal atoms like Pb, Cu, and Ag followed [12]. It was observed that increasing forces have to be applied in the respective order. With still increasing forces, it was shown on Cu(211) that it is also possible to release native substrate atoms from sixfold coordinated kink sites (Fig. 7a–c) and even from sevenfold coordinated regular step-edge sites (Fig. 7d–f) [26]. This important result opens the way for structuring the surface itself with the promising prospect that also deeper lying substrate layers may be included in the buildup of artificial

Figure 5. Sequence of STM pictures showing the gradual buildup of the millennium number "2000" with 47 CO molecules on a Cu(211) substrate. Figure 6. STM image (60×60 Å) of Br on Cu(100) at RT. The tunnel current is reduced halfway up the image. The tracks in the 3 nA (lower half) area are single atoms hopping from site to site. When the current is reduced the bromine atoms stop moving, for example, those marked A, B, C, and D. Reprinted with permission from [27], T. Fishlock et al., *Nature* 404, 743 (2000). © 2000, Macmillan Magazines Ltd.
Figure 7. Manipulation of native Cu atoms from sixfold coordinated kink sites out of defect steps (a–c) and out of sevenfold coordinated regular step sites (d–f) on Cu(211). Notice the appearance of adatom/vacancy pairs in the latter case. Reprinted with permission from [28], G. Meyer et al., *Phys. Rev. Lett.* 78, 1512 (1997). © 1997, American Physical Society.

prototype structures. It could also be shown that vacancies at step edges of regularly stepped surfaces like Cu(211) can be "healed out" by manipulating single atoms into them. Interestingly, a larger force is required for this purpose than for manipulation along defect-free step edges, indicating that a local barrier due to atom relaxations around the vacancy has to be surmounted [28]. The manipulation of "native" substrate atoms on Cu(211) to different positions allowed determination of adsorbate adsorption sites [29]. Manipulation of Cu atoms perpendicular to the step edges on Cu(211) can also lead to particle exchange at the steps [30]. Data storage employing adatoms and vacancies with writing, reading, and deleting capabilities thus can constitute the utmost limit of storage density [26].

The structure presented in Figure 8 shows the formation of an artificial metallic structure. By lateral manipulation 36 Ag atoms have been positioned in a circle with diameter of 31.2 nm on a Ag(111) surface [23]. The electrons of the surface state are scattered at the adatoms resulting in an energy dependent interference pattern as well, visible in Figure 8. The closed scattering geometry results in an (imperfect) confinement of the electrons inside of the quantum corral as has been demonstrated by Crommie et al. [31]. Experiments with quantum corrals are discussed in Section 11. For more examples of lateral manipulation see references in Table 1.

4. PULLING, PUSHING, AND SLIDING OF ATOMS AND SMALL MOLECULES

In manipulation experiments performed with Cu atoms, Pb atoms, and CO molecules on Cu(211) different manipulation modes, depending on the applied tip–particle force (qualitatively measured by the tunneling resistance), could be distinguished [5,23]. These manipulation modes are shown in Figure 9. Pb (and also Cu and other metal) atoms could be manipulated via attractive tip–adatom interactions in a way in which they follow the tip discontinuously by hopping from one adsite to the next (pulling mode, Fig. 9a, b,
Figure 8. Series of images displaying the formation of a circular quantum corral consisting of 36 native Ag atoms on a Ag(111) surface by lateral manipulation. Circular standing electron waves result from the scattering of the surface electrons with the adatoms. The diameter of the corral is 31.2 nm. Reprinted with permission from [23], S.-W. Hla et al., *Phys. Rev. B* (2003). © 2003, American Physical Society.

e–g). Upon application of larger forces than for pulling, Pb atoms could also be manipulated attractively in a continuous way (sliding mode, Fig. 9c); in this mode the tip–particle interaction is increased so strongly that the tip–particle-system scans the corrugation of the substrate, while the particle–substrate interaction is still strong enough to keep the particle on the substrate. Finally, single CO molecules as well as rows of several CO molecules could reliably be manipulated via repulsive interaction (pushing mode, Fig. 8d), whereby the intrinsic step edges, on top of which the CO molecules are bound, act as railway trails [5]. Using tip induced migration Ag atoms were moved on a Ag(100) surface as can be seen in Figure 10. Depending on the applied voltage the atoms were moved in a pushing or pulling mode along the closed packed rows or across the rows respectively [32,33]. By use of tip induced motion of Ag atoms on the same surface the adsorption site of PTCDA has been determined [34].

On the closed-packed metal surface the direction of the adparticle movement can be chosen freely and here the manipulation mode additionally depends upon the direction.

The manipulation curves from the lateral manipulation of Ag atoms on a Ag(111) surface therefore display additional features. A continuous transition from pulling along the closed-packed [110] direction to sliding along the [211] direction has been observed [23].

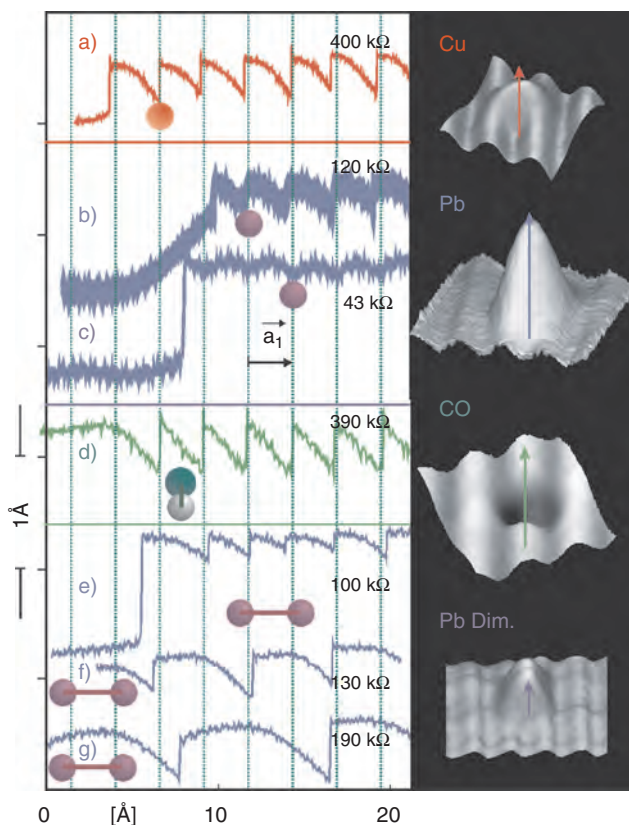
The tunneling resistance necessary to move a Ag atom on a Ag(111) surface was determined by systematically varying the manipulation parameters over a wide range. An extensive set of several thousand computer-automated manipulations has been taken for this purpose. The atom manipulations were performed by using tunneling current values ranging from 8 to 950 nA and tunneling voltages ranging from ±10 to ±55 mV. Figure 11a shows a plot for the probability of a successful atom manipulation versus tunneling current at −45 mV bias. At this bias, the probability of a successful atom manipulation changes from ~0 below 147 nA to ~1 above 250 nA and an average threshold current is determined as 200 nA. The entire measurement procedure is repeated for a wide range of bias voltages. Evaluation of these measurements yields the minimum current necessary to move the atom as a function of the tunneling voltage averaged over all surface directions. Figure 11b depicts the results, which clearly display a linear dependence between the tunneling voltage and the threshold current, independent of the bias polarity. In this low bias regime, influence of electric field effects in the manipulation process is negligible. From the slope of the curve in Figure 11b, a tunneling resistance of (210 ± 19) kΩ has been measured. This linear relationship unambiguously reveals that the tunneling resistance is the ultimate parameter to move an atom within the bias range used in this experiment. This tunneling resistance value corresponds to a tip–atom distance of (1.3 ± 0.2) Å before the formation of an ohmic point contact, as can determined from $I–Z$ spectra. The lateral center-to-center distance between the apex atom and the adatom was measured to be typically 3.5–4.2 Å,


Figure 9. Tip height curves during manipulation of (a) a Cu atom, (b, c) a Pb atom, (d) a CO molecule, and (e–g) a Pb dimer along step edges on Cu(211). The tip is moved from left to right and respective tunneling resistances are indicated. The vertical dotted lines correspond to fcc sites next to the step edge. The initial sites of the manipulated particles are indicated. Notice that in the attractive manipulation modes (a, b, e–g: pulling and c: sliding) the particles first hop toward the tip and then follow it, whereas in the repulsive mode (d: pushing) the particle performs hops away from the tip [5]. depending on the exact path of the atom as discussed in detail in [23]. Since this is a distance where the tip and manipulated atom wavefunctions are overlapping to form bonds, the chemical nature of tip–atom interaction is proven to be the main force in the lateral manipulation process. Theoretical calculations have been made for the pulling of a Cu atom adsorbed at a Cu step edge only. The calculated threshold distances are in fair agreement with the experimental findings for the pulling of Ag atoms on a Ag(111) surface. The calculated force necessary to move a Cu atom is estimated to be 10–100 pN [35].

5. VERTICAL MANIPULATION

Vertical manipulation was first reported by Stroscio and Eigler [1], who demonstrated an atomic switch by transferring repeatedly a Xe atom from the surface to the tip and vice versa. Other experiments with Xe used another method to prove successful transfer of Xe to the tip: A Xe atom was picked up to the tip apex and used for imaging the same area as before with the bare tip. The markedly improved resolution proved that the single Xe atom "sharpens" the
Figure 10. Schematic representation of the STM image resulting from (a) attractive or (b) repulsive tip–adatom interaction during tip-induced diffusion of Ag atoms on Ag(110). A* 66, 675 (1998). © 1998, Springer-Verlag.

tip [36]. Theoretical calculations for the manipulation of Xe atoms can be found in [10,37–40].

The pickup of single CO molecules to the tip is interesting, as it is well known that CO stands upright on metal surfaces with the carbon atom binding to the substrate. Upon transfer to the tip, the molecule consequently has to turn around (Fig. 12a). A reliable experimental procedure for transferring single CO molecules to the tip apex and back to a Cu surface was found to require ramping of the tunneling voltage and simultaneous decrease of the tip–CO distance [5]. While the vertical transfer of a Xe atom at higher voltages is attributed to a polarizing effect of the electric field, the transfer of CO is caused by tunneling into an electronic resonance; See section 7.

An advantageous by-product of the ability to deliberately transfer CO to the tip is demonstrated in Figure 12b. As one can see in Figure 12b, all species imaged with a clean metal tip appear as depressions. When a CO molecule (denoted in this case by the white arrow) is transferred to the tip apex, all CO molecules change their appearance to protrusions (Fig. 12b, left), whereas the oxygen atom in the upper left part of Figure 12b (right) retains its appearance [5]. Thus, chemical contrast in STM imaging is achieved, a phenomenon very useful for the analytic abilities of the STM.

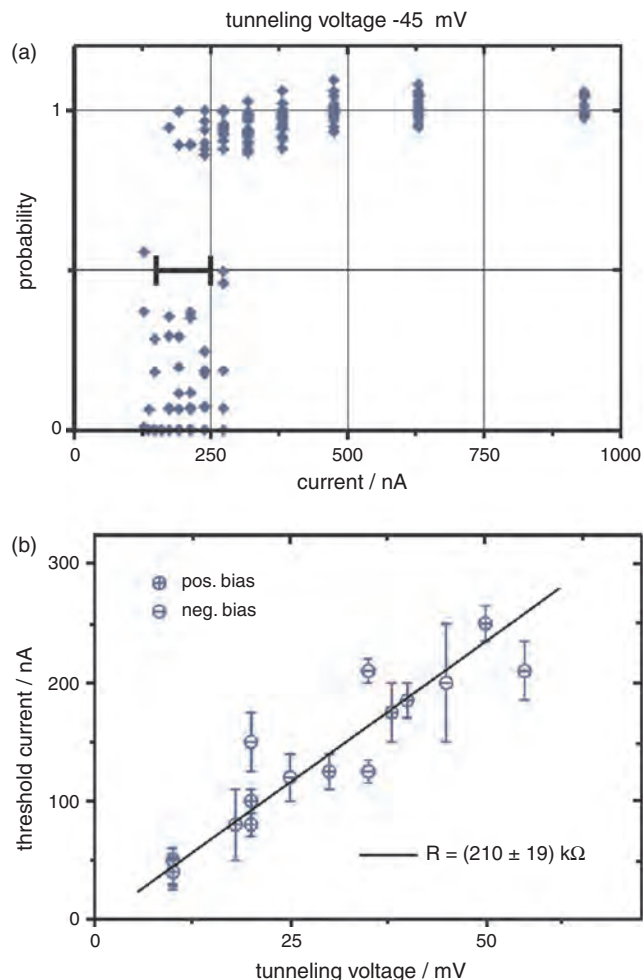
The dependence of STM images on parameters like the chemical constitution of the tip or the density of adsorbed species on the surface is, however, still an open problem, as can be realized from Figure 13 [41]. In Figure 13a we show a regular adlayer of CO on Cu(211) with (3×1) periodicity. With the knowledge that the coverage is 2/3 of a monolayer, a structural model like the one illustrated in Figure 13b, where CO molecules occupy on-top and bridge sites, thus maximizing their mutual distance, appears


Figure 11. Threshold tunneling current and resistance for a successful atom manipulation. (a) The probability for an Ag atom to move along with the STM tip versus the tunneling current at a fixed voltage of −45 mV. (b) The threshold current between ±10 to ±55 mV determined by 3857 automated atomic manipulations shows a linear dependence on the tunneling voltage [23]. Image courtesy of K.-F. Braun.

plausible. Figure 13c–e shows, however, that laterally manipulating together two CO molecules into adjacent on-top sites changes the image from two minima into one maximum located between the two on-top sites. Thus, upon formation of a CO "dimer," a dramatic change in the appearance of the two CO molecules has occurred (Fig. 13d). By separating the two CO molecules their appearance changes to the initial shape. Using the lateral manipulation technique also an extended domain of the (3×1) structure was formed (Fig. 13f) leading to the conclusion that the model depicted in Figure 13g is the proper one and has to replace that of Figure 13b.

Single atoms have been extracted from semiconductor surfaces with a related technique: The tip is brought close to the surface to induce a strong chemical bond and a voltage pulse of several volts induces field evaporation of the substrate atom ("chemically assisted field evaporation" [42] or "transfer on contact"). Using this technique, Becker et al. [43] were the first to report in 1987 the creation

of an atomic-scale "bit" by removing single Ge atoms from Ge(111). The mechanism was investigated by Lyo and Avouris upon experimenting with Si(111)7×7 [42]. Using the same surface Ushida et al. [44] found that center atoms in the 7×7 reconstruction are more frequently removed than atoms near corner holes and concluded that the latter are more strongly bound by 0.1 eV. Similar conclusions for Ge(111)2×8 were reported by Molinas-Mata et al. [45]. Very recently, the removal of Si atoms from a Si(111)5×2-Au surface at room temperature (RT) as a memory application has been discussed [46]. An artificial structure using this technique was made by Hosoki et al. [47] on the MoS$_2$ surface by extracting sulfur atoms (see Fig. 14).

6. VIBRATIONAL SPECTROSCOPY WITH THE SCANNING TUNNELING MICROSCOPY

Whereas spectroscopy of electronic states employing the STM has been used since for more than 10 years, vibrational spectroscopy was pioneered only in 1998, when Stipe et al. [48] showed that the C–H stretch mode could be observed on single C$_2$H$_2$ molecules adsorbed on a Cu(100) surface. A pronounced isotope effect from 358 to 256 meV was observed when using C$_2$D$_2$. Noticeably, with C$_2$HD, the individual ends of the molecule could be determined by measuring the vibrational energies at the respective parts of the mixed isotope molecule (Fig. 15) [24]. In a fascinating extension of this work, Ho performed *vibrational microscopy* of the C–D stretch mode in C$_2$HD by tuning the voltage to the energy of the C–D stretch (Fig. 16) [24]. In STM inelastic electron tunneling spectroscopy (IETS), the sample bias is increased and when it crosses the threshold for excitation of

a vibrational mode, a new inelastic tunneling channel opens, giving rise to a change in conductance dI/dV. To make this change clearly visible the second derivative d^2I/dV^2 is measured using lock-in techniques.

The CO frustrated translational and rotational modes [49] as well as the internal stretching mode on Cu(100) and Cu(110) [50] were observed soon after. In Figure 17
Figure 16. Vibrational microscopy of the C–D stretch in the mixed isotope of acetylene (C_2HD) on Cu(001) at 9 K. results related to the frustrated low energy modes are shown, which have been obtained after having transferred a single CO molecule on the tip by vertical manipulation; the frustrated rotational and vibrational modes of CO on Cu(211) are observed at energies of 5.8 and 35.9 meV, respectively [51].

Inelastic tunneling spectra with a CO or ethylene modified tip have been taken on O_2 and CO on a Ag(110) surface [52]. A number of systems have been characterized by vibrational spectroscopy including larger molecules such as ethioporphyrin-I on Cu(001) [53] as well as single atoms like H and D on Cu(001) [54]. Inelastic tunneling electrons can excite rotational or translational degrees of freedom of a molecule (see Section 7) or even break chemical bonds (see Section 8). Vibrational spectra of water have been taken on Ag(111) [55] and Cu(111) [56]. The excitation of a fullerene-cage vibrational mode by inelastic tunneling electrons has been observed with d^2I/dV^2 spectroscopy along with vibrational maps on single C_{60} molecules adsorbed on Ag(110). The inelastic signal showed strong variations depending on the molecular orientation which is attributed to the different degrees of symmetry of the absorbed molecule [57].

7. EFFECTS DUE TO ELECTRON CURRENT

A detailed analysis of the vertical transfer mechanism of CO molecules on Cu(111) [58] showed that a minimum tunneling bias of 2.4 V is required to excite a molecule. This corresponds to the onset of the CO derived $2\pi^*$ level of the CO/Cu(111) system as known from two photon photoelectron spectroscopy. The hopping rate depends linearly on the tunneling current, which indicates that a one-electron process is the basis of the excitation mechanism. The probability per tunneling electron to induce a hop of a CO molecule depends on the applied bias and has a value below 10^{-10}, if the bias does not exceed 3 V. A strong isotope effect for the quantum yield of the hopping process can be found using

$^{12}C^{16}O$ and $^{13}C^{18}O$. Within the framework of the Menzel–Gomer–Redhead model this isotope effect can be used to estimate a per excitation probability for a hop of a CO molecule of 5×10^{-9} and a fraction of 0.5% of the electrons making up the tunneling current passing through the $2\pi^*$ level of the CO molecules; the lifetime of the electrons in the antibonding $2\pi^*$ level is as short as 0.8–5 femtoseconds [58]. Thus, the CO transfer depends on an effect induced by the electrons provided by the tunneling current. The approach of the tip in the pickup procedure just increases the probability that the molecule is "caught" at or near the tip apex [59].

Electrons tunneling inelastically through molecules can also be used to induce rotational or translational motion, although the injection at high symmetry points does not result in a preferential direction. The current induced lateral hopping of CO molecules on Pd(110) has been demonstrated recently by Komeda et al. [60]. Detailed studies of the rotation of oxygen molecules on a Pt(111) surface and acetylene molecules on a Cu(100) surface have been done by Stipe et al. [61,62]. The electron induced hopping and desorption of hydrogen on a Ge(111)-$c(2 \times 8)$ surface has been investigated by Dujardin et al. [63]. Hydrogen on Si(100) can be desorbed by resonant electronic excitation as well as by multiple vibrational excitation [64,65]. The specific desorption of lines of hydrogen from a hydrogen terminated Si(100) surface followed by the adsorption of Ga constitutes the first example of an artificially formed metallic wire with a diameter of one atom [66] (Fig. 18).

STM investigations of the adsorption of water on Cu(111) at low temperatures (Fig. 19) showed that starting from the adsorbed monomers, the formation of small water clusters

Figure 19. Small crystalline ice clusters formed from monomers via excitation of vibrational modes of the water molecules. Reprinted with permission from [56], K. Morgenstern and K.-H. Rieder, *J. Chem. Phys.* 116, 5746 (2002). © 2002, American Institute of Physics.

and of the cyclic hexamer could be induced by exciting vibrational modes of the molecule with electrons from the STM tip [56]. Crystallization, dissociation, and substrate oxidation can be induced with electrons of higher energy [67].

The hopping movements of Cl atoms on a Si(111)-(7×7) surface can be induced by electron injection with a STM tip positioned laterally displaced from the atom. Thereby electrons can be trapped resonantly by the antibonding orbital associated with a Cl atom, leading to an instabilization of the bond and a diffusion of the Cl atom. The radial probability of the hopping exhibits an anisotropic spread with an oscillatory dependence on the distance from the tip position. This result is interpreted in terms of a coherent wave packet propagation of electrons in a surface resonance band [68].

8. CHEMISTRY WITH THE STM TIP

The combination of several manipulation techniques makes it possible to do surface chemistry at the atomic level which involves dissociation of the parent molecules, lateral manipulation (to account for the diffusion steps), and synthesis of the reactants. The dissociation of a molecule with a STM was first investigated by Dujardin et al. [69]. By scanning $B_{10}H_{15}$ molecules adsorbed on a Si(111)-(7×7) surface with a tunneling voltage ≥ 4 V dissociation into a variety of fragments was observed. O_2 molecules on a Si(111)-(7×7) surface have been dissociated by electron injection into unoccupied adsorbate levels with tunneling voltages above 6 V [70]. Dissociation by vibrational heating of O_2 molecules on a Pt(111) surface was done at much lower voltages. Here multiple intramolecular vibrational excitations via a resonant inelastic electron tunneling process resulted in bond breaking [71]. HS and DS molecule fragments on Si surfaces can be dissociated at low voltages as well as at high voltages [72,73].

It was recently shown that it is possible to induce all steps of a complex chemical reaction with the STM tip at such low temperatures, at which the reaction would not proceed naturally. Specifically, all elementary steps of a century old basic aromatic ring coupling mechanism known as the Ullmann reaction [74] were induced on single molecules using

the STM tip at 20 K on a Cu(111) substrate. The synthesis of biphenyl out of iodobenzene on copper

$$2 \langle \bigcirc \rangle I + 2Cu = \langle \bigcirc \rangle \langle \bigcirc \rangle + 2CuI$$
essentially consists of three steps: Dissociation of iodobenzene (C_6H_5I) to phenyl (C_6H_5) and iodine, diffusion of phenyl to find another phenyl as a reaction partner, and their chemical association to form biphenyl ($C_{12}H_{10}C_{12}H_{10}$). Figure 20 shows the steps of the reaction sequence. First, the iodine atoms originating from two C_6H_5I molecules adsorbed at a Cu(111) step (Fig. 20a) have been separated from the parent molecules by injecting 1.5 eV energy tunneling electrons from the tip (Fig. 20b). The iodine (smaller hills) and phenyl (larger hills) are further separated with the tip (Fig. 20c). Then, the iodine atom placed between the two phenyls has been removed to the lower terrace by using lateral manipulation (Fig. 20d). The left phenyl is then repositioned close to the right phenyl by pulling with the tip and then the injection tunneling electrons with an energy of 500 meV is needed for the chemical association of the phenyl couple (Fig. 20e). The formation of biphenyl is verified by pulling the synthesized molecule from its front end with the tip [75]. In this image sequence, the top and bottom images exactly represent the left and right side of the Ullmann equation.

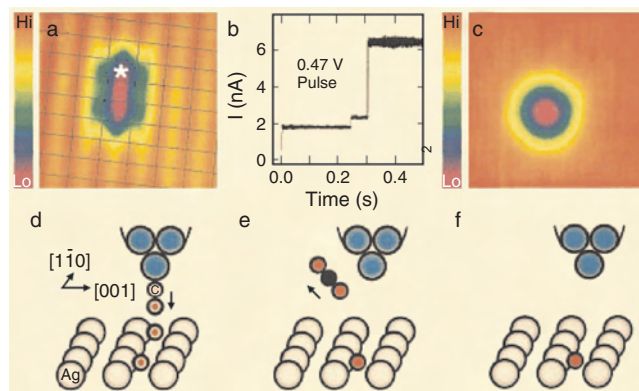
The CO oxidation reaction was induced with STM in two ways on Ag(110) by Hahn and Ho [76]. Oxygen atoms were prepared by dissociation of single oxygen molecules using tunneling electrons of a certain energy [71], whereby the two oxygens remain close to each other (Fig. 21a). Then a CO molecule was manipulated toward an oxygen atom pair by repeatedly applying sample bias pulses over the CO until a
Figure 20. STM tip-induced single-molecule Ullmann reaction sequence on a Cu(111) substrate at 20 K. All reaction steps including dissociation of parent iodobenzene molecules, motion of phenyl reactants and iodine by-products, and association of phenyl reactants to the final product, biphenyl, are induced with the STM tip. Reprinted with permission from [128], S.-W. Hla and K.-H. Rieder, *Superlatt. Microstruct.* 31, 63 (2002). © 2002, American Physical Society.


Figure 21. Reaction of CO molecule released from CO-functionalized tip with an O atom adsorbed at the Cu(100) surface. Reprinted with permission from [24], W. Ho, *J. Chem. Phys.* 117, 11033 (2002). © 2002, American Institute of Physics.

O–C–O complex was formed, which could be recognized due to its characteristic STM appearance. With a further pulse over the CO in the complex, formation of CO was induced, whereby the product immediately desorbed. In the second variant (Fig. 21d–f), a CO molecule was picked up to the tip apex and transferred back to the surface over an oxygen atom thus inducing CO_2 formation again with immediate desorption of the product leaving only one of the initial oxygen atoms at the surface (Fig. 21c). The product formation was recognized via a sudden change of the tunneling current (Fig. 21f) [24].

An interesting mechanism for an STM induced single molecule reaction was reported by Kim et al. [77]. The molecule *trans*-2-butene (C_4H_8) was transformed into 1,2-butadiene (C_4H_6) by inducing electrons of sufficient energy to excite a specific vibrational mode to an amplitude such that two hydrogens were shaken off. The parent molecule as well as the product were identified by both their appearance in the STM images (Fig. 22) and their vibrational spectra (Fig. 23).

Vertical manipulation has been used to transfer CO molecules between a Ag(110) surface and the tip. By transferring the CO molecules from the Ag surface to the tip and back to single Fe atoms deposited on the surface with the technique discussed in Section 7 the formation of ironcarbonyl complexes $Fe(CO)_n$ (with $n = 1, 2$) could be induced (Fig. 24) [78].

Okawa and Aono [79] recently showed that a diacetylen chain polymerization can be induced in a self-assembled monolayer of 10,12-nonacosadiyonic acid on graphite under ambient conditions (Fig. 25a). After creation of an artificial defect with the STM tip by applying a positively pulsed sample bias, the polymerization of a single diacetylene monolayer chain was initiated at another surface location with an opposite voltage pulse. After progression of the chain reaction, the polymer chain was terminated at the artificial defect site. This experiment combines the advantage of topochemical reactions for nanoscale patterning of surfaces with the ability to induce reactivity locally.

Lopinski et al. [80] generated molecular lines on H-terminated Si(100) by creating dangling bonds at the surface and exposing them to styrene vapor, whereby a benzyl
Figure 22. Hydrogen stripping reaction induced by exciting a high energy vibrational mode in 1,3 butadiene on Pd(110) using tunneling electrons. The product is *trans*-2-transbutene. radical is formed which is stabilized by H abstraction from the neighboring Si–H site. Thus, the propagating species, the dangling bond, is regenerated. The process leads to the formation of lines with potential use as molecular wires by planting individual phenyls on the surface that line up in a typical π–π stacking (Fig. 25b).

9. MANIPULATION OF LARGE MOLECULES

The investigation of organic molecules is of interest from both fundamental and technological viewpoints. Due to their complexity and high number of internal degrees of freedom large molecules display more variety for manipulation than atoms and small molecules.

Cu–TBPP molecules (Fig. 26b) adsorbed on a Cu(100) surface at RT do not exhibit thermally activated diffusion and are therefore suitable for manipulation experiments. These molecules can be imaged at large tunneling resistances of several GΩ and exhibit tip-induced molecular flexure at tunneling resistances of the order of several hundred MΩ. At even smaller junction resistances of about 10 MΩ it is possible to laterally move the molecules without rupture or fragmentation of intramolecular bonds. Elastic scattering quantum chemistry (ESQC) calculations revealed an uncorrelated motion of the four ligands in a stick–slip

motion. The molecule is moved in the pushing mode while the tip–surface distance is controlled with a closed feedback loop [81,82]. The lateral manipulation in the constant-height mode at low temperature has been analyzed in detail and will be described in Section 10.

Whereas benzene molecules exhibit high thermal mobility on metal surfaces at RT, this is not the case for the structurally related cyclopentadienyl C_5H_5. This strongly chemisorbed radical can be moved by tip-induced migration at RT. At gap resistances of $\sim$200 MΩ the molecule starts to migrate parallel to the $\langle 110 \rangle$ direction independent of the polarity (Fig. 27, middle). The images reveal a repulsive interaction between tip and molecule which moves in steps of one lattice constant in length (Fig. 27, right). It is proposed that the molecule is tilted upright before jumping to the next site thereby reducing the motion barrier [83].

Benzoate molecules adsorb upright on a Cu(110) surface at RT and form a $c(8 \times 2)$ superstructure. Imaging this surface with a STM induces molecular motion which has been analyzed quantitatively. A model is proposed describing the vibrational excitation via a negative ion intermediate state involving a field-induced shifting of the resonance [84].

Self-assembled stripes of zinc porphyrin molecules can be formed by deposition from solution onto the surface of graphite. This system can be imaged at RT under ambient
Figure 27. Left: STM image showing cyclopentadienyl C_5H_5 molecules on a Ag(110) at RT. Middle: At gap resistances of $\sim$200 MΩ the molecule starts to migrate parallel to the $\langle 110 \rangle$ directions. conditions with a gap resistance of 70 MΩ. At a reduced gap resistance of 10 MΩ the molecules can be moved laterally to create breaks in such a stripe [85].

C_{60} molecules are covalently bound on a Si(100)2 × 1 surface and have been laterally manipulated at RT. The molecules can be pulled, thereby moving in 1–3 lattice constants steps (Fig. 28a). At smaller tip–surface distances the tip–molecule interaction is repulsive and the C_{60} molecules

are moved in a pushing mode in single lattice constant steps (Fig. 28b). The probabilty for a successful manipulation can in this case reach ~100% (Fig. 28c). In spite of rather high electric fields (tunneling voltages ranging from −1 to −5 V) chemical forces are suggested to dominate [86].

The polar molecule 1-nitronaphtalene forms self-assembled decamers on a Au(111) surface due to its electrostatic interaction. At 50 K these decamers can be stably imaged with a gap resistance of 60 GΩ and laterally moved at a reduced tunneling resistance of 25 MΩ without changing their internal structure [87].

By using lateral manipulation it became possible to reveal the restructured metal surface beneath adsorbed HtBDC molecules. These molecules form a self-assembled double-row structure on a Cu(110) surface at RT (Fig. 29ab). At temperatures <160 K the thermally activated diffusion is suppressed and the surface can be imaged with a tunneling gap of about 1 GΩ. The adsorbed molecules can then be removed at a tunneling resistance of 1 MΩ by changing the tunneling current or voltage or both (Fig. 29c). It is found that ≅14 Cu atoms are expelled from the surface in

two adjacent [1$\bar{1}$0] rows, forming a base for anchoring of the molecules which is the driving force of the self-assembly [88].

A similar effect was revealed upon adsorption of so-called lander molecules $C_{90}H_{98}$ onto a Cu(110) surface at RT. Subsequent images and manipulation experiments were performed between 100 and 200 K. Figure 29 shows a manipulation sequence where a molecule is removed from a step edge thereby making a double row of Cu atoms visible. The molecule diffuses toward the step edges at RT and reshapes the fluctuating Cu step adatoms into a toothlike structure. Theoretical calculations showed a higher energy gain for this conformation than the energy required for the creation of the Cu rows [89,90].

The manipulation of the polar molecule phosphangulene adsorbed on a Ag(111) surface was investigated in detail at low temperature. By lateral and vertical manipulation the molecule could be switched between three different conformations which were identified by ESQC calculations. The lateral manipulation of the three-lobed type is shown in Figure 30a, b. Whereas at tunneling resistances of 0.5 MΩ pushing, sliding, and pulling were observed, at higher resistances up to 10 MΩ only pulling was possible. Experiments with different polarity indicated that the molecular dipole has a minor effect on the lateral manipulation. Usually the lateral displacement was accompanied by a rotation of the molecule also visible in Figure 30. The interconversion between different conformations is possible with lateral manipulation as well (Fig. 30) [91].

The manipulation at low temperature of a single TBPP molecule offers the opportunity to demonstrate the principle of a conformational molecular switch [92]. Lateral and vertical manipulation were used to selectively modify the molecular conformation, by rotating single legs in and out of the porphyrin plane.

STM images of single TBPP molecules deposited on the stepped Cu(211) surface are shown in Figure 31a. The molecules show eight lobes, corresponding to four legs oriented nearly flat on the surface [93]. In a few cases (Fig. 31b), a single brighter lobe appears among the double lobes, indicating that one leg is rotated nearly perpendicular to the plane of the substrate.

Calculations show that in the case of flat legs (Fig. 31a) a tilt angle of 10° relative to the surface is present, while in the case of Figure 31b one leg is rotated by 55°. Molecular models (Fig. 31c and d) roughly visualize the two different conformations of the molecule.

A further step toward the implementation of a molecular switch is to use manipulation techniques to reversibly modify the molecular conformation. The switching of a single leg in and out of the porphyrin plane is possible by lateral and vertical movement of the tip to push the leg down.
Figure 31. (a) STM image of a Cu–TBPP molecule on Cu(211) lying flat on the surface and oriented parallel to the intrinsic step edges. (b) STM image of a Cu–TBPP molecule on Cu(211) showing one leg rotated out of the porphyrin plane. (c) and (d) Sketch of the approximate molecular conformation for (a) and (b). (e) Current through a single leg versus the tip–surface distance during a vertical manipulation process leading to a leg's rotation. STM images of the molecule before and after the manipulation are shown in the inset. The black dot in the left image shows the exact position of the tip during the vertical manipulation [92]. Figure 30. The upper image shows the lateral manipulation of a phosphangulene molecule which usually results in a rotation at the same time. The tip–height curves recorded during the manipulation process show pulling, sliding, and pushing behavior at the indicated threshold resistances. The lower images show the interconversion between different conformations induced by lateral manipulation. Reprinted with permission from [91], R. Lin et al., *Surf. Sci.* 477, 198 (2001). © 2001, Elsevier Science.

To experimentally demonstrate the principle of the molecular switch, the interaction between tip apex and leg during a vertical manipulation sequence was quantitatively investigated, as shown in Figure 31e. By measuring the current passing through a single leg in real time during its rotation it could be shown that the tunneling current through one leg strongly depends on the extent of its rotation. Molecular mechanics calculations show that a rotation of 90° should induce a change in resistance of over six orders of magnitude.

It recently became possible to directly determine the energy required to rotate a leg of a Cu–TBPP molecule adsorbed on a Cu(100) surface at RT by using noncontact atomic force microscopy (AFM). Figure 32a shows frequency–distance curves recorded above the molecule and the bare surface. The substracted curve (Fig. 32b) can be converted into short-range tip–molecule force (Fig. 32c). In combination with theoretical calculations an upper limit of 100 zJ required to rotate a di-phenyl-butyl leg was deduced [94].

10. INTRAMOLECULAR MECHANICS DURING THE MANIPULATION OF A LARGE MOLECULE

The technique of single particle manipulations by means of the STM can also be applied to the controlled displacement of large molecules at room temperature [81,83]. To understand and control the process, it is, however, necessary to experimentally measure the intramolecular movement during the manipulation by recording the feedback signal in real time. To assure a low noise level and high stability this experiment was performed at low temperature.

Single TBPP molecules deposited on different Cu substrates were manipulated at low temperature (Fig. 33). Due to the complicated structure of the molecules and their high conductance, controlled lateral manipulation was performed in constant height mode [22]. As shown in Figure 33a, TBPP on Cu(100) shows four bright lobes with some lateral residual echoes, while the porphyrin ring is hardly visible [92]. Calculations of the STM image show that each lobe corresponds to a leg oriented nearly perpendicular to the surface, at an angle of about 80°.

TBPP molecules were manipulated by pushing at one of the legs. The exact path followed by the tip is shown in Figure 33c. The recorded manipulation signal is presented in Figure 33d. The sequence reflects first of all the Cu(100) lattice periodicity, but details in each period do not resemble the regular sawtooth signals recorded during STM manipulations of atoms and diatomic molecules. Zoomed parts of the signal show a specific intraperiod signature, peculiar to this specific type of manipulation.

To extract from the manipulation signal the details about the intramolecular mechanics occurring during a manipulation sequence, calculations and computer simulations were performed, revealing that the main contributor to the signal is the leg which directly interacts with the tip apex and that a minor contribution comes from the leg in front of the tip. The movements are very small; oscillations of the legs amount only to a few half degrees. Such a very fine analysis
Figure 32. (a) Frequency–distance curves recorded via noncontact AFM above Cu–TBPP molecules and the bare Cu(100) surface at RT. The subtracted curve (b) can be converted into the short-range tip–molecule force (c) during the rotation of one leg of a Cu–TBPP molecule [94]. Image courtesy of Ch. Loppacher.

demonstrates, however, that detailed "on line" information on the internal mechanics of a molecule can be extracted from $I(x)$ during many periods [95].

11. PHYSICS WITH ARTIFICIAL STRUCTURES

The lateral manipulation technique has been used to investigate the coupling between magnetic atoms exhibiting Kondo resonances. A Kondo resonance occurs when a magnetic

impurity in a metal couples to surrounding conduction electrons. This coupling causes conduction electrons to form a highly correlated nonmagnetic ground state screening the magnetic moment of the impurity and leads to a narrow Kondo resonance at the Fermi energy. dI/dV spectra taken over single Ce atoms on Ag(111) at low temperature show a clear antiresonance at the Fermi energy [96]. The probing of a localized state immersed in a continuum by STM can proceed either through the localized state or directly into the continuum leading to quantum interference. In the limit where the transition into the localized state approaches zero ($q \approx 0$) this results in the observed antiresonance as first elucidated by Fano [97]. Similar results were obtained from Co atoms on Au(111) shown in Figure 34. Here the higher transition rate into the localized state ($q \approx 0.7$) results in an asymmetric lineshape [98]. Artificially created Co dimers on the other hand showed an abrupt disappearance at separations less than 6 Å resulting from a reduced exchange coupling between Au conduction electrons and ferromagnetic Co dimers [99]. Using lateral manipulation Cr dimers and trimers were fabricated on the same surface. The measurements showed that only one of the trimer configurations exhibits a Kondo resonance [100].

An elliptic quantum corral has been constructed by Manoharan et al. [101,102] as a mirror for electron waves. By dI/dV spectroscopy the Kondo resonance of a magnetic atom located in one focus was detected at the other focus. Figure 35 shows an elliptical quantum corral made of 36
Figure 34. The dI/dV spectra of a single Co atom adsorbed on a Au(111) surface is displaying a Kondo resonance. The dashed line denotes a calculation with a modified Fano theory ($q \approx 0.7$). cobalt atoms positioned on a copper [111] surface. When a magnetic cobalt atom is placed at a focus point of an elliptical corral (upper left), the Kondo resonance also appears at the other focus (lower left) while it does not when the atom is moved out of the focus. The projection of information from an atom to another place where there is no atom is named the "quantum mirage" effect; a possible application
Figure 35. The upper STM images show the topography of an elliptical arrangement of 36 cobalt atoms positioned on a Cu(111) surface; the lower images are the associated dI/dV maps at the Kondo resonance. When a Co atom is placed at a focus the resonance appears at the other focus too (left image) while it does not when it is moved out of the focus. Reprinted with permission from [101], H. Manoharan et al., *Nature* 403, 512 (2000). © 2000, Macmillan Magazines Ltd.

for data transfer in future nanoscale electronics is discussed [101,102].

The formation of closed-packed metallic atomic structures is possible as well. Figure 36 shows a single Cu atom within two parallel closed-packed atomic Cu chains at a distance of 3.5 nm on a Cu(111) surface. At a temperature of 12 K the single Cu atom starts a thermally activated diffusion while the atomic lines remain stable. The surface-state mediated interaction [103] of the single Cu atom with the atomic lines results in an anisotropic movement, guided by the electron standing wave pattern of the atomic lines [104,105].

Large functionalized structures of CO molecules on a Cu(111) surface were assembled by manipulation with a STM recently by Heinrich et al. [106]. Thereby a cascade effect was employed where the motion of one CO molecule caused the subsequent motion of another CO molecule which itself caused a further CO molecule to move and so on. Linear arrangements of such a cascade can serve to transport one bit of information from one place to another. The crossed combination of several cascades made it possible to built logical gates and other devices.

The base unit consists of three CO molecules initially arranged in a bent line; see Figure 37. This configuration decays to an energetically favorable triangular arrangement. The underlying process was identified to be quantum tunneling and temperature independent below 6 K. At higher temperatures the hopping rate was thermally activated with an anomalously low Arrhenius prefactor, resulting from tunneling from an excited vibrational state. The hopping rate is furthermore sensitive to other surrounding adsorbates or defects and also dependent on the direction. These units,

called "chevrons," can then be combined into a linear arrangement yielding a cascade and with two cascades logical gates can be constructed; see Figure 38. The combination of basic logical units then made it possible to construct a two-input sorter and a three-input sorter, consisting of 545 CO molecules (Fig. 39). The decay time of a single chevron is typically 5 minutes at 5 K resulting in an operating time

Figure 36. Two parallel dense-packed Cu rows on Cu(111) were formed by lateral manipulation of 44 Cu adatoms for the construction of an open quantum box. The single Cu adatom put into the center was used for studies of its thermal motion in the confined structure [104]. Image courtesy of J. Repp.

of about 1 hour for the three-input sorter. After the one-time operation the device needs to be reset by moving the CO molecules back into their initial position which typically needs several hours.

Next to the image mode STM has provided means to probe the electronic properties of surfaces locally by scanning tunneling spectroscopy (STS). Thereby the tip is held fixed in position and the tunneling voltage is swept over the range of interest. By a lock-in technique the first derivative of the tunneling current dI/dV is recorded which is a direct measure of the local density of states (LDOS). STS performed at a fixed energy over an area records the LDOS in dI/dV maps. The construction of artificial atomic structures alters the LDOS strongly locally and can therefore ideally be investigated by STS and dI/dV mapping.

Au atoms adsorbed on a NiAl(110) surface were laterally manipulated to form compact chains 2–20 atoms in length. The Au atoms could reproducibly be moved at a junction resistance of 200 kΩ and attached or detached from the end of the chain with the same tunneling resistance. Single Au atoms show an electronic resonance at 1.95 eV above the Fermi energy resulting from an unoccupied Au state hybridized with the NiAl states. Moving the atoms together results in the evolution of one-dimensional electronic density oscillations. Figure 40 shows dI/dV maps of an 11-atom chain taken at different voltages. The measurement of the varying wavelength yields an effective electronic mass of 0.4 ± 0.1 [53,107].

The LDOS inside a triangular quantum corral has been analyzed carefully yielding the electron lifetime as a major property of surfaces [108]. Electron lifetimes have been measured with a STM on the defect-free terrace on Ag(111) by Li et al. [109] at the dispersion minimum of the surface state and as a function of energy by Bürgi et al. [110] and Bauer et al. [135]. Values for other noble metal surfaces have been determined [111] as well inside a Mn atom resonator [112].

By means of lateral manipulation 51 Ag atoms have been precisely positioned at a distance of five lattice constants to form a triangle with a base length of 245 Å as shown in Figure 41. The electrons of the surface state present on the Ag(111) surface are scattered by these Ag adatoms, resulting in a complex standing wave pattern. Energy resolved

data ranging from −55 to +796 meV with respect to the Fermi level were taken in the spectroscopic mode as shown in Figure 42. The displayed images were recorded at energies where the wavelength of the electrons is in resonance with the triangle resulting in a strong enhancement of the intensity.

Calculations of the wave pattern have been performed based on a multiple scattering approach [113]. Adjusting the calculations to the data yields the parameters of the scatterers on the one hand and the phase-relaxation length of the electrons on the other hand. The phase-relaxation length of an electron is the distance an electron can travel without losing its phase information [114] and is directly related to the lifetime of an electron. The spatial decay of the quantum mechanical interference pattern is influenced by the loss of coherence which is expressed in the phase-relaxation length and which is measured here.

Figure 43 depicts the result of the evaluations for the electron lifetime as a function of energy. The measurements clearly show a sharp maximum at the Fermi energy in accordance with Fermi liquid theory for a two-dimensional electron gas. Furthermore two pronounced edgelike features show up in the data at +65 and +300 meV as indicated in Figure 43. These features can be attributed to the dispersion minimum of the surface state and the transition of the surface state into the projected bulk states. Below these energies the inelastic scattering of surface electrons with other electrons is increased resulting in the observed decrease of the electron lifetime. Finally a fine structure can be observed which has to be attributed to the influence of the triangle [108].

The controlled atomic manipulation allows the design of arbitrary scattering geometries and on the basis of a deeper understanding of the electron lifetimes it should become possible to even engineer the lifetimes which are a key quantity in quantum computing and quantum transportation.
12. TOWARD MANIPULATION ON THIN INSULATING FILMS

The prospects of atomic/molecular manipulation lie in the formation of electronic and mechanical devices on the atomic scale. These range from monomolecular devices [115] to atomic scale structures built up atom by atom. A device of the last kind has been proposed by Wada et al. and is called an atomic relay (Fig. 44) [66,116,117]. This and similar devices are characterized by a switching which incorporates the movement of only a single atom. These atomic relays can be integrated to build up complex logic networks including memory cells.

With regard to the existing atomic manipulation experiments, one important problem arises. When an atom or molecule is adsorbed on a metallic surface it has a strong electronic interaction with the metallic reservoir of electrons. Therefore the electronic and mechanical properties of adsorbates are strongly disturbed on metal substrates. With regard to applications it will be very important to electronically decouple adsorbates from the substrate or to be able to
vary the strength of the electronic coupling. This decoupling from the substrate is obviously indispensable for devices like atomic relays, but it is certainly very important for a lot of other systems.

Ultrathin films of insulating materials represent a convenient way to perform these kind of experiments. Not only can the molecules be significantly decoupled with varying degrees from the substrate by changing the thickness of the insulating layers, but at same the time it is still possible to continue to use STM to perform the experiments. For bulk insulators certainly AFM would be necessary, a technique which has been improved amazingly during the last decade, but its application in atomic manipulation especially at low temperatures is still very difficult. Transfer of the STM manipulation techniques is therefore presently pursued to thin films of insulators like alkali halides and simple oxides.

The ability of the STM to operate on insulating films relies on the fact that a finite density of electronic states extending from the metal substrate through the insulating film into the vacuum exists, high enough to support a very small but still measurable tunneling current. For example insulating layers of NaCl of up to a thickness of 4 ML can be routinely imaged with the STM [118]. Even atomic resolution has been observed on these films. As has been shown these NaCl films can be grown in a surprisingly perfect and defect-free manner on different metal substrates, with islands several micrometers in size extending smoothly even
Figure 43. The full circles connected by straight lines denote the measured lifetimes. The open triangle is a measured value on a defect-free terrace [109,111] and the solid line represents an extrapolation of the measurements in [110] taken above 1 eV. The dashed line is an adaptation to the theoretical calculation for Cu(111) [130]. Reprinted with permission from [108], K.-F. Braun and K.-H. Rieder, *Phys. Rev. Lett.* 88, 096801 (2002). © 2002, American Physical Society.

across substrate defect steps (known as carpet growth mode) [118–123]. As has been shown by photoemission, NaCl layers of a thickness equal to or higher than two monolayers show a bandgap with a width similar to bulk material.

The system NaCl on Cu(211) is interesting for several reasons. For substrate temperatures below 200 K the growth of chainlike NaCl islands with monoatomic height is observed as modeled in Figure 45a. An atomically resolved image (Fig. 45b) reveals that only the anions are observed. Figure 45c–e proves that these chains can be cut by lateral manipulation, whereby the NaCl entities are pushed (Fig. 45f).

If the growth temperature exceeds ~300 K [i.e., in the range of emerging kink site mobility for bare Cu(211)], the initially flat (211) surface drastically reorganizes upon NaCl submonolayer deposition. This behavior is in sharp contrast to the common growth features of alkali halides on close-packed metal surfaces [118] which is characterized by weak interactions between the inert overlayer and the metal substrate. On Cu(211) a regular one-dimensional (1D) hill-and-valley structure is formed which is composed of (311) and (111) facets [120] (Fig. 46a,b). The facet arrangement relative to the Cu(211) surface is visualized schematically in Figure 46d (top view) and e (side view). The facets are
Figure 44. A proposed atomic scale device called an atomic relay by Wada et al. [66,116,117]. This device is characterized by a switching which incorporates the movement of only a single atom. These atomic relays can be integrated to build up a complex logic network including memory cells. Reprinted with permission from [66], Y. Wada, *Surf. Sci.* 386, 265 (1997). © 1997, Elsevier Science.

built up by incorporating additional Cu atom rows along the intrinsic step direction. Note that the resulting (311) facet is also a stepped plane, which exhibits a reduced step separation of 4.23 Å. It is important to notice that NaCl grows selectively on the (311) facets only and thereby creates a regular surface pattern with alternating stripes of NaCl-covered areas and bare metal facets. This is evident from the STM topograph in Figure 46b which shows discrete stripes with a pronounced corrugation of cubic symmetry according to (100)-terminated NaCl. The characteristic size of this surface pattern (i.e., the periodic facet separation) can be adjusted by the growth temperature and ranges from ~30 Å at 300 K to 230 Å at 600 K [121]. The restructuring process observed here is driven by an exceptionally high energetic stability of the NaCl(100)-covered (311) facets, which is due to Coulomb interactions between the ionic charges of the alkali halide layer and electrostatic dipoles associated with the steps of the metal template [122] (the step dipoles arise from the well known Smoluchowski smoothing effect of the electron charge [124]). This 1D patterning process is also applicable to other ionic insulator/metal combinations since it is based on a stability criterion with rather general requirements, namely (i) a charge-modulated template (this is an inherent feature of stepped and kinked metal surfaces) [124] and (ii) lattice matching between the ions of the film and the charge modulation of the metal template. Due to the selectivity of the alkali halide-induced faceting process a modulation in surface chemical composition is established.
Figure 45. (a) Model of a NaCl chain oriented perpendicularly to an intrinsic step on a Cu(211) surface. (b) Atomically resolved STM image of a NaCl chain. (c–e) Cutting of two NaCl chains by lateral manipulation with the STM tip. (f) Tip–height curves demonstrating that the NaCl clusters are pushed. Reprinted with permission from [131], G. Meyer et al., *Single Molecules* 1, 79 (2000). © 2000, Wiley-VCH.

Hence, one obtains a nanoscale masking effect of the surface which can be controlled by the growth temperature. This gives at hand a prerequisite substrate for the lateral structuring of subsequently deposited material by selective decoration [125]. The formation of regular pyramids starting from a regularly kinked vicinal Cu(532) surface was demonstrated recently; therefore 2D regular patterning can be achieved too. Only two sides of the pyramids are covered with NaCl leaving a 2D array of metallic areas, which can be used for further reactions [41].

These examples have important implications for further manipulation work: They show (1) that the insulator films can be machined and (2) that self-assembly can give rise to regular structures with alternating insulating and metallic parts, so that, for example, a conducting molecule could be manipulated to lie on the insulator with one end touching the metal and by using the STM tip as second electrode conductivity measurements may become feasible along the molecule.

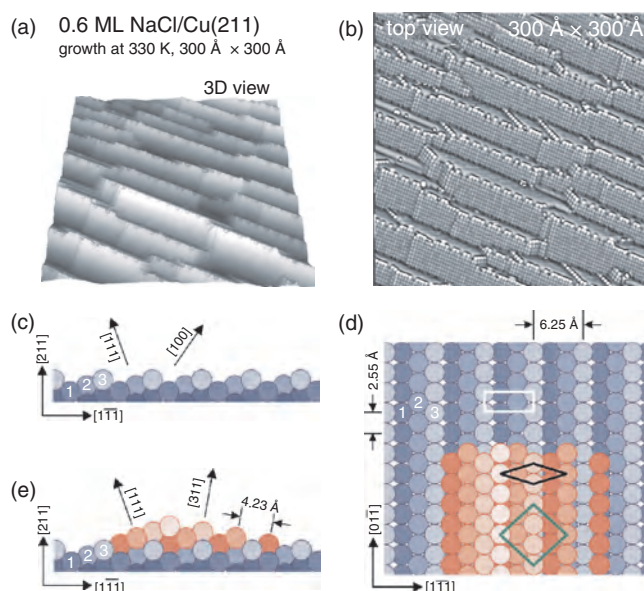
While no lateral manipulation experiments on insulators have been reported to date, theoretical studies have been performed. In the case of NaCl(001), the manipulation of a Au atom and the formation of Au dimers and trimers on this surface have been investigated by Bouju et al. [126]. Already several of the future difficulties common to manipulation on insulators have been addressed in this work. So one of the major problems will be that the binding energy between metal atoms is in general much higher than the


Figure 46. (a, b) STM topographs (1.1 nA, −330 mV) visualizing the mesoscopic faceting effect in 3D view representation (a) and in top view after depositing 0.6 ML NaCl on Cu(211) at 330 K (b). The image on the right shows that NaCl-covered (311) facets (cf. corrugation with cubic symmetry) alternate with bare Cu(111) facets. (c)–(e) Sphere model of the Cu(211) substrate surface in side view along the intrinsic (100) steps (c) and in top view [upper part of (d)]. The primitive rectangular unit cell is denoted by the white line and nonequivalent surface atoms are numbered. The lower part of the top view scheme (d) and the side view in (e) shows a ridge built up by a (111)/(311) facet pair. Fölsch.

binding between the metal atoms and the insulator substrate. This results in the problem that the formation of metastable structures like atomic wires will be more difficult than on metallic substrates. An analogous problem will be the strong attractive interaction between the STM tip apex and the adsorbates, which might result in an unwanted transfer of the metal atom to the tip even before the lateral force is large enough to move the adatom.

This underpins the necessity to uncover the basic adsorbate–substrate interaction properties by manipulation/diffusion experiments. Certainly future successful manipulation experiments and the buildup of atomic scale structures will strongly rely on the right selection of the insulating film materials.

13. SUMMARY

In this chapter, lateral manipulation of atoms and molecules and the buildup of artificial nanoscale structures on metallic surfaces is discussed using the technique of "soft manipulation," in which basically only tip–particle forces are employed. Such structures can be used as quantum laboratories, which allow detailed investigations of important physical quantities like electron lifetimes. Vertical manipulation experiments show that besides tip/particle forces electronic effects are also important for the transfer of particles like CO and Xe from the substrate to the tip

and vice versa. Electric current effects play also dominant roles in STM-induced chemical modifications of molecules like dissociation. A combination of all parameters (forces, current, field) is required to associate several species and to form new chemical entities. Moreover, manipulation of single large molecules opens the route to the creation of electronic devices at the nanoscale and to the ability to control the internal mechanics of a molecule by the STM tip. Engineering with single molecules and single atoms offers in combination with self-organization processes the ability to create novel man-designed artificial entities. Consequently engineering of functional structures including construction elements formed in an atom-by-atom manner certainly no longer belongs to the realm of mere utopia.

GLOSSARY

Lateral manipulation An adparticle on the surface is moved with the STM tip along the surface to the desired place without losing contact with the substrate. In lateral manipulation three basic different modes can be discerned: (1) pulling where the adparticle discontinuously follows the tip from one adsorption site to another due to attractive forces; (2) pushing where the adparticle moves discontinuously in front of the tip due to repulsive interaction; and (3) sliding where the adparticle is trapped under the tip and follows its motion instantaneously and continuously. See also Sections 3 and 4.

Manipulation curve Tip height recorded during the lateral manipulation in the constant current mode. The manipulation curve yields information about the tip–adparticle and the adparticle–surface interaction. See Section 4. If the lateral manipulation is performed in the constant height mode the current is recorded instead. See Section 10.

Quantum corral An artificial atomic structure arranged in a closed geometry (e.g., triangle, circle etc.). The scattering of surface electrons results in confinement with a strongly altered electronic structure. See Sections 4 and 11.

Soft manipulation Mainly the tip-adparticle forces are employed for the manipulation which can be tuned by changing the distance between the tip and the manipulated particle. Only in this regime can adparticles be moved with atomic precision. See Sections 3 and 4.

Tip-induced migration/diffusion Taking along a particle with the tip in an uncontrolled, accidental manner. Obviously, this variant does not allow the buildup of artificial structures in a particle-by-particle manner with atomic precision. See Section 3.

Vertical manipulation An adparticle is deliberately picked up with STM tip and then released back to the surface. See Section 5.

Atomic Structure of Defects in Semiconductors

I. Yonenaga

Tohoku University, Sendai, Japan

CONTENTS

1. INTRODUCTION

The increasing nano and atomic scale miniaturization and large scale integration of advanced semiconductor devices demand improved understanding of structural defects such as dislocations, impurity–defect complexes, etc., which play a vital role in the device function. Thus, their atomic and electronic structures have been the subject of intense theoretical and experimental investigation (for example, [1–3]). Various *ab initio* calculations have been reported on the assumption of the atomic structure of the defects (for example, [4–8]). Experimentally, high resolution electron microscopy (HREM) [9, 10], scanning tunneling microscopy, and Z-contrast (high-angle annular dark field) imaging in scanning transmission electron microscopy [11] are valuable techniques which lead structural information on defects in real space to be ascertained on the nano and atomic scale. Generally, the atomic arrangements in the vicinity of structural defects within semiconductor materials have been determined from projected end-on images and Z-contrast imaging. A number of reports on the defects within semiconductors have been published (e.g., [12–16]). However,

such structural defects are generally unstable under the electron beam and are susceptible to change the structure or dynamic motion during observation and a complete understanding of the microstructure of such defects has not been achieved. To date, there have been several detailed quantitative reports of atom positions and displacements around such defects using HREM (e.g., [17–25]).

This chapter reviews the current knowledge of fundamental defects, mainly dislocations and stacking faults, typically observed in deformed GaAs by HREM and the numerical evaluation of their atomic structure. After preliminary description of the structure of semiconductor materials in Section 2, atomic structure and HREM images of perfect and dissociated dislocations and misfit dislocations at the thin film/substrate interfaces are shown in Section 3, and then, defects induced through dislocation interaction, climb of dislocations, and defect complexes derived by point defect and impurity agglomerations are described in subsequent Sections 4, 5, and 6. In Section 7, the recent development of the direct determination of the atomic positions and their displacements is shown for a 60° dislocation and a Z-shaped dipole. Finally, the formation mechanism of the Z-shaped dipole is discussed in Section 8. Only some limited examples of typical HREM and Z-contrast images will be shown from a huge number of reports in the present field.

Here, it should be noted that high resolution electron microscopy for end-on imaging and Z-contrast imaging is a powerful technique to understand the detailed structure of defects quantitatively though the results should be verified with numerical simulations from geometrical models [11, 23, 26].

2. CRYSTAL STRUCTURE

Tetrahedrally coordinated semiconductors crystallize in the diamond-cubic (e.g., diamond, Si, Ge), sphalerite (zinc-blende) (GaAs, InP, CdTe, ZnSe, etc.), or wurtzite structure (GaN, ZnO, etc.). Each atom possesses four nearest neighbors with covalent and ionic nature bonding depending on its electronic affinity. Crystals can be considered as

an assembly of corner-sharing tetrahedra. The diamond-cubic structure of elemental semiconductors consists of two interpenetrating face-centered cubic (fcc) basis lattices, displaced from one another by one-quarter of the cubic diagonal length. Deducing the stacking order of the closed packed planes ... ABCABC... in fcc structure, the {111} planes stack as ... AaBbCcAaBbCc... by doubling the atoms in the stacking sequences, as shown in Figure 1a. Here A, B, C and a, b, c notes the atoms on the basis sublattices, respectively. Thus, Aa, Bb, and Cc show the positions of [111] bonds connecting the basis sublattices. In III–V and II–VI compound semiconductors the two different atoms of the basis lattices are of different natures, which gives sphalerite and wurtzite structure in the case of the cubic [... AaBbCcAaBbCc... stacking of (111) planes] and hexagonal [... AaBbAaBb... stacking of (0001) planes] symmetry, respectively. Figure 1b shows the atomic arrangement of the stacking of {111} planes in III–V or II–VI sphalerite structure. The (111) atomic planes to be occupied only by III (II) atoms and those only by V (VI) atoms are stacked alternatively, repeating a wide and a narrow interatomic plane also alternatively. The ratio of the two
interatomic-plane distances is 3:1 in the stacking of {111} planes in sphalerite structure and (0001) planes in wurtzite structure. SiC is a typical poly-type material, possessing various crystal structures called 3C, 4H, 6H, and 15R. According to the Ramsdell [27] notation, the number gives the periodicity of the tetrahedral stacking along the axis perpendicular to the basal plane (0001) and the letter (C, H, and R) indicates the symmetry of the resulting structure (cubic, hexagonal, and rhombohedral) [28]. The sphalerite and wurtzite structures are 3C and 2H, respectively, in the notation.

3. DISLOCATIONS

3.1. Perfect Dislocations

Dislocation is a defect controlling the plasticity of crystals by the glide motion and plays a detrimental role in the efficiency of various semiconductor devices. Originating from their basis lattices, the diamond-cubic and sphalerite structure crystals have the dislocation Burgers vectors $a/2[1\bar{1}0]$ on the slip planes {111} as fcc crystals, whereas the wurtzite structure crystals have $a/3[1\bar{2}10]$ on (0001). These dislocations are called *perfect type*. Due to a high Peierls stress dislocations in a semiconductor with the diamond or sphalerite structure are energetically stable when they lie parallel to the ⟨110⟩ directions on the {111} planes whereas dislocations in wurtzite structure crystals are stable when they lie parallel to the $a/3 \langle 1\bar{2}10 \rangle$ on (0001). Thus, the shape of a stable dislocation loop is hexagonal with two opposite screw segments and four 60° segments as seen in Figure 2a. These are such types of dislocations that the dislocation lines make angles of 60° and 0°, respectively, with the Burgers vector [29]. A dislocation lying along some direction deviated from the ⟨110⟩ may be regarded as comprising a number of ⟨110⟩ segments connected by kinks. Figure 2b and c show the atomic arrangements around 60° and screw dislocations in a sphalerite structure crystal. Here, the dislocation

Figure 1. Atomic arrangement of the stacking of {111} planes (a) in diamond-cubic structure and (b) in III–V or II–VI sphalerite structure. In sphalerite structure open circles represent group III (II) atoms and solid circles group V (VI) atoms.
Figure 2. (a) A dislocation loop on a slip plane and atomic arrangements around perfect (*shuffle set*) dislocations in a sphalerite structure crystal. (b) A 60° dislocation and (c) screw dislocation.

is a perfect one and terminates at the wide-type {111} inter-atomic planes, called a *shuffle set* in the terminology of Hirth and Lothe [30]. Differing from the diamond structure crystal, 60° dislocations have geometrical dangling bonds emerging from either group III (II) or V (VI) atoms at the core in III–V (II–VI) compound crystals with the sphalerite or wurtzite structure. The former type of dislocation is termed α-type and the latter β-type, showing the different dynamic properties.

Figure 3a shows a HREM image of a dislocation within plastically deformed GaAs. The image was obtained with the incident electron beam parallel to [01$\bar{1}$] (see [24]). The white spots in the HREM image were found to correspond to columns of the Ga and As atom pairs, that is, the *dumbbells* with a short separation (0.14 nm) in the [01$\bar{1}$] projection. Careful measurement of the image with a Burgers circuit around the defect confirms that the dislocation is a perfect-type 60° dislocation. An extra half-plane due to the edge component of the dislocation can be seen clearly as indicated by an arrow. The atomic structure is schematically shown in Figure 2b. Even now there is controversy over whether such a shuffle-set dislocation moves through the wide-type {111} interatomic planes during a plastic deformation [31–33]. However, the configuration is indispens-

able to cross-slip in dislocation multiplication process during plastic deformation [34].

Figure 3b shows a high resolution Z-contrast image of a threading dislocation viewed along the [0001] *c*-axis direction within wurtzite GaN film grown by metal-organic vapor phase epitaxy [35]. The bright spots are atomic columns of alternating Ga and N atoms determined by intensity distribution. From drawing the Burgers circuit around the dislocation the dislocation core is known to have an edge Burgers vector component of $a/3[11\bar{2}0]$. Two extra half-planes {10$\bar{1}$0} meeting at the core at an angle of 60° between them can be seen clearly. The eightfold ring structure can be seen, meaning the formation of dimers at the core. The core structure, sketched in Figure 3c, well corresponds to the model proposed by theoretical calculation [36]. Sixty degree perfect dislocations with a Burgers vector of $a/3[11\bar{2}0]$ on the basal plane were found in pulverized GaN at room temperature [37]. Perfect screw dislocations with a Burgers vector perpendicular to the basal plane were observed in GaN [35]. Screw dislocations with a large magnitude of the Burgers vector are considered to be associated with the formation of hollow tubes 5–25 nm across (micropipe and nanotube) [38]. Micropipes are typically observed in GaN heteroepitaxially grown sapphire substrates [39, 40].

3.2. Dissociated Dislocations

Generally a glide dislocation in a semiconductor with the diamond or sphalerite structure is dissociated into two Shockley-type partial dislocations bounding a strip of intrinsic stacking fault by following the reaction

$$(a/2)[1\bar{1}0] = (a/6)[1\bar{2}1] + (a/6)[2\bar{1}\bar{1}] \qquad (1)$$

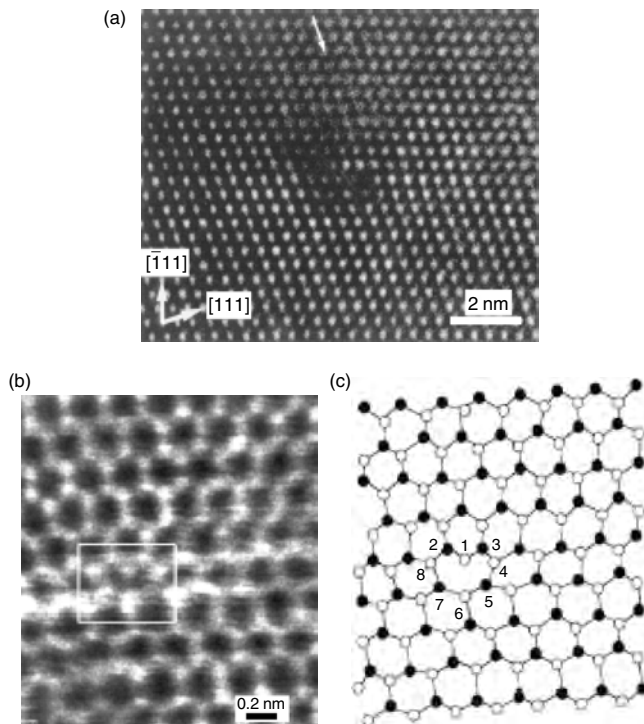
In the terminology of Hirth and Lothe [30], the dislocation is of the *glide set* and moves through the narrow-type {111} interatomic planes. Thus, in the hexagonal shape of a stable dislocation loop, the 60° segment consists of a 90° Shockley partial and a 30° Shockley partial bounding a strip of stacking fault, while the screw segment consists of two 30° Shockley partials as seen in Figure 4a. Dislocations have geometrical dangling bonds emerging from either group III (II) or V (VI) atoms at the core in the narrow-type interatomic plane in III–V (II–VI) compounds. Contrary to the shuffle set dislocations, the former type of dislocation is termed β-type and the latter α-type in the glide set. A 60° dislocation marked α in Figure 4a consists of a 90° Shockley partial and a 30° Shockley partial both of α-type as drawn in Figure 4b. A dislocation segment located on the opposite side of an α-type segment in the same hexagonal loop is always of β-type. Figure 4c shows that a 60° dislocation of β-type consists of a 90° Shockley partial and a 30° partial, both of β-type. A screw dislocation consists of a 30° Shockley partial of α-type and a 30° Shockley partial of β-type, as shown in Figure 4d. No distinction of α and β type is available in the diamond-type semiconductor. The difference in the core structure of α and β dislocations leads to the different effects of impurities on them in compound semiconductors. In the wurtzite structure a dislocation on the basal plane dissociates into two partial dislocations in


Figure 3. (a) HREM image of a perfect 60° dislocation in plastically deformed GaAs. Figure 4. (a) A dislocation loop on a slip plane, and atomic arrangements at the core of (b) an α dislocation, (c) a β dislocation, and (d) a screw dislocation (*glide set*) in a III–V (II–VI) compound. The shaded regions denote an intrinsic stacking fault. In diamond-cubic structure open and solid circles all represent group IV atoms and there is no distinction between an α dislocation and a β dislocation. In sphalerite structure open circles represent group III (II) atoms and solid circles group V (VI) atoms.

a similar way. Here, it is commonly accepted that the geometrical dangling bonds are reconstructed to make bonds between two atoms neighboring each other along the dislocation line [41].

Figure 5a shows a typical HREM image of a 60° dislocation in deformed GaAs in the [01$\bar{1}$] projection. In the image, differing from that in Figure 3a, the 60° dislocation is known to dissociate into two partial dislocations of 30° and 90°, denoted A and B, respectively, bounding a strip of intrinsic stacking fault. The type of the dislocation, whether α or β, corresponding to Figure 4b or c, was not clarified. Figure 5b shows a HREM image of a screw dislocation, dissociated into two 30° partials, in GaAs, corresponding to Figure 4d. The difference of the dissociation width originates from the dislocation nature. The width of the stacking fault is typically of the order of 6–10 nm in elemental and III–V compound
Figure 5. End-on HREM images of (a) a 60° and (b) a screw dislocation in deformed GaAs in the [01$\bar{1}$] projection. Normally the 60° dislocation dissociates into two partial dislocations of 30° and 90°, denoted A and B respectively, and the screw dislocation dissociates into two 30° partials, A and B, bounding a strip of intrinsic stacking fault.

semiconductors such as Si, Ge, GaAs, InP, CdTe, ZnSe, etc. The width can be applied for estimating the stacking fault energy in various semiconductors together with their ionicity [42] as shown in Table 1 [28, 37, 43–55].

Figure 6 shows a plane-view image of a dissociated 60° dislocation in Si [18]. Shockley partial dislocations of 90° and 30° were observed to be dissociated by a stacking fault

^{a} SiC: typical polytypes.
Figure 6. Plane-view HREM image of a dissociated 60° dislocation in Si in the [111] projection. The 90° and 30° partial dislocations with kinks are shown by black lines. Reprinted with permission from [18], H. R. Kolar et al., *Phys. Rev. Lett.* 77, 4031 (1996). © 1996, American Physical Society.

in width of 5.8 nm. Such a kind of a plane-view image can be obtained under the condition of forbidden reflections arising from the stacking fault that separates partial dislocations [56]. On the 90° partial dislocation, kinks can be seen clearly. The dynamic motion of kinks was observed directly in an atomic scale during *in situ* observation at 600 °C. Such a direct observation addressed the understanding of the elementary process of dislocation motion. Such a plane-view observation has been attempted also for Ge and GaAs [57, 58].

In addition to the direct observations of partial dislocations by the plane-view imaging, the investigation of the electronic structure of the partial dislocations has been conducted in Si by electron energy loss spectroscopy (EELS) [59] and by convergent beam electron diffraction (CBED) [60] to clarify the core reconstruction of dislocations as mentioned previously. It is thought that the geometrical dangling bonds make bonds between neighboring atoms in a single or double period along the dislocation line [61, 62].

Here it might be noted that as seen in Figures 3a and 5a, dislocations are found both in undissociate (perfect) and dissociate states in some semiconductors [15, 24]. In GaN, for example, 60° undissociate (perfect) and dissociate dislocations with a Burgers vector of $a/3[11\bar{2}0]$ on the basal plane were reported [37]. There is controversy over which type of dislocation plays a detrimental role in plastic deformation [31]. It is necessary to discuss their energetic stability in motion and in rest [63, 64].

In semiconductor crystals the dislocation velocity v is described using the empirical equation as a function of the stress τ and temperature T

$$v = v_0(\tau/\tau_0)^m \exp(-Q/k_B T) \qquad (2)$$

where $\tau_0 = 1$ MPa. k_B is the Boltzmann constant. The constants v_0, m, and Q are experimentally determined constants. The different types of dislocations in any compound semiconductors have different mobilities and show different physical characteristics in a variety of interactions with impurities [65–68]. Thus, the determination of the dislocation type, α or β, is important to understand the dislocation activities originating from the atomic structure of dislocation cores. For the determination of dislocation type the CBED technique [69] is useful as will be shown. The type of partial dislocation, α or β, in SiC was distinguished by the evaluation of the image contrast of the large difference in atomic number of the constituents [70].

3.3. Misfit Dislocations

Epitaxial semiconductor films are important and lead to various applications in the present microelectronics and optoelectronics technology. The lattice parameter difference between the grown thin film and substrate leads to the generation of misfit dislocations in the interface when the film thickness exceeds a certain critical magnitude. There has been a lot of effort to observe such interfacial dislocations and twins in various epitaxial semiconductor systems. At the interface an array of Lomer dislocations and 60° dislocations has been observed in the heteroepitaxial interface of, for example, ZnTe on GaAs by HREM [71, 72] and of CdTe on GaAs by high resolution Z-contrast imaging [16]. Lomer dislocations are generated by the mutual interaction of dislocations as will be described. Figure 7 shows a Z-contrast image of 60° dislocation at the interface of GaAs on Si and plausible atomic structure [73]. The ellipse-like white spots in the image correspond to columns of the Ga and As atom pairs (i.e., the *dumbbells*). The dislocation core was known to have dangling bonds emerging from As atoms at the interface. Sources for misfit dislocation were found at
Figure 7. (a) High resolution Z-contrast image of a 60° misfit dislocation viewed along the [1$\bar{1}$0] direction at GaAs/Si and (b) the atomic structure model of the dislocation core. The epitaxial-grown GaAs appears brighter than the substrate Si in the Z-contrast imaging since GaAs is heavier than Si. Reprinted with permission from [73], S. Loptin et al., *Appl. Phys. Lett.* 81, 2728 (2002). © 2002, American Institute of Physics.

surface ripple troughs in InGaAs on GaAs heteroepitaxy [74]. The electronic structure of 60° dissociate misfit dislocations generated at the heteroepitaxial interface of GeSi on Si has been investigated by the EELS method to clarify the core reconstruction [75]. The EELS method and Z-contrast imaging are successfully applied to evaluate quantitatively the composition and also the compositional variation at the interfaces of Si/GeSi/Si multiepitaxial layers [76].

4. DISLOCATION INTERACTION

4.1. Lomer–Cottrell Dislocation

Reaction between two dislocations gliding on the intersecting slip planes can lead some types of dislocation junctions, among which a *Lomer–Cottrell* dislocation is well known. Lomer–Cottrell dislocations are found in Si [77] and in subboundaries and heteroepitaxial interfaces in GaAs on Si [73, 78] and ZnTe on GaAs [17]. Figure 8a shows a HREM end-on image of a Lomer–Cottrell dislocation within bulk GaAs deformed plastically. Two extra half {111} planes, emerging at the core at an angle of 55° between them, can be seen. The image is consistent with the asymmetrical structure as shown in Figure 8b, where the stacking fault extends slightly only on one {111} glide plane [79]. Lomer–Cottrell dislocations are sessile since the Burgers vector $a/2[1\bar{1}0]$ perpendicular to the dislocation line [110] is not on the slip plane and acts as a strong barrier for the motion of other dislocations, leading a strong work-hardening of materials.

4.2. Z-Shape Faulted Dipole

Figure 9a is a high-resolution image of a Z-shape defect within deformed GaAs recorded with the incident electron beam parallel to $[01\bar{1}]$. The three intrinsic stacking faults and four partial dislocations (i.e., two stair-rod and two 90° Shockley partial dislocations) delineating the defect can be seen clearly [21, 80]. A stair-rod partial dislocation is sessile since the Burgers vector $a/6\langle 110\rangle$ perpendicular to the dislocation line is not on a slip plane. A Burgers circuit around the whole defect shows no closure error, which confirms the defect to be a faulted dipole. Schematic illustration of the

Figure 9. (a) HREM image of a Z-shape faulted dipole in deformed GaAs. (b) Schematic illustration showing the configuration of intrinsic stacking faults and partial dislocations which form the Z-shape faulted dipole. (c) Atomic arrangements around a Z-shaped faulted dipole. (d) and (e) Enlarged images of the central stacking fault and the lower stacking fault in the Z-shape faulted dipole, respectively, obtained with defocus conditions different from that of (a). (a) Reprinted with permission from [24], I. Yonenaga et al., *Mater. Sci. Eng. A* 309–310, 125 (2001). © 2001, Elsevier Science. (b) Reprinted with permission from [23], D. Shindo et al., *Mater. Characterization* 44, 375 (2000). © 2000, Elsevier Science.

Figure 8. (a) HREM image of a Lomer–Cottrell dislocation within bulk GaAs deformed plastically. The images are consistent with the asymmetrical structure as shown in Figure 6b. Single and double lines mean that an atom located at the corner of hexagons puts out one or two interatomic bonds.

configuration of the intrinsic stacking faults and partial dislocations that form the Z-type faulted dipole is shown in Figure 9b. Figure 9c shows the atomic arrangement around a Z-shaped faulted dipole. The contrast from the stacking faults is consistent with them being of the intrinsic, while extra half-planes located at the top and bottom stacking fault also imply this to be a vacancy-type defect [13]. By the CBED technique it was found that the partial dislocations at the top of this Z-shape defect are to be of the α-type, while those at the bottom of the defect are β-type [81]. Z-shape defects are generated following the interaction of dissociated α and β dislocations, having opposite Burgers vectors and moving on parallel slip planes, and become a stable Z-shape configuration, confined to lie along $\langle 1\bar{1}0\rangle$ directions [82, 83]. Z-shape faulted dipoles are sessile. Similar Z-shape dipoles are also reported in Ge [84] and Si [85].

Figure 9d and e shows an enlarged image of the central stacking fault, lying between the two stair-rod partial dislocations, and the lower stacking fault between the stair-rod dislocation and 90° Shockley partial dislocation in the Z-shape faulted dipole, respectively. The white spots in the HREM image were confirmed to correspond to columns of the Ga and As atom pairs in the [011] projection. By drawing the line AB in the central region between the two stair-rod dislocations of the defect in Figure 9a, the white spots (dumbbells) in the region are found to be displaced parallel to the (111) plane asymmetrically on either side of the defect. In addition, it is remarkable to see splitting of the white spots on the central stacking fault in contrast to the lower and upper stacking faults. These aspects of the central stacking fault are quite distinct and very different from the atomic arrangement of other stacking faults.

5. DISLOCATION CLIMB

It is well known that dislocations can glide easily on their slip plane during electron microscope observation. The phenomenon is termed *recombination enhanced motion* of a dislocation and is considered to be caused by nonradiative electron–hole recombination at the dislocation [86]. The energy released by recombination is converted to a lattice vibration and can affect the elementary process of dislocation motion. Also, after prolonged electron irradiation, dislocations climb by absorbing or eliminating intrinsic point defects. Figure 10 shows a high resolution image of the faulted dipole modified during the irradiation [87]. Even though the whole image shows signs of irradiation damage, it is clearly seen that both β- and α-type 90° Shockley partial dislocations (A and D, respectively) have climbed from the stacking fault plane a few atomic distances in length to the position A' and D'. This means that the 90° partials have climbed through absorption of both Ga and As interstitials. However, it is noted that the β partial dislocation has climbed over a longer distance than the α partial.

From these observations, we can consider a climb process of a 90° Shockley partial dislocation as follows. During electron irradiation, the same number of Ga and As interstitials are generated, and these migrate and collapse to form perfect dislocation loops on the partial dislocations. This is in
Figure 10. HREM image of a Z-shape faulted dipole showing the modification by the prolonged electron irradiation. The 90° partial dislocations A and D have climbed to A' and D', respectively, during irradiation. Reprinted with permission from [87], I. Yonenaga et al., *Mater. Sci. Eng. A* 253, 148 (1998). © 1998, Elsevier Science.

good accordance with a model based on the observations by weak-beam transmission electron microscopy [88]. Climb of dissociated dislocations was also reported in Si [89].

The force necessary to nucleate a perfect dislocation loop AA' of size l is given by the interaction force between a partial dislocation (A) and a perfect dislocation (A'),

$$F_{AA'} = -(3/16)Ga^2/\pi l \tag{3}$$

where a is the lattice constant and G is the shear modulus. The osmotic force for dislocation climb due to an interstitial concentration is given by the equation [29]

$$F_O = (\sqrt{6}/4)\,kTa\Omega^{-1}\,\ln(c/c_0) \tag{4}$$

where c_0 is the equilibrium concentration and Ω is the atomic volume. For nucleation of a perfect dislocation loop on a partial dislocation, the osmotic force due to the saturation of interstitials is balanced with the elastic interaction force between the relevant dislocations:

$$F_{AA'} + F_O = 0 \tag{5}$$

Accordingly, at room temperature, the required supersaturation of interstitials should be of the order of 10^7 cm^{-3} which will be obtained by irradiation.

6. DEFECT COMPLEXES

In semiconductor crystals various kinds of defect complexes have been found by transmission electron microscopy including HREM. Here a few typical examples of HREM observations are shown. Figure 11a shows a HREM image of a hydrogen-induced platelet in Si viewed along the [110] direction [90]. The size is a few tens of nanometers. The image with one extra row of bright dots inserted into the {111} stacking planes is due to hydrogen atoms breaking the [111] atomic bonds and saturating the broken bonds between the adjacent wide-type interatomic (111) planes. The structure shown in Figure 11b has been derived theoretically from the energetic calculation [91]. The defect acts as a nucleation site of {111} cleavage in the *smart cut* technique in hydrogen implantation.

In implanted or irradiated Si wafers rodlike defects running along ⟨110⟩ directions are generated. Figure 12 shows a HREM image of a rodlike defect with a {311} habit plane [92]. The defects are generated by precipitation of excess interstitials on {311} planes as a single layer of hexagonal Si.

HREM investigations of atomic structure of impurity precipitates, especially NiSi$_2$, CoSi$_2$, Cu$_3$Si, etc., in Si, have been applied to relate to their electronic structures for the harmful degradation of the devices [93].

7. NUMERICAL ESTIMATION OF ATOMIC DISPLACEMENT AROUND THE DEFECTS

Quantitative evaluation of the atomic displacement around the defects has been attempted in a perfect 60° dislocation [24] and a central stacking fault of the Z-shape defect [21].

Figure 13 shows the variation of the displacement of the (111) layers along the [111] direction (i.e., the component of the displacement perpendicular to the extra half-plane) as a function of distance from the dislocation core for the perfect 60° dislocation in Figure 3a. Here, the displacement is defined as a difference between the (111) layer spacing and that of the perfect crystal. The displacement of the white spots is essentially zero in the region far from the dislocation core in the left side. The displacement of the white spots becomes large gradually through the following ∼15 (111) layers (≈5 nm) from the dislocation core. The upper layers above the glide plane show negative displacement while the

[311]

Figure 13. Variation of the displacement of white dots from the (111) planes along the [111] direction plotted against distance from the 60° perfect dislocation core in Figure 3a. The displacements of white dots on the three layers closest to the glide plane ($\bar{1}11$), either upper or lower side, are given with various symbols.

lower layers below that show positive displacement, which mean the existence of compressive and expansive strain of the dislocation with an edge component. On the right side the changes of the displacement of the upper and lower layers decrease from ∼15 (111) layers away from the dislocation core. Finally the total difference of the displacement of the upper and lower layers is 0.326 nm, corresponding to the displacement by one perfect dislocation.

Figure 14a shows the deviation of the white spots from the line AB along the [$\bar{2}11$] direction, that is, the component of the deviation parallel to the central stacking fault of the Z-shape defect in Figure 7a, as a function of distance from the stacking fault. The deviation of the white spots is essentially zero in the regions far from the stacking fault and increases in an antisymmetric manner from both sides. The extent of deviation of the white spots then decreases gradually through the following ∼10 (111) layers (≈3.3 nm). Such deviations were almost homogeneously distributed along the central stacking fault. Figure 14b shows the changes of the displacement of the (111) layers, which is defined as a difference between the (111) layer spacing and that of the perfect crystal. The predominant deviations of the white spots occur along the direction parallel to the central stacking fault along [$\bar{2}11$], which means the central stacking fault was generated by a shear process. That is, the motion of a Shockley partial dislocation between the two 30° Shockley partials of an original dislocation dipole results in the formation of one stacking fault and two stair-rod dislocations [94, 95].

8. FORMATION MECHANISM OF THE CENTRAL stacking fault OBSERVED IN Z-SHAPED DIPOLES

Furthermore, the atomic arrangement around the central stacking fault of the Z-shape defect and the formation process have been discussed in comparison with theoretical simulation [21]. First, an intrinsic stacking fault can be generated into a perfect crystal, with Ga and As atoms on the (111) planes in the perfect crystal being displaced at a narrower interatomic plane . . . CcAa/BbCc . . . according to the faulting procedure in a sphalerite structure as shown in

Figure 15. Model of atomic structure and formation of (a) a perfect sphalerite crystal viewed along [01$\bar{1}$]. (b) Schematic indicating the faulting procedure required to create an intrinsic stacking fault **SF**. (c) The atomic shif to reproduce the splitting of white spots corresponding to the observed central stacking fault in the Z-shape faulted dipole. The arrows in (b) and (c) denote the atomic shifting to create an intrinsic stacking fault and the splitting of white spots, respectively. Open and solid circles in the figures correspond to Ga and As atoms, respectively.

Figure 14. (a) Variation of the displacement of white dots on the ($\bar{1}$11) plane in the vicinity of the central stacking fault from ($\bar{1}$11) along the [$\bar{2}$11] direction and (b) from the (111) planes along the [111] direction plotted against distance from the stacking fault observed in the Z-shape faulted dipole in Figure 9a. Circles, squares, and diamonds correspond to measurements from HREM images with different defocus conditions. Reprinted with permission from [24], I. Yonenaga et al., *Mater. Sci. Eng. A* 309–310, 125 (2001). © 2001, Elsevier Science.

Figure 15a and b. Ga and As atoms combined at a wide-type interatomic plane displace as a unit (e.g., Aa, Bb...). The faulting between the 30° Shockley partial dislocations of a dislocation dipole is induced through shear displacement of $(a/6)$ [11$\bar{2}$] or $(a/6)$ [1$\bar{2}$1] type dislocations (inclined to the plane of the page). Thus, the pair Bb of Ga and As atoms above a narrow-type (111) interatomic plane and that Aa below the plane, resulting in the intrinsic stacking fault, are displaced by components $(a/24)$ [21$\bar{1}$] and $(a/24)$ [$\bar{2}$11] in opposite directions parallel to the plane of the page. The extent of displacement of Ga and As atom pairs located at successive planes decreases away from the stacking fault. However, no explicit splitting of the Ga and As atom pairs along the central stacking fault was obtained in the consideration of shear mode.

In order to reproduce the observed splitting of the white spots, the As and Ga atoms combined at the stacking fault plane in the model of Figure 15b were shifted in the range of 20–50% in [$\bar{2}$11] and [21$\bar{1}$] directions, respectively, along the stacking fault plane as shown in Figure 15c. The shift of the As and Ga atoms was given as the percentage of the increased distance between Ga and As atoms, relative to that of the perfect crystal, at the intrinsic stacking fault plane in the model. Essentially the stacking fault width of a dissociated dislocation is given by the balance between the interaction force of two partial dislocations and the interfacial energy of the stacking fault. Conversely, the central stacking fault of a Z-shape defect is induced by the motion of a $(a/6)$[112] Shockley partial dislocation between a pre-existing dipole of two dissociated dislocations. Generally, the mutual interaction of two stair-rod partial dislocations is weaker than that of two Shockley partial dislocations, and the width of the former might become narrower if the two stair rods are mobile. The induced stacking fault in a Z-shape defect thus may show some relaxation due to these competing interaction energies, thereby giving it a nature different from that of an intrinsic stacking fault.

GLOSSARY

Burgers vector A translation vector of the crystal lattice representing the displacement of the material to create a defect such as a dislocation, stacking fault, etc.

Defect An irregularity (imperfection) of the atomic arrangement in the crystalline structure (point, line, and planar defects).

Dislocation A line defect running along the certain directions in which there is an atomic displacement from the regular arrangement in the crystalline structure.

Misfit dislocation A dislocation induced by the difference of the lattice constants at the epitaxial film and substrate interface.

Recombination enhanced motion A promotion of dislocation motion induced by the optical and electrical excitations.

stacking fault A planar defect in the crystal structure in which there is a change from the regular sequence of positions of atomic planes in the crystal structure.

CONTENTS

1. INTRODUCTION

Diamond films grown by chemical vapor deposition (CVD) have a great number of potential applications in nanotechnology including electronic devices, sensors, field emission (FE) electron sources, and microelectromechanical systems (MEMS). Current commercial applications include cutting tools, heat spreaders, optical windows, and speaker diaphragms. These applications utilize the unique bulk and surface properties of diamond such as extreme hardness, high thermal conductivity, wide bandgap, optical transparency from infrared to ultraviolet wavelengths, high FE current, and low frictional coefficient. There are numerous good books [1–5], conference proceedings [6–7], and review articles [8–16] on the CVD growth and properties of diamond films. Our focus in this review article, however, is to present a comprehensive and up-to-date description of the atomic structure of diamond surfaces as determined using scanning tunneling microscopy (STM) in air and ultrahigh vacuum (UHV). We emphasize the diamond (100) surface and UHV STM techniques. In Section 2, we describe the development of CVD diamond growth techniques and the basic properties and applications of diamond films. In Sections 3 and 4 we describe the CVD diamond growth and STM techniques, respectively. In Section 5, we describe the atomic structure of diamond (100), (111), and (110) surfaces.

STM in UHV has been extensively used to study the surface structure and epitaxial growth of Si and other semiconductors at the atomic scale [17–19]. However, UHV STM has not been extensively used to study diamond [20–24]. Most STM studies of diamond have been performed in air where sample preparation is limited to room temperature techniques and usually a hydrogen-terminated surface [25–33]. A recent study reported that STM was not possible in UHV because the diamond surface was not conductive enough until it was exposed to air [33]. One would like to see UHV STM results of diamond comparable in quality to those that have been reported for Si. The STM techniques described in this review article can be used to study adsorbates and processes such as etching, diffusion, and growth with atomic resolution. Such studies are crucial in understanding the growth and properties of diamond surfaces, which are currently not well understood. Earlier reviews of diamond surfaces describe structure and chemistry [34, 35], electronic properties [36, 37], and tribological properties [38].

2. DEVELOPMENT OF CHEMICAL VAPOR DEPOSITION DIAMOND TECHNIQUES

2.1. Historical Development

Diamond is metastable at atmospheric pressure and transforms into a stable form, graphite, when heated above 1700 °C in vacuum [39]. In the past, diamond has been used exclusively as a gemstone and cutting material. In 1955, General Electric reported a technique to produce diamond from solid carbon in a liquid melt by using high temperatures (1500–2000 °C) and high pressures at which diamond is stable (50–100 kbar) [40]. Although this process has been extensively used to produce diamond for commercial applications such as abrasives and cutting tools [41], it has proven to be limited in electronic applications because diamond

crystal sizes are small and the temperatures needed would melt most materials on which it would be useful to deposit diamond. During the 1970s and 1980s, the growth of diamond at high rates using CVD at low substrate temperatures (700–1000 °C) and low pressures (30 Torr) was developed [42–45]. This process uses atomic hydrogen and a gas such as methane (CH_4) that contains carbon. Although diamond is metastable under these conditions, it is believed that atomic hydrogen etches away stable graphitic forms of carbon, and promotes diamond growth by terminating the diamond surface in an sp^3 configuration. However, the exact growth mechanism is not well understood. CVD is compatible with microfabrication techniques and scalable to large areas. In addition, CVD growth conditions such as gas species, substrate temperature, and bias can be controlled, resulting in a variety of carbon-based films with useful properties, such as amorphous diamond, amorphous carbon, tetrahedral amorphous carbon, diamond-like carbon, and nanocrystalline diamond films [46–53]. During the past two decades, there has been considerable worldwide interest in the growth and properties of such carbon films.

The history of the development of CVD diamond growth techniques has been described in detail [42, 43, 45, 54]. In 1952, W. G. Eversole at the Union Carbide Corporation demonstrated CVD growth of diamond on diamond seeds using carbon monoxide (CO) at temperatures of 900–1000 °C and pressures of 100–300 atmospheres [42, 55]. He also grew diamond using hydrocarbons and other carbon-containing gases and used a cyclic growth/etch process to remove codeposited graphite. Independently, B. V. Spitsyn and B. V. Deryagin in the Soviet Union grew diamond on diamond seeds using carbon tetrabromide (CBr_4) and carbon tetraiodide (CI_4) [43]. In these experiments, growth rates were less than 0.001 μm/hr, too low for commercial applications. During the 1960s, research on CVD diamond growth techniques was continued by a few researchers including Angus in the United States and Deryagin's group [42, 43, 54]. Angus developed a cyclic process that consists of a growth cycle followed by an etching cycle in which only atomic hydrogen was used to efficiently remove graphite. The atomic hydrogen was produced by using a hot-tungsten filament to dissociate molecular hydrogen (H_2); however, growth rates remained too low. In the mid-1970s and early 1980s, the Soviet group made significant advances by using both a carbon source and atomic hydrogen during growth, which increased the growth rate to on the order of 1 μm/hr and nucleated diamond on nondiamond substrates [43, 44]. During the early 1980s, Setaka's group in Japan developed CVD techniques that used a hot-tungsten filament [45, 56] or microwaves [57] to dissociate a hydrocarbon gas and H_2. Positively biasing the substrate was found to increase the diamond nucleation density and growth rate [45]. In Japan, other CVD techniques were developed, including low pressure DC and RF plasma techniques with growth rates of 20 μm/hr; atmospheric pressure techniques using DC, RF, and microwave plasmas with growth rates of up to 900 μm/hr; and oxygen-acetylene combustion flame techniques with growth rates of 100 μm/hr [45]. These techniques share in common the use of a carbon containing gas and hydrogen or oxygen, which are activated at high temperatures. In atmospheric and combustion flame

techniques, the growth rate is higher because the gas temperature is higher; however, the film quality is lower.

These innovations triggered considerable research in the United States, Europe, and the rest of the world in CVD diamond synthesis. Since the late 1980s, the cost of growing diamond films has decreased from $5,000/carat to below $5/carat [58]. It is now possible to grow polycrystalline diamond films on a variety of substrates including Si, W, Ta, Mo, Ni, Cu, and SiO_2, and to produce high-quality free-standing films that are on the order of 2 mm thick and 6 inches in diameter [59, 60].

In the early 1990s, it was predicted that by the year 2000 diamond films would be extensively used in a wide range of technological applications from cutting tools to electronic devices, and the market for diamond films would be $2 billion per year [13]. Several companies currently produce diamond films for heat spreaders, tool coatings, optical windows, and other applications [61–68]. However, market predictions have not been met mainly due to the high cost of growing thick films and the inability to grow single-crystal films on nondiamond substrates [13]. Heat spreaders and optical windows require thick high-quality polycrystalline films having a low concentration of nondiamond carbon phases and other defects. Widespread commercial use of these products has been limited by the high cost of growing and polishing such films [58].

Applications in coatings for cutting tools have been limited by poor film adhesion and roughness [9, 58]. Poor film adhesion is due to the difference in thermal expansion coefficient between diamond and tool materials and the dissolution of carbon in Co, Ni, and Fe at high temperatures. Film adhesion has been improved by lowering the growth temperature and using diffusion barriers. Several companies currently produce polycrystalline diamond coated drills, end mills, etc. for the cutting of nonmetallic materials, such as graphite and plastic composites, and nonferrous materials such as aluminum and copper [61–64, 67, 68]. For applications that require precise cutting of aluminum, such as in the automobile industry, diamond coatings with small crystallite size are being investigated [9].

Applications in electronic devices have been limited by grain boundaries in polycrystalline films and by the lack of dopants having low activation energies. Although p-type doping with B is possible, the large activation energy of 0.37 eV results in room-temperature conductivities that are low and highly temperature dependent [69–72]. N-type doping with P has been reported [69, 70, 73, 74]. However, phosphorus has a large activation energy of 0.5 eV and electron mobilities of doped films are low. Sulfur has been predicted to have an activation energy of 0.2 eV, and is currently being investigated [69].

Although applications that require thick high-quality polycrystalline or single crystal diamond films have been limited, there are a number of applications in areas that use thin polycrystalline films, such as ultraviolet photodetectors [11, 75, 76], pressure and acceleration sensors [77, 78], electrodes [79], surface-acoustic-wave (SAW) devices [71], field emitters [80], MEMS [81–85], probes for atomic force microscopy [86], and X-ray lithography masks [87]. In addition, research in CVD diamond growth has generated considerable interest in the growth of smooth hard films such

as diamondlike carbon, nanocrystalline diamond, and boron-
and nitrogen-containing films [8, 46–50, 81]. Such films have
low wear rates and frictional coefficients that have applica-
tions in MEMS and coatings for medical implants and hard
disks.

2.2. Basic Properties of Diamond

Diamond crystallizes in the face-centered cubic (fcc) unit
cell structure with a basis at each lattice site consisting of
two carbon atoms at (0,0,0) and (1/4,1/4,1/4) [88]. There are
eight atoms per unit cell. A schematic of the unit cell in
three dimensions is shown in Figure 1. In the bulk, each
atom is covalently bonded to four nearest neighbors, and the
bonds form a regular tetrahedron centered about the atom.
The tetrahedral bonding configuration is due to the direc-
tional nature of the covalent bonds and also occurs in Si and
Ge. The side of the unit cell in diamond measures 3.56 Å,
making diamond the material with the highest atomic den-
sity. For comparison, the side of the unit cell in Si and
Ge is 5.43 and 5.65 Å, respectively. The high atomic den-
sity of diamond is responsible in part for its excellent fric-
tional coefficient, thermal conductivity, hardness, and opti-
cal transparency.

The surface of a crystal often has an atomic structure
that is different than that of the bulk. Figures 2–4 show
schematics of the bulk-terminated diamond (100), (111), and
(110) surfaces, respectively, in which atoms at the surface
have the same atomic structure as atoms in the bulk. As
shown in Figures 2–4, atoms at the surface are bonded to
fewer than four atoms, resulting in dangling bonds. The
atoms near the surface reposition themselves to form sta-
ble energy configurations. As a result, atoms from the top-
most layer to a few atomic layers in the bulk participate
in surface reconstructions. The reconstructions result in dif-
ferent atomic structures and electronic states from those
of the bulk. Many solid-state phenomena such as etching,
epitaxial growth, adsorption, oxidation, diffusion, and phase
transformations take place near the surface and are deter-
mined by near-surface atomic configurations [17, 18]. There-
fore, studying the surface of materials and understanding
the nature of structures and reactions of surface atoms has
been a primary aim of researchers around the world for
decades. Diamond surfaces are known to be hydrogen termi-
nated after growth. Annealing at 1,000 °C in UHV removes
the hydrogen termination and produces a clean surface. The
reconstructions of diamond surfaces are described in detail
in Section 5.

The properties listed in Table 1 are what make diamond
such an attractive material for nanotechnology applications.
Diamond is the hardest material known. It has a high car-
rier mobility, high dielectric breakdown field, and room-
temperature thermal conductivity that is five times greater
than that of copper. These properties make single crystal
diamond an excellent semiconductor for high power and
high speed applications [89]. Diamond has a wide bandgap
of 5.45 eV, and is inert and tolerant to high energy radiation,
which makes it ideal for applications in harsh environments
such as high temperature, chemical, and space environments
[77, 90].

Electronic applications of polycrystalline diamond films
include ultraviolet photodetectors, high energy particle
detectors, gas sensors, accelerometers, electrodes, SAW fil-
ters, and FE sources. Due to its wide bandgap of 5.45 eV,
diamond absorbs radiation at wavelengths <200 nm and
is insensitive to radiation at wavelengths >230 nm. These
properties have applications in solar blind ultraviolet detec-
tors [11, 75, 76], such as those used in space missions.
The wide bandgap, high carrier mobility, and high dielec-
tric breakdown field of diamond has applications in high-
energy particle detectors having low leakage noise and a
large collection distance [91]. Diamond films have been uti-
lized in hydrogen, oxygen, and carbonmonoxide gas sensors
that operate at high temperatures and in harsh environments
[77, 92, 93]. Such sensors consist of a catalytic film of Pd or

Diamond (110)

Figure 4. Schematic of the diamond (110) surface.

SnO_x that is deposited on an insulating diamond film that is grown on a boron-doped diamond film.

Boron-doped diamond films have an electrical resistance that varies with mechanical strain. This property, called piezoresistance, is due to the lifting of the degeneracy between light and heavy holes by strain. Piezoresistive diamond films have been utilized in pressure and acceleration sensors [77, 78]. Boron-doped diamond films also have excellent electrochemical properties such as stability and wide potential window [79]. These properties can be used in electrodes for biomedicine, harsh environments, and reactions involving high cathodic potentials. The high velocity of sound in diamond has applications in high-frequency SAW filters for cell phones [71]. In addition, CVD diamond films and diamond-coated microtips are being investigated for use as electron field emitters in flat panel displays, miniature X-ray sources, and other vacuum microelectronics applications [94–97]. These applications utilize the high FE current observed from diamond films. The high FE was initially

thought to be due to the negative electron affinity (NEA) of the hydrogen-terminated surface. It is now thought that other mechanisms play a role in FE such as defects, surface conductivity, and local field enhancement due to microstructures on the surface, back contact, or in the bulk [80, 94]; however, the exact mechanism is not known.

The surface properties of diamond are also unique and have many potential applications. Hydrogen-terminated diamond surfaces are inert and have *p*-type conductivity with a low activation energy of approximately 0.05 eV [74]. Oxygen-terminated surfaces are nonconducting. These properties can be used to fabricate field effect transistors. Clean diamond surfaces are highly reactive and can be functionalized with organic molecules for applications in chemical and biological sensors and molecular electronics [98–100]. Hydrogen-terminated diamond, nanocrystalline diamond, and diamond-like carbon films have low wear rates and frictional coefficients [38, 46–51, 81, 101–104]. Such films are currently being investigated as a material for MEMS and coatings for medical implants.

2.3. UHV STM of Diamond

CVD diamond films are typically grown from a mixture of a hydrocarbon gas, such as CH_4, and H_2 that is broken by a hot-tungsten filament or microwaves into hydrocarbon radicals and atomic hydrogen [1–5]. The ratio of H_2 to hydrocarbon gas is about 1–2%. The mechanism for CVD diamond growth and the role of atomic hydrogen in this process are not well understood. Understanding the CVD diamond growth process at the atomic level is crucial in successfully growing films at high growth rates with reliable properties. A basic assumption concerning the CVD diamond growth

Table 1. Properties of diamond.

Property	Value	Units
Hardness	1.0×10^4	Kg/mm^2
Strength, tensile	>1.2	Gpa
Strength, compressive	>110	Gpa
Coefficient of friction (dynamic)	0.03	Dimensionless
Sound velocity	1.8×10^4	m/s
Density	3.52	g/cm^3
Young's modulus	1.22	Gpa
Poisson's ratio	0.2	Dimensionless
Thermal expansion coefficient	1.1×10^{-6}	K^{-1}
Thermal conductivity	20.0	W/cm-k
Thermal shock parameter	3.0×10^8	W/m
Debye temperature	2,200	K
Optical index of refraction (@591nm)	2.41	Dimensionless
Optical transmissivity (from nm to far IR)	225	Dimensionless
Dielectric constant	5.7	Dimensionless
Dielectric strength	1.0×10^7	V/cm
Electron mobility	2,200	cm^2/V-s
Hole mobility	1,600	cm^2/V-s
Electron affinity	NEA	eV
Band gap	5.45	eV
Electron saturated velocity	2.7×10^7	cm/s
Hole saturated velocity	1.0×10^7	cm/s
Resistivity	10^{13}–10^{16}	Ω-cm
Graphitization temperature (vacuum)	>1,700	°C

process is that it involves the formation of carbon complexes on the growth surface. Atomic hydrogen is well known to etch graphitic forms of carbon and diamond. Also, the etch rate of diamond is much slower than that of graphite. Therefore, it is believed that the graphitic forms of carbon are removed during the CVD growth process, thus leaving the diamond by selective etching. In addition, atomic hydrogen is believed to play a role in the formation of sp^3 bonded carbon precursors on the growth surface.

By using UHV STM one can investigate the surface of a conducting material and resolve the atomic structure [105]. This technique has been instrumental in understanding the atomic surface structure and the etch and growth processes of other semiconducting materials such as Si and Ge [17–19]. Other techniques such as X-ray diffraction and ion channeling give information about the bulk properties of crystalline materials [106]. Although low-energy-electron-diffraction (LEED) and transmission electron microscopy are used extensively in materials analysis [107], neither give real spatial information about a sample surface. STM is unique in that it has the ability to give real spatial locations of atoms at the atomic scale, thus revealing vacancies, adatoms, adsorbates, and bond length.

Since the surface of a material is the location where deposition of other atoms and chemical reactions occur, it is important that the surface be the focus of study when one wants to understand in detail crystal etching, growth, and other processes. In the case of diamond, it is important to understand the role of atomic hydrogen and its reaction with the diamond surface during CVD diamond production. There is no better way to understand this and other processes than at the atomic scale where one can observe by UHV STM the results of a physical process or chemical reaction atom-by-atom.

UHV STM has many advantages over STM in air such as sample surface cleanliness, ability to prepare the surface, the possibility of the use of electrochemically etched tungsten tips that result in sharper images, and *in-situ* tip cleaning. Tunneling current versus voltage (*I-V*) spectroscopy using STM is also more reliable in UHV [18]. Originally, when diamond (100) was studied by STM it was done in air [25–33]. This was on the assumption that diamond is a relatively inert material and that the diamond (100) surface would be minimally contaminated by air. Also, air experiments limited the STM to PtIr or gold tips, as well as prevented reliable tip cleaning. Consequently, the air experiments were limited to the inert hydrogen-terminated diamond surface, and the image quality was poor and unreliable.

3. CVD GROWTH OF DIAMOND

3.1. Growth Techniques

The most widely used CVD techniques to grow diamond films are the hot-tungsten filament and microwave plasma techniques. Figure 5 shows a picture of a hot-tungsten filament reactor in which an epitaxial diamond film is being grown on a synthetic diamond (100) substrate. There are four main parameters for diamond growth: gas mixture,
Figure 5. Picture inside a hot-filament CVD diamond growth system. The sample holder is on a linear translator for translation into a UHV STM system.

gas pressure, substrate temperature, and filament temperature. Typical growth conditions are H_2 and CH_4 flow rates of about 200 and 1 standard cubic centimeters per minute (sccm), respectively, pressures of approximately 30–100 Torr, sample temperatures of 800–1000 °C, and a filament temperature of about 2,000 °C. To grow diamond on Si requires that the substrate be pretreated by scratching it with diamond powder or using bias enhanced nucleation techniques in which the substrate is negatively biased under a hydrocarbon plasma for about 20 minutes.

In order to produce high quality diamond via CVD, the vapor quality must be controlled. It is imperative that the ratio of the main constituent gasses (hydrogen, the catalyst, and methane, the carbon source) be closely monitored in order to produce a consistent crystal morphology. By varying the ratio, one can choose the dominant growth of low index faces in polycrystalline films. Typically, this is done by a combination of gas flow meters and metering valves. To increase the electrical conductivity of films at room temperature, doping with boron at high concentrations is carried out. For example, diborane (B_2H_6) gas is introduced during growth at concentrations on the order of 10 ppm relative to H_2. The conductivity is due to impurity bands or hopping mechanisms [72].

Figure 6 shows an atomic force microscopy (AFM) image of a polycrystalline diamond film grown on a Si substrate for 12 hours using the hot-tungsten filament technique. The sample temperature was 900 °C and the CH_4/H_2 concentration was 1%. As shown in Figure 6, the film has crystallites with exposed square {100} and triangular {111} faces and oriented with the ⟨110⟩ direction normal to the substrate. Such a film is defined to have a {100}{111}⟨110⟩ texture [108]. In Figure 6, the {111} faces are rough and microfaceted, and the {100} faces are smooth.

3.2. Texture of Polycrystalline Diamond Films

The texture of polycrystalline diamond films can be understood using the primary bonded chain (PBC) [109, 110] and Van der Grift [111] models. The PBC model is used to explain differences in the growth velocities of crystallographic faces. The growth velocity of a crystallographic
Figure 6. AFM image of a CVD grown polycrystalline diamond film showing {100} and {111} faces oriented in the ⟨110⟩ direction.

Figure 7. Shape of diamond crystallites as a function of α that is proportional to the ratio of growth velocities of {100} and {111} faces.

face is defined as the growth rate normal to the surface. A PBC consists of a linear chain of atoms that grows preferentially along the chain. The diamond lattice has only one PBC, which consists of a zig-zag linear chain of atoms in the ⟨110⟩ direction (see Fig. 4). The diamond {111} faces contain three PBCs in nonparallel directions, the diamond {110} and all faces in the ⟨110⟩ zone except the {111} faces contain one PBC, and the diamond {400} and all other faces contain no PBCs [110, 112]. Therefore, {111} faces have slow growth velocities, and {110} and {100} faces have significantly faster growth velocities. Faces with fast growth velocities grow themselves out to a point or edge and, consequently, are not observed in crystallites. As a result, diamond crystallites should have an octahedral shape with {111} faces. Most natural diamond crystals are observed to have this shape [112]. However, CVD grown diamond crystallites are observed to have shapes that range from cubic to cubo-octahedral to octahedral depending on growth conditions. The range of shapes that occurs during CVD growth shows that the growth velocity of {100} faces is comparable to that of {111} faces. This is thought to occur as a result of the introduction of additional PCBs on the (100) surface by a hydrogen-terminated 2×1 reconstruction or an adsorbate layer [112].

Figure 7 shows the shape of diamond crystallites as a function of the ratio of growth velocities of {100} and {111} faces. In Figure 7, the growth parameter $\alpha = \sqrt{3} V_{100}/V_{111}$, where V_{100} and V_{111} are the {100} and {111} growth velocities, respectively. At $\alpha = 1$, crystallites are cubic with {100} faces and corners in the ⟨111⟩ direction; at $\alpha = 1.5$, they are cubo-octahedral with square {100} and triangular {111} faces and corners in the ⟨110⟩ direction; and, at $\alpha = 3$, they are octahedral with {111} faces and corners in the ⟨100⟩ direction. By varying CVD growth conditions, this range of shapes can be observed. The value of α for a growth experiment is difficult to predict because it depends on various conditions such as sample temperature, CH_4/H_2 concentration, and reactor geometry. The value of α can be determined after growth by measuring the dimensions of isolated
crystallites and using the equations,

$$\alpha = \frac{a + \sqrt{2}b}{a + 2/3\sqrt{2}b} \qquad \text{for } 1 \leq \alpha \leq 1.5$$

$$\alpha = 3\frac{c + d}{c + 2d} \qquad \text{for } 1.5 \leq \alpha \leq 3$$

where a, b, c, and d are as shown in Figure 7. It is generally observed that α decreases as the substrate temperature increases and the CH_4 concentration decreases [9, 112].

The Van der Grift model [111] provides an explanation for the development of texture in polycrystalline films in terms of evolutionary competition between crystallites that have nucleated on the substrate. This model assumes that crystallites nucleate on the substrate with random orientations. During growth, crystallites oriented such that the fastest growth direction is normal to the substrate will overgrow all other crystallites. Crystallites oriented with their fastest growth direction normal to the substrate will have specific faces that are exposed on the surface, such as shown in Figure 7. Eventually, such crystallites cover the surface of the film resulting in a specific texture. As a result of this process, the film also has a columnar cross-sectional structure.

The Van der Grift model describes polycrystalline film growth for conditions that are consistent with the model's assumptions that diffusion does not affect cystallite shape and new phases and orientations do not form during growth. These assumptions are met for a range of CVD diamond growth conditions, allowing texture to be controlled by varying growth conditions [9, 108]. However, at high CH_4 concentrations and high temperatures, nondiamond carbon phases develop. In addition, twinning easily occurs on {111} faces, and penetration twins occur on {100} and {111} faces. These processes have a significant effect on the morphology and growth rate of polycrystalline diamond films [113, 114]. For example, at low temperatures, twinning on {111} faces frequently occurs and films develop a {111}⟨110⟩ texture independent of methane concentration [9].

For a given α, multiply twinned diamond crystallites form with untwinned crystallites. Untwinned crystallites have shapes shown in Figure 7. Figure 8a and b show scanning electron microscopy (SEM) images of multiply twinned
Figure 8. SEM image of multiply twinned diamond crystallites. (a) Icosahedra with 20 {111} faces. (b) Decahedra with ten {111} and 5 {100} faces. Bar denotes 1 μm.

diamond crystallites that have icosahedral and decahedral shapes, respectively. The icosahedra has twenty {111} faces, and the decahedra has ten triangular {111} faces and five square {100} faces. These shapes are due to the formation of five $\Sigma = 3$ twins [114]. Depending on α, multiply twinned crystallites show reentrant grooves between {111} and {100} faces [115], as observed in Figure 8. Reentrant grooves between {111} faces have enhanced growth and greatly increase the growth rate of {111} faceted crystals [116].

Polycrystalline diamond films having a specific texture are grown by varying growth conditions such as sample temperature and CH_4/H_2 concentration. For example, by setting growth conditions such that $1.56 < \alpha < 1.73$, diamond films with a {100}{111}⟨110⟩ texture were grown [108]. By increasing α to slightly greater than 1.73, films with {100} faces in a near ⟨100⟩ direction were grown [108]. By increasing α further, films with a {100}{111}⟨100⟩ texture were grown [108]. With α increased to about 2.60, films with a {111}⟨100⟩ texture were grown [108].

4. SCANNING TUNNELING MICROSCOPY

4.1. Principle of Operation

The experimental techniques used to characterize surfaces are often based on different physical phenomena. Prior to the invention of STM, the atomic structure of surfaces was characterized using LEED and other techniques that gave indirect and incomplete information. Not until STM [105] and other scanning probe techniques were invented was a detailed understanding of the atomic structure of surfaces possible.

The basic principle of STM is quantum mechanical tunneling of electrons between a conducting tip and sample. Quantum tunneling is the transmission of electrons through a potential barrier higher than the energy of the electrons. Tunneling can be observed when a tip under bias is positioned above a sample at a distance of approximately 10 Å. The direction that the electrons flow, tunneling into unoccupied states or from occupied states on the surface, is controlled by the polarity of the tip. The tunneling current at small bias is described by the following equation [18]

$$I \propto (V/s)\exp(-A\phi^{1/2}s)$$

where $A = (2m/h^2)^{1/2} = 1.025/(\text{eVÅ})$, I is the tunneling current, V is the bias voltage applied between the tip and

sample, ϕ is the local barrier height, s is the tip-to-sample distance, and m is the mass of the free electron. This equation shows that I decreases exponentially as s increases. Assuming a barrier height of about 4 eV, I decreases by about an order of magnitude for every 1 Å increase in s. The order of magnitude change in I with changes in s on the order of 1 Å is responsible for atomic resolution in STM.

To obtain an image using STM requires positioning the tip into tunneling range and scanning the tip above the surface with atomic resolution. This requires highly precise control of tip positioning and isolation of the STM system from external vibrations. In the early years of STM, achieving atomic resolution was hindered by these difficulties. When G. Binning et al. [105] published the first STM image of the Si (111) 7×7 surface reconstruction in 1983, the results were not widely accepted because only a few groups were able to reproduce them [117–119].

Tip positioning is accomplished using a piezoelectric material that changes length under the application of a voltage. Piezoelectric scanners can be designed to have a resolution less than 1 Å in the x- and y-directions and 0.05 Å in the z-direction, and movement that is approximately independent along each axis and linearly proportional to the applied voltage. A common design is the tube scanner [120], which consists of a hollow piezoelectric tube, as shown in Figure 9. The tube scanner has a scanning range on the order of microns that is determined by the diameter and length of the tube, and is compact and rigid for vibration isolation. The inner surface of the tube is coated with a single silver electrode, and the outer surface is coated with four electrodes arranged in opposing pairs, as shown in Figure 9. To perform x- and y-motion, voltages are applied to the appropriate electrodes to bend the tube. To perform z-motion, the same voltage is added to all four electrodes. Figure 10 shows a schematic of a commercial STM head consisting of a tube scanner mounted in an inchworm motor [121]. The inchworm motor moves the tube scanner over a distance of several millimeters with a step size on the order of a micron. As shown in Figure 10, the motor is composed of piezoelectric actuators that move the inchworm by using a controlled sequence in which clamps 1 and 3 are activated and deactivated, and segment 2 is contracted and extended [121]. The inchworm motor and tube scanner move the tip from a distance of millimeters from the sample to within tunneling range. The STM head is mounted on a base plate

that is isolated from vibrations by springs. For UHV applications, the STM head is mounted on a UHV flange, as shown in Figure 11. Other piezoelectric devices for moving the tip and scanner to within tunneling distance are inertial sliders that use the stick-slip principle [18].

After the tip is positioned within tunneling distance, a digital or analog feedback loop is used to maintain a constant tip-to-sample distance to keep the tip from crashing into the surface. As shown in Figure 12, the tunneling current is converted to a voltage using a current-to-voltage converter. The voltage is compared with a reference value that is set by the user. The feedback loop minimizes the difference between the measured and reference voltages by adjusting the z-position of the tip. Digital feedback loops have the

Figure 12. Block diagram of a digital feedback loop of an STM system.

advantages that they are assembled using standard boards and are flexible. In a digital feedback loop, the difference voltage is sent to a conventional proportional and integral controller, as shown in Figure 12. The integral gain controls the speed of the feedback response. If the integral gain is set too low, feedback operation is slow and the tip will crash. If it is set too high, the tip will oscillate. Proportional gain controls how far the tip is advanced for a given difference value.

To obtain an STM image, the tip is moved across the surface by modulating the scanner in the x- and y-direction, as depicted in Figure 13. Typical tunneling currents are between 0.1 and 1.0 nA with a bias on the order of a volt. Depending on which mode of operation the STM system is in, the feedback is either on or off. With the feedback

off, the tunneling current between the sample and tip is recorded as the tip is scanned in the x- and y-directions. With the feedback on, the tunneling current is held constant by maintaining a constant tip-to-sample separation by also modulating the z-direction as the tip is scanned in the x- and y-directions. This second mode of operation, called topographic, is the most common and produces a three-dimensional image of the surface.

In addition to imaging, STM can be used to measure the local surface density of states and barrier height with atomic resolution. These techniques involve measuring at a specific atomic location I as a function of V at fixed s, and I as a function of s at fixed V [18]. These techniques are referred to as I-V and I-Z spectroscopy, respectively.

4.2. Preparation of the STM Tip

The tip is one of the most critical parts of an STM system. The shape and material of the tip influences imaging and spectroscopic measurements. Multiple tips can result in superimposed images. The best images are obtained when a single sharp tip scans over a flat surface. The most widely used tip materials are platinum-iridium (Pt-Ir) and tungsten (W). Pt-Ir tips are stable in air and can be easily prepared by cutting a Pt-Ir wire using a wire cutter. They can also be electrochemically etched in a molten CaCl solution. W tips form a thin oxide layer in air, and can only be used in UHV after the oxide layer has been removed by heating. The advantages of W tips are that they can be made ultrasharp by using electrochemical etching techniques [122] and can be cleaned in UHV resulting in reliable imaging and spectroscopic measurements.

Ultrasharp W tips have been reported to produce clear large-area atomic resolution STM imaging of clean boron-doped epitaxial diamond (100) films [21]. Figure 14a is an SEM image of an ultrasharp STM tip. The tip was made by electrochemically etching a 0.020 inch diameter tungsten wire in a 1 molar solution of NaOH [24]. Figure 14b shows a schematic for electrochemically etching ultrasharp tungsten tips. The drop technique [123] shown in Figure 14b is employed because it gives the best tip geometry. Also, the drop section of the tungsten wire provides an event that can be electronically detected and used to signal that the etch process has completed. The electronic control box provides the bias voltage and the circuitry to detect the drop and terminate the etching process by opening the electrical circuit. It is important that the voltage be controlled electronically because a manually operated switch cannot be opened quickly enough in order to obtain an ultrasharp tip. It is also possible to shut off the bias voltage too soon. If that occurs then the tip will have a stretched and curved tail, as shown in Figure 15a. The curvature is probably due to recoil of the tip as the drop section falls and no longer supplies tension to the submicron tip. A small delay after the drop section has fallen, on the order of a few microseconds, is necessary to etch away the tail portion. If the shut off delay is too long, the tip sharpness rapidly decreases. Figure 15b shows the sharpest tip that typically can be obtained using a manual cutoff.

5. ATOMIC STRUCTURE OF DIAMOND SURFACES

5.1. Diamond (100) Surface

5.1.1. Air and UHV STM Results

STM imaging of diamond film is possible by increasing the conductivity of the surface by doping the film with boron or terminating the surface with hydrogen. The first reports of STM imaging of diamond were carried out in air using a Pt-Ir tip. Turner et al. [25] reported STM imaging of boron-doped polycrystalline diamond films with nanometer resolution. Everson and Tamor [26] imaged boron-doped polycrystalline diamond films with near-atomic resolution.

The first atomic resolution imaging of diamond was reported by Tsuno et al. [27] who imaged epitaxial diamond (100) films in air using a Pt-Ir tip. The epitaxial films were grown on high pressure/high temperature (HPHT) grown synthetic diamond (100) substrates using the microwave plasma technique. A $2 \times 1/1 \times 2$ dimer reconstruction was observed with anisotropic extension of dimer rows. The 2×1 reconstruction after growth is known to be monohydride terminated [34], and is denoted as diamond (100)-2×1:H. Figure 16 shows an air STM image of the diamond
Figure 15. (a) SEM image of a tungsten tip made with an electronic system that was shut off too soon showing a curved end. (b) SEM image of the sharpest tungsten tip that can typically be made using a manual shut-off. Bar denotes 1 μm.

(100)-2 × 1:H surface from [30]. The surface consists of atomic planes with dimer rows rotated in the xy-plane 90° relative to the dimer rows in the upper or lower atomic planes. Each carbon atom in a dimer is attached to one hydrogen atom. In Figure 16, there are two different types
Figure 16. Atomic resolution air STM image of the diamond (100)-2 × 1:H surface. Reprinted with permission from [30], Th. Frauenheim et al., *Phys. Rev. B* 48, 18189 (1993). © 1993, American Physical Society.

of steps, denoted S_A and S_B. S_A and S_B steps are single atomic layer steps that have dimer rows parallel and perpendicular to the step edge, respectively. D_A and D_B steps are double atomic layer steps that have dimer rows parallel and perpendicular to the step edge, respectively. Figures 17a–c show schematic representations of the hydrogen-terminated diamond (100)-1 × 1, 2 × 1, and 3 × 1 reconstructions, respectively.

Tsuno et al. [31] also used air STM to study epitaxial diamond (100) films grown on synthetic diamond substrates that were misoriented 4.3° from ⟨001⟩ towards ⟨110⟩ ±3°. The films were grown using the microwave plasma technique at CH$_4$ to H$_2$ concentrations from 2–6%. The films were not annealed in a hydrogen plasma after growth. At a methane concentration of 2%, a single domain 2 × 1 surface was observed consisting of D_A steps. The formation of D_A steps was attributed to a step flow growth mode in which dimer rows preferentially grow in the direction of the dimer rows. At a methane concentration of 6%, 2 × 1/1 × 2 domains were observed using LEED indicating the formation of two-dimensional islands.

Kuang et al. [32] used air STM to study boron-doped epitaxial diamond (100) films that were grown on natural diamond substrates using the microwave plasma technique. After growth, the films were annealed in a hydrogen plasma for 10 minutes at 875 °C. Observed were D_B steps, local hydrogen-terminated 3 × 1 reconstructions, antiphase boundaries, and dimer vacancies. The D_B steps were thought to be nonbonded. As shown schematically in Figure 17c, the hydrogen-terminated diamond (100)-3 × 1 reconstruction, denoted as diamond (100)-3 × 1:1.3H, consists of alternating rows of dihydride and monohydride terminated subunits. It was thought that the diamond (100)-3 × 1:1.3H reconstruction exists only locally due to strong steric repulsion between hydrogen atoms [32]. In contrast, the Si (100)-3 × 1:1.3H reconstruction is observed over large areas using STM [19].

Polycrystalline diamond films have also been used to study the diamond (100) surface with atomic resolution. Busmann et al. [28] imaged polycrystalline diamond films with nanometer resolution using a mechanically prepared Pt-Ir tip. Observed were disordered structures of clusters 5–30 nm in size. Zimmermann-Edling et al. [29] studied polycrystalline diamond films at the micron and atomic scale, and observed a diamond (100)-(2 × 1):H reconstruction on the {100} faces of crystallites. In the above experiments, the films were not intentionally doped and the
Figure 17. Schematics of the hydrogen-terminated diamond (100) surface. (a) 1 × 1:2H. (b) 2 × 1:H. (c) 3 × 1:1.3H.

conductivity was due to hydrogen-termination or amorphous carbon regions. Busmann et al. [33] carried out a detailed investigation of the atomic structure of {100} faces of polycrystalline films as a function of morphology and texture. The morphology and texture was varied by changing only the substrate temperature during growth. At $\alpha = 2.8$, a rough surface was observed that could not be imaged with atomic resolution. At $\alpha = 1.5$, a diamond (100)-2 × 1:H reconstruction with islands was observed. At $\alpha = 1.3$, a diamond (100)-2 × 1:H reconstruction was observed with a clear atomic step structure in which S_B steps were broader than S_A steps. This was attributed to a step-flow growth mode in which dimer rows grow in the direction of the rows. At $\alpha = 1.2$, a 2 × 1 reconstruction was observed with strongly asymmetric islands that was attributed to a nonhydrogen terminated diamond (100)-2 × 1 reconstruction.

Using LEED, Marsh and Farnsworth [124] and Lurie and Wilson [125] showed that polished diamond (100) substrates display a 1 × 1 pattern. The diamond (100)-1 × 1:2H reconstruction is shown schematically in Figure 17a. Since this surface is not observed using STM, it is believed that the 1 × 1 LEED pattern is due to a rough surface consisting of a distribution of dihydride and monohydride units [34]. Annealing of polished substrates in UHV at temperatures >1000 °C results in a 2 × 1 LEED pattern [125] that is due to the clean diamond (100)-2 × 1 surface. This surface is described in detail in the next section. Exposure of the clean diamond (100)-2 × 1 surface to atomic hydrogen results in a 2 × 1 LEED pattern that is due to the diamond (100)-2 × 1:H surface [34]. Theoretical studies show that the most stable configuration for the clean and hydrogen-terminated diamond (100) surfaces is the 2 × 1 reconstruction with symmetric dimers [34]. For clean and hydrogen-terminated diamond (100)-2 × 1 surfaces, theoretical studies predict that single and double layer steps are nonbonded [126].

Air STM has also been used to image natural and synthetic diamond (100) substrates. In these studies, the conductivity was due to boron doping. Couto et al. [127] studied the morphology of HPHT grown type IIb diamond (100) substrates after polishing along easy and difficult directions. Different polishing mechanisms were observed. Nutzenadel et al. [128] studied natural doped diamond (100) substrates that were etched in a hydrogen plasma, and observed a diamond (100)-2 × 1:H reconstruction and large atomically flat terraces.

UHV STM is required to study clean diamond surfaces because such surfaces are highly reactive. In UHV, the surface can be prepared in a controlled manner making possible detailed studies of adsorbates, diffusion, etching, and growth. Tsuno et al. [20] used UHV STM to study clean boron-doped epitaxial diamond (100) films and observed a diamond (100)-2 × 1 reconstruction. Stallcup et al. [22, 23] used UHV STM to study hydrogen-terminated epitaxial diamond (100) films after growth. The surfaces of the films were observed to be amorphous at the atomic scale. After 5 minutes of exposure to atomic hydrogen, the surfaces were observed to consist mostly of 2 × 1:H regions. Stallcup and Perez [21] also used UHV STM to study anisotropic etching of boron-doped epitaxial diamond (100) films by atomic hydrogen, as described in detail in the next section. Recently,

Bobrov et al. [129] used UHV STM to image clean insulating natural diamond (100) substrates with atomic resolution using resonant electron injection into the conduction band. In these experiments, the tip-to-sample bias was approximately 5.4 V, corresponding to an energy higher than the work function of diamond of 5.3 eV. At such a high bias, the STM operates in the near-field emission regime that typically has a resolution on the order of 3 nm. In the case of diamond, it was thought that atomic resolution is possible due to the large dz/dV slope at resonance. It was thought that the sample conducted the tunneling current due to the long diffusion lengths in diamond of 150–250 μm.

5.1.2. Anisotropic Etching

The diamond (100) surface is of particular interest because epitaxial diamond (100) films grow smooth at substrate temperatures of approximately 1000 °C, unlike epitaxial diamond (111) and (110) films that grow rough [2]. The growth of smooth diamond (100) films is not well understood. Surface diffusion of adsorbates, which is responsible for the growth of most smooth films, is not widely accepted as responsible for the growth of smooth diamond (100) films because the hydrogen-terminated surface prevents diffusion [129]. Diffusion on the diamond (100) surface during growth has been modeled as occurring along surface sites where hydrogen has been removed by abstraction [131]. However, recent theoretical models have shown that the addition of surface diffusion to models would lead to higher growth rates than are experimentally observed [132]. Other mechanisms that have been proposed to explain the growth of smooth diamond (100) films are anisotropic etching [133] and preferential etching of undercoordinated atoms [132]. Using UHV STM, Stallcup and Perez [20] found that etching by atomic hydrogen is highly temperature dependent resulting in a rough and pitted surface at T ≈ 200 °C and T ≈ 500 °C, respectively. At T ≈ 1000 °C, etching results in a smooth surface and is highly anisotropic occurring predominantly in the direction of dimer rows. This observation supports recent theoretical models that propose anisotropic etching as the mechanism for the growth of smooth diamond (100) films.

Previous STM results on the hydrogen-terminated diamond (100)-2 × 1:H surface [22, 23] were limited to small area scans due to tunneling instabilities resulting from physisorbed hydrogen and carbon on the sample surface. Imaging such a surface with loosely bound atoms was problematic and short-lived but necessary in order to study the CVD diamond growth process. Scanning tips did not last long because of contamination from the surface to the tip. During instances of tunneling current instabilities caused by this contamination, "tip crashes" would occur and often this resulted in rendering the tip useless. In this case, a "tip crash" is when the STM feedback overcorrects or undercorrects as a result of the current instabilities and the tip comes into hard contact with the sample surface, usually deforming the tip.

The results in [21] are without these problems because of three factors. The first important factor is that the samples were etched by atomic hydrogen after growth for at least five minutes, thereby removing the excess and

loosely bound carbon from the surface. The second factor is that desorbing the loosely bound hydrogen from the surface by heating the substrate to 800 °C for one minute resulted in improvement of the tunneling current stability, which produced clearer STM images. Further heating to 1000 °C removed the hydrogen-terminated surface and further enhanced the STM image quality. These techniques for cleaning the diamond surface can only be performed in UHV. The third and very important factor was the use of ultrasharp tungsten tips that were described in Section 3. These factors make possible atomic resolution STM imaging over large areas measuring 80×80 nm^2. From images of large areas, both the atomic structure and large-scale morphology of the surface resulting from etching, growth, and other processes can be studied.

The CVD diamond films were grown epitaxially on 2 mm $\times$ 2 mm $\times$ 0.25 mm type 2b (100) diamond substrates. The films were grown for two hours in a UHV compatible hot tungsten filament CVD reactor and were approximately 2 microns thick. The films were doped with boron during growth to increase their conductivity for STM studies. Without the incorporation of boron, the diamond surface would have become highly insulating when the hydrogen was desorbed by heating in UHV. The CVD growth pressure was 30 Torr with the hydrogen, methane, and diborane gases having flow rates of 200 sccm, 0.5 sccm, and 6.0 sccm, respectively. The substrates were resistively heated to 900 °C using a tantalum heater foil. The tungsten filament temperature was that typically used for CVD diamond growth of 2200 °C. The growth process was terminated by shutting off the methane flow and maintaining all of the other parameters for 5 minutes. This step was a post-growth etch with atomic hydrogen. The filament was then turned off followed by the sample heater and then the hydrogen flow being turned off. After the growth process was terminated, the CVD reactor was evacuated to 1×10^{-8} Torr and the samples were transferred to the UHV STM chamber via a linear translator without exposure to air.

After verifying by STM that the diamond films were of good quality, the samples were returned to the CVD reactor, via the linear translator, for additional exposure to atomic hydrogen. The hydrogen flow rate, pressure, and filament temperature were 200 sccm, 30 Torr, and 2200 °C, respectively. These parameters were the same as those for the CVD diamond growth to ensure that the diamond surface was exposed to the same amount of atomic hydrogen flux as during growth. From this point on, two different groups of experiments were done. In Group A, the sample temperature was a constant of 500 °C and the atomic hydrogen exposure times were 2, 7, 12, and 17 minutes. After each additional exposure, the sample was translated to the UHV STM and analyzed to determine if additional etching had an effect on the surface morphology. In the group B experiments, the exposure time was held constant, 5 minutes, with the substrate temperature being the variable and having the values of 200 °C, 500 °C, and 1000 °C. Each diamond sample was then returned to the UHV STM to determine whether the atomic surface structure had changed as a result of the atomic hydrogen etching at the different temperatures. Tunneling currents of 1 nA with a sample bias of −1 to −1.5 V were used.

Figure 18 shows a UHV STM image of a CVD grown boron doped epitaxial diamond (100) film after exposure to atomic hydrogen for 5 minutes at a sample temperature of 500 °C. As previously discussed, the diamond (100)-2×1 surface exposed to atomic hydrogen is known to be monohydride terminated. In Figure 18, unmarked arrows indicate regions where S_A steps were etched perpendicular to the rows resulting in islands marked I. The islands are believed to be due to etching and not the growth process because the islands were not observed until the 500 °C etching. The islands have a 3×1 reconstruction consisting of a wide monohydride-terminated row and a narrow dihydride-terminated row, as indicated in Figure 18. The 3×1 reconstruction on diamond (100) has been previously observed along step edges [32]. There are many antiphase boundaries in Figure 18 marked Φ, and these boundaries are necessary in order for a terrace to accommodate both 2×1 and 3×1 reconstructions.

Figure 19 shows a UHV STM image of an epitaxial diamond (100) film after exposure to atomic hydrogen for 10 min at 500 °C. A square etch pit several atomic layers deep and containing a bright circular structure having a diameter of approximately 2.5 nm is observed. Other regions of the film showed similar etch pits with bright structures. The bright structures are conjectured to be etch byproducts or groups of hydrogen atoms because the structures disappear after the sample is heated to 1000 °C, as shown in Figure 20a and b. It is well known that hydrogen can be stored in carbon nanotubes and nanostructured carbon materials. Similar sized bright structures have been observed in etched Si and attributed to etch byproducts [19]. The pit in Figure 19 is pyramidal in shape and has {111} faces. This shows that, at 500 °C, the etch rate in the {111} direction is slower than that in the {100} and {110} directions.
Figure 18. Atomic resolution UHV STM image of the diamond (100)-2×1:H surface after etching by atomic hydrogen for 5 min at 500 °C obtained using an ultrasharp tungsten tip. Observed are 2×1 and local 3×1 reconstructions, islands marked I, and dimer phase shifts marked Φ. Both S_A and S_B steps are rough. Reprinted with permission from [21], R. E. Stallcup and J. M. In order to further explore pit formation and how pits evolve, the previously mentioned Group A experiments were done. Figure 20a and b show the results of the 500 °C time exposure experiments of Group A. These results show
Figure 20. UHV STM image of a CVD epitaxial diamond (100) film after sequential exposures to atomic hydrogen at 500 °C showing the evolution of pits. (a) After a total of 7 min of exposure. (b) After exposure to 0.001 Torr of oxygen for 1 min and an additional 5 min atomic hydrogen etch for a total of 12 min. The unmarked arrows indicate hydrogen that has aggregated in the etch pits. α indicates the original nucleated etch pits, and β indicates the new etch pits that were nucleated by the oxygen.

that the pit nucleation density does not significantly change with added exposure to atomic hydrogen. But, with increasing exposure time, the pits increase in area and depth, which is what one might expect with additional surface etching. Although the pits are becoming larger with additional atomic hydrogen exposure, the pits on each new surface are about the same size relative to each other. The small variation in pit size indicates that over time no new pits are being nucleated. The arrows marked α in Figure 20a and b are indicating the original pits. Only until exposure to oxygen and then further etching with atomic hydrogen are new pits nucleated, as indicated in Figure 20b by the arrows marked β. It is unknown what the cause of nucleation is for the first group of pits, but it is hypothesized that they are the result of lattice dislocations. It is well known that etch pits on crystal surfaces are nucleated on lattice dislocations [88]. Figure 20a and b show the dramatic improvement in the STM imaging of diamond (100) after annealing in UHV. Figure 20a is a UHV STM image of the hydrogen saturated 2 × 1 surface before annealing in UHV. Figure 20b shows the sample after it was heated to 1000 °C for 1 minute, resulting in desorbtion of all the hydrogen in the etch pits and removal of the hydrogen that terminated the 2 × 1 surface. Note the dramatic improvement in image quality shown in Figure 20b after the 1000 °C anneal.

Figures 21–24 show UHV STM images of the Group B variable temperature experiments in which the diamond (100)-2 × 1 surface was exposed to atomic hydrogen for 5 minutes at substrate temperatures of 200, 500, and 1,000 °C. In these images, the diamond (100) surface was heated to 1000 °C for 1 minute in UHV after the atomic hydrogen exposure in order to desorb the hydrogen physisorbed and chemisorbed on the surface. Using LEED and electron-energy-loss spectroscopy, it has been reported that desorbtion of hydrogen at 1,000 °C in UHV results in a nonhydrogen terminated diamond (100)-2 × 1 surface [34], in agreement with Figures 21–24. The stability of the
Figure 21. Nonhydrogen terminated diamond (100)-2 × 1 surface after atomic hydrogen exposure for 5 min at 200 °C. Reprinted with permission from [21], R. E. Stallcup and J. M. Perez, *Phys. Rev. Lett.* **86**, 3368 (2001). © 2001, American Physical Society.

tunneling current was found to increase after the hydrogen desorbtion. For example, Figures 22 and 23 show tiled STM images obtained one after the other showing excellent reproducibility. As shown in Figures 21–24, the diamond (100)-2 × 1 surface has dimer rows that are narrower than those in the diamond (100)-2 × 1:H surface. In addition, in the diamond (100)-2 × 1 surface, individual dimers are not observed.

Figures 21–24 show that the temperature of the surface during exposure to atomic hydrogen had a significant effect on the resulting morphology. It was found that the morphologies shown in Figures 21–24 are due to the atomic hydrogen exposure at the various temperatures instead of the subsequent annealing at 1,000 °C in UHV. For example, additional annealing of the surface at 1,000 °C in UHV for 15 minutes did not result in any observable changes in morphology. In addition, films with any one of the three different morphologies shown in Figures 21–24 could be converted to any of the two other morphologies by simply etching at that specific temperature. For example, a film with the smooth morphology of Figure 24 was exposed to atomic hydrogen with a sample temperature of 200 °C and resulted in producing a surface morphology like that of Figure 21. The observed morphology was then changed back to the smooth morphology by etching at 1,000 °C.

As shown in Figure 21, exposure at 200 °C results in a very rough surface at the atomic scale. The rough surface shows that etching at 200 °C is isotropic. No large pits are observed, and the largest domain size is about 6.25 nm². As shown in Figure 22, exposure at 500 °C results in a surface that is smoother at the atomic scale with larger domains measuring about 100 nm². In addition, this surface contains large single atomic layer vacancy islands, single height steps, and deep pits. The pits have a pyramidal shape, as was previously discussed in the Group A experiments. The vacancy islands have an average length along the dimer rows that is 2.1 times greater than the average length perpendicular to the dimer rows. This shows that etching at 500 °C is anisotropic and that it is 2.1 times more likely to occur along the dimer rows than perpendicular to them. Shown in Figures 23 and 24, exposure at 1,000 °C results in a smooth surface with single and double atomic steps, and the largest domains of the three experiments measuring approximately 350 nm².

The step morphology in Figures 23 and 24 shows that S_B steps, in which the dimer rows are perpendicular to the steps, are very rough. However, S_A steps, in which the dimer rows are parallel to the steps, are very smooth. In contrast, the 500 °C etched sample shown in Figure 22 has rough S_A steps. In addition, S_A steps having a few dimer rows above them are not etched, as shown by the unmarked arrow in Figure 24. In Figures 23 and 24, vacancy islands consist mainly of single row vacancies and no large pits, and there are D_A steps in which the middle S_B step has been completely etched. These observations show that etching at 1000 °C is highly anisotropic with the etch rate along the dimer rows much greater than that perpendicular to the rows.

The anisotropic etching in the direction of dimer rows supports recent theoretical models of the growth of smooth diamond (100) films. Figure 25 shows a schematic of the diamond (100)-2 × 1:H surface. In theoretical models, growth on this surface occurs by the adsorption of CH_3 on surface sites where hydrogen has been abstracted [130]. The adsorbates then form methylene bridges and dimers. In the anisotropic etching model described in [133], extension of the dimer row at atoms 1 and 2 in Figure 25 can occur as long as hydrocarbons have not adsorbed at the dimer bonds to their right. For example, the presence of a methylene bridge between atoms 3 and 4 will prevent adsorption of CH_3 at atoms 3 or 1 due to steric repulsion, and growth will wait until this methylene bridge is etched. Growth of dimers at S_A steps, corresponding to atoms 5 and 6 in Figure 25, is not kinematically stable against etching because all dimers grown at S_A steps are similar to dimers at the ends of S_B steps and can be etched [133]. In contrast, only the last dimer in a row of an S_B step has a high probability of being etched. For example, atoms 7 and 8 can be etched only after atoms 9 and 10 are etched. Therefore, growth at S_B steps can proceed via dimer row extension and produce a continuous monolayer. The UHV STM results described above provide direct evidence for this model. A recent model that considers the preferential etching of undercoordinated atoms predicts the observed growth rate and a smooth surface [132].

5.1.3. Steps and Defects

Steps and defects on the surface play an important role in the growth of films and nanostructures. As previously described, the diamond (100)-2 × 1:H surface is inert and
consists of single- and double-layer steps, local 3 × 1 reconstructions, phase shifts, and dimer vacancies. The clean diamond (100)-2 × 1 surface is reactive and has been investigated as a substrate for metal films [134], buckyballs [135], functionalized organic molecules [98–100], and mechanosynthesis of nanostructures [136]. Stallcup and Perez [137] studied the atomic structure of steps and defects on the diamond (100)-2 × 1 surface using UHV STM and found that single- and double-layer steps are rebonded. The main types of defects observed were single, multiple, and row dimer vacancies, and antiphase boundaries. Buckling of dimers was not observed, in agreement with theoretical predictions that dimers are symmetric [138].

Figure 26 shows schematics of single S_A and S_B, and double D_A steps on the diamond (100)-2 × 1 surface. As shown in Figure 26, rebonded S_B steps have edge atoms on the bottom plane that are bonded. For such steps, the distance from edge dimers on the upper plane to the nearest dimer row on the bottom plane is $3d$, where d is the lattice constant of the unreconstructed 1 × 1 surface. For nonbonded S_B steps, the distance from edge dimers to the nearest dimer row on the bottom plane is $2d$. D_A steps consist of an S_A step on an S_B step, and have edge atoms on the bottom plane that are rebonded or nonbonded in a manner similar to that of S_B steps. For the Si (100)-2 × 1 surface, UHV STM studies have shown that S_B and D_A steps are rebonded [17, 18]. Theoretical studies of this surface have shown that rebonded steps are more energetically favorable than nonbonded steps because they have fewer dangling bonds per step length [139]. In contrast, for the diamond (100)-2 × 1 surface, theoretical studies predict that S_B and D_A steps are nonbonded because carbon dimers form strong double bonds that effectively reduce the number of dangling bonds [126].

Boron-doped epitaxial diamond (100) films were grown and imaged using UHV STM as described in the section on anisotropic etching. After growth, the films were exposed to atomic hydrogen for 10 minutes at 900 °C to produce a smooth surface. Figure 27 shows a UHV STM image of a clean diamond (100)-2 × 1 film showing S_B, S_A, and D_A steps. Figure 28a is a higher resolution image of the same

full dimer row on the bottom plane is $3d$. In Figure 28b, the dimer row indicated by the unmarked arrow forms a local nonbonded step. On the Si (100)-2 × 1 surface, local nonbonded steps are thought to be stabilized by vacancies [17, 18]. Therefore, the nonbonded step in Figure 28b is attributed to vacancy V indicated by the arrow in Figure 28a. Figure 29 shows a UHV STM image of a rebonded D_A step in which the bonding configuration of edge atoms on the bottom plane is similar to that of rebonded S_B steps. The observation of rebonded steps on the diamond (100)-2 × 1 surface contradicts recent theoretical predictions that single- and double-layer steps are nonbonded [126].

Also observed in Figures 27 and 28 are defects consisting of dimer vacancies indicated by V that are single, multiple, and arranged in rows parallel and perpendicular to dimer rows. The density of single and multiple vacancies is about 8×10^{12}/cm^2. In addition, a large number of antiphase boundaries indicated by P are observed on type A steps. The antiphase boundaries occur such that the phase shift is accommodated at a step edge, or vacancy row that is perpendicular to the boundary and has a width of d and $2d$ on either side of the boundary. It is thought that antiphase boundaries are formed during exposure to atomic hydrogen and remain after desorption of hydrogen at 1000 °C. Evidence of buckled dimers or stabilization of buckled dimers by steps and vacancy defects was not observed. On the Si (100)-2 × 1 surface, buckled dimers are stabilized by such structures at room temperature [17, 18]. These observations are consistent with theoretical predictions that the diamond (100)-2 × 1 surface has symmetric dimers and the Si (100)-2 × 1 surface has asymmetric dimers [138].

5.2. Diamond (111) Surface

STM studies of the diamond (111) surface have been carried out in air using polycrystalline [33, 140, 141] and homoepitaxial [142] diamond (111) films. To our knowledge, UHV STM studies of the clean diamond (111) surface have not been reported. Large-area air STM studies of diamond (111) films show that the surface is rough with islands having {111} faces [33, 140, 141]. Figure 30 shows a large-area UHV STM image of an epitaxial diamond film grown on a synthetic diamond (111) substrate [143]. The film was not annealed in UHV after growth. In Figure 30, the derivative of the data, dz/dx, is shown in order to accentuate steps. Observed are triangular islands oriented in the $\langle 111 \rangle$ direction, mono-atomic steps, and screw dislocations [143]. While the film is defective, it is in atomic registry with the crystalline substrate.

Figure 30. Large-area UHV STM image of an unannealed epitaxial diamond (111) film.

Atomic resolution studies of diamond (111) films show coexisting regions having 1×1, 2×1, 2×2, and $\sqrt{3}X\sqrt{3}R30°$ reconstructions [30, 33, 140–142]. Figure 31 shows an atomic resolution UHV STM image of an unannealed epitaxial diamond (111) film showing a 1×1 reconstruction [143]. Theoretical calculations show that the only stable 1×1 structure is the diamond (111)-1×1:H surface [30], shown schematically in Figure 32. Therefore, this surface is thought to be the surface observed using STM [33]. Calculations also show that the hydrogen-terminated 2×1 single chain and Pandey [144] reconstructions are stable [30], as shown in Figure 33a and b. The diamond (111)-2×1 surface observed using STM is thought to be either of these two reconstructions [33]. The diamond (111)-2×2 and $\sqrt{3}X\sqrt{3}R30°$ reconstructions observed using STM are thought to be due to adsorbed hydrocarbon radicals [33]. Calculations also predict that the clean diamond (111)-2×1 single chain and Pandey reconstructions, and clean and hydrogen-terminated $\sqrt{3}X\sqrt{3}R30°$ reconstructions are
Figure 31. Atomic resolution UHV STM image of an unannealed epitaxial diamond (111) film showing a 1×1 structure.

stable [30]. However, STM imaging of such surfaces has not been reported. LEED studies have shown that the diamond (111) surface annealed in UHV at temperatures higher than 1,000 °C shows a 2×1 pattern [34, 145]. This 2×1 surface changes to a 1×1 surface after exposure to atomic hydrogen [34, 145].

5.3. Diamond (110) Surface

Few STM studies of the diamond (110) surface have been reported. Mercer et al. [146] used AFM to study diamond (110) substrates after exposure to atomic hydrogen at

C(111) 2 × 1 : H (SC)

Figure 34. Large area UHV STM image of an epitaxial diamond film grown on a synthetic diamond (110) substrate. Observed is a rough surface having striations.

a temperature of 900 °C. They observed that atomic hydrogen exposure results in a very rough surface at the micron scale with deep pits having {111} faces. They also observed that polished diamond (110) substrates have pits with {111} faces. Lim et al. [147] used UHV STM to study epitaxial diamond films grown on a synthetic diamond (110) substrate. The epitaxial films were not annealed in UHV after growth. The surface of the film was observed to consist of striations with {111} faces on the side and {100} faces on top, as shown in Figure 34. Using LEED, Lurie and Wilson [125] observed a 1×1 pattern for polished diamond (110) substrates and no reconstructions after annealing the substrate at 1000 °C in UHV. Cheng et al. [148] used LEED to study the etching of diamond (110) substrates by atomic hydrogen and found that {111}-oriented facet formation occurs.

As shown in Figure 4, the bulk-terminated diamond (110) surface consists of zig-zag chains of atoms having one dangling bond per atom. For the clean and hydrogen-terminated surface, theoretical studies of Davidson and Pickett [149] predict weak dimerization of the chains. Calculations of Alfonso et al. [150] predict a buckling of nondimerized chains for the clean surface and bulk-like nondimerized chains for the hydrogen-terminated surface. Kern and Hafner [151] recently predicted no buckling or dimerization and an inward shift of the top layer for the clean surface and a bulk-like structure for the hydrogen-terminated surface. Using UHV STM, Lim et al. [147] observed isolated regions on unannealed epitaxial diamond (110) films showing a zig-zag atomic structure that was ascribed to the hydrogenated (110) surface.

6. CONCLUSIONS

In conclusion, the atomic structure of diamond surfaces has been successfully studied using STM. Although diamond is an insulator, STM imaging is possible by increasing the surface conductivity by doping the film with boron or hydrogen terminating the surface. UHV STM results of diamond comparable in quality to those that have been reported for Si are possible by cleaning the surface in UHV and using ultrasharp tungsten tips. For the diamond (100) surface, air STM has been used to study the atomic structure of the hydrogen-terminated surface. UHV STM studies of the clean surface have revealed the atomic-scale properties of steps, defects, and the atomic hydrogen etching mechanism. For the diamond (111) surface, air STM studies have shown various reconstructions of the hydrogen-terminated surface. There have been no reports of studies of the clean surface using UHV STM. For the diamond (110) surface, there have been few STM studies, mainly because the surface is very rough. The UHV STM techniques described can be used to study etching, adsorbates, growth, and other processes at the atomic scale that are crucial in understanding the growth and properties of diamond.

GLOSSARY

Diamond film Diamond deposited as a film using chemical vapor deposition with hydrogen and a carbon-containing gas such as methane. Typical substrate temperatures and gas pressures are 700–900 °C and 30 Torr, respectively.

Diamondlike carbon film An amorphous and typically hydrogenated carbon film.

Epitaxial film A single crystal film in atomic registry with the substrate.

Nanocrystalline diamond Carbon film having nanometer-size grains and mostly sp^3 bonding. Such films are made using buckyballs or a carbon containing gas and Ar or N gas that are activated using a microwave plasma or laser.

Polycrystalline film A film composed of crystallites having different orientations and separated by grain boundaries.

Scanning tunneling microscopy (STM) A technique for imaging the surface of a conductor with atomic resolution that uses tunneling between the surface and a sharp tip that is scanned across the surface using a piezoelectric device.

Surface reconstruction Rearrangement of atoms in the near surface region from their bulk positions.

Ultrahigh vacuum (UHV) A vacuum having a pressure $<10^{-9}$ Torr.

Atomic Wires

I. N. Yakovkin

National Academy of Sciences of Ukraine, Kiev, Ukraine

CONTENTS

The variety of atomic wires can now be synthesized on furrowed and stepped surfaces, which provides opportunities for systematically tailoring surface properties. One of the most important issues for investigators in the field is the metallicity of the atomic wires and how one can control this metallicity. Hence, the nature of nonmetal-to-metal transition is a key problem. The different ways of casting the explanation of the nonmetal-to-metal transition (NMT) has provoked the classification of the NMT into types such as the Mott-Hubbard, the Wilson, and the Peierls transitions. In fact this complexity is illusionary; there is a single phenomenon, which is revealed by the gap at E_F, which is characteristic for a dielectric state, and closing this gap leads to the NMT.

In the present article, the NMT is analyzed from the viewpoint of transformation of band structure. This approach provides results that can be directly justified by angle-resolved photoemission (ARUPS) and other techniques that allow band structure mapping to be undertaken near the Fermi level. This is illustrated by the example of Mg atomic wires adsorbed on a Mo(112) surface, one archetypal example much exploited in this review. The band structure approach to explaining the NMT in monovalent crystals is brought into sharp perspective through the consideration of a coupling of adjacent atoms (Peierls' distortion) that results in a lowering of the total energy and affects an even number of valence electrons in the unit cell.

At low coverages, alkali, alkaline earth, and rare earth layers adsorbed on furrowed transition metal surfaces—such as the Mo(112) surface—demonstrate a quite unusual behavior. In contrast to well-known formation of one-dimensional wires lying in furrows of reconstructed surfaces of semiconductors and noble metals, these metals adsorbed on the W(112), Mo(112), and Re(1010) surfaces tend to form commensurate linear structures built of mono-atomic chains directed across the furrows. Monte Carlo simulations of the increasing disorder of the chains with increasing temperature provide a transparent presentation of typical fluctuations in such linear structures. Such studies provide insight into the parameters of indirect interaction that are the basis for the formation of the atomic wires. As with most "metallic" wires on semiconductor surfaces, the linear alkaline earth chains on the furrowed transition metal surfaces do not exhibit strong metallic character but, rather, may be considered as dielectric atomic chains. Such a behavior results from interaction with the substrate, which "ties up" the valence electrons in the adsorption bonds. The local character of these bonds is replaced by a metallic one when the lattice period of the adsorbed layer becomes incoherent with the substrate period along the furrows. In this coverage range, both theory and experiment indicate a Wilson-type NMT transition in the adsorbed layers. Atomic wires, adsorbed on furrowed transition metal surfaces, seem very attractive for the study of fundamental physical problems such as NMT in overlayers.

1. INTRODUCTION

"Wires" call to mind an association with something long and thin and definitely metallic. To this end, atomic chains built from atoms of a metal represent a limiting case of a wire. When adsorbed on stepped or reconstructed surfaces, many metals tend to form long linear or zigzag chains lying in the troughs of the substrate surface. This feature may be considered the "self-assembly" of adsorbed atoms into atomic wires, supported by a "steering effect" along substrate furrows or step edges.

The great interest in the quite special behavior of atomic wires [1–19], in large part, has been caused by the potential

for the creation of conductors of the smallest possible dimensions. The investigation of such systems provides a unique perspective on the limits of nanotechnology [17–28]. The present capabilities of modern techniques, such as scanning tunneling microscope (STM) atomic manipulation, gives the experimentalist precise control of the formation of atomic wires on various substrates. It is now becoming possible to create both single atomic chains and arrays of atomic wires with desirable electronic properties. This opens a new branch of nanotechnology—nanoelectronics [17–28].

Electronic properties of atomic chains depend substantially on the substrate. The Si(111) surface is a particularly convenient substrate, not only for achieving metallic character, but also for obtaining straight and regular step arrays. Thus, stepped (vicinal) Si surfaces, with a slight misfit from the low-index crystallographic plane, form suitable templates for the fabrication of atomic wires [18–26]. The distance between the atomic wires can be adjusted in a wide range by controlling the preparation parameters, and thus the fabrication, by design, of a wide range of novel artificial materials is possible.

To obtain good templates for tailoring atomic wires, one can also explore vicinal surfaces of transition metals, for example, Pt(997), a highly stepped Pt(111) surface [19]. More suitable substrates, however, are the inherently furrowed (112) surfaces of W or Mo and (10$\bar{1}$0) faces of hexagonal close-packed (hcp) Re [29, 30]. These surfaces have very similar structures, which can be described as built from close-packed (2.73–2.76 Å) atomic rows with rather large spacing between them (4.43–4.45 Å). Here the surface potential is corrugated, and one can expect similar formations of the chains of adsorbed alkali or alkaline earth atoms lying in the deep furrows. In fact, at low coverages, the adlayers usually form chains orthogonal to the expected direction. Increasing coverage results in a decrease in spacing between the adatoms due to compression of the films along the furrows, which leads to dramatic transformations of the electronic structure of the overlayers [29, 30]. Hence, at a complete monolayer coverage, the films may be better characterized as metallic chains lying along the substrate furrows. In the case of adsorption of rare earths, the situation is more complicated because of strong interaction with the transition metal surface, which can cause, at elevated temperature, reconstruction of the substrate surface. Nevertheless, in the second layer of Gd on a Mo(112) surface [31], well-developed self-assembled arrays of atomic wires have been found (Fig. 1).

It should be clarified what is actually implied when we speak about the metallicity of adsorbed layers [32, 33]. Of course, metallic wires must be conductive. However, there are inherent problems with direct measurement of the conductance of adsorbed wires [14, 24–27]. Apart from obvious technical complications, any extrinsic contact would unavoidably affect the properties of adsorbed layers, and therefore only limited information could be obtained. On the other hand, a metal can be characterized by the absence of a gap at the Fermi energy and, to some extent, by collective electronic excitations [29, 30, 34]. If we accept these criteria of metallicity, the state of the adsorbed films can be probed (at least in principle) by electron spectroscopy techniques such as ultraviolet photoelectron spectroscopy
Figure 1. Gd atomic wires on the Mo(112) surface. STM images, obtained for two different scales, illustrate a "self-assembly" forming atomic wires (Courtesy of Ya. B. Losovyj, private communication).

(UPS) [35, 36], inverse photoelectron spectroscopy (IPES) [37], STS (scanning tunneling spectroscopy) [38–40], and electron energy loss spectroscopy (EELS) [34, 41–43]. From the theory side, a metallic state can be better characterized by bands crossing E_F, which also provides a nonzero density of states at the Fermi energy.

Strange as it may sound, in most cases "metallic" wires demonstrate dielectric behavior. For example, STM, core-level and valence-band UPS, and IPES studies of Cs on various $A_{III}B_V$ semiconductor surfaces (GaAs(110), InAs(110), and InSb(110)) reveal the dielectric state of the adsorbed Cs film, even at complete monolayer coverages [44–50].

The issue of metallicity of adsorbed atomic wires is further complicated by the presence of the substrate surface. In many experiments, it is not always clear whether just the adsorbed layer or the semiconductor surface attains a metallic character. In the case of a metallic substrate the situation becomes even more involved. Nevertheless, there are several examples of such adsorption systems for which a NMT has been observed by UPS and EELS [51–57]. The evidence of metallization of adsorbed layers in such experiments is obtained from the increase in the density of states at the Fermi energy (UPS), the appearance of bands crossing E_F (ARUPS), and the appearance of characteristic losses that can be attributed to plasmon excitations.

Actually, our understanding of the electronic structure of atomic wires is based on certain model descriptions of adsorption systems. The more realistic the model, the better the explanation of various phenomena at the surface. To this end, it should be noted that the term "atomic wires" inherently implies a model treatment of wires as free atomic chains. Hence, to learn more about the metallicity of atomic wires, its seems reasonable to study the experimental data within a framework of certain theoretical models, such as a one-dimensional chain or a free monolayer.

The quasi-"one-dimensional" outlook of atomic wires provokes a number of theoretical considerations of electronic structure that are both interesting and exciting, but applying these ideas to real adsorption systems, in terms of a model one-dimensional system, must be done with extreme care. Predictions for one-dimensional electron systems are very exotic [1–18, 58–60]. The increasing amount of correlation between electrons in one dimension results in different

statistics for quasi-particles. In three dimensions the electronic and optical properties of metals are well described by the Fermi liquid theory. In one-dimensional metallic systems the electron-phonon interaction leads to the Peierls instability, whereas the electron-electron interaction may lead to Luttinger liquid behavior. In a Luttinger liquid [58], the electron losses its identity and separates into two quasi-particles, a spinon that carries spin without charge and a holon that carries the positive charge of a hole without spin. It seems possible (in principle) to visualize a holon in a Luttinger liquid as a charge density wave and a spinon as a spin density wave, which might allow one to justify the theory through experimental confirmation from electron spectroscopies applied to atomic wires [9–11, 59, 60].

However, we live in a three-dimensional world, and therefore for real material systems such one-dimensional concepts, as well as main statements based on these theoretical concepts, must be accepted very cautiously. In fact, an atomic wire is not a one-dimensional system. Indeed, atomic size in a wire is compatible with the period and, in many cases, with the length of the wire. The "degree" of the one-dimensionality becomes a challenge when possible mechanisms of the NMTs in atomic wires are considered.

The issue of "dimensionality" emphasizes a fundamental problem of relation between many-body and one-particle approaches in solid-state physics. Usually all discrepancies in calculated band structures with experiment are attributed to limitations of local density approximation (LDA) or, furthermore, density functional theory (DFT) [61–64]. Of course, the band structure rigorously describes only the ground state of an electronic system and cannot treat coherent excitations (plasmons). However, the modern understanding of the band structure [61] implies that it is pertinent to one-particle excitations, that is, for quasi-particles (still called "electrons"), which are not just the "real" electrons as in the Hartree-Fock method. This means that the band structure approach can be applicable to the interpretation, in large measure, of photoemission and inverse photoemission spectra. In spite of many limitations, theory does often give the correct physical picture of surface electronic structure. We will revisit the well-known failure to describe the NMT in the case of monovalent metals, which implies involving many-body effects through the Mott-Hubbard scheme [65], as discussed in some detail below.

In the following sections, we will first consider several examples of real atomic wires built on various semiconductor surfaces (Section 2). The metallicity of atomic wires, which is a focus of this chapter, requires consideration of various types of NMTs and their applicability to the transformations of the electronic structure of adsorbed layers. These issues are discussed in Section 3. The band structure approach to the NMT is the perspective from which this chapter has been prepared. An example of the power of this approach is Mg overlayers on Mo(112), and both band mappings by ARUPS and calculated band structures of this system are presented in Section 4.

2. ATOMIC WIRES ON SEMICONDUCTOR SURFACES

Metals on semiconductors generate a large variety of low-dimensional surface structures with interesting electronic properties. There have been reports of correlation effects destroying the metallicity of surfaces despite an odd electron count per unit cell [66–70], which is somewhat related to the anomalous surface corrugation by charge density waves or by large atomic displacements [71–75]. There has also been mention of metallic nanowires [76–78], of a surface state with mixed dimensionality [19], of spin-charge separation in a Luttinger liquid [1, 2, 60, 79–81], and of a surface with an even electron count becoming metallic [20]. Theory predicts a variety of exotic phases in such low-dimensional systems, which are generated by the increased interactions and subsequent correlations that electrons experience when they are confined.

2.1. Alkali Metal Chains on Reconstructed Si Surfaces

Alkali metal adsorption on a Si(100) surface is among the most heavily investigated systems in surface physics and surface science. The Si(100) surface reconstructs, as a result of dimer formation, and this 2×1 surface has been the substrate of choice for many alkali metal overlayer studies. The adsorption of alkali metals on Si(100) is supposed to lead to the formation of a metallic overlayer with increasing coverage, and the Si(100)2×1 reconstructed surface is considered nonreactive with respect to alkali metal adsorption. Yet this system remains controversial. Details of charge transfer to the substrate and the overlayer structure are not completely resolved and call into question whether the substrate or the alkali metal overlayer undergo the nonmetal-to-metal phase transition [82].

The 2×1 reconstruction of the Si(100) surface has been characterized by a variety of techniques [82, 83], including STM studies [84]. The buckling of the surface remains a subject of controversy, particularly with respect to the charge distribution of the buckled dimer [85], though recent photoemission studies indicate that the surface dimers are essentially covalent [86]. One problem with the symmetric 2×1 reconstruction of the Si(100) surface is that the surface is metallic in the one-electron picture [87–89]. However, a metallic surface is inconsistent with experiment [90–92]; thus the addition of spin considerations is necessary theoretically to open up a gap [87, 89].

The issue of the adsorption site for alkali metals, which is important with regard to the possible metallicity of atomic wires, is further complicated by the fact that under some circumstances alkali metals will induce 3×2 or 4×1 reconstruction of the Si(100) surface [93–97]. While there have been some theoretical and experimental indications that initial adsorption at least partly favors the highly coordinated sites [93, 94, 98–108], recent STM studies indicate adsorption into T sites [84, 109, 110], largely consistent with LEED intensity analysis [111]. On the other hand, it is important to realize that the theoretically derived "most stable" binding sites are dramatically affected by the choice of the basis function cutoff used in the calculation [112].

There is a general consensus [88, 98–103, 113–126] that at one-half monolayer coverage, the alkali metal overlayer on Si(100) is one-dimensional rows of atoms, that is, atomic wires, with a spacing of 3.84 Å and with the rows more widely separated by some 7.68 Å. Aruga et al. [113] reported a metallic state of K linear chains adsorbed on the reconstructed Si(001)2 × 1 surface. Evidence for metallization [113, 119–126] of the K wires, lying on top of the rows of the reconstructed substrate, was derived from the overlayer plasmon dispersion in a K adlayer measured by angle-resolved electron energy loss spectroscopy. At saturation coverage, the intraband plasmon mode was observed, which could identify a metallic character of the K chains. It was proposed that "the K chains adsorbed on Si(001) are in the nature of a one-dimensional metal." (It should be mentioned here that nature does not provide any example of a real one-dimensional material!)

However, according to suggested estimates [113] of the dipole moments of adsorbed K atoms, the adlayer must be strongly polarized, if not ionized. This follows from a decrease in the work function as well as from the significantly reduced (17%) interatomic distance between adjacent K atoms (3.84 Å along the chain, and the K diameter is 4.62 Å). Therefore, the K valence electrons must all be essentially localized to provide a polar covalent bonding with the semiconductor surface and can hardly be considered as nearly free electrons that are the signature of the metallic state for simple metals. Such a behavior has been reported for Mg layers adsorbed on the $Cr_2O_3(111)$ surface [127]. In contrast to the expected metallic state for a complete Mg monolayer, metallization of the film starts only with the formation of the second layer. Again, a dielectric state of the Mg monolayer results from a strong polar covalent bonding with the substrate. This feature seems typical for adsorption on dielectric and semiconductor surfaces and, unfortunately, prevents observation of metallization within the first monolayer or lesser coverage for alkali metals on silicon [32, 69].

Work with Si(111) [128] suggests that alkali metal interaction with the silicon substrate results in different amounts of charge transfer to the surface as a consequence of changes in the extent of electron occupancy of the gap states at the surface. For clean Si(111), alkali metal adsorption appears to be covalent as in the case of Si(100); indeed there are results obtained with metastable (He*) deexcitation spectroscopy (MDS) studies of cesium adsorption on Si(111) [129] and lithium on Si(111) [130] that are similar to those obtained with Si(100). There are differences between alkali metal adsorption on Si(100) and Si(111) nonetheless.

Total energy calculations [99–102] suggest that alkali metal adsorption induces a substantial surface reconstruction on Si(111), though calculated band structures can still be compared to the photoemission results for Cs on Si(111) [131]. Na [132] and Li [133] adsorption on Si(111) destroys the 2 × 1 reconstruction on Si(111) [99]. Cs adsorption, on the other hand, changes the 2 × 1 reconstruction to a ($\sqrt{3} \times \sqrt{3}$)-R30 reconstruction [134], whereas K adsorption preserves the 2 × 1 reconstruction [135].

Band structure measurements from Reihl and co-workers [132–135] suggest that for Cs, Na, and Li adsorption, the surface remains semiconducting to quite high alkali metal coverages close to one monolayer, in contrast to the total

energy calculation [115] for K on Si(111). Jeon et al. [136] have also used the STM in the microscopy and spectroscopy modes to show that the Na/Si(111) system is a Mott insulator and that a Mott-Hubbard transition occurs as the second layer begins to form at a coverage greater than 2/3. The problem with these measurements, as pointed out by Weitering and Perez [137], is that an STM cannot tell the difference between a Si atom and a Na atom. The 1 × 3 structure, which Jeon et al. [136] believed to be a third of a monolayer of sodium, is, in fact, reconstructed Si, with a sodium coverage as low as 0.1 of a monolayer, as this is all that is required to reconstruct the Si(111) [137, 138].

The charge transfer from the adsorbed alkali metal to the silicon dangling bond is also uncertain. The calculated charge densities [99–104, 114–116, 126] suggest a nearly complete charge transfer to the silicon dangling bond, indicative of a fairly ionic bond. Ishida and Terakura [126] and others [103, 104] suggest that the adatom is essentially neutral if the electron density is averaged in the alkali adatom sphere. The brightly imaged Li, K, or Cs adatoms on Si(100) in STM pictures have suggested that the alkali adatoms are not completely ionized upon adsorption [84], though the appearance of the lobes of charge density perpendicular to the Si(100) dimer rows for lithium adatoms has been taken as evidence of a charge redistribution due to the silicon-lithium interaction [109, 110].

The degree of charge transfer may in fact be a problem of definition, and the degree of charge transfer may depend solely upon how space is assigned to the alkali metal atoms or silicon dangling bonds [102, 126]. Hybridization between the semiconductor substrate and the alkali metal s,p states undoubtedly plays a role, but relating hybridization to charge transfer, with all of the problems associated with image plane location and atomic locations and size, is difficult at best.

With the large charge transfer to the surface, theory [99–103, 108, 126] predicts that the Si(100) surface becomes metallic at a half-monolayer alkali metal coverage. In the picture where there is a large charge transfer to the silicon, the Si(100) surface has a half-filled band at half-monolayer alkali metal coverage. The silicon surface becomes semiconducting as this band fills completely, which would occur at one monolayer coverage of alkali metal. This is consistent with the increase and subsequent decrease of the apparent density of states with increasing alkali metal coverage, as observed both in MDS [139] and photoemission [140, 141]. In this scheme it is the silicon surface, not the alkali metal overlayer, which becomes metallic. In fact, in this picture, the alkali metal overlayer has no free electron band below the Fermi energy since there is, after all, a depletion of electrons from the alkali metal layer, and therefore the overlayer is essentially nonmetallic [99–103, 126]. Indeed, in the experimental band structure [141–143], the electronic structure of the Si(100)–2 × 1 potassium overlayer resembles a semiconductor consistent with this picture.

There is evidence that the surface of Si(100) does not become semiconducting with alkali metal coverages greater than half a monolayer. Inverse photoemission studies [144] provide strong indications that the high-coverage potassium overlayers are metallic, at coverages where the MDS and photoemission intensities at the Fermi energy are no longer

at a maximum. Other band structure studies also suggest an onset to metallicity at close to one monolayer of coverage. On this basis of changes in band structure, Reihl et al. [133] suggested that the NMT occurs at one monolayer, in agreement with Tikhov et al. [145]. The energies of potassium desorption [146] also indicate that for coverages greater than half a monolayer, the adlayer is metallic. The core level shift data from Soukiassian et al. [147] for Na 2p and Cs 4d also indicate an onset of metallicity, but well above half a monolayer. The appearance of a plasmon loss near the alkali metal core-level feature was interpreted to mean that it is the alkali metal overlayer, not the substrate, which goes metallic [147]. In addition, core-level binding energy shifts [148] and second-harmonic generation signals [149] suggest that the onset of metallicity occurs at very low alkali metal coverages (0.25) and the surface remains metallic to saturation (monolayer coverage), as is also indicated by the plasmon-induced electron energy loss [120, 121]. It should be noted that the plasmon data are complicated by the presence and persistence of a clean Si(100) electron energy loss feature at 1.7 eV due to single particle excitations [90, 121, 150–153], and some results indicate the onset of metallicity at relatively low coverages.

2.2. Fabrication of Metallic Atomic Wires

In recent years, several metallic chain structures have been found on semiconductor surfaces [1–28]. The Si(111) substrate has been particularly useful as a substrate, not only as a laboratory for achieving metallic character in surfaces and ultrathin overlayers, but also as a surface for obtaining particularly straight and regular step arrays.

Beyond the flat Si(111) surface, there are opportunities for using stepped Si(111) surfaces to produce tailored, one-dimensional structures with exotic electronic states [18–21, 24–28, 74]. Low step densities, formed with a miscut angle of about 1°, stabilize a single domain of the one-dimensional 532 structure. High miscut angles, such as 9.5° for Si(557) [18–21], create a whole new category of one-dimensional structures that incorporate a step into the unit cell (Fig. 2).

Several of the structures induced by Au on flat and stepped Si(111) have been reported to be metallic [18–21]. Another metallic chain structure is formed by In on Si(111) [79]. One-dimensional structures of Au on Si(111) give a nice example of the options for tailoring electronic states. The number of atomic chains can be modified by adding steps and by varying the Au coverage. This affects the electron count in the unit cell and is critical for metallic versus insulating character.

Gold adsorbed on stepped (vicinal) Si(111) surfaces forms two distinct one-dimensional structures: highly stepped Si(557)-Au (metallic) and flat Si(111)5 × 2-Au (semiconducting) [18, 19]. Both exhibit the chains along the ⟨110⟩ direction. The Si(111)5 × 2-Au surface contains two rows of Au atoms separated by a single Si row spacing, according to transmission electron microscopy and diffraction. The Si(111)532-Au surface contains one such chain per unit cell, and the Si(557)-Au contains two chains with a spacing of two rows. In addition, the electron count differs in these two structures [19]. The Si(557)-Au surface, with an even
Figure 2. Templates for atomic wires. The images have been obtained with STM with the method of step decoration. (a) Stepped Si surface decored by CaF_2 adsorbed molecules. (b) Ag wires provide bright decoration of the step edges on Pt(997), a highly stepped Pt(111) surface. Reproduced with permission from [18], F. J. Himpsel et al., *J. Phys.: Condens. Matter* 13, 11097 (2001). © 2001, IOP Publishing Ltd.

electron count, is metallic and seems to defy the conventional wisdom that an even electron count produces a semiconductor and an odd count a metal. Si(111)5 × 2-Au, on the other hand, exhibits a pseudo-gap where the "parabolic" free electron-like band abruptly loses spectral weight before reaching the Fermi level [18, 19].

Metallic behavior is deduced from the observation that the bands extend all the way up to the Fermi level E_F for Si(557)-Au, as in a metal. By way of contrast, the flat Si(111)-Au surface shows a band that does not reach E_F. Another metallic chain structure is formed by In on Si(111) [18, 19]. Vicinal Si surfaces, with adsorbed Au atomic wires, can, in turn, serve as a template for fabrication of mesoscopic wires of Pb [23]. The spontaneous formation of mesoscopic Pb wires, on a 4° off-cut Si(001) vicinal surface, Si(755), Si(533), and Si(110) substrates, was studied by low-energy electron microscopy. Before the deposition of Pb the substrates were modified by predeposition of a submonolayer amount of Au followed by annealing. The Au-induced reconstruction creates quasi-one-dimensional facets and superstructures. Their widths ranged from several hundred nanometers, in the case of the vicinal Si(001) surfaces, down to atomic-scale dimensions, for the Si(110) surface. The best-developed arrays of parallel aligned mesoscopic wires were obtained during the deposition of Pb on substrates cooled slightly below room temperature [23]. Wires with length-to-width ratios reaching 130 were produced on the Si(755) and the Si(533) substrates. The width of these nanowires was uniform over the whole substrate and was about 60 nm. The driving forces for the formation of the mesoscopic wires are the anisotropic strain due to the large misfit between the Pb and the Si lattice and one-dimensional diffusion of Pb.

2.3. Surface Plasmon Modes and Metallicity of Overlayers

The work discussed above raises the issue of what is a metallic state [32, 33] and whether the appearance of the plasmon peak is indeed indicative for the NMT in adsorbed layers. If

we accept the concept of a one-dimensional K metal [121, 131], derived from anisotropy in the plasmon dispersion, it is then quite difficult to explain a dielectric state for adsorbed Cs films. Furthermore, plasmons can be excited in semiconductors, such as silicon, and not just metallic systems. Hence, identification of a metallic state of films and adlayers by EELS needs additional justification.

In general, the EEL spectra contain information about one-particle and collective excitations in bulk as well as in the surface region [154–162]. It is not easy to distinguish the yields from surface and bulk, especially in the presence of an adsorbed layer. Therefore, it is essential to characterize the excitations from the substrate and the adsorbed layer.

A true surface plasmon is a monopole sheet of charge, whose field at $q = 0$ penetrates infinitely into the bulk, that is, the surface plasmon depends upon the bulk charge density [32, 33, 163–165]. This means that such a mode cannot directly characterize excitations just in the adsorbed layers. At submonolayer coverages, there exists so-called multipole surface plasmon mode [32, 33, 163–170] that is dipolar in character and, consequently, because of a fast decay of the field along both vacuum and the bulk directions, develops in very thin films [164, 165]. Thus, the multipole mode of collective excitations is extremely well localized within the surface region, so that its energy, which is usually about 0.6–0.8 of the bulk plasmon energy, is roughly determined by a local electronic density at the surface [164, 165]. A detailed analysis of the collective excitations in thin adsorbed films has shown [163, 164] that with increasing density and thickness of the overlayer film, these modes transform into ordinary surface and bulk plasmons characteristic for the adsorbate.

With an oscillating electrostatic field normal to the surface, this multipole mode (MM), in contrast to a "regular" surface plasmon, can be excited directly by incident photons, which will lead to a strong absorption resonance of the incident light. This occurs when the energy of the incident radiation is close to the energy of the multipole mode [33, 164–170]. The excitation and subsequent decay of the multipole surface plasmons [163–170] are intimately related to enhanced surface photoemission—the surface photoeffect [29, 165–168, 171–177] predicted by Makinson [178].

Obviously, a bulk plasmon as well as a multipole surface plasmon, once excited, can contribute to the photoemission intensity to the extent that each decays to a single-particle excitation with a final-state electron that can escape from the solid [164, 165]. A bulk plasmon that propagates away from the surface also results in strong absorption that can contribute to the photoemission, as in the special cases of a strong coupling of the plasmon with interband transitions in d-metals [164], but generally this is not pronounced. In contrast, the multipole modes are located just at the surface. Therefore, the decay of the MM to electronic excitations gives rise to the resonance in the intensity of the surface photoemission. It should be mentioned, however, that a detailed description of induced electromagnetic fields near the surface (suggested by Feibelman [177]) does not require the MM excitation but provides, nonetheless, explanation of the surface photoeffect in excellent agreement with results of photoemission studies from simple metal surfaces and thin films [165–168, 171, 172, 179–181].

The multipole modes have been directly observed by EELS for surfaces of simple metals [168]. For transition metals, a strong decay of the plasmons due to a high density of states, provided by the d bands, makes the EELS spectra too involved to detect the multipole modes unambiguously. Thus it is not surprising that, for transition metal surfaces, the surface photoeffect has been observed only for Mo(112) [182].

2.4. The "One-Dimensional" Concept and the Free Monolayer Model

While it might appear that the multipole modes might be described as "two-dimensional excitations," it should be emphasized that these excitations imply a polarization in direction normal to the surface. This feature makes multipole modes, in fact, three-dimensional objects. This is in contrast with inherently one-dimensional Luttinger liquid [58].

It has been put forth that the Luttinger liquid is the proper model for describing an interacting one-dimensional electron system without a gap in the spin or charge excitation channel [2–10]. The characteristics of these excitations must be significantly different from those of the Fermi liquid model for 3D systems. It is one of the peculiarities of Luttinger liquids that elementary excitations are not quasi-particles with charge e and spin $\frac{1}{2}$, but collective charge and spin density fluctuations with bosonic character, so-called spinons and holons. These spin and charge excitations propagate with different velocities, which leads to the separation of spin and charge [2–10, 18].

It was suggested that angle-resolved photoemission studies [3, 4] on "one-dimensional" $SrCuO_2$ and CuO chains revealed excitations that could not be explained within the conventional band theory, but required a picture in which the spin and charge degrees of freedom for a single electron were separated. Using the one-particle Green function approach for the Tomonaga–Luttinger model of one-dimensional interacting fermions, Meden and Schönhammer [17] have obtained spectral functions that determine photoemission and inverse-photoemission spectra. With this theory, the dispersion relationship can be explained by underlying spinon and holon branches, indicating separated spin and charge excitations [3, 4, 17].

The possibility of the opening of a pseudo-gap that could affect the metal-to-nonmetal transition was questioned by Lieb and Wu [6]. The ground-state energy, wave function, and chemical potentials, obtained with the short-range, one-band model for electron correlations in a narrow energy band, suggested that the ground state should not exhibit the conductor-insulator transition with increasing correlation strength.

Apart from the spin-charge separation, suppression of spectral weight at the Fermi energy E_F is a characteristic feature of a Luttinger liquid. Such a suppression of spectral weight has been reported for a number of quasi-1D compounds (for example, "Berchgaard salts") by photoemission experiments [59]. Another example is the atomic Au wires on vicinal Si(111). With this system Segovia et al. [2] found collective excitations in photoemission spectra, as one could expect for one dimensional systems. On the other hand,

interpretation of these experiments is still ambiguous. Thus, for Au on the Si(557) surface, Altmann et al. [19] have found that the observed band splitting at E_F rules out the spinon-holon splitting suggested as its origin initially [9, 10, 17]. Indeed, spinon and holon bands are to converge at E_F, and therefore a natural interpretation of the splitting is a closely spaced doublet of ordinary bands crossing E_F.

As commonly recognized, in three dimensions the electronic and optical properties of metals are qualitatively described by the Fermi-liquid theory. There is no reason for the existence of inherently one-dimensional systems, with the associated exotic behavior, in our three-dimensional world. We note that the suggested transformation of electronic excitations into spinons and holons, that is, bosonic excitations, ultimately negates any meaning of a Fermi energy and therefore all related electronic phenomena. Hence, to get exotic behavior one must study extremely exotic systems, but not atomic wires on semiconductor surfaces, which may be better characterized as real objects, with strong anisotropy of electronic properties.

As is evident from the above arguments, the appearance of a loss peak that corresponds to plasmon mode excitations cannot, by itself, prove the existence of a metallic state, nor prove, in particular, the existence of metallic character in the adsorbed layer. Therefore, it is quite important to also explore another approach to determining the presence or absence of metallic character, namely, band structure measurements and calculation.

In the band structure picture, a nonmetal must have a gap at the Fermi energy, while a metallic state could be convincingly characterized by bands crossing the Fermi level. Unfortunately, in reality, the situation is very complicated because of strong complex interactions in the system, and therefore interpretation of the results is not always as straightforward as one would expect. Thus, there is only qualitative agreement between the experimental [140–142] and the theoretical band structures. The theory does not agree with the dispersion relationship for the unoccupied bands, determined by inverse photoemission [88, 133, 144], or the dispersion relationship obtained from photoemission for the occupied bands [102, 140]. The occupied density of states seen in metastable deexcitation spectroscopy [130] and photoemission [140, 141] does resemble the calculated density of states in some calculations [116, 126] but not others [104, 108].

A free monolayer, possible only in model calculations [182–187], avoids the complications caused by the influence of a substrate surface. Obviously, such a simplification can provide only a qualitative description of the electronic structure of adsorbed layers (specifically, atomic wires). Nevertheless, as will be illustrated below by several examples, the free monolayer approach is really capable of explaining many important features of metallic films adsorbed on transition metal surfaces, in particular, the NMT in alkaline earth films with increasing coverage [187]. Application of this idealized model to metal films adsorbed on semiconductor surfaces, however, is rather ambiguous because of a localized character of adsorption bonds, which results in substantial redistribution of valence electrons within the surface region. To this end, it may be noted that it was suggested [18] that interaction with a semiconductor surface should be less important than that with a metal surface. This statement, it was argued, is in line with empirical considerations, by the lack of the band hybridization that should occur when the bands of the adsorbed metallic layer appear in the energy gap of the substrate. In fact, the situation is just opposite. Usually, in semiconductors, there are narrow bands of surface states in the vicinity of the Fermi energy, which provide strong polar covalent bonding to the adsorbed metal atoms. These bonds remain of a local character even at a complete monolayer coverage, which prevents metallization of the adsorbed films [127]. In the case of a metal substrate, while at low adsorbate coverages the bonding should be somewhat similar (i.e., localized), near a complete monolayer, because of metallization of the overlayer [29, 30, 51–54], the bonding attains a metallic (delocalized) character. Hence, the film acquires a certain "independence," which makes the free monolayer approximation more realistic.

3. THE NONMETAL-TO-METAL TRANSITION IN FREE MONOLAYERS

Because of strong interaction of the Fermi electrons with phonons, structural instability is characteristic of low-dimensional metals [188]. Hence, unsupported linear metallic atomic wires must be unstable, and therefore the interaction with the substrate surface is essential for the appearance of the appropriate film structures, particularly linear or zigzag atomic chains. Nevertheless, many important properties of the atomic wires can be learned by studying the electronic structure of free, unsupported monolayers. This simple model allows for rigorous band structure calculations for various spacings between atoms. We can describe the dramatic changes in the state of the system, NMT, which must take place with increasing density of a crystal built from atoms of "nominal" metal.

To calculate electronic structure, one may choose, depending on the type of interactions between adsorbed atoms, between quantum-chemical calculations for clusters and the crystal-based band structure approach that is valid for infinite periodic monolayers [182–187]. Each approach has its place. That is, when the attraction between adsorbed particles results in the growth of islands [189–192], it worthwhile to simulate the onset of metallicity by increasing the cluster size [192–194]. On the other hand, when metallization is caused by a compression of adlayers with repulsion between adatoms, which is mostly the case for alkali and alkaline earth layers adsorbed on smooth transition metal surfaces [29, 30], the calculations for free periodic monolayers with decreasing lattice period [186, 187] seem to be more appropriate for simulating the adsorbed film. In each case, there is the essential issue of what a metal is. Comparison between approaches makes the question rather critical. Thus, a metal may be considered a piece of matter that exhibits conductivity, in other words, that has a certain density of states in the vicinity of the Fermi energy. Such a metal may be a cluster of sufficient size, a liquid or a fluid. Alternatively, a metal is associated with a metallic band structure, whose existence necessarily implies periodicity that is characteristic for crystals. In the literature, this distinction

between the two possible definitions of a metal is usually obscured, thus leaving the reader to guess which approach is actually adopted.

The system studied by the widest variety of approaches, perhaps, is mercury [32, 195–200]. The evolution of the electronic structure of adsorbed films of mercury shows different behavior on different substrates. Various experimental and theoretical approaches have been applied, giving a comprehensive description of the role of a strain in adsorbed Hg layers [195, 196], as well as the critical volume and coordination number [197–200] in the NMT. While fully metallic behavior in Hg clusters occurs for free clusters 70 to 110 atoms [197, 198] in size, corresponding to a coordination number of 9 to 20, the deviation from nonmetallic behavior and the transition toward metallic behavior begins at a coordination number of about 6. A similar cluster approach for Cs overlayers on GaAs [199] has revealed the critical coordination number to be about 3.

What we underscore here is that the cluster-based calculations definitely suggest a nonmetallic state for a coordination number of 2. This means that this approach precludes dielectric behavior in atomic wires for any spacing between atoms.

We will consider the NMT from the point of view of the crystal-based approach, and therefore the complex issues of the "degree" of metallicity (which appears in sufficiently large but still finite sized clusters), density of impurities, and finite temperatures (better described by Anderson transition, but in only three dimensions [201–203]) remain beyond the scope of this chapter. In other words, we will deal with perfect infinite crystals at zero temperature limit to outline basic principles of the NMT resulted from increasing density.

3.1. The Wilson Transition

Most handbooks on solid-state physics associate NMT with the names Mott and Hubbard [65, 204–208] (Mott-Hubbard transition) but sometimes omit Wilson [209, 210], who first (in 1931) described NMT for divalent atoms in a two-band model. The Wilson transition is illustrated in Figure 3 by results of model calculations for free Mg monolayers with a square lattice. When spacing between divalent atoms in
a crystal is large, the lower s-band is filled and the upper p-band is empty. This results in a dielectric state (at $T = 0$, in the most rigorous definition, the Fermi level locates at the topmost occupied level that is the edge of the s band, as shown in Fig. 3). As the spacing decreases, increasing overlap of atomic orbitals is followed by increasing width of the bands and their hybridization. The gap at E_F vanishes and the crystal becomes metallic.

Wilson's NMT does not need any special transformation of the structure, and, thus, with decreasing spacing between adsorbed alkaline earth atoms, the NMT is revealed by the rise in the density of states at the Fermi level, which can be observed by ultraviolet photoelectron spectroscopy (UPS) [51–54]. Obviously, a metallic substrate complicates the study of the NMT in adsorbed layers but, on the other hand, provides a unique opportunity to change the density of the adlayer over a rather wide range. To this end, it is important to understand how the changing spacing, between atoms in a free monolayer film, would be revealed in the evolution of the electronic structure. This can be performed by band structure calculations for various structures and lattice densities.

Wimmer [183, 184] and Boettger and Trickey [185] calculated the band structure, density of states (DOS), and cohesive energies for close-packed monolayers of free alkali and alkaline earth. Both studies reported a metallic state in monolayers for lattice spacings that were chosen to be equal to experimental bulk lattice constants or related to the minimum in total energies. According to these calculations, a hexagonal lattice structure has the lowest total energy and, therefore, is the most probable structure for free alkaline earth monolayers.

Transformations of the band structure of alkaline earth free hexagonal monolayers [187] with increasing lattice periods have been studied by the LAPW method for thin films. Results of these calculations revealed a Wilson-type transition that occurs at certain critical spacings between alkaline earth atoms. Thus, when interatomic spacing is large, a dielectric state of Be, Mg, or Ca layers is evident from the band gap at E_F, separating s and p bands (the predominantly s and p characters of the bands are derived from the partial DOS). As the density increases, the bands gradually become wider and hybridization makes the gap close. For close-packed monolayers, the band structure clearly shows a metallic state with two parabolic bands crossing the Fermi level. A rather high DOS at E_F is provided by both the s and p partial densities, which indicates that the metallic state is established because of the s-p band hybridization. This is characteristic of the Wilson NMT. Such a behavior is typical also for Sr and Ba, apart from the substantial contribution of d states to the DOS at E_F.

The issues concerning the role of the coordination number in the NMT have been investigated by calculating the evolution of band structures for bulk Ba and various monolayer structures of Ba as a function of increasing lattice constant [211]. Among the alkaline earth metals, Ba is attractive for model studies because it is rather close in size and behavior to Hg, of which metallization with decreasing spacing is a classic example of the NMT [65]. The calculations were performed by the scalar relativistic (film-) LAPW method [212], assuming a bcc structure for the bulk Ba and hexagonal,

Figure 3. The Wilson transition in a Mg monolayer with a square lattice. A decreasing lattice constant results in a metallic state, which is evident from closing of the gap at E_F.

square, and diluted linear structures for monolayers. In the latter case, a rectangular lattice with a longer period of 10 Å was employed to simulate the absence of electron density overlap between the linear chains, while the atomic spacing along the chains was varied. Using essentially the same methods for the bulk and the monolayers, the role of the coordination and dimensionality of the system has been studied by comparing, for each different lattice geometry, the interatomic spacing that corresponds to a sharp rise of DOS at E_F.

The main result in comparing the nearest-neighbor distances between Ba atoms, which is related to the critical NMT point [211], can be summarized as follows. The transition point for bcc Ba corresponds to the nearest-neighbor distance of 7.9 Å, which is much greater than the value of 5.7 Å for the NMT in the monolayers with a hexagonal or square lattice. There is a generally larger critical spacing associated with the larger coordination number in the bulk (8 for bcc Ba), as compared with 6 for hexagonal, 4 for square, and 2 for linear lattices. However, the comparison shows that the critical spacing does not scale as a simple inverse function of the coordination number.

Hence, quasi-one-dimensional atomic wires can be metallic provided that the interatomic spacing is small enough—the NMT in these wires must occur at much smaller lattice periods than in a bulk crystal. This feature may be a reason why Yamada [24] claimed that one-dimensional Mg chains are always nonmetallic. Indeed, apart from well-known limitations of the tight-binding approach when used for simple metals, these calculations do not address the possibility of a small compression of the wires, which is typical for adsorbed layers. For example, in the (1×1)Mg/Mo(112) structure [29, 52–54], the distance between Mg atoms in the wires lying in the furrows is 2.73 Å, which is approximately 14% less than the distance between Mg atoms in a bulk crystal. Figure 4 shows the results of model self-consistent LAPW calculations of one-dimensional band structures for linear Mg wires at various characteristic distances between atoms.
Figure 4. The Wilson transition in linear Mg chains. While for $a = 3.5$ Å the Mg chain is dielectric, at $a = 3.2$ Å, which is about the bulk lattice period of hcp Mg, the wire becomes metallic. For the p(1×1)Mg/Mo, the distance between Mg atoms located in the furrows is 2.73 Å, and the wires are definitely metallic.

Whereas for $a = 3.5$ Å the chain is obviously dielectric, at $a = 3.2$ Å, which is about the bulk lattice period of hcp Mg, the wire becomes metallic. It should be noted that the position of the Fermi level is determined here from the density of states evaluated while accounting for other chains, which form a rectangular unit cell of the monolayer. In other words, despite of negligible overlap of wave functions of the atoms in neighboring chains (with 10 Å spacing), the system, in fact, still remains three-dimensional (in the direction of the normal to the model monolayer, wave functions are evaluated by numerical integration).

3.2. Mott-Hubbard Transition and the "Failure" of Band Theory

No ghost "many-body effects" are needed to describe the Wilson transition—this can be done solely in terms of electronic band structure transformations resulting from the increasing density of the crystal. This mechanism evidently fails to directly explain the NMT in alkali crystals. Indeed, in considering one-electron (per atom) systems, it seems that the crystal must be metallic, because the lower s band is half-filled, regardless of the lattice constant. For this reason, it has been claimed that a band structure approach should be invalid for the case of strongly localized valence electrons. Thus, it has become a conventional wisdom that the DFT needs certain many-body corrections to account for enhanced correlations that appear in Mott insulators and ferromagnets. To date, it is generally believed that while the NMT in divalent crystals still can be explained as a Wilson transition (that is, in terms of hybridization of the s and p bands), the NMT in monovalent metals unavoidably involves many-body effects and therefore must be attributed to the Mott-Hubbard transition [32, 33, 61, 65, 126, 213–220].

Mott and Hubbard [65, 204–208] suggested a semiempirical picture of the transformation from metallic to insulating phase based on considerations of the gain in total energy. Using atomic ionization potential, affinity, and Hubbard interaction energies U, they have obtained a rather transparent explanation of the transition from localized to delocalized states of valence electrons with decreasing spacing between alkali atoms.

Let us consider two well-known explanations of the Mott-Hubbard transition with changing spacing between monovalent atoms. When the spacing is large, a transfer of an electron from an atom to a neighboring atom would be very unfavorable because of the large increase U in the total energy, which can be roughly estimated as the difference between the ionization potential and the electron affinity of the atom. This is a dielectric state, and valence electrons stay bounded with their atoms. Such a state is described by two narrow Hubbard bands (or several bands in some more sophisticated approaches) that originate from atomic occupied (ns^1) and empty states, separated by an energy U. With decreasing lattice period, increasing overlap of atomic wave functions leads to an increase in the widths B_{upper} and B_{lower} of the upper and lower Hubbard bands, respectively. The resulting increase in widths leads to band tail overlap, which corresponds to the transition to a metallic state. Establishment of a metallic state results in a decrease in

total energy, which largely compensates for the lost U, and electrons gain some freedom (delocalize). The criterion of the NMT [32, 65] may be roughly estimated from the relationship between U and the widths of Hubbard bands as

$$(B_{\mathrm{upper}} + B_{\mathrm{lower}})/2 = U$$

This interpretation of the NMT, in general, seems very reasonable. Indeed, there must be a transition to a dielectric state when the spacing between monovalent atoms becomes large. What is questionable here, however, is validity of the linear combination of atomic orbitals (LCAO) approach based on tight-binding approximation. Such an approach might be more or less justified for describing the dielectric state but becomes, obviously, rather poor for attempting to describe the nearly free electron bands in a simple metal.

Another popular explanation of the Mott-Hubbard transition is based on the consideration of screening (which is a many-body effect) and its dependence on electron density [32, 65]. The screening parameter l_s (inverse screening length) is introduced through the Thomas-Fermi approximation:

$$V(r) = (-e^2/r) \exp(-l_s r)$$

When the screening length exceeds the distance between monovalent atoms, the crystal will be metallic; otherwise the electrons will remain bounded to the ions and therefore the crystal will be a dielectric. Such a description presents an attempt to explain NMT by starting from a metallic state, for which the Thomas-Fermi approximation is acceptable. However, near the transition point and for a dielectric state, the system must be very far from a free-electron gas, and thus macroscopic parameters of screening can lose their physical meaning.

Another challenge with regard to the Mott-Hubbard transition is the order of transition and related transformations in the magnetic state. Though it is generally believed that the Mott-Hubbard transition must be of the first order [32, 65], the situation with magnetic transition is still unclear. Mott [65, 204, 205] considered an array of hydrogen atoms at zero temperature fixed rigidly on a lattice. The ground state of this system can be characterized as follows. At very high density the system will be a paramagnetic metal, while at low densities it will be an insulator and probably antiferromagnetic. Between these two limits there must be a transition from metallic to insulating behavior and from paramagnetic to antiferromagnetic behavior. Thus, Mott [65] suggested that with a decreasing lattice constant, there will occur, at some critical interatomic distance, the dielectric-metal and magnetic transitions (that is, in fact, a single transition). In contrast, the Hubbard model [207] predicted two separate phase transitions that should occur at two different distances between monovalent atoms.

This problem was studied by Rose et al. [221], who used tight-binding band calculations to describe a hydrogen crystal at various interatomic spacings. They also found two separate transitions that originated from the indirect overlap of the spin-split bands. As the spacing decreases, first, the second-order transition from a spin-ordered (ferromagnetic) state to a paramagnetic state occurs. Then, second, with a

further decrease in the spacing, the first-order phase transition from the dielectric state to the metallic state occurs.

For atomic wires, the picture seems even more complicated because of enhanced correlations in a one-dimensional case [1, 32]. Using the short-range one-band model for electron correlations in a narrow energy band, Lieb and Wu [6] have found the ground-state energy, wave function, and chemical potentials in the one-dimensional case. Based on these results, they have found that the ground state exhibits no conductor-insulator transition as the correlation strength is increased.

In contrast, on the basis of self-consistent DFT calculations, Zabala et al. [16] predicted that three-dimensional nanowires of simple metals should undergo a transition from a spin-polarized magnetic state at critical radii. Noteworthy here is that the wires are considered as three-dimensional objects, for which an inherently one-dimensional description, pertinent to excitations in Luttinger liquid [1], is not applicable.

To find a guideline in this quite involved situation and to gain a clear description of the NMT, we will adopt the band structure approach. The present understanding of band structure [61] precludes assigning true one-electron meaning to the bands, as suggested by the Hartree-Fock approach. Rather, the bands should be treated as energies of quasi-particles that may be considered as electrons combined with exchange-correlation holes. Therefore, the many-body effects are in fact included in the band structure (apart from coherent excitations that cannot be treated in the model of quasi-particles with weak interaction). These ideas, first suggested by Wigner and Slater [222–224], have found their justification in the famous Hohenberg-Kohn-Sham DFT [225–227] as well as in a number of experiments. It is the introduced effective exchange correlation potential that has connected the many-body effects to the band structure, thus unavoidably changing its original one-electron meaning.

In some special cases, however, the applicability of the DFT approach was questioned. It was established that the local spin density approximation (LSDA) fails to describe correctly the electronic structure of strongly correlated systems such as Mott insulators, insulator ferromagnets, and 4f metals [228–230]. The inability of LSDA to correctly describe 4f metals occurs mainly because of the incorrect position of spin up f↑ and spin down f↓ bands if the 4f electrons are treated as bands (not as core states) [231–233]. The increasingly compelling evidence that gadolinium was a local moment system with correlated electrons [234, 235] provoked the development of an improved version of the LSDA method by including the Hubbard U, taken from the mean-field approach to the many-body problem [228, 229]. To date, the LSDA $+ U$ method is widely recognized and has proved fruitful in recent calculations of the bulk and surface electronic structure of Gd [236–238]. Because of a better accounting of the intra-atomic correlations, the 4f minority band rises away from the Fermi level, while the 4f majority band increases in binding energy to the correct position [236]. Implementation of the LSDA in the LAPW method for thin films has been accomplished [237], and calculated self-consistent densities of states for Gd(0001) surface provide a reasonable positioning of the occupied 4f

band. Again, inclusion of the Hubbard U allowed for a correct estimation of the magnetic moment as well as of the width of the s-d valence band (above 4 eV) [238]. Nonetheless, the correlation U remains something of a "fudge" factor even in *ab initio* calculations.

On the other hand, the LSDA + U results ultimately predict the existence of the spin minority unoccupied band approximately at +2 eV above E_F. This band originates from the Gd 4f spin minority localized "atomic" state and therefore is very narrow (0.5 eV [236, 238]). This band results in an extremely sharp peak in the unoccupied DOS (the "pure" LSDA approach puts this peak on E_F [236]). The challenge here is that for the Gd surface, such a peak is very difficult to observe in angle-resolved inverse photoemission [239], and the existing assignment cannot be completely definitive.

An alternative approach to the rare earths, with consideration of 4f states as core states, has been argued [240] to be relevant, because of a strong localization of the 4f electrons within the Gd core. It has been suggested [233] that the "first-principle" (pure) LSDA approach can be rescued and resuscitated, provided that the 4f states are treated as core states. Bylander and Kleinman [231, 232], in considering 4f states, proposed that the key to the problem is that exchange and correlation should be treated differently for core states and for bands. Thus, LSDA must be adequate for valence electrons in the band states, whereas for core electrons the Hartree-Fock approximation seems more appropriate. It should be mentioned also that the authors have questioned the validity of the LSDA + U approach in providing a correct electronic structure of Gd.

The example of Gd electronic structure illustrates the essential issues concerning the validity of band structure for strongly correlated systems. Indeed, regardless of the actual description of the system, to obtain some physical picture one needs consideration of the bands. Having the "tentative" band structure, it is possible to estimate certain "many-body corrections" such as the Hubbard U [228, 229] and the inner potential, which is roughly equal to one-half of the bandwidth [32, 182]. However, it is this method, but not the band structure, that has inherent problems, because if the bands are invalid, they cannot be used to properly evaluate the corrections. To this end, using LSDA in a slab model, the electronic structure of the Gd(0001) surface has been obtained in good agreement with spin-resolved ARUPS and IPES results [241], which indicates the validity of the band structure approach, even in the case of localized 4f states.

For the sake of completeness, the very recent evidence of limitations of DFT should be mentioned as well. Using a number of the most sophisticated calculational techniques, Feibelman et al. [112] have suggested that DFT total energy calculations are incapable of predicting correct atomic structures. This tends to negate the value of all total energy calculations performed to date and does not open any new options as an alternative either. The only hope that remains is that, in fact, increasing matrix size (used to achieve a unique convergence) could result in unexpected mathematical problems with numerical stability and applicability of standard diagonalization procedures. In any case, fortunately, this issue concerns only total energy, but not band structure calculations.

Hence, the band structure approach, buttressed with the density functional theory, gives a *correct* description of the ground state of a crystal. Therefore, it must explain the NMT in alkali crystals as well. Indeed, increasing the lattice spacing cannot cancel the band structure because its formation is determined only by the periodicity of a crystal. As the spacing increases, the local density approximation becomes worse, but the challenge is to obtain a qualitative picture of the transition rather than achieve great accuracy in band structure calculations. If, for divalent atoms, the band approach is valid, how can such calculations be completely invalid for monovalent metals?

3.3. Peierls Transition

A natural explanation of the dielectric state of an expanded alkali chain is the Peierls' distortion [188]—a charge wave that provides a coupling of adjacent atoms (Fig. 5). This coupling leads to a doubling of the period along the chain and thus to an associated decrease in the Brillouin zone. Then the Fermi level falls within the gap that opens at the new edges of the zone, which gives rise to a dielectric state.

The Peierls instability is induced by strong electron-phonon interactions, enhanced by so-called nesting—overlap of parts of the Fermi surface as a result of a translation, $|\mathbf{k}| = 2k_F$. For a spherical Fermi surface of a simple metal, the nesting is negligible and therefore the metal can be stable. In contrast, for a single one-dimensional metallic chain of atoms, the Fermi surface consists of two points, $k = +k_F$ and $k = -k_F$, which results in a perfect nesting and thus leads to instability of the chain. This is why the Peierls distortion is usually considered as a characteristic of essentially one-dimensional metals. However, substantial nesting appears also for a three-dimensional, periodic sequence of noninteracting (or weakly interacting) chains [2–4, 8–17]. In this case, the Fermi surface is very flat and can be approximated by two parallel planes that are perpendicular to the chain direction and can be shifted onto each other by the translation $|\mathbf{k}| = 2k_F$. Hence, the Peierls instability results from the strong anisotropy of metallic chains (wires) rather than from just one-dimensional properties of the system.
Figure 5. The Peierls transition. Coupling of the atoms in the metallic chain opens the gap at E_F.

It is this behavior that allows one to expect the Peierls distortion and related opening of the gap at E_F for real atomic wires.

In other words, an atomic wire must be unstable toward static periodic lattice distortions due to lowering of the total energy when the gap opens. On the other hand, such a distortion increases the phonon energy, and, hence, the instability of the metallic chain will occur below the Peierls temperature.

In spite of the expectation of dielectric character (due to Peierls instability), some of the atomic wires, such as Au on stepped a Si(557) surface, were found to be metallic [18, 19]. To explain this result, it was suggested [18] that the metal atoms at a silicon surface were locked into the silicon crystal lattice. This provides a means for "anchoring" the chain to prevent dimerization.

3.4. Zigzag Structures and the "Gapless" Peierls Transition

It has been noticed that various adsorbates tend to form zigzag chains when adsorbed to metal or semiconductor surfaces. For example, Cs on A_{III}-B_V(110) surfaces (GaAs and InSb) forms stable one-dimensional zigzag chains extending for several hundred angstroms along the [110] direction [44–46] (Fig. 6), as observed in scanning tunneling microscopy (STM). At 40% of saturation coverage, the quasi-linear chain phase evolves into a 2D cluster layer. Over this whole coverage range, the 1D chains and 2D clusters are found to be insulating. The measured tunneling gap, which narrows with the transition from the 1D to the 2D film structure, provides strong evidence for a band gap and the insulating state of Cs at coverages below a monolayer [44]. The metallic character is observed only with formation of the second Cs overlayer [44].

Such zigzag structures can be a result of Peierls-like distortions but are accomplished by a transverse displacement of every other atom in the chain, and one might expect that this distortion could open up a gap at the Fermi energy. This idea was very attractive, in particular, in the picturesque explanation of a dielectric state of zigzag Cs chains on GaAs. However, purely transverse displacement of the atoms in alkali metal chains will not open a gap at the zone edge, as
illustrated by Figure 7. Such a behavior has been explained by Batra [99, 100], who has found that a transverse distortion does not lift the degeneracy at the Brillouin zone edge. Hence, in spite of lowering energy, a transverse distortion, the "gapless Peierls transition," cannot result in a dielectric state of the Cs atomic wire. This is why the nonmetal state of zigzag Cs chains on GaAs was suggested to be an example of a Mott insulator [47, 48, 100–102, 213–220, 242–248].

These ideas have provoked a number of investigations focused on the search for the gapless Peierls transition in adsorbed atomic wires. For alkali metals on Si(100), the long chains of alkali metal atoms for the metallic half-monolayer coverage surface could potentially exhibit a Peierls-like phase distortion. Longitudinal distortions for such chains are unlikely (spacing distortions along the chain) because of the close spacing between alkali atoms, and in general these "steric" effects favor transverse distortion [102, 104]. However, strong interaction with a semiconductor surface complicates interpretation, and the results obtained thus far are not clearly indicative of the Peierls transition. A more fruitful approach in seeking the evidence for the Peierls transition [100] has been investigation of the trivalent metal overlayers, like Al, Ga, and In, on reconstructed semiconductor and metal (Cu(110) [248–250]) surfaces.

Symmetric dimer formation, rather than the more conventional transverse bulking of the gapless Peierls phase, has been proposed for the 3×2 (third of a monolayer), 2×2 (half monolayer), and other structures observed by low-energy electron diffraction for gallium overlayers on Si(100) [143, 251–253]. Similar results from STM studies [251] tend to confirm that the structures formed by gallium on Si(100) are either more akin to a conventional Peierls distortion (as opposed to a transverse distortion) or a dimer row formation. This is supported by photoemission [143]. Such structures are, in fact, different from both the expected longitudinal and transverse Peierls phase distortions. In Figure 7 (on the right), model band structure calculations are shown to illustrate the opening of the gap in this more complex situation.

Figure 6. Zigzag Cs wires on GaAs. STM images of Cs chains on the GaAs(110) surface at $\theta = 0.03$. Left: Overview (1370×1370 Å). Right: A single Cs zigzag chain (70×70 Å). Figure 7. The "gapless" Peierls transition. While a transverse distortion does not open the gap at E_F, rotation of the pairs of monovalent atoms in the chain leads to a dielectric state.

Arsenic overlayers are also seen to form symmetric dimer rows on Si(100) [82, 254–256]. The results for As on Ge(100) 2×1 reconstructed surfaces are very similar [57]. Again, the increasing binding energy of the surface state bands for As on Si(100) [201–203] is not consistent with a gapless, purely transverse Peierls phase transition. Unlike the clean Si(100) reconstructed surface, the dimers of arsenic on Si(100) form filled bonding and antibonding surface states, though these states are not resolved in photoemission [254, 256].

The deposition of indium tends to result in metallic indium island formation [258], but symmetric dimer formation is also observed with submonolayer coverages [258–260]. Given the tendency for indium to aggregate into islands, this overlayer system may not be particularly suitable for investigating a Peierls phase transition. Antimony presents a similar complication, with the observed tendency for the formation of Sb_4 tetramers on top of a chemisorbed Sb layer on Si(100) [261, 262]; nonetheless it is clear that Sb on Si(100) will form dimer rows at submonolayer coverages [260, 263, 264]. As a consequence of the Sb filling of the dangling bond states, a suppression of the silicon surface band structure is seen with Sb adsorption [259].

In adsorbed layers, the Peierls transition from the metallic to the dielectric state has indeed been reported for trivalent Tl and In wires on furrowed $p(1 \times 2)Si$ and GaAs(110) semiconductor surfaces [79]. This mechanism of NMT must be valid for alkali wires [216–218] as well and indicates the importance of further experimental investigations of electronic states of atomic alkali chains for elucidation of this fundamental phenomenon. In particular, the NMT in adsorbed alkali layers with increasing density must be accompanied by a structural phase transition—in the quasi-one-dimensional case of the linear chains, by the change from the coupled to the uniform distribution of atoms along the chains.

Concerning the gapless Peierls transition, it should be noted that though a purely transverse distortion does not lift degeneracy at the Brillouin zone edges, a rotation of pairs of metal atoms in the chain (that is, complex longitudinal-transverse distortion) does result in an opening of the gap (Fig. 7). Experimentally, it will be very difficult to distinguish between purely transverse and such complex distortions. Nevertheless, this task is quite interesting and therefore is worthy of some effort.

In summary, identification of Peierls-like transitions in atomic wires may be characterized as a cornerstone problem in the experimental confirmation of the theory of NMT. By considering Peierls-like distortions, one can reduce the Mott-Hubbard transition to a picture with Wilson-like hybridization, and thus it can be addressed with the band structure approach.

4. ATOMIC WIRES ON FURROWED TRANSITION METAL SURFACES

As follows from previous sections, direct application of theory to atomic wires on semiconductor surfaces is complicated by strong local adsorption interactions, particularly by the localized bonds with possible charge transfer. To this end, another kind of substrate may be more appropriate—namely, furrowed transition metal surfaces. It might be surprising that a metallic substrate, with its huge bath of free electrons, would provide a better substrate than a good dielectric, but this is indeed the case. We can expect that near a monolayer of coverage the adsorption bonds will be smeared out, giving rise to metallic bonding with the surface. Hence the films will acquire a certain degree of "independence," which means that the free monolayer model would provide a much better description of the band structure of adsorbed layers than in the case of semiconductor substrate surfaces.

On the other hand, a metal substrate complicates the experimental determination of both metallic and nonmetallic states of an adsorbed metal layer. In photoemission, evidence for the metallization of overlayers can be obtained from an increase in the density of states at Fermi energy and, in the case of angle-resolved photoelectron spectroscopy, from the appearance of surface bands crossing the Fermi level [32]. However, the identification of such a behavior in the photoelectron spectra is not always an easy task, and this is where a comparison with the calculated band structure is essential. Additional evidence for the metallization of overlayers can be obtained with EELS [29, 30, 32–34]. In contrast to semiconductor substrate surfaces, energies of surface and bulk plasmons for transition metals are usually far larger than the plasmon energies in alkali or alkaline earth overlayers. This facilitates identification of the electron losses.

To study the transformation of the state of the overlayers it is reasonable to use, as a substrate, those transition metals that have a low bulk density of states at E_F, such as W or Mo [212, 265]. The (112) surface of these bcc metals, as well as (10$\underline{1}$0) faces of hexagonal close-packed (hcp) structures, has a furrowed structure built from close-packed (2.73–2.76 Å) atomic rows with rather large spacing between them (4.43–4.45 Å). Here the surface potential is corrugated, and one can expect a similar formation of the chains of adsorbed atoms lying in the deep furrows. In fact the adlayers form chains orthogonal to the expected direction. Thus, as found by LEED studies, at low coverages, many alkali, alkaline earth, and rare earth metals form linear chains—wires—directed across the furrows [29, 30, 51–57, 266–279] (Fig. 8). Increasing coverage can result either in a decrease in the spacing between the chains or in the destruction of the chain structure, depending on the size and dipole moment of adatoms. Evolution of electronic structure with increasing coverage has been the most extensively studied for Mg on the Mo(112) surface [51–54]. Mg atoms at low coverages form such chains with little lateral overlap between valence orbitals of adjacent atoms. At these low coverages, it is now an issue whether these wires are metallic or dielectric. Near the completion of a monolayer, the spacing between Mg atoms along the furrows (2.73 Å for the $p(1 \times 1)$ structure) becomes smaller than that across the furrows (4.45 Å), and, with increasing coverage, one may presume dramatic changes in electronic structure resulting from the compression of the Mg wires along the furrows.
Figure 8. Linear structures on the furrowed transition metal surfaces. Note that preferable distances between various atomic chains depend on the substrate, in spite of the same atomic structures of the surfaces. Reprinted with permission from [30], I. N. Yakovkin, *J. 4.1. Lateral Interaction and Formation of Linear Structures

Formation of the commensurate p($1 \times n$) linear structures originates from substrate-mediated "indirect" interaction [266, 280–287]. While the distances between the chains in these structures correspond to n periods of the substrate along the furrows, the period along the chains is dictated by the width of the furrows.

Gurney's model [288] suggests a partial transfer of a valence electron of an adsorbed atom, ideally a simple metal, to the metal or semiconductor substrate surface. The adatom acquires a positive charge, which, together with its image in the substrate, forms a dipole. At low coverages, increasing density of the dipoles leads to a linear decrease of work function. For higher coverages, mutual depolarization of the dipoles results in a gradual decrease of the charge transfer within the double electrical layer, and the film becomes "neutral." This can be associated with the metallization of the overlayer. This simple description of the charge transfer from the adsorbed layer to the surface has recently been questioned [124–126], causing an extensive discussion [148, 289–306] on the nature of adsorption bonding. For example, from the calculated charge distribution for Cs on W(110) [306], it appears more appropriate to speak about a strong polarization of the adatom rather than charge transfer. However, these results better demonstrate that importance of the covalent part of the adsorption bonding (even for alkali metals) than prove the absence of the charge transfer because of the lack of a definition of the position of the surface plane, which may be arbitrarily chosen.

Regardless of which description is adopted, the decrease of work function reveals the dipole moment μ of adsorbed alkali and alkaline earth atoms, which can be derived through the Helmholz equation. Lateral interaction between the dipoles with a parallel orientation is repulsive with energy

$$E_{\text{d-d}} = 2\mu^2/r^3$$

where r is the distance between adatoms, and the factor of 2 is due to the location of the screening electrons at the surface but not at the position of the image [280]. For example, taking a typical value of the initial dipole moment of Sr on a Mo(112) surface of 2.9 Debyes [270], one can estimate the energy of the dipole-dipole interaction between Sr atoms in adjacent furrows to be about 119 meV. This is why the formation of the linear wires directed across the furrows is so surprising! Hence, there must also be a another, strong interaction that can provide the effective attraction between the adatoms in spite of their substantial polarization.

Indirect interaction between adsorbed atoms on a metal surface [280–284] is intimately related to the oscillations in electron density that occurs during screening for an impurity in the volume of a metal [285–287]. The energy of the substrate-mediated (indirect) interaction E_{in} at the surface [266] can asymptotically be estimated as

$$E_{\text{in}} \sim r^{-n} \cos(2k_{\text{F}}r + \eta)$$

This energy of the indirect interaction oscillates with distance (Fig. 9), whereas the period is determined by the Fermi vector k_{F}. Indeed, as illustrated by Figure 8, various adsorbates on the W(112) form a p(1×7) linear structure [266], which indicates the minimum in potential of the indirect interaction between the chains at a distance of 7 periods of the substrate along the furrows.

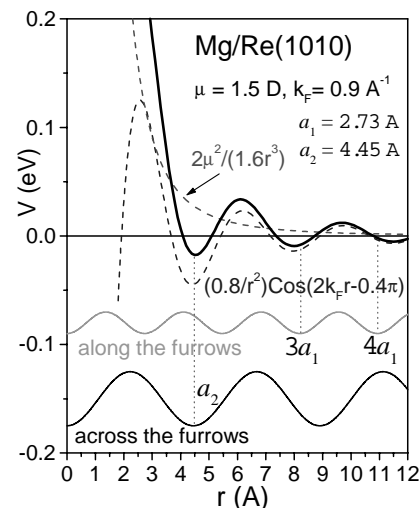
For Mo(112), presumably because of the smaller size of the Fermi surface, the period of oscillations of the potential seems to fall between 4 and 5 periods of the substrate. Of course, at such a large spacing between the chains, indirect interactions cannot provide any significant displacement of the adatoms from adsorption sites, which is evident from the formation of the coherent (that is, with periods related to several periods of a substrate) linear structures. Therefore, in this situation, the preferable distance between the chains can be 4 or of 5 periods of the Mo(112) surface along the furrows, which is consistent with LEED-derived results


Figure 9. The lateral interactions between adsorbed atoms. The effective potential (solid line) is the sum of indirect and dipole-dipole interactions. Formation of the film structures also depends on the surface corrugation, shown schematically at the bottom.

[269–277]. For example, at low coverages, Li and Mg on Mo(112) form the p(1 × 4) structure, while Sr and Ba form the p(1×5) structure. On the Re(10$\underline{1}$0) surface, the effective minimum in the potential of the lateral interaction occurs at the distance between Mg chains of 3 periods of the surface [272]. Hence, despite the quite similar geometry of the substrates, spacing between adsorbed chains is different for these surfaces, which is most likely a consequence of the differences in surface electronic structure that places the pertinent Fermi wave vectors k_F at different values (for each surface).

The effectiveness of the interaction depends on the decay length, which is determined by a power law functional of the distance between the adatoms [266, 287]. It is intuitively clear that the strength of the interaction must depend on the number of electrons that take part in the Friedel oscillations, in other words, density of states at Fermi energy and direction in k-space. Thus, a spherical Fermi surface provides a strong screening and an unfavorable r^{-5} decay, whereas flat electronic jacks lead to much better r^{-2} behavior [266], which is much better for interactions on a longer length scale. The most effective decay function, r^{-1}, for the indirect interaction was predicted for the case of surface bands crossing the Fermi level [266]. Because of a deep minimum in the bulk density of states for W or Mo at the Fermi energy [212, 265], it is just such surface states that can provide the quantity of electrons required for the formation of the chains.

The existence of the surface bands crossing the Fermi level has been confirmed, for the Mo(112) surface, by UPS and IPES experiments [51–54, 182, 307–309] as well as by the band structure calculations [182, 265, 309]. For the M$\underline{o}$(112), "true" surface states occur only in the vicinity of the $\overline{\Gamma}$ point and presumably lie within a gap that relates to d states of different symmetry [182]. Nonetheless, the surface resonance bands crossing the E_F, found from calculations, can facilitate the formation of the linear chains of adsorbed alkali and alkaline earth layers.

Such a band crossing the Fermi level is essential for possible surface reconstruction [310–322] that causes a relative gap to open at Fermi the energy, thus decreasing the total energy of the system. This mechanism was suggested for the reconstruction of the Mo(112) surface induced by hydrogen, oxygen, or carbon adsorption [308]. In particular, oxygen adsorption on Mo(112) leads to a surface reconstruction. However, it is still possible to obtain a p(1 × 2) linear structure of the oxygen layer on an unreconstructed surface of Mo(112). This feature, due to conservation of the Brillouin zone size in the $\overline{\Gamma Y}$ direction (that is, across the furrows), has permitted direct identification of the Mo(112) surface bands through the study of the changes in position and dispersion of the bands both with and without oxygen adsorption. Recent IPES (inverse photoemission spectroscopy) data, combined with band structure calculations and symmetry assignments for the surface states [309], supplements our understanding of the electronic structure of the Mo(112) surface, derived from extensive UPS and EELS studies [51–54, 182, 307, 308].

Because of d electrons in the valence band, rare earth adsorbates generally exhibit stronger bonding with transition metal surfaces. Thus, adsorption of rare earth metals [55–57,

278, 279] at elevated temperatures causes a reconstruction of the Mo(112) surface. In particular, a small amount of Dy will drive a compound reconstruction [279] of the Mo(112) surface that can be assigned to a "glassy" state. This means that the Mo(112) surface is not rigid enough to provide a template for the formation of robust rare earth wires across the furrows. In contrast, the rare earths La, Sm, Gd, Dy, and Ho do form the p(1 × 7) structure on the W(112) surface [266].

No reconstruction of the Mo(112), W(112), or Re(10$\underline{1}$0) surfaces has been reported with the adsorption of alkali or alkaline earth metals. Having almost identical atomic structures, these surfaces do allow for comparative studies of the influence of the electronic structure of the substrate on the properties of adsorbate.

4.2. Monte Carlo Simulations of the Order–Disorder Transition in Overlayers

Strength of the lateral interaction can be roughly estimated by studying the disordering of the structures of adsorbed layers with increasing temperature. A structure that is well ordered at low temperature can undergo disordering as the temperature increases. This order–disorder transition [267] is due to thermal fluctuations, which can be related to atoms "jumping" to neighboring adsorption sites. The transition point T_{tr} corresponds to the temperature for which the energy of the fluctuations $k_B T$ reaches the energy of the lateral interaction. Then, through measurement of the temperature dependence of the intensity of the LEED reflections related to the overlayer structure, the energies of interaction between the adatoms can be derived. The value of T_{tr} is usually determined by the inflection point in the $I(T)$ plot.

In the case of linear structures, however, the $I(T)$ dependence is of a gradual character [266, 269–272], which can be attributed to a strong anisotropy in the lateral interactions [272]. Generally one presumes that the indirect interaction along a wire must be much stronger than the interaction between the wires. This feature can result in two sequential stages of the disordering with increasing temperature [272]. In the first stage, characteristic fluctuations correspond to adatoms shifted along the furrows from their position in the chains to adjacent adsorption sites (transverse distortions). Increasing the number of these displaced adatoms leads to the formation of fragments of linear chains shifted relative to their initial position. Therefore, the first stage is the loss of coherence in the interchain distances. The second stage is characterized by a disruption of the chains.

Justification of such a picture of the order–disorder transition in linear structures can be obtained from Monte Carlo simulations [323–328] of the distribution of adatoms at various temperatures. Within the lattice gas model, dynamical equilibration of a structure is achieved by moving randomly chosen particles to neighboring sites along the furrows. The probability of each replacement (one "jump") of the particle is determined by the partition function $\exp(-\Delta E/k_B T)$ or, if the replacement leads to a decrease in the total energy, that is, $\Delta E < 0$, the probability is taken to be unity. As a result of such an equilibration procedure (typically 10–20 jumps per particle are required), at low temperatures,

well-ordered structures of adlayers are formed, whereas at higher temperatures, the adlayers become disordered. The relative intensity of the corresponding LEED reflections can then be evaluated in kinematic approximation, which gives the model $I(T)$ plot required for comparison with experiment. Consideration for the experimental parameters, particularly the typical coherence width for LEED, makes one inclined to choose the size of the matrix to be about 100×100 Å^2, with periodic boundary conditions. Obviously, formation of the actual overlayer structure depends on the coverage and assumed lateral interactions that can be introduced as parameters that are determined from comparison with experiment. In the case of alkali and alkaline earth adsorption on furrowed surfaces, apart from a long-range dipole-dipole repulsion (which requires one to take into account all particles located at the sites within a rather large circle around the one particle under consideration), the indirect interaction is described by parameters E_1, the energy of attraction between adjacent atoms in a chain, and E_2, effective attraction along the furrows at favorable distances derived from LEED experiments.

Shown in Figure 10 are results of the Monte Carlo simulation [328] for $\theta = \frac{1}{4}$ at $T < T_{tr}$ and $T > T_{tr}$. As seen from the top panel, apart from several typical defects, at low temperature, a well-ordered p(1×4) structure is formed, representing the structure of Sr layers on Re(10$\underline{1}$0) or Na on Mo(112). Though increasing the temperature of the system leads to disordering of the p(1×4) structure, as seen in the bottom panel of Figure 10, at $T \approx 1.5 \cdot T_{tr}$ some fragments
Figure 10. "Snapshots" of the distributions of adsorbed atoms [328] for $\theta = 0.25$. At low temperature, $T < T_{tr}$ (top), a well-ordered p(1×4) structure is formed, representing the structure of Sr layers on Re(10$\underline{1}$0) or Na on Mo(112). At $T \approx 1.5 \cdot T_{tr}$ (bottom), the film is disordered, but some fragments of the chains still exist, thus revealing a two-stage transition. Reprinted with permission from [30], I. N. Yakovkin, *J. Nanosci. Nanotech.* 1, 357 (2001). © 2001, American Scientific Publishers.

of the chains still exist, thus confirming the above suggestion concerning the character of the typical thermal excitations in the linear structures. It is the possibility of fitting experimental $I(T)$ plots not only at the transition point but over a wide temperature range that allows for an independent determination of the parameters of lateral interaction. For example, the energy of attraction between adjacent atoms in Li chains on Mo(112) has been found to be 20 meV, which is consistent with recent evaluations [278] obtained by adopting the Ising model for the approximation of nearest-neighbor interactions.

From the simulations [328], the most important trends in the lateral interaction can be derived. First, the effective attraction along the chains of alkaline earth adatoms substantially exceeds that obtained for alkalis. This enhanced strength of the alkaline earth wires becomes even more evident if we recall that this indirect interaction must compete with the dipole-dipole repulsion between the adatoms. Then, second, among alkaline earth adsorbates (as well as among alkalis), the strength of the wires increases with a decrease in the dipole moment. It is also worth mentioning that the indirect interaction between atoms of transition metals, reported in an ion field microscopy study of migrations of atomic pairs and clusters [284], much exceeds effective attraction between alkaline earth adatoms, which can be attributed to the significant role of d orbitals in the indirect interaction.

4.3. Nonmetal-to-Metal Transition in Mg Layers Adsorbed on the Mo(112) Surface

Nearly free electrons in simple metals have a parabolic energy dependence (dispersion) on the wave vector. In contrast, a dielectric state is characterized by a flat valence band that does not cross the Fermi level. Hence, the postulated NMT in adsorbed alkaline earth films must be accompanied by a significant transformation of the band structure. In particular, a decreasing distance between linear Mg chains on Mo(112) with increasing coverage should be followed by evolution of the bands from a flat to a parabolic shape along the $\overline{\Gamma}$–$\overline{X}$ direction in the Brillouin zone (BZ) that in real space corresponds to the direction along the furrows (Fig. 11). Such a transformation must result in the appearance of a band crossing the Fermi level, thus proving that metallization of the film occurs.

These ideas have been confirmed in a detailed ARUPS study of the band transformations with increasing Mg coverage on the Mo(112) surface conducted by Zhang et al. [53, 54]. For the commensurate p(1×2) structure, the distance between the chains (5.46 Å) substantially exceeds the diameter of the Mg atom (3.20 Å). Therefore, at $\theta \leq 0.5$, there should be no significant coupling between the Mg chains. The dispersion along $\overline{\Gamma}$–$\overline{X}$ of the surface resonance (SR) band of -1.6 eV (here and below, the bands are denoted by their energy at $\overline{\Gamma}$ point relatively to the Fermi level) is rather weak (a "flat" band that is characterized by a large effective mass [54]). As the coverage increases, this band gradually attains the parabolic shape inherent for nearly free electrons. For coverages above one monolayer, this SR band is similar to that reported for the Mg(0001) surface [304, 329].

Presented in Figure 11 are the results of self-consistent calculations (performed with the linearized augmented
Figure 11. The surface bands [330] along the $\overline{\Gamma}$–$\overline{X}$ for the p(1 × 2) (left) and p(1 × 1) (right) Mg/Mo(112) (dashed lines). The experimental data by Zhang et al. [53] for surface sensitive bands for the Mg/Mo(112) are shown by solid dots. Increasing Mg coverage results in increasing dispersion of the bands and in the band crossing of the Fermi level.

plane wave method for thin films) of the electronic structure of Mg layers, adsorbed on the Mo(112) surface [330], for two characteristic coverages: $\theta = 0.5$, when the alkaline earth films are believed to be dielectric, and $\theta = 1$, when the films are metallic. The states with predominantly surface weight—surface states and resonances—are marked by dashed lines.

As the coverage increases, the one-dimensional compression of the Mg layer along the furrows results in increasing dispersion of the bands and in an increase in the local density of states within the Mg layer. The most convincing evidence of the metallization of adsorbed Mg film is the appearance of the -0.5 eV surface resonance band, which, having a parabolic shape, crosses the Fermi level along the $\overline{\Gamma}$–$\overline{X}$ direction related to the direction along the furrows (see Fig. 11). Such a behavior is typical for nearly free electrons in simple metals and is therefore indicative of metallicity. Indeed, for the p(1 × 2) Mg/Mo(112) adsorption system, this band is absent both in ARUPS data [53, 54] (shown by symbols in the Fig. 11) and in the calculated band structure. It is the one-dimensional compression of the Mg layer along the Mo(112) furrows that leads to a loss in coherence with substrate and attainment of the metallic state of the film.

The increasing density of the adsorbed layer leads to noticeable changes in the charge distribution of the resonances. Thus, for the p(1 × 1) Mg, the -1.5 eV surface resonance attains certain "metallic" features, such as a more pronounced s character of the charge distribution [330]. In other words, the polar covalent bonding at low coverage transforms to a more delocalized electron "state,"

that is, metallic adsorption bonding at higher coverages. Indeed, on breaking bonds with the substrate, which results from the commensurate-incommensurate phase transition, the valence electrons are largely restored to the Mg film and thus provide the basis for the overlayer film metallization. In this situation the adsorbed films attain a certain independence from the substrate, and the free-monolayer model can give a qualitatively correct description of the surface electronic structure.

5. CONCLUSION

A variety of atomic wires can now be synthesized on furrowed and stepped surfaces, which provides opportunities to systematically tailor the surface properties. These almost one-dimensional systems can be formed by both self-assembly and artificial preparation with STM techniques for a wide variety of adsorbate and substrate combinations. The very unusual electronic features of such systems provide for new possibilities in atomic chain electronics.

For further progress in this new field of nanotechnology, much of the underlying physics remains to be investigated. One of the most important issues here is the metallicity of the atomic wires and how one can control this metallicity. Hence, the nature of the NMT is a key problem to be investigated. Strange as it sounds, but after half a century of study of this fundamental problem of solid state physics, there is no general consensus about mechanisms of the NMT. In large measure, this situation has been provoked by the huge variety of approaches—such as many-body considerations, band structure methods, growing clusters within "first-principle" quantum chemical calculations, and so on—that have, thus far, failed to provide a unified picture.

In this chapter, the NMT is analyzed from the viewpoint of transformation of the band structure. The reason for this choice is simple. The atomic wires are real, that is, three-dimensional, material objects. This implies that exotic one-dimensional theories need not necessarily be involved for an explanation of their behavior. With regard to a many-body approach, it should be mentioned that, aside from its recognized validity in all possible cases, little gain in understanding can be extracted from this quite sophisticated view. Understanding means that a clear picture of a phenomenon is evident. It is very possible that such simple insights can be drawn with semiempirical mean-field approximations that include a variety of parameters such as Hubbard's U. Nature requires a natural explanation, which, for NMT, can be obtained in terms of transformations of the band structure.

The different ways of describing the NMT have provoked the classification of the NMT into different types, such as the Mott-Hubbard, Wilson, and Peierls. In fact, there is a single phenomenon, revealed in the closing of the gap at E_F, which is characteristic for a dielectric state. Obviously, the gap implies the existence of at least two bands—one below and one above E_F. Whether these bands are called Hubbard bands (that appear through a semiempirical tight-binding approach while claiming to account for many-body effects) or ordinary bands (which can be obtained by using band structure calculation techniques) obviously depends on the approach and view one wishes to apply. Whereas the

former method allows, at best, only qualitative comparison with experiment, the latter provides results that can be directly justified by ARUPS and other techniques that allow band structure mapping, as illustrated in this chapter for Mg atomic wires adsorbed on a Mo(112) surface.

In this context, the issue of the ability of the band structure approach to explain NMT in monovalent crystals is of particular importance. This challenge has provoked much discussion about the interplay between a classical solid-state many-body consideration and the band structure approach. However, there is a simple argument that leads one to advocate the band method. If many-body effects can be avoided in explaining the NMT in divalent crystals, which follows from excellent agreement with experiment, how many body effects could be crucial for the case of monovalent metals? No compelling reason has yet been given, though the suggestion that it is essential has been implicit in many theoretical arguments to date. Hence, there should be another explanation of the nonmetallic state that extends to monovalent crystals. The coupling of adjacent atoms, which results in a lowering of the total energy, affects an even number of valence electrons in the unit cell and could be the unifying idea extending a band structure picture to monovalent systems. Such a coupling is not a particularly one-dimensional effect that can only be attributed to the Peierls distortion, but also occurs in adsorbed films (charge density waves) and in bulk crystals (recall the Jones model for semimetal properties of Bi).

Speaking about the metallicity of atomic wires, we should keep in mind that in reality there must always be present a substrate surface, which unavoidably affects the properties of the overlayers. The interaction with a semiconductor surface can be strong enough even to effect "anchoring" of adsorbed atomic wires, and therefore arguments based on a one-dimensional approach or free monolayer model may be suspect. The success of the application of the free monolayer models in describing atomic wires on furrowed transition surfaces seems to occur because of the nonlocal (metallic) character of adsorption bonding at coverages near a complete monolayer. It should be mentioned here that the classical example of NMT in Hg overlayers has been observed so clearly because of rather weak interaction (as derived from a small heat of adsorption) with a metal surface.

Alkali, alkaline earth, and rare earth atomic wires on furrowed transition metal surfaces, which at low coverages are directed across the furrows, are a consequence of indirect interaction between adsorbed atoms. These wires are robust enough to provide, at room temperature, well-ordered commensurate linear structures observed by LEED. The parameters of the indirect interaction can be evaluated by comparison of experimental results and dependences of LEED intensity derived from Monte Carlo simulations with increasing temperature that causes disordering of the adlayer structures.

As with most "metallic" wires on semiconductor surfaces, the linear alkaline earth chains on the furrowed transition metal surfaces do not exhibit metallicity, but, rather, they may be considered as dielectric atomic chains. Such a behavior results from the interaction with the substrate, which "ties up" the valence electrons in the adsorption bonds. The local character of these bonds is replaced by a metallic

one when the lattice period of the adsorbed layer becomes incoherent with the substrate period along the furrows. In this coverage range, both theory and experiment indicate a Wilson-type NMT in the adsorbed layers.

In summary, recent achievements in the fabrication of atomic wires on semiconductor surfaces, particularly metallic Au wires on stepped Si surfaces, provide a basis for the development of novel materials and thus open new perspectives for nanoelectronics. On the other hand, atomic wires, adsorbed on furrowed transition metal surfaces, still seem to be more attractive for the study of fundamental physical problems such as NMT in overlayers. The author's viewpoint here is that a theory should not break with experiment, and, hence, direct comparison of the obtained theoretical results with experiment—such as has been demonstrated in the band structure approach—is an essential ingredient for progress.

GLOSSARY

Angle-resolved ultraviolet photoelectron spectroscopy (ARUPS) (synonyms: angle-resolved photoemission, valence band spectroscopy). The major technique for mapping surface and bulk electronic band structures.

Indirect interaction Lateral interaction between adsorbed atoms which is accomplished through electrons of the substrate. Potential of this kind of interaction oscillates with distance between adsorbed atoms and therefore may result in effective attraction at rather large spacings.

Inverse photoelectron spectroscopy (IPES) Efficient method for investigation of "empty" electronic states above the Fermi level.

Linear augmented plane waves (LAPW) Linearized modification (1975) of Slater's augmented plane wave method (1937) for band structure calculations. Linearization provides a gain in computation time (about 10^2) and thus allows for self-consistent calculations.

Monte Carlo simulations Effective method for the "computer experiment" which provides, in particular, a clear illustration for ordering of adsorbed atoms.

Scanning tunneling microscope (STM) A recently developed device which allows for viewing the surface with atomic resolution. Because of the possibility of atomic manipulation, it gives the experimentalist precise control of the formation of atomic wires on various substrates.

Scanning tunneling spectroscopy (STS) Electron spectra are obtained by using electronic derivation of the tunneling current in STM.

Self-assembling A popular term which implies that ordering of a system can be gained through its own potential (or Providence). Because of thus introduction of a certain mystification, it is better avoided in scientific publications.

Ultraviolet photoelectron spectroscopy (UPS) (usually, angle-integrated).

Augmented Waves for Nanomaterials

Pavel N. D'yachkov

Russian Academy of Sciences, Moscow, Russia

CONTENTS

1. INTRODUCTION

It is now generally accepted that in-depth knowledge of the electronic structure and properties of nanomaterials is of great scientific and technological importance. We are now being confronted with the acute problem of first-principle calculation of nanomaterial characteristics. For bulk solids, an augmented plane-wave (APW) method was developed by Slater back in 1937 [1–3]. After a time, the computationally faster linear-APW (LAPW) formalism was presented [4–10]. During the past decades, the techniques for APW and LAPW calculations have reached the point at which, with the aid of large computers, a solution of the band structure problem may be obtained for particular crystals, including those with heavy metals [11, 12]. There is good reason to believe that the LAPW method is one of the most accurate computational schemes in bulk solid-state electronic structure theory. These developments have challenged the generalization of the LAPW approach to low-dimensional systems such as nanofilms, nanowires, nanotubes, and clusters.

In this review, we give a brief overview of the linear augmented wave (LAW) methods for the electronic structure of nanomaterials. These methods are based on a generalization of the bulk LAPW approach. In common with the standard and most simple bulk LAPW (3D-LAPW) technique, the one-electron potential is used and is constructed using a muffin-tin (MT) approximation. In the MT approximation, a one-electron potential is spherically symmetric in the atomic region and constant in the interstitial region [13]. The constant potential can be taken as the origin for measurements of energy. However, the electronic potential of the nanomaterials differs drastically from that of the bulk system [14, 15]. In reality, the infinite motion of electrons is possible in any direction in crystals, but it is obviously limited in the case of nanomaterials by their size and shape. For example, in the case of nanofilm, there are two vacuum regions above and below the film. The film and vacuum regions are separated by the essentially impenetrable approximately planar potential barriers that are obviously absent in the case of bulk crystal. The term film-MT potential is taken to mean that the one-electron potential is spherically symmetric in the atomic regions and constant in the interstitial region up to the planar potential barriers. In the case of nanotubes with approximately cylindrical symmetry, the cylindrical-MT potential is constant in the interstitial region up to the cylindrical potential barrier. For an approximately spherical nanocrystal, quantum dot, or cluster, the system to be studied and vacuum regions are separated by the spherical potential barrier (spherical-MT potential), and so on.

There are procedures to account for potential variations between the interstitial and vacuum regions; however, for the sake of simplicity, we suggest here that the interstitial and vacuum regions are separated by the step potential barriers. For the same reason, we do not discuss here the full-potential version of the LAW methods, in which one takes into account the one-electron potential variations in the intresphere regions, as well as a nonspherical part of the potential in the MT regions.

The characteristic feature of the LAW methods is that the basis functions in the interstitial regions (where variations in the potential are relatively smooth) are augmented inside the MT spheres by the functions constructed from the exact solutions in these spheres (where variations in the potential are large and the potential is approximately equal to the atomic one). The basis functions in the interstitial regions are different in various materials due to a variety of boundary conditions. These functions are the plane waves in the case of bulk crystals, the cylindrical waves in the case of nanotubes, the spherical waves in the case of

spherical nanocrystals and quantum dots, and so on. In line with the type of basis functions in the interstitial regions, one obtains the 3D-LAPW method for crystals, the linear augmented cylindrical-wave (LACW) method for nanotubes, the linear augmented spherical-wave (LASW) method for spherical systems, and so forth.

2. ONE-ELECTRON ORBITALS AND SECULAR EQUATIONS

In the LAW methods, the concept of one-electron orbitals is used [2, 3, 16–18]. It is assumed that separate electrons in a polyatomic system are characterized by wave functions of their own, or spin orbitals. Each spin orbital ψ_i represents a function of spatial coordinates of the electron and its spin. It is assumed in the simplest approach that spin orbitals can be written as products of spatial and spin functions $\psi_i(\mathbf{r})\alpha$ and $\psi_i(\mathbf{r})\beta$, where α and β are the spin functions of electrons with spins "up" and "down," respectively. The spatial function $\psi_i(\mathbf{r})$ is called an orbital. A study of the electronic structure of a multiatomic system therefore reduces to a study of its orbitals. These orbitals are functions defined in three-dimensional space and are therefore easy to visualize. The $\psi_i(\mathbf{r})$, together with the corresponding one-electron energies E_i, are found by solving the one-electron Schrödinger equation

$$\widehat{H}\psi_i(\mathbf{r}) = E_i\psi_i(\mathbf{r}) \tag{1}$$

with effective one-electron Hamiltonian (in atomic rydberg units)

$$\widehat{H} = -\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) + U \equiv -\Delta + U \tag{2}$$

This Hamiltonian contains the electron kinetic energy operator, $-\Delta$, and the operator U describing the summed action on the electron in consideration of all the other electrons in the system and all its nuclei α. Finding U is a nontrivial task, which is solved by different quantum chemical methods. For instance, in the Hartree–Fock approximation, U is a nonlocal operator [16]. In the LAW methods, the local density approximation $U = U(\mathbf{r})$ is commonly used [19–21]:

$$U(\mathbf{r}) = -2\sum_\alpha \frac{Z_\alpha}{|\mathbf{r} - \mathbf{R}_\alpha|} + 2\int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}\,dr' + V_{X\alpha}(\mathbf{r}) \tag{3}$$

where Z_α and $\mathbf{R}_\alpha$ are the nuclear charge and coordinate and $\rho(\mathbf{r})$ is the electron density. The first term in (3) describes attraction between the electrons and nuclei, the second one corresponds to the mutual repulsion of electrons, and $V_{X\alpha}(\mathbf{r})$ is the exchange correlation potential. A frequently used equation for $V_{X\alpha}(\mathbf{r})$ is [2, 3]:

$$V_{X\alpha}(\mathbf{r}) = -6\alpha\left(\frac{3}{8\pi}\rho(\mathbf{r})\right)^{1/3} \qquad \alpha = 2/3 \tag{4}$$

In the MT approximation in (3), Z_α is substituted for the MT-sphere effective charge and the integral over all space is exchanged for the integral over the intersphere region.

In all LAW methods, the basis functions $\varphi_n(\mathbf{r})$ are everywhere continuous and differentiable, and the Rayleigh–Ritz variational principle is then easily applied. Expanding the electronic wave functions

$$\psi_i(\mathbf{r}) = \sum_n c_{i,n}\varphi_n(\mathbf{r}) \tag{5}$$

and applying the variational principle then yield the secular equations:

$$\det\|\langle\varphi_n|\widehat{H}|\varphi_m\rangle - E\langle\varphi_n|\varphi_m\rangle\| = 0 \tag{6}$$

$$\sum_n[\langle\varphi_n|\widehat{H}|\varphi_m\rangle - E_i\langle\varphi_n|\varphi_m\rangle]c_{i,n} = 0 \tag{7}$$

where $\langle\varphi_n|\widehat{H}|\varphi_m\rangle$ and $\langle\varphi_n|\varphi_m\rangle$ are the Hamiltonian $\widehat{H}$ and overlap matrix elements, respectively. The most important feature of the LAW secular equations (6) and (7) is that the Hamiltonian and overlap matrices are energy independent, which permits the simultaneous determination of the eigenvalues E_i and eigenvectors $c_{i,n}$.

3. IDENTITIES FOR THE RADIAL WAVE FUNCTION INSIDE THE MUFFIN-TIN SPHERES

Let us consider a single MT sphere and derive some formulas common to all LAW methods [4, 5]. Inside the MT sphere α, the Hamiltonian $\widehat{H}$ is spherically symmetric. The radial wave function $u_{l,\alpha}(E_{l,\alpha}, r)$ is taken to be the solution of the radial Schrödinger equation with energy $E_{l,\alpha}$:

$$\widehat{H}u_{l,\alpha}(r) = E_{l,\alpha}u_{l,\alpha}(r) \tag{8}$$

In the LAW formalism, $E_{l\alpha}$ is kept fixed within some energy region. In rydberg units, this equation takes the form:

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}(ru_{l,\alpha}) + \left[E_{l,\alpha} - V_\alpha(r) - \frac{l(l+1)}{r^2}\right]u_{l,\alpha} = 0 \tag{9}$$

where $V_\alpha(r)$ is the local density spherically symmetric potential in the region of the MT sphere α and $E_{l,\alpha}$ are the constant-energy parameters. The functions $u_{l,\alpha}(E_{l,\alpha}, r)$ are normalized inside the MT spheres with radius r_α as

$$\int_0^{r_\alpha} u_{l,\alpha}^2 r^2\,dr = 1 \tag{10}$$

$$\int_0^{r_\alpha} u_{l,\alpha}\widehat{H}u_{l,\alpha}r^2\,dr = E_{l,\alpha} \tag{11}$$

Differentiating (8) and (9) with respect to energy yields a differential equation for the radial energy derivative functions $\dot{u}_{l,\alpha}(E_{l,\alpha}, r) = \partial u_{l,\alpha}(E_{l,\alpha}, r)/\partial E_{l,\alpha}$:

$$\widehat{H}\dot{u}_{l,\alpha}(r) = u_{l,\alpha}(r) + E_{l,\alpha}\dot{u}_{l,\alpha}(r) \tag{12}$$

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}(r\dot{u}_{l,\alpha}) + u_{l,\alpha} + \left[E_l - V_\alpha(r) - \frac{l(l+1)}{r^2}\right]\dot{u}_{l,\alpha} = 0 \tag{13}$$

The functions $u_{l,\alpha}(E_l, r)$ and $\dot{u}_{l,\alpha}(E_l, r)$ will be orthogonal as can be seen by differentiating (10) with respect to energy

$$\int_0^{r_\alpha} u_{l,\alpha}\dot{u}_{l,\alpha}r^2\,dr = 0 \tag{14}$$

and

$$\int_0^{r_\alpha} \dot{u}_{l,\alpha} \widehat{H} u_{l,\alpha} r^2 \, dr = 0 \qquad \int_0^{r_\alpha} u_{l,\alpha} \widehat{H} \dot{u}_{l,\alpha} r^2 \, dr = 1$$

$$\int_0^{r_\alpha} \dot{u}_{l,\alpha} \widehat{H} \dot{u}_{l,\alpha} r^2 \, dr = E_{l,\alpha} N_{l,\alpha} \tag{15}$$

where

$$N_{l,\alpha} = \int_0^{r_\alpha} (\dot{u}_{l,\alpha})^2 r^2 \, dr \tag{16}$$

Multiplying (9) by $r^2 \dot{u}_{l,\alpha}$ and (13) by $r^2 u_{l,\alpha}$, subtracting (13) from (9), and integrating $\int_0^{r_\alpha} dr$ then yield the identity:

$$\int_0^{r_\alpha} r \left(\dot{u}_{l,\alpha} \frac{\partial^2}{\partial r^2} (r u_{l,\alpha}) - u_{l,\alpha} \frac{\partial^2}{\partial r^2} (r \dot{u}_{l,\alpha}) \right) dr = 1 \tag{17}$$

Moreover, we have

$$\int r \left(\dot{u}_{l,\alpha} \frac{\partial^2}{\partial r^2} (r u_{l,\alpha}) - u_{l,\alpha} \frac{\partial^2}{\partial r^2} (r \dot{u}_{l,\alpha}) \right) dr$$

$$= r^2 \left(\dot{u}_{l,\alpha} \frac{\partial}{\partial r} u_{l,\alpha} - u_{l,\alpha} \frac{\partial}{\partial r} \dot{u}_{l,\alpha} \right) \tag{18}$$

Finally, from (17) and (18), we obtain

$$r^2 \left[\dot{u}_{l,\alpha}(r) u'_{l,\alpha}(r) - u_{l,\alpha}(r) \dot{u}'_{l,\alpha}(r) \right]\big|_{r=r_\alpha} = 1 \tag{19}$$

where $u'_{l,\alpha} = \partial u_{l,\alpha}/\partial r$ and $\dot{u}'_{l,\alpha} = \partial \dot{u}_{l,\alpha}/\partial r$ are radial derivatives of the $u_{l,\alpha}$ and $\dot{u}_{l,\alpha}$ functions.

4. LINEAR AUGMENTED PLANE-WAVE METHOD

4.1. Bulk LAPW Method

It is instructive to start with the 3D-LAPW method for a bulk crystal [4, 5].

4.1.1. Forming the Bulk Basis Functions

In the interstitial region (Ω_{II}), the one-electron potential is constant, and the basis functions $\varphi_n(\mathbf{r})$ (5) are the plane waves

$$\varphi_{II,n}(\mathbf{k}, \mathbf{r}) = (1/\Omega)^{1/2} \exp(i\mathbf{K}_n \mathbf{r}) \tag{20}$$

which are the solutions of the Schrödinger equation with Hamiltonian $\widehat{H} = -\Delta$. Here, Ω is the volume of the unit cell, $\mathbf{K}_n = \mathbf{k} + \mathbf{k}_n$, $\mathbf{k}$ is the reduced wave vector, and $\mathbf{k}_n$ is the reciprocal lattice vector.

Inside the muffin-tin spheres (Ω_I), the basis function $\varphi_n(\mathbf{r})$ is a linear combination of spherical solutions. In the local spherical coordinate system $\rho = \{\rho, \theta, \varphi\}$, it takes the form

$$\varphi_{I\alpha,n}(\rho, \theta, \varphi) = \sum_{lm} [A^n_{lm,\alpha} u_{l,\alpha}(E_{l\alpha}, \rho)$$

$$+ B^n_{lm,\alpha} \dot{u}_{l,\alpha}(E_{l\alpha}, \rho)] Y_{lm}(\hat{\rho}) \tag{21}$$

where $\sum_{lm} \equiv \sum_{l=0}^{\infty}, \sum_{m=-l}^{l}$ and $Y_{lm}(\hat{\rho}) \equiv Y_{lm}(\theta, \varphi)$. The plane wave (20) can be written in terms of the local coordinate system $\{\rho, \theta, \varphi\}$:

$$\varphi_{II,n}(\rho, \theta, \varphi) = (1/\Omega)^{1/2} \exp(i\mathbf{K}_n \mathbf{R}_a) \exp(i\mathbf{K}_n \rho) \tag{22}$$

Here, $\mathbf{R}_\alpha = (X_\alpha, Y_\alpha, Z_\alpha)$ is the position vector of the αth atom in the unit cell and $\mathbf{r} = \mathbf{R}_a + \rho$. The joining condition across the muffin-tin-sphere boundary results from expanding the plane wave in terms of spherical harmonics [16]:

$$\exp(i\mathbf{K}_n \rho) = 4\pi \sum_{lm} i^l j_l(|\mathbf{K}_n|\rho) Y^*_{lm}(\widehat{K}_n) Y_{lm}(\hat{\rho}) \tag{23}$$

and requiring that each angular momentum term be continuous with continuous derivative. This gives the coefficients $A^n_{lm,\alpha}$ and $B^n_{lm,\alpha}$:

$$A^n_{lm,\alpha} = 4\pi r_\alpha^2 \Omega^{-1/2} i^l \exp(i\mathbf{K}_n \mathbf{R}_a) Y^*_L(\widehat{K}_n) a_{l,\alpha}(n) \tag{24}$$

$$B^n_{lm,\alpha} = 4\pi r_\alpha^2 \Omega^{-1/2} i^l \exp(i\mathbf{K}_n \mathbf{R}_a) Y^*_L(\widehat{K}_n) b_{l,\alpha}(n) \tag{25}$$

Here, j_l is a spherical Bessel function of order l, $\widehat{K}_n = \mathbf{K}_n/|\mathbf{K}_n|$ and $\hat{\rho} = \rho/|\rho|$ are unit vectors, and

$$a_{l,\alpha}(n) = j'_l(K_n r_\alpha) \dot{u}_{l,\alpha}(r_\alpha) - j_l(K_n r_\alpha) \dot{u}'_{l,\alpha}(r_\alpha) \tag{26}$$

$$b_{l,\alpha}(n) = j_l(K_n r_\alpha) u'_{l,\alpha}(r_\alpha) - j'_l(K_n r_\alpha) u_{l,\alpha}(r_\alpha) \tag{27}$$

where we used (19).

4.1.2. Bulk LAPW Hamiltonian and Overlap Matrices

The basis functions (20)–(27) satisfy the cellular boundary conditions and connectivity across the muffin-tin spheres. We can now apply this basis set to form a trial function (5) and calculate matrix elements in the secular equations (6) and (7). The overlap matrix is given by

$$\langle \varphi_m | \varphi_n \rangle = U_{m,n} + \frac{4\pi}{\Omega} \sum_\alpha r_\alpha^4 \exp[i(\mathbf{k}_m - \mathbf{k}_n)\mathbf{R}_\alpha]$$

$$\times \sum_{l=0}^{\infty} (2l+1) P_l(\widehat{K}_m \widehat{K}_n) S^{m,n}_{l,\alpha} \tag{28}$$

where

$$U_{m,n} = \delta_{m,n} - \frac{4\pi}{\Omega} \sum_\alpha r_\alpha^2 \frac{j_1(|\mathbf{k}_m - \mathbf{k}_n|r_\alpha)}{|\mathbf{k}_m - \mathbf{k}_n|}$$

$$\times \exp[i(\mathbf{k}_m - \mathbf{k}_n)\mathbf{R}_\alpha] \tag{29}$$

$$S^{m,n}_{l,\alpha} = a_{l,\alpha}(m) a_{l,\alpha}(n) + N_{l,\alpha} b_{l,\alpha}(m) b_{l,\alpha}(n) \tag{30}$$

In (28), the $U_{m,n}$ is the contribution from the interstitial region, and the second term is the contribution from all the MT spheres. To calculate the overlap integral (28) and (29), we take into account that

$$\int_{\Omega_\alpha} \exp[i(\mathbf{k}_m - \mathbf{k}_n)\rho] \, d\rho = 4\pi r_\alpha^2 \frac{j_1(|\mathbf{k}_m - \mathbf{k}_n|r_\alpha)}{|\mathbf{k}_m - \mathbf{k}_n|} \tag{31}$$

A spherical harmonic sum rule

$$\sum_{m=-l}^{l} Y_{lm}(\widehat{K}_m)Y_{lm}^*(\widehat{K}_n) = \frac{(2l+1)}{4\pi}P_l(\widehat{K}_m\widehat{K}_n) \quad (32)$$

has been used to obtain the Legendre polynomials $P_l(\widehat{K}_m\widehat{K}_n)$, where $\widehat{K}_m\widehat{K}_n$ is a scalar product of the unit vectors $\widehat{K}_m$ and $\widehat{K}_n$.

Similarly,

$$\langle\varphi_m|\widehat{H}|\varphi_n\rangle = \mathbf{K}_n\mathbf{K}_m U_{m,n} + \frac{4\pi}{\Omega}\sum_\alpha r_\alpha^4 \exp\big[i(\mathbf{k}_m-\mathbf{k}_n)\mathbf{R}_\alpha\big]$$

$$\times \sum_{l=0}^{\infty}(2l+1)P_l(\widehat{K}_m\widehat{K}_n)(E_{l,\alpha}S_{l,\alpha}^{m,n}+\gamma_{l,\alpha}^{m,n}) \quad (33)$$

where

$$\gamma_{l,\alpha}^{m,n} = \big\{\dot{u}_{l,\alpha}(r)u'_{l,\alpha}(r)\big[j'_l(K_m r)j_l(K_n r)+j_l(K_m r)j'_l(K_n r)\big]\big\}_{r=r_\alpha}$$

$$-\big[\dot{u}'_{l,\alpha}(r)u'_{l,\alpha}(r)j_l(K_m r)j_l(K_n r)$$

$$+\dot{u}_{l,\alpha}(r)u_{l,\alpha}(r)j'_l(K_m r)j'_l(K_n r)\big]_{r=r_\alpha} \quad (34)$$

4.2. Film LAPW Method

A thin film with one or several monoatomic layers is a two-dimensional nanomaterial. The film LAPW (2D-LAPW) method was developed in [7, 22–25] and applied to systems such as transition metal layers. The film is periodic in the x–y plane. The potential is spherically symmetric inside the MT spheres Ω_I and it is constant in the interstitial region Ω_{II}. For the sake of simplicity, we suggest that the interstitial and vacuum regions be separated by the two impenetrable planar step potential barriers Ω_{III} so that the wave function is equal to 0 on the boundaries at $z = \pm\frac{1}{2}d$. A distance d is to be chosen in such a way that an essential part of the electronic density of a system is located between the potential walls.

4.2.1. Forming the Film Basis Functions

In analogy with the bulk LAPW method, in the interstitial region the basis function is the product of a two-dimensional plane wave in the x–y plane and a one-dimensional symmetrized plane (standing) wave in the z direction:

$$\varphi_{nm}^\pm(\mathbf{k},\mathbf{r}) = (2/\Omega)^{1/2}\exp\big[i(\mathbf{k}+\mathbf{k}_m)\mathbf{r}\big] \times \begin{cases} \cos(k_n z); & (+) \\ \sin(k_n z); & (-) \end{cases}$$

$$(35)$$

Here, $(+)$ and $(-)$ denote states, which are, respectively, symmetric and antisymmetric with respect to the z reflection; $\mathbf{k}$ is a two-dimensional crystal momentum vector, $\mathbf{k}_m$ is a two-dimensional reciprocal lattice vector, Ω equals the volume of the unit cell between $z = \pm\frac{1}{2}d$, and k_n is defined as

$$k_n = \begin{cases} (n+1/2)2\pi/d; & (+) \\ n2\pi/d; & (-) \end{cases} \quad n = 0, 1, 2, \ldots \quad (36)$$

thus forcing a node at $z = \pm\frac{1}{2}d$ for both $(+)$ and $(-)$ states.

Inside the αth MT sphere in the unit cell, the basis function is expanded in spherical harmonics times a radial function and its energy derivative

$$\varphi_{I\alpha,nm}^\pm(\rho,\theta,\varphi) = \sum_{lm}\big[A_{lm,\alpha}^\pm u_{l,\alpha}(E_l,\rho)+B_{lm,\alpha}^\pm\dot{u}_{l,\alpha}(E_l,\rho)\big]$$

$$\times Y_{lm}(\theta,\varphi) \times \begin{cases} i^l; & (+) \\ i^{l-1}; & (-) \end{cases} \quad (37)$$

Here, as distinct from the analogous equation (21) in the 3D-LAPW method, the phase coefficients i^l and i^{l-1} for states $(+)$ and $(-)$ are added to simplify the equations. Using (23), the $A_{lm,\alpha}^\pm$ and $B_{lm,\alpha}^\pm$ coefficients are determined by matching (37) onto the symmetrized plane-wave basis function equation (35) so that the basis function and its derivative are continuous across the MT-sphere boundary:

$$A_{lm,\alpha}^\pm(nm) = 4\pi r_\alpha^2\Omega^{-1/2}e^{i\mathbf{K}_m\cdot\mathbf{R}_\alpha}a_{l,\alpha}(nm)Y_{L,\alpha}^\pm(nm) \quad (38)$$

$$B_{lm,\alpha}^\pm(nm) = 4\pi r_\alpha^2\Omega^{-1/2}e^{i\mathbf{K}_m\cdot\mathbf{R}_\alpha}b_{l,\alpha}(nm)Y_{L,\alpha}^\pm(nm) \quad (39)$$

where

$$Y_{lm,\alpha}^\pm(nm) = 2^{-1/2}\big[\exp(ik_n Z_\alpha)Y_{lm}(\mathbf{K}_m+\mathbf{k}_n)$$

$$\pm\exp(-ik_n Z_\alpha)Y_{lm}(\mathbf{K}_m-\mathbf{k}_n)\big] \quad (40)$$

and

$$a_{l,\alpha}(nm) = j'_l(G_{nm}r_\alpha)\dot{u}_{l,\alpha}(r_\alpha)-j_l(G_{nm}r_\alpha)\dot{u}'_{l,\alpha}(r_\alpha) \quad (41)$$

$$b_{l,\alpha}(nm) = j_l(G_{nm}r_\alpha)u'_{l,\alpha}(r_\alpha)-j'_l(G_{nm}r_\alpha)u_{l,\alpha}(r_\alpha) \quad (42)$$

Here, $\mathbf{K}_m = \mathbf{k}+\mathbf{k}_m$, $\mathbf{k}_n = k_n\hat{z}$, and $G_{nm} = |\mathbf{K}_m+\mathbf{k}_n| = |\mathbf{K}_m-\mathbf{k}_n|$.

4.2.2. Film LAPW Hamiltonian and Overlap Matrices

The overlap matrix in the basis (35)–(37) is the sum of the contributions from the interstitial region and from all the MT spheres:

$$\langle\varphi_{n'm'}^\pm|\varphi_{nm}^\pm\rangle = U_{n'm',nm}^\pm + \frac{4\pi}{\Omega}\sum_\alpha r_\alpha^4\exp\big[-i(\mathbf{k}_m-\mathbf{k}_{m'})\mathbf{R}_\alpha\big]$$

$$\times\sum_{l=0}^{\infty}(2l+1)S_{l,\alpha}^{n'm',nm}P_{l,\alpha}^\pm \quad (43)$$

$$U_{n'm',nm}^\pm = \delta_{n'm',nm}\epsilon_n^\pm - \frac{4\pi}{\Omega}\sum_\alpha r_\alpha^2\exp\big[-i(\mathbf{k}_m-\mathbf{k}_{m'})\mathbf{R}_\alpha\big]$$

$$\times\big\{\cos\big[(k_n-k_{n'})Z_\alpha\big]J_\alpha\big(G_{n'm'}^+,G_{nm}^+\big)$$

$$\pm\cos\big[(k_n+k_{n'})Z_\alpha\big]J_\alpha\big(G_{n'm'}^+,G_{nm}^-\big)\big\} \quad (44)$$

The quantities in (43) are defined as follows:

$$S_{l,\alpha}^{n'm',nm} = a_{l,\alpha}(n'm')a_{l,\alpha}(nm)+N_{l,\alpha}b_{l,\alpha}(n'm')b_{l,\alpha}(nm) \quad (45)$$

$$P_{l,\alpha}^\pm = \big\{\cos\big[(k_n-k_{n'})Z_\alpha\big]P_l(\widehat{G}_{n'm'}^+\widehat{G}_{nm}^+)$$

$$\pm\cos\big[(k_n+k_{n'})Z_\alpha\big]P_l(\widehat{G}_{n'm'}^+\widehat{G}_{nm}^-)\big\} \quad (46)$$

with $J_\alpha(\mathbf{x},\mathbf{y}) = j_1(|\mathbf{x}-\mathbf{y}|r_\alpha)/|\mathbf{x}-\mathbf{y}|$, $\epsilon_n^- = 1$, $\epsilon_n^+ = (1+\delta_{n,0})$, and $\mathbf{G}_{nm}^\pm = \mathbf{K}_m \pm k_n\hat{z}$.

The Hamiltonian matrix is given as the sum of two terms

$$\langle\varphi^{\pm}_{n'm'}|\widehat{H}|\varphi^{\pm}_{nm}\rangle = G^2_{n'm'}U^{\pm}_{n'm',nm} + \frac{4\pi}{\Omega}\sum_{\alpha}r^4_{\alpha}\exp[-i(\mathbf{k}_m-\mathbf{k}_{m'})\mathbf{R}_{\alpha}]$$

$$\times\sum_{l=0}^{\infty}(2l+1)(E_{l,\alpha}S^{n'm',nm}_{l,\alpha}+\gamma^{n'm',nm}_{l,\alpha})P^{\pm}_{l,\alpha} \quad (47)$$

where

$$\gamma^{n'm',nm}_{l,\alpha} = \dot{u}_{l,\alpha}(r)u'_{l,\alpha}(r)\big[j'_l(G_{n'm'}r)j_l(G_{nm}r)$$

$$+ j_l(G_{n'm'}r)j'_l(G_{nm}r)\big]\big|_{r=r_{\alpha}}$$

$$- \big[\dot{u}'_{l,\alpha}(r)u'_{l,\alpha}(r)j_l(G_{n'm'}r)j_l(G_{nm}r)$$

$$+ \dot{u}_{l,\alpha}(r)u_{l,\alpha}(r)j'_l(G_{n'm'}r)j'_l(G_{nm}r)\big]_{r=r_{\alpha}} \quad (48)$$

4.3. Bar LAPW Method

The LAPW formalism for one-dimensional systems of a nanosize cross section having a translation symmetry in one direction (bar LAPW method or 1D-LAPW) is developed in [26–28] and applied to a series of nanomaterials, including conjugated carbon polymers and carbon nanotubes intercalated with transition metals [29, 30]. This approach is a further extension of the bulk and film LAPW theory to nanowires with specific geometry.

As infinite motion of electrons is only possible in one direction (along the z axis) and it is limited to perpendicular directions, we suggest that the system be confined between four plane impenetrable barriers, so that the wave function is equal to 0 on this boundary. An essential part of the electronic density of a system is located in the infinite bar with an $a \times b$ cross section.

4.3.1. Forming the Bar Basis Functions

In the interstitial region, the basis functions are the solutions of a wave equation for motion of a free electron in the potential bar with dimension $a \times b \times \infty$. Here, the basis function $\varphi_{m^{\pm}n^{\pm}p}(k, \mathbf{r})$ is a product $\psi^{\pm}_m(x)\psi^{\pm}_n(y)\psi_p(z,k)$. For the z direction, we have

$$\psi_p(z,k) = c^{-1/2}\exp(iK_pz)$$
$$K_p = k+k_p, k_p = p(2\pi/c), \ p=0,\pm1,\pm2,\dots \quad (49)$$

where c is a lattice constant for the z direction, k is a one-dimensional crystal momentum, $-\pi/c \le k \le \pi/c$. For the directions x and y, the solutions take a form of standing waves

$$\psi^{\pm}_m(x) = (2/a)^{1/2}$$

$$\times \begin{cases} \cos(k_mx); & (+), \\ \quad m=1,3,5,\dots \\ \sin(k_mx); & (-), \\ \quad m=2,4,6,\dots \end{cases} \quad k_m=(\pi/a)m \quad (50)$$

$$\psi^{\pm}_n(y) = (2/b)^{1/2}$$

$$\times \begin{cases} \cos(k_ny); & (+), \\ \quad n=1,3,5,\dots \\ \sin(k_ny) & (-), \\ \quad n=2,4,6,\dots \end{cases} \quad k_n=(\pi/b)n \quad (51)$$

Inside the αth MT sphere, the basis function is written as

$$\varphi^{\pm,\pm}_{I\alpha,mnp} = \sum_{lm}\big[A^{m^{\pm}n^{\pm}p}_{lm,\alpha}u_{l,\alpha}(E_l,\rho)+B^{m^{\pm}n^{\pm}p}_{lm,\alpha}\dot{u}_{l,\alpha}(E_l,\rho)\big]Y_{lm}(\hat{\rho})i^f$$

$$(52)$$

Here, $f = l$ for $(+, +)$, i^{l-1} for $(+, -)$ and $(-, +)$, and i^{l-2} for $(-, -)$. The coefficients $A^{m^{\pm}n^{\pm}p}_{lm,\alpha}$ and $B^{m^{\pm}n^{\pm}p}_{lm,\alpha}$ are readily calculated from the expansion of the waves (49)–(51) in terms of Y_{lm} (22):

$$A^{m^{\pm}n^{\pm}p}_{lm,\alpha} = 4\pi r^2_{\alpha}\Omega^{-1/2}e^{iK_pZ_{\alpha}}a_{l,\alpha}(m,n,p)Y^{m^{\pm}n^{\pm}p}_{lm,\alpha} \quad (53)$$

$$B^{m^{\pm}n^{\pm}p}_{lm,\alpha} = 4\pi r^2_{\alpha}\Omega^{-1/2}e^{iK_pZ_{\alpha}}b_{l,\alpha}(m,n,p)Y^{m^{\pm}n^{\pm}p}_{lm,\alpha} \quad (54)$$

Here,

$$Y^{m^{\pm}n^{\pm}p}_{lm,\alpha} = (1/2)\big\{\exp[i(\mathbf{k}_m+\mathbf{k}_n)\mathbf{R}_{\alpha}]Y^*_{lm}(\mathbf{k}_m+\mathbf{k}_n+\mathbf{K}_p)$$

$$+\delta_1\exp[i(\mathbf{k}_m-\mathbf{k}_n)\mathbf{R}_{\alpha}]Y^*_{lm}(\mathbf{k}_m-\mathbf{k}_n+\mathbf{K}_p)$$

$$+\delta_2\exp[i(-\mathbf{k}_m+\mathbf{k}_n)\mathbf{R}_{\alpha}]Y^*_{lm}(-\mathbf{k}_m+\mathbf{k}_n+\mathbf{K}_p)$$

$$+\delta_3\exp[i(-\mathbf{k}_m-\mathbf{k}_n)\mathbf{R}_{\alpha}]Y^*_{lm}(-\mathbf{k}_m-\mathbf{k}_n+\mathbf{K}_p)\big\} \quad (55)$$

where $\delta_1 = \delta_2 = \delta_3 = 1$ for $Y^{m^+n^+p}_{lm,\alpha}$, $\delta_1 = \delta_3 = -1$ and $\delta_2 = 1$ for $Y^{m^+n^-p}_{lm,\alpha}$, $\delta_2 = \delta_3 = -1$ and $\delta_1 = 1$ for $Y^{m^-n^+p}_{L,\alpha}$, $\delta_1 = \delta_2 = -1$ and $\delta_3 = 1$ for $Y^{m^-,n^-,p}_{lm,\alpha}$. Finally,

$$a_{l,\alpha}(mnp) = j'_l(G_{mnp}r_{\alpha})\dot{u}_{l,\alpha}(r_{\alpha}) - j_l(G_{mnp}r_{\alpha})\dot{u}'_{l,\alpha}(r_{\alpha}) \quad (56)$$

$$b_{l,\alpha}(mnp) = j_l(G_{mnp}r_{\alpha})u'_{l,\alpha}(r_{\alpha}) - j'_l(G_{mnp}r_{\alpha})u_{l,\alpha}(r_{\alpha}) \quad (57)$$

where $G_{mnp} = |\mathbf{K}_p \pm \mathbf{k}_m \pm \mathbf{k}_n|$.

4.3.2. Bar LAPW Hamiltonian and Overlap Matrices

Using the basis (49)–(57), we obtain the overlap matrix:

$$\langle\varphi^{\pm,\pm}_{m'n'p'}|\varphi^{\pm,\pm}_{mnp}\rangle = U^{\pm\pm,\pm\pm}_{m'n'p',mnp} + \frac{4\pi}{\Omega}\sum_{\alpha}r^4_{\alpha}\exp[-i(k_p-k_{p'})Z_{\alpha}]$$

$$\times\sum_{l=0}^{\infty}(2l+1)S^{m'n'p',mnp}_{l,\alpha}$$

$$\times\sum_{i=1}^{4}x^{m^{\pm'}n^{\pm'},m^{\pm}n^{\pm}}_{i\alpha}P^{m'n'p',mnp}_{i,l} \quad (58)$$

where

$$U^{\pm\pm,\pm\pm}_{m'n'p',mnp} = \delta_{m^{\pm'}n^{\pm'}p',m^{\pm}n^{\pm}p} - \frac{4\pi}{\Omega}\sum_{\alpha}r^2_{\alpha}\exp[-i(k_p-k_{p'})Z_{\alpha}]$$

$$\times\sum_{i=1}^{4}x^{m^{\pm'}n^{\pm'},m^{\pm}n^{\pm}}_{i\alpha}J_{\alpha}\big(G^{m'n'mn,p-p'}_i\big) \quad (59)$$

The $x_{i\alpha}^{m^{\pm'}n^{\pm'},\,m^{\pm}n^{\pm}}$ coefficients are presented in Table 1, where $A_1 = X_\alpha(k_m + k_{m'})$, $B_1 = Y_\alpha(k_n + k_{n'})$, $A_2 = X_\alpha(k_m - k_{m'})$, $B_2 = Y_\alpha(k_n + k_{n'})$, $A_3 = X_\alpha(k_m + k_{m'})$, $B_3 = Y_\alpha(k_n - k_{n'})$, $A_4 = X_\alpha(k_m - k_{m'})$, and $B_4 = Y_\alpha(k_n - k_{n'})$.

In (59), $J_\alpha(G_i) = j_1(|\mathbf{G}_i|r_\alpha)/|\mathbf{G}_i|$, where

$$\mathbf{G}_1^{m'n'mn,\,p-p'} = \mathbf{k}_m + \mathbf{k}_{m'} + \mathbf{k}_n + \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'}$$

$$\mathbf{G}_2^{m'n'mn,\,p-p'} = \mathbf{k}_m - \mathbf{k}_{m'} + \mathbf{k}_n + \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'}$$

$$\mathbf{G}_3^{m'n'mn,\,p-p'} = \mathbf{k}_m + \mathbf{k}_{m'} + \mathbf{k}_n - \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'} \qquad (60)$$

$$\mathbf{G}_4^{m'n'mn,\,p-p'} = \mathbf{k}_m - \mathbf{k}_{m'} + \mathbf{k}_n - \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'}$$

Finally,

$$S_{l,\alpha}^{m'n'p',\,mnp} = a_{l,\alpha}(m'n'p')a_{l,\alpha}(mnp)$$
$$+ N_{l,\alpha}b_{l,\alpha}(m'n'p')b_{l,\alpha}(mnp) \qquad (61)$$

$$P_{i,l}^{m'n'p',\,mnp} = P_l\big(K_i^{m'n'p',\,mnp}/G_{n'm'p'}G_{nmp}\big) \qquad (62)$$

$$K_1^{m'n'p',\,mnp} = -k_mk_{m'} - k_nk_{n'} + K_pK_{p'}$$

$$K_2^{m'n'p',\,mnp} = k_mk_{m'} - k_nk_{n'} + K_pK_{p'}$$

$$K_3^{m'n'p',\,mnp} = -k_mk_{m'} + k_nk_{n'} + K_pK_{p'} \qquad (63)$$

$$K_4^{m'n'p',\,mnp} = k_mk_{m'} + k_nk_{n'} + K_pK_{p'}$$

The Hamiltonian matrix elements have the form:

$$\langle \varphi_{m'n'p'}^{\pm,\pm} | \widehat{H} | \varphi_{mnp}^{\pm,\pm} \rangle$$

$$= (k_m^2 + k_n^2 + K_p^2)\delta_{m^{\pm'}n^{\pm'}p',\,m^{\pm}n^{\pm}p}$$

$$- \frac{4\pi}{\Omega}\sum_\alpha r_\alpha^2 \exp[-i(k_p - k_{p'})Z_\alpha]$$

$$\times \sum_{i=1}^{4} x_{i\alpha}^{m^{\pm'}n^{\pm'},\,m^{\pm}n^{\pm}} J_\alpha\big(G_i^{m'n'mn,\,p-p'}\big)K_i^{m'n'p',\,mnp}$$

$$+ \frac{4\pi}{\Omega}\sum_\alpha r_\alpha^4 \exp[-i(k_p - k_{p'})Z_\alpha]$$

$$\times \sum_{l=0}^{\infty}(2l+1)\big[S_{l,\alpha}^{m'n'p',\,mnp}E_{la} + \gamma_{l,\alpha}^{m'n'p',\,mnp}\big]$$

$$\times \sum_{i=1}^{4} x_{i\alpha}^{m^{\pm'}n^{\pm'},\,m^{\pm}n^{\pm}} P_{i,l}^{m'n'p',\,mnp} \qquad (64)$$

where

$$\gamma_{l,\alpha}^{m'n'p',\,mnp} = \dot{u}_{l,\alpha}u'_{l,\alpha}[j'_l(G_{m'n'p'}r)j_l(G_{mnp}r)$$
$$+ j_l(G_{m'n'p'}r)j'_l(G_{mnp}r)]|_{r=r_\alpha}$$
$$- [\dot{u}'_{l,\alpha}u'_{l,\alpha}j_l(G_{m'n'p'}r)j_l(G_{mnp}r)$$
$$+ \dot{u}_{l,\alpha}u_{l,\alpha}j'_l(G_{m'n'p'}r)j'_l(G_{mnp}r)]_{r=r_\alpha} \qquad (65)$$

4.4. Cluster LAPW Method

The cluster LAPW method (0D-LAPW or linear augmented standing-wave method, LAStW) is a final extension of the LAPW theory to low-dimensional systems. Consider an important case of a tetragonal nanocrystal or cluster and assume that the multiatomic system is confined in an impenetrable potential box with dimension $\Omega = a \times b \times c$ so that an essential part of the electronic density is located in the box and the cluster wave function is equal to 0 on the boundary.

4.4.1. Forming the Cubic Cluster Basis Functions

In the interstitial region, the basis function $\varphi_{m^{\pm}n^{\pm}p^{\pm}}(k,\mathbf{r})$ is a product $\psi_m^{\pm}(x)\psi_n^{\pm}(y)\psi_p^{\pm}(z)$ of three standing waves

$$\psi_m^{\pm}(x) = (2/a)^{1/2}$$

$$\times \begin{cases} \cos(k_m x); & (+), \\ \quad m = 1,3,5,\dots \\ \sin(k_m x); & (-), \\ \quad m = 2,4,6,\dots \end{cases} \quad k_m = (\pi/a)m \quad (66)$$

Table 1. The coefficients $x_{i\alpha}^{m^{\pm'}n^{\pm'},\,m^{\pm}n^{\pm}}$ [26].

$m^{-'}n^{+'},\,m^-n^-$	$-\cos A_1 \sin B_1$	$\cos A_2 \sin B_2$	$-\cos A_3 \sin B_3$	$\cos A_4 \sin B_4$
$m^{-'}n^{-'},\,m^+n^+$	$\sin A_1 \sin B_1$	$-\sin A_2 \sin B_2$	$-\sin A_3 \sin B_3$	$\sin A_4 \sin B_4$
$m^{-'}n^{-'},\,m^+n^-$	$-\sin A_1 \cos B_1$	$\sin A_2 \cos B_2$	$\sin A_3 \cos B_3$	$-\sin A_4 \cos B_4$
$m^{-'}n^{-'},\,m^-n^+$	$-\cos A_1 \sin B_1$	$\cos A_2 \sin B_2$	$\cos A_3 \sin B_3$	$-\cos A_4 \sin B_4$
$m^{-'}n^{-'},\,m^-n^-$	$\cos A_1 \cos B_1$	$-\cos A_2 \cos B_2$	$-\cos A_3 \cos B_3$	$\cos A_4 \cos B_4$

$$\psi_n^\pm(y) = (2/b)^{1/2}$$

$$\times \begin{cases} \cos(k_n y); & (+), \\ \quad n=1,3,5,\dots \\ \sin(k_n y); & (-), \\ \quad n=2,4,6,\dots \end{cases} \qquad k_n = (\pi/b)n \quad (67)$$

$$\psi_p^\pm(z) = (2/c)^{1/2}$$

$$\times \begin{cases} \cos(k_p z); & (+), \\ \quad p=1,3,5,\dots \\ \sin(k_p z); & (-), \\ \quad p=2,4,6,\dots \end{cases} \qquad k_p = (\pi/a)p \quad (68)$$

Inside the αth MT sphere, the basis function can be written as

$$\varphi_{I\alpha, mnp}^{\pm,\pm,\pm} = \sum_{lm} \left[A_{lm,\alpha}^{m^\pm n^\pm p^\pm} u_{l,\alpha}(E_l, \rho) \right.$$

$$\left. + B_{lm,\alpha}^{m^\pm n^\pm p^\pm} \dot{u}_{l,\alpha}(E_l, \rho) \right] Y_{lm}(\hat{\rho}) i^f \qquad (69)$$

Here, $f = l$ for $(+, +, +)$; i^{l-1} for $(-, +, +)$, $(+, -, +)$, and $(+, +, -)$; i^{l-2} for $(+, -, -)$, $(-, +, -)$, and $(-, -, +)$; and i^{l-3} for $(-, -, -)$. The coefficients $A_{lm,\alpha}^{m^\pm n^\pm p^\pm}$ and $B_{lm,\alpha}^{m^\pm n^\pm p^\pm}$ are readily calculated from the expansion of the waves in terms of Y_{lm} (22):

$$A_{lm,\alpha}^{m^\pm n^\pm p^\pm} = 4\pi r_\alpha^2 \Omega^{-1/2} a_{l,\alpha}(m, n, p) Y_{lm,\alpha}^{m^\pm n^\pm p^\pm} \qquad (70)$$

$$B_{lm,\alpha}^{m^\pm n^\pm p^\pm} = 4\pi r_\alpha^2 \Omega^{-1/2} b_{l,\alpha}(m, n, p) Y_{lm,\alpha}^{m^\pm n^\pm p^\pm} \qquad (71)$$

Here,

$$Y_{lm,\alpha}^{m^\pm n^\pm p^\pm} = (8)^{-1/2} \big\{ \delta_1 \exp\big[i(k_m X_\alpha + k_n Y_\alpha + k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(\mathbf{k}_m + \mathbf{k}_n + \mathbf{k}_p)$$

$$+ \delta_2 \exp\big[i(-k_m X_\alpha + k_n Y_\alpha + k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(-\mathbf{k}_m + \mathbf{k}_n + \mathbf{k}_p)$$

$$+ \delta_3 \exp\big[i(k_m X_\alpha - k_n Y_\alpha + k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(\mathbf{k}_m - \mathbf{k}_n + \mathbf{k}_p)$$

$$+ \delta_4 \exp\big[i(-k_m X_\alpha - k_n Y_\alpha + k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(-\mathbf{k}_m - \mathbf{k}_n + \mathbf{k}_p)$$

$$+ \delta_5 \exp\big[i(k_m X_\alpha + k_n Y_\alpha - k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(\mathbf{k}_m + \mathbf{k}_n - \mathbf{k}_p)$$

$$+ \delta_6 \exp\big[i(-k_m X_\alpha + k_n Y_\alpha - k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(-\mathbf{k}_m + \mathbf{k}_n - \mathbf{k}_p)$$

$$+ \delta_7 \exp\big[i(k_m X_\alpha - k_n Y_\alpha - k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(\mathbf{k}_m - \mathbf{k}_n - \mathbf{k}_p)$$

$$+ \delta_8 \exp\big[i(-k_m X_\alpha - k_n Y_\alpha - k_p Z_\alpha)\big]$$

$$\times Y_{lm}^*(-\mathbf{k}_m - \mathbf{k}_n - \mathbf{k}_p) \big\} \qquad (72)$$

The values of δ_i are presented in Table 2.

Table 2. Values of δ_i in (72).

	δ_1	δ_2	δ_3	δ_4	δ_5	δ_6	δ_7	δ_8
$m^+ n^+ p^+$	1	1	1	1	1	1	1	1
$m^- n^+ p^+$	1	−1	1	−1	1	−1	1	−1
$m^+ n^- p^+$	1	1	−1	−1	1	1	−1	−1
$m^+ n^+ p^-$	1	1	1	1	−1	−1	−1	−1
$m^- n^- p^+$	1	−1	−1	1	1	−1	−1	1
$m^- n^+ p^-$	1	−1	1	−1	−1	1	−1	1
$m^+ n^- p^-$	1	1	−1	−1	−1	−1	1	1
$m^- n^- p^-$	1	−1	−1	1	−1	1	1	−1

Finally,

$$a_{l,\alpha}(mnp) = j_l'(g_{mnp} r_\alpha) \dot{u}_{l,\alpha}(r_\alpha) - j_l(g_{mnp} r_\alpha) \dot{u}_{l,\alpha}'(r_\alpha) \quad (73)$$

$$b_{l,\alpha}(mnp) = j_l(g_{mnp} r_\alpha) u_{l,\alpha}'(r_\alpha) - j_l'(g_{mnp} r_\alpha) u_{l,\alpha}(r_\alpha) \quad (74)$$

where $g_{mnp} = |\mathbf{k}_p \pm \mathbf{k}_m \pm \mathbf{k}_n|$.

4.4.2. Cluster LAPW Hamiltonian and Overlap Matrices

Using the standing-wave basis, we obtain the overlap matrix:

$$\langle \varphi_{m'n'p'}^{\pm,\pm,\pm} | \varphi_{mnp}^{\pm,\pm,\pm} \rangle = U_{n'm'p',nmp}^{\pm\pm\pm,\pm\pm\pm}$$

$$+ \frac{4\pi}{\Omega} \sum_\alpha r_\alpha^4 \sum_{l=0}^\infty (2l+1) S_{l,\alpha}^{m'n'p',mnp}$$

$$\times \sum_{i=1}^8 x_{i\alpha}^{m^{\pm'} n^{\pm'} p^{\pm'}, m^\pm n^\pm p^\pm} P_{i,l}^{m'n'p',mnp} \qquad (75)$$

where

$$U_{n'm'p',nmp}^{\pm\pm\pm,\pm\pm\pm} = \delta_{m^{\pm'} n^{\pm'} p^{\pm'}, m^\pm n^\pm p^\pm} - \frac{4\pi}{\Omega} \sum_\alpha r_\alpha^2 \sum_{i=1}^8 x_{i\alpha}^{m^{\pm'} n^{\pm'} p^{\pm'}, m^\pm n^\pm p^\pm}$$

$$\times J_\alpha\big(g_i^{m'n'p',mnp}\big) \qquad (76)$$

The $x_{i\alpha}^{m^{\pm'} n^{\pm'} p^{\pm'}, m^\pm n^\pm p^\pm}$ coefficients are presented in Table 3, where

$$A_1 = X_\alpha(k_m + k_{m'}) \quad B_1 = Y_\alpha(k_n + k_{n'}) \quad C_1 = Z_\alpha(k_p + k_{p'})$$

$$A_2 = X_\alpha(k_m - k_{m'}) \quad B_2 = Y_\alpha(k_n + k_{n'}) \quad C_2 = Z_\alpha(k_p + k_{p'})$$

$$A_3 = X_\alpha(k_m + k_{m'}) \quad B_3 = Y_\alpha(k_n - k_{n'}) \quad C_3 = Z_\alpha(k_p + k_{p'})$$

$$A_4 = X_\alpha(k_m - k_{m'}) \quad B_4 = Y_\alpha(k_n - k_{n'}) \quad C_4 = Z_\alpha(k_p + k_{p'})$$

$$A_5 = X_\alpha(k_m + k_{m'}) \quad B_5 = Y_\alpha(k_n + k_{n'}) \quad C_5 = Z_\alpha(k_p - k_{p'})$$

$$A_6 = X_\alpha(k_m - k_{m'}) \quad B_6 = Y_\alpha(k_n + k_{n'}) \quad C_6 = Z_\alpha(k_p - k_{p'})$$

$$A_7 = X_\alpha(k_m + k_{m'}) \quad B_7 = Y_\alpha(k_n - k_{n'}) \quad C_7 = Z_\alpha(k_p - k_{p'})$$

$$A_8 = X_\alpha(k_m - k_{m'}) \quad B_8 = Y_\alpha(k_n - k_{n'}) \quad C_8 = Z_\alpha(k_p - k_{p'})$$

$$(77)$$

In (76), $J_\alpha(g_i) = j_1(|\mathbf{g}_i r_\alpha|)/|\mathbf{g}_i|$, where

$$\mathbf{g}_1^{m'n'p',mnp} = \mathbf{k}_m + \mathbf{k}_{m'} + \mathbf{k}_n + \mathbf{k}_{n'} + \mathbf{k}_p + \mathbf{k}_{p'}$$

$$\mathbf{g}_2^{m'n'p',mnp} = \mathbf{k}_m - \mathbf{k}_{m'} + \mathbf{k}_n + \mathbf{k}_{n'} + \mathbf{k}_p + \mathbf{k}_{p'}$$

$$\mathbf{g}_3^{m'n'p',mnp} = \mathbf{k}_m + \mathbf{k}_{m'} + \mathbf{k}_n - \mathbf{k}_{n'} + \mathbf{k}_p + \mathbf{k}_{p'}$$

$$\mathbf{g}_4^{m'n'p',mnp} = \mathbf{k}_m - \mathbf{k}_{m'} + \mathbf{k}_n - \mathbf{k}_{n'} + \mathbf{k}_p + \mathbf{k}_{p'}$$

$$\mathbf{g}_5^{m'n'p',mnp} = \mathbf{k}_m + \mathbf{k}_{m'} + \mathbf{k}_n + \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'} \qquad (78)$$

$$\mathbf{g}_6^{m'n'p',mnp} = \mathbf{k}_m - \mathbf{k}_{m'} + \mathbf{k}_n + \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'}$$

$$\mathbf{g}_7^{m'n'p',mnp} = \mathbf{k}_m + \mathbf{k}_{m'} + \mathbf{k}_n - \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'}$$

$$\mathbf{g}_8^{m'n'p',mnp} = \mathbf{k}_m - \mathbf{k}_{m'} + \mathbf{k}_n - \mathbf{k}_{n'} + \mathbf{k}_p - \mathbf{k}_{p'}$$

Finally,

$$S_{l,\alpha}^{m'n'p',mnp} = a_{l,\alpha}(m'n'p')a_{l,\alpha}(mnp)$$
$$+ N_{l,\alpha}b_{l,\alpha}(m'n'p')b_{l,\alpha}(mnp) \qquad (79)$$

$$P_{i,l}^{m'n'p',mnp} = P_l(k_i^{m'n'p',mnp}/g_{n'm'p'}g_{nmp}) \qquad (80)$$

$$k_1^{m'n'p',mnp} = -k_m k_{m'} - k_n k_{n'} - k_p k_{p'}$$

$$k_2^{m'n'p',mnp} = k_m k_{m'} - k_n k_{n'} - k_p k_{p'}$$

$$k_3^{m'n'p',mnp} = -k_m k_{m'} + k_n k_{n'} - k_p k_{p'}$$

$$k_4^{m'n'p',mnp} = k_m k_{m'} + k_n k_{n'} - k_p k_{p'} \qquad (81)$$

$$k_5^{m'n'p',mnp} = -k_m k_{m'} - k_n k_{n'} + k_p k_{p'}$$

$$k_6^{m'n'p',mnp} = k_m k_{m'} - k_n k_{n'} + k_p k_{p'}$$

$$k_7^{m'n'p',mnp} = -k_m k_{m'} + k_n k_{n'} + k_p k_{p'}$$

$$k_8^{m'n'p',mnp} = k_m k_{m'} + k_n k_{n'} + k_p k_{p'}$$

The Hamiltonian matrix elements have the form:

$$\left\langle \varphi_{m'n'p'}^{\pm,\pm,\pm} | \hat{H} | \varphi_{mnp}^{\pm,\pm,\pm} \right\rangle$$

$$= (k_m^2 + k_n^2 + k_p^2)\delta_{m^{\pm'}n^{\pm'}p^{\pm'},m^\pm n^\pm p^\pm} - \frac{4\pi}{\Omega}\sum_\alpha r_\alpha^2$$

$$\times \sum_{i=1}^{8} x_{i\alpha}^{m^{\pm'}n^{\pm'}p^{\pm'},m^\pm n^\pm p^\pm} J_\alpha\left(g_i^{m'n'p',mnp}\right)k_i^{m'n'p',mnp}$$

$$+ \frac{4\pi}{\Omega}\sum_\alpha r_\alpha^4 \sum_{l=0}(2l+1)\left[S_{l,\alpha}^{m'n'p',mnp}E_{l\alpha} + \gamma_{l,\alpha}^{m'n'yyp',mnp}\right]$$

$$\times \sum_{i=1}^{8} x_{i\alpha}^{m^{\pm'}n^{\pm'}p^{\pm'},m^\pm n^\pm p^\pm} P_{i,l}^{m'n'p',mnp} \qquad (82)$$

where

$$\gamma_{l,\alpha}^{m'n'p',mnp} = \dot{u}_{l,\alpha}u'_{l,\alpha}\left[j'_l\left(g_{m'n'p'}r\right)j_l\left(g_{mnp}r\right)\right.$$
$$\left. + j_l\left(g_{m'n'p'}r\right)j'_l\left(g_{mnp}r\right)\right]\big|_{r=r_\alpha}$$
$$- \left[\dot{u}'_{l,\alpha}u'_{l,\alpha}j_l\left(g_{m'n'p'}r\right)j_l\left(g_{mnp}r\right)\right.$$
$$\left. + \dot{u}_{l,\alpha}u_{l,\alpha}j'_l\left(g_{m'n'p'}r\right)j'_l\left(g_{mnp}r\right)\right]_{r=r_\alpha} \quad (83)$$

5. LINEAR AUGMENTED CYLINDRICAL-WAVE METHOD

The synthesis of nanotubes [31], which represent graphite layers convoluted in cylinders, as well as implanting metal atoms in such cylinders [32], opens the way to producing a new class of nanowires [33, 34]. For theorists, the basic challenge is interpreting and predicting the properties of these cylindrical systems.

5.1. Rod LACW Method

The rod LACW method is an extension of the 1D-LAPW method to cylindrical nanowires [35–37]. In the LACW theory under consideration, we use the step cylindrical-MT one-electron potential; that is, we consider that the potential is spherically symmetric in the vicinity of atoms Ω_I and constant in the Ω_{II} space among them and that the system is confined in an impenetrable potential box of cylindrical shape Ω_{III}. The radius a of the cylinder is chosen so that the cylinder includes a significant portion of the electron density of the nanorod.

5.1.1. Forming the Rod Basis Functions

To form the basis functions (linear augmented cylindrical waves, LACWs), the solutions of the wave equation for the cylindrical interstitial and MT regions should be sewn together so that the resulting LACWs and their first derivatives are continuous. In the interstitial region, the LACWs are the solutions of the Schrödinger equation for free electron movement in a cylinder of size $\pi a^2 \times \infty$. When expressed in cylindrical coordinates Z, R, and Φ, this equation takes the form:

$$\left\{-\left[\frac{1}{R}\frac{\partial}{\partial R}R\frac{\partial}{\partial R} + \frac{1}{R^2}\frac{\partial^2}{\partial\Phi^2} + \frac{\partial^2}{\partial Z^2}\right] + U(R)\right\}\Psi(Z,R,\Phi)$$
$$= E\Psi(Z,R,\Phi) \qquad (84)$$

where the potential $U(R) = 0$ at $R \le a$ and $U(R) = \infty$ at $R > a$. Let

$$\Psi(Z,R,\Phi) = \Psi_P(Z,k)\Psi_M(\Phi)\Psi_{|M|,N}(R) \qquad (85)$$

be the solutions of (84). As in the bar-LACW method, the $\Psi_P(Z,k)$ function describes the movement of an electron along the z axis in the one-dimensional system, (49). The function

$$\Psi_M(\Phi) = (2\pi)^{-1/2}\exp(iM\Phi) \qquad M = 0,\pm 1,\pm 2,\dots \qquad (86)$$

corresponds to the axial component, and $\Psi_{|M|,N}(R)$ corresponds to the transverse component of the wave function that is the solution of the equation

$$\left(-\frac{1}{R}\frac{d}{dR}R\frac{d}{dR} + \frac{M^2}{R^2}\right)\Psi_{|M|,N}(R)$$
$$+ U(R)\Psi_{|M|,N}(R) = E_{|M|,N}\Psi_{|M|,N}(R). \qquad (87)$$

Here, $E_{|M|,N}$ is the energy spectrum, and N is the radial quantum number. The energy

$$E = K_p^2 + E_{|M|,N} \qquad (88)$$

corresponds to the wave function $\Psi(Z, R, \Phi)$. At $R \leq a$, (87) is written in the form:

$$\left(\frac{d^2}{dR^2} + \frac{1}{R}\frac{d}{dR} + \kappa_{|M|,N}^2 - \frac{M^2}{R^2}\right)\Psi_{|M|,N}(R) = 0 \qquad (89)$$

where $\kappa_{|M|,N} = (E_{|M|,N})^{1/2}$. After substituting $\kappa R = x$ and $\Psi(R) = y(x)$ into (89), it reduces to the canonical Bessel equation $x^2 y'' + xy' + (x^2 - M^2)y = 0$. Its solutions are referred to as cylindrical functions of Mth order [38–40]. The finite at the origin $R = 0$ solution of (89) is $\Psi_{|M|,N}(R) = CJ_M(\kappa_{|M|,N}R)$, where J_M is the Bessel cylindrical function of Mth order. The condition of the vanishing of the wave function at the impenetrable barrier $\Psi_{|M|,N}(a) = J_M(\kappa_{|M|,N}a) = 0$ determines the corresponding energy spectrum:

$$E_{|M|,N} = (\alpha_{|M|,N})^2/a^2 \qquad (90)$$

Here, $\alpha_{|M|,N}$ is the Nth root of the Bessel function of Mth order $(N = 1, 2, \ldots)$. The constant $C = \sqrt{2}/[a|J_M'(\kappa_{|M|,N}a)|]$, where J_M' is a derivative of the Bessel function, is determined from the normalization of the function $\Psi_{|M|,N}(R)$:

$$\int_0^a \Psi_{M,N}^2(R)R\,dR = 1 \qquad (91)$$

Finally, the basis function in the Ω_{II} region takes the form:

$$\Psi_{II,PMN}(Z, R, \Phi) = \left[\sqrt{\Omega}|J_M'(\kappa_{|M|,N}a)|\right]^{-1} \times \exp[i(K_P Z + M\Phi)]J_M(\kappa_{|M|,N}R) \quad (92)$$

Here, $\Omega = \pi c a^2$.

Inside the MT sphere α in the local spherical coordinate system, the basis function $\Psi_{I\alpha,PMN}(\rho, \theta, \varphi)$ is expanded in spherical harmonics according to (21) with the coefficients $A_{lm,\alpha}^{PMN}$ and $B_{lm,\alpha}^{PMN}$ selected so that both the basis function Ψ_{PMN} and its derivative have no discontinuity at the boundary of MT spheres. To do this, let us express the $\Psi_{II,PMN}$ function through the cylindrical coordinates Z_α, Φ_α, and R_α of the center of the αth sphere and through the local spherical coordinate system ρ, θ, and φ (Fig. 1).

Figure 1. General cylindrical and local spherical coordinates [35].

Let $Q = Q(Z, R, \Phi)$ be the point with coordinates Z, R, and Φ in the general cylindrical coordinate system and with coordinates ρ, θ, and φ in the local spherical coordinate system. Then, taking into account $Z = Z_\alpha + \rho\cos\theta$ and $\Delta\Phi = \Phi_\alpha - \Phi$, we have

$$\Psi_{II\alpha,PMN}(\rho, \theta, \varphi)$$
$$= \left[\sqrt{\Omega}|J_M'(\kappa_{|M|,N}a)|\right]^{-1}\exp[i(K_P Z_\alpha + M\Phi_\alpha)]$$
$$\times \exp(iK_P\rho\cos\theta)e^{-iM\Delta\Phi}J_M(\kappa_{|M|,N}R) \qquad (93)$$

Using the theorem of addition (expansion) for cylindrical functions F_M (Fig. 2) [38, 39], according to which

$$e^{iM\psi}F_M(\kappa r_1) = \sum_{m=-\infty}^{\infty} J_m(\kappa r_3)F_{m+M}(\kappa r_2)e^{im\varphi} \qquad (94)$$

where F_M is the cylindrical Bessel functions of the first J_M or second Y_M kind and κ is an arbitrary complex number, we can write

$$e^{-iM\Delta\Phi}J_M(\kappa_{|M|,N}R) = (-1)^M \sum_{m=-\infty}^{\infty} J_m(\kappa_{|M|,N}\rho\sin\theta)$$
$$\times J_{m-M}(\kappa_{|M|,N}R_\alpha)e^{im\varphi} \qquad (95)$$

Finally, the function $\Psi_{II\alpha,PMN}(\rho, \theta, \varphi)$ takes the form:

$$\Psi_{II\alpha,PMN}(\rho, \theta, \varphi) = \left[\sqrt{\Omega}|J_M'(\kappa_{|M|,N}a)|\right]^{-1}$$
$$\times\exp[i(K_P Z_\alpha + M\Phi_\alpha)]\exp(iK_P\rho\cos\theta)$$
$$\times(-1)^M \sum_{m=-\infty}^{\infty} J_{m-M}(\kappa_{|M|,N}R_\alpha)$$
$$\times J_m(\kappa_{|M|,N}\rho\sin\theta)e^{im\varphi} \qquad (96)$$

From the equality of $\Psi_{I\alpha}$ and $\Psi_{II\alpha}$ and of their derivatives at the sphere boundary, we have

$$A_{lm,\alpha}^{PMN} = r_\alpha^2 D_{lm,\alpha}^{PMN} a_{lm,\alpha}(PMN) \qquad (97)$$
$$B_{lm,\alpha}^{PMN} = r_\alpha^2 D_{lm,\alpha}^{PMN} b_{lm,\alpha}(PMN) \qquad (98)$$

where

$$D_{lm,\alpha}^{PMN} = \sqrt{\pi}\left\{\sqrt{\Omega}|J_M'(\kappa_{|M|,N}a)|\right\}^{-1}\left\{\frac{(2l+1)[(l-|m|)!]}{[(l+|m|)!]}\right\}^{1/2}$$
$$\times (-1)^{[0.5(m+|m|+l)]}i^l\exp[i(K_P Z_\alpha + M\Phi_\alpha)]$$
$$\times (-1)^M J_{m-M}(\kappa_{|M|,N}R_\alpha), \qquad (99)$$

Figure 2. Illustration of the theorem of addition for cylindrical functions [35].

$$a_{lm,\alpha}(PMN) = I_2(r_\alpha)\,\dot{u}_{l,\alpha}(r_\alpha) - I_1(r_\alpha)\dot{u}'_{l,\alpha}(r_\alpha) \quad (100)$$

$$b_{lm,\alpha}(PMN) = I_1(r_\alpha)u'_{l,\alpha}(r_\alpha) - I_2(r_\alpha)u_{l,\alpha}(r_\alpha) \quad (101)$$

Here, I_1 and I_2 are integrals of the augmented Legendre polynomials $P_l^{|m|}$:

$$I_1 = 2\int_0^{\pi/2} \exp\big[i(K_P r_\alpha \cos\theta)\big]J_m\big(\kappa_{|M|,\,N}r_\alpha \sin\theta\big)P_l^{|m|}$$
$$\times\,(\cos\theta)\sin\theta\,d\theta \quad (102)$$

$$I_2 = 2\int_0^{\pi/2} \exp\big[i(K_P r_\alpha \cos\theta)\big]\big[iK_P \cos\theta\,J_m\big(\kappa_{|M|,\,N}r_\alpha \sin\theta\big)$$
$$+\,(1/2)\kappa_{|M|,\,N}\sin\theta\big]\big[J_{m-1}\big(\kappa_{|M|,\,N}r_\alpha \sin\theta\big)$$
$$-\,J_{m-1}\big(\kappa_{|M|,\,N}r_\alpha \sin\theta\big)\big]P_l^{|m|}(\cos\theta)\sin\theta\,d\theta \quad (103)$$

5.1.2. Rod LACW Hamiltonian and Overlap Matrices

With the use of the equations for the basis functions, we can calculate the overlap and Hamiltonian matrices:

$$\langle\Psi_{P'M'N'}|\Psi_{PMN}\rangle$$
$$= \delta_{P'M'N',PMN} + 2\pi\big[\Omega\big|J'_{|M'|}(\kappa_{|M'|,N'}a)J'_{|M|}(\kappa_{|M|,N}a)\big|\big]^{-1}$$
$$\times(-1)^{M+M'}\sum_\alpha \exp\big\{i[(k_P - k_{P'})Z_\alpha + (M - M')\Phi_\alpha]\big\}$$
$$\times\sum_{m=-\infty}^{\infty} J_{m-M'}\big(\kappa_{|M'|,N'}R_\alpha\big)J_{m-M}\big(\kappa_{|M|,N}R_\alpha\big)$$
$$\times\bigg\{I_3 - r_\alpha^4 \sum_{l=|m|}^{\infty} \frac{(2l+1)[(l-|m|)!]}{2[(l+|m|)!]}S_{lm,\alpha}^{P'M'N',PMN}\bigg\} \quad (104)$$

$$\langle\Psi_{P'M'N'}|\widehat{H}|\Psi_{PMN}\rangle$$
$$= \big(K_{P'}K_P + \kappa_{|M'|,N'}\kappa_{|M|,N}\big)\delta_{P'M'N',PMN}$$
$$-\,2\pi\big[\Omega\big|J'_{|M'|}(\kappa_{|M'|,N'}a)J'_{|M|}(\kappa_{|M|,N}a)\big|\big]^{-1}(-1)^{M+M'}$$
$$\times\sum_\alpha \exp\big\{i[(k_P - k_{P'})Z_\alpha + (M - M')\Phi_\alpha]\big\}$$
$$\times\sum_{m=-\infty}^{\infty} J_{m-M'}\big(\kappa_{|M'|,N'}R_\alpha\big)J_{m-M}\big(\kappa_{|M|,N}R_\alpha\big)$$
$$\times\,W_{\alpha m}^{P'M'N',PMN}, \quad (105)$$

where

$$W_{\alpha m}^{P'M'N',PMN} = K_{P'}K_P I_3 + \kappa_{|M'|,N'}\kappa_{|M|,N}I'_3 + m^2 I_4$$
$$-\,r_\alpha^4 \sum_{l=|m|}^{\infty} \frac{(2l+1)[(l-|m|)!]}{2[(l+|m|)!]}$$
$$\times\big(E_{l\alpha}S_{lm,\alpha}^{P'M'N',PMN} + \gamma_{lm,\alpha}^{P'M'N',PMN}\big), \quad (106)$$

$$I_3 = 2\int_0^{\pi/2}\int_0^{r_\alpha} \cos\big[r(k_P - k_{P'})\cos\theta\big]J_m\big(\kappa_{|M'|,N'}r\sin\theta\big)$$
$$\times J_m\big(\kappa_{|M|,N}r\sin\theta\big)\sin\theta r^2\,d\theta\,dr$$

$$I'_3 = 2\int_0^{\pi/2}\int_0^{r_\alpha} \cos\big[r(k_P - k_{P'})\cos\theta\big]J'_m\big(\kappa_{|M'|,N'}r\sin\theta\big)$$
$$\times J'_m\big(\kappa_{|M|,N}r\sin\theta\big)\sin\theta r^2\,d\theta\,dr$$

$$I_4 = 2\int_0^{\pi/2}\int_0^{r_\alpha} \cos\big[r(k_P - k_{P'})\cos\theta\big]J_m\big(\kappa_{|M'|,N'}r\sin\theta\big)$$
$$\times J_m\big(\kappa_{|M|,N}r\sin\theta\big)\big(\sin\theta\big)^{-1}\,d\theta\,dr \quad (107)$$

$$S_{lm,\alpha}^{P'M'N',PMN} = a_{lm,\alpha}^*(P'M'N')a_{lm,\alpha}(PMN)$$
$$+\,N_{l,\alpha}b_{lm,\alpha}^*(P'M'N')b_{lm,\alpha}(PMN) \quad (108)$$

$$\gamma_{lm,\alpha}^{P'M'N',PMN} = (I_2^*I_1 + I_1^*I_2)\dot{u}_{l,\alpha}u'_{l,\alpha} - I_2^*I_2\dot{u}_{l,\alpha}u_{l,\alpha}$$
$$-\,I_1^*I_1\dot{u}'_{l,\alpha}u'_{l,\alpha} \quad (109)$$

We calculated integrals I_1–I_4 by numerical methods.

5.2. Tube LACW Method

In the LACW method with the rod-MT approximation, the electron potential of a polyatomic system is assumed to be constant in the interatomic space up to an impenetrable cylindrical potential barrier. Thus, electrons are allowed to move throughout the interior of the potential cylinder; that is, the interior of a nanopolymer of near-cylindrical shape is free of cavities as, for example, in intercalated carbon nanotubes. On the other hand, a number of important polymeric systems have near-cylindrical symmetry and an interior cylindrical hole. Among these systems are, for example, original all-carbon and boron nitride nanotubes and MX_2 nanotubes (M = W, Mo; X = S, Se). Here, we extend the LACW method to nanotubes with an interior hole [41–43].

5.2.1. Forming the Tube LACW Basis Functions

We assume that the effective one-electron potential is constant in the interspherical region up to the two cylindrical potential barriers: the exterior cylinder of radius a and the interior cylinder of radius b. In this region, the basis functions are the solutions of the Schrödinger equation for free electron movement inside an infinite tube with outer radius a and inner radius b. This equation has the same form (84) as in the case of a nanorod; however, the potential is

$$U(R) = \begin{cases} 0, & b \le R \le a \\ \infty, & R < b,\ R > a \end{cases} \quad (110)$$

Because of the cylindrical symmetry of the potential $U(R)$, the wave function has the form (85), where $\Psi_{|M|,\,N}(R)$ is the solution of the Bessel equation (89) with new boundary conditions $\Psi_{|M|,\,N}(a) = \Psi_{|M|,\,N}(b) = 0$. Any solution of the Bessel equation can be represented as a linear combination of its partial solutions—cylindrical Bessel functions of the first J_M and second Y_M kinds

$$\Psi_{M,\,N}(R) = C_{M,\,N}^J J_M(\kappa_{|M|,\,N}R) + C_{M,\,N}^Y Y_M(\kappa_{|M|,\,N}R) \quad (111)$$

Here, $C_{M,\,N}^J$ and $C_{M,\,N}^Y$ are the constants chosen in such a way as to ensure the normalization of the $\Psi_{|M|,\,N}(R)$ function

$$\int_b^a \Psi_{M,\,N}^2(R)R\,dR = 1 \quad (112)$$

and its vanishing at the interior and exterior potential barriers:

$$\Psi_{M,N}(a) = C^J_{M,N} J_M(\kappa_{|M|,N} a) + C^Y_{M,N} Y_M(\kappa_{|M|,N} a) = 0 \tag{113}$$

$$\Psi_{M,N}(b) = C^J_{M,N} J_M(\kappa_{|M|,N} b) + C^Y_{M,N} Y_M(\kappa_{|M|,N} b) = 0 \tag{114}$$

[Note that, for a cylinder without a hole, the coefficient $C^Y_{M,N}$ in (111) vanishes, because the function $Y_M(\kappa_{|M|,N} R)$ has a singularity at $R = 0$; however, we are interested in the solutions of the Schrödinger equation that are finite and continuous everywhere over the region.] From the set of equations (113) and (114), we can easily derive the equation for finding $\kappa_{|M|,N}$:

$$J_M(\kappa_{|M|,N} a) Y_M(\kappa_{|M|,N} b) = J_M(\kappa_{|M|,N} b) Y_M(\kappa_{|M|,N} a) \tag{115}$$

In our work, we solve this equation numerically (we determine the segments containing at least one root, which was found by bisecting the segment). From (113) and (114), the relationship between $C^J_{M,N}$ and $C^Y_{M,N}$ can be found:

$$C^Y_{M,N} = -C^J_{M,N} \frac{J_M(\kappa_{|M|,N} a)}{Y_M(\kappa_{|M|,N} a)} \tag{116}$$

To calculate the integral (112), let us use the equation

$$\int z F_M(\kappa z) G_M(\kappa z)\, dz$$
$$= \frac{z^2}{2} F_M(\kappa z) G_M(\kappa z) - \frac{z^2}{4} \big[F_{M-1}(\kappa z) G_{M+1}(\kappa z)$$
$$+ F_{M+1}(\kappa z) G_{M-1}(\kappa z) \big] \tag{117}$$

for an indefinite integral and the recurrence formulas

$$z F_{M-1}(z) = z F'_M(z) + M F_M(z) \tag{118}$$

$$- z F_{M+1}(z) = z F'_M(z) - M F_M(z) \tag{119}$$

where F_M and G_M are any two cylindrical functions, in particular, J_M and Y_M. Then,

$$\frac{R^2}{2} \big[C^J_{MN} J'_M(\kappa_{|M|,N} R) + C^Y_{MN} Y'_M(\kappa_{|M|,N} R) \big]^2 \Big|_b^a = 1 \tag{120}$$

Finally, the basis function $\Psi_{II,PMN}(Z, R, \Phi)$ in the region Ω_{II} in the general cylindrical coordinate system takes the form:

$$\Psi_{II,PMN}(Z, R, \Phi)$$
$$= \frac{1}{\sqrt{2\pi c}} \exp[i(K_P Z + M\Phi)] \big[C^J_{M,N} J_M(\kappa_{|M|,N} R)$$
$$+ C^Y_{M,N} Y_M(\kappa_{|M|,N} R) \big] \tag{121}$$

Here, the $\kappa_{|M|,N}$ values are found from (115), and $C^J_{M,N}$ and $C^Y_{M,N}$ are derived from the set of equations (120) and (116).

Inside the MT sphere α in the local spherical coordinate system, the LACW has the same form as in the case of bulk or nanorod. In order to determine the coefficients A^{PMN}_{lm} and B^{PMN}_{lm}, let us again use the theorem of addition for cylindrical functions (Figs. 1 and 2). In the local spherical coordinate system, the function $\Psi_{II\alpha,PMN}(\rho, \theta, \varphi)$ for a cylinder with a hole takes the form:

$$\Psi_{II\alpha,PMN}(\rho, \theta, \varphi)$$
$$= (2\pi c)^{-1/2} \exp\big[i(K_P Z_\alpha + M\Phi_\alpha)\big] \exp(iK_P\rho\cos\theta)(-1)^M$$
$$\times \sum_{m=-\infty}^{\infty} \big[C^J_{M,N} J_{m-M}(\kappa_{|M|,N} R_\alpha) + C^Y_{M,N} Y_{m-M}(\kappa_{|M|,N} R_\alpha) \big]$$
$$\times J_m(\kappa_{|M|,N}\rho\sin\theta)e^{im\varphi} \tag{122}$$

Finally, we obtain that the A_{lm} and B_{lm} coefficients can be calculated from (97) and (98) with

$$D^{PMN}_{lm,\alpha} = \frac{1}{\sqrt{2c}} \left\{ \frac{(2l+1)[(l-|m|)!]}{[(l+|m|)!]} \right\}^{1/2} (-1)^{[0.5(m+|m|+l)]} i^l$$
$$\times \exp\big[i(K_P Z_\alpha + M\Phi_\alpha)\big]$$
$$\times (-1)^M [C^J_{M,N} J_{m-M}(\kappa_{|M|,N} R_\alpha)$$
$$+ C^Y_{M,N} Y_{m-M}(\kappa_{|M|,N} R_\alpha)] \tag{123}$$

5.2.2. Tube LACW Hamiltonian and Overlap Matrices

The overlap and Hamiltonian matrices in this case have the form:

$$\langle \Psi_{P'M'N'} | \Psi_{PMN} \rangle = \delta_{P'M'N',PMN} - \frac{1}{c}(-1)^{M+M'}$$
$$\times \sum_\alpha \exp\{i[(K_P - K_{P'})Z_\alpha + (M - M')\Phi_\alpha]\}$$
$$\times \sum_{m=-\infty}^{\infty} \big[C^J_{M',N'} J_{m-M'}(\kappa_{|M'|,N'} R_\alpha)$$
$$+ C^Y_{M',N'} Y_{m-M'}(\kappa_{|M'|,N'} R_\alpha) \big]$$
$$\times \big[C^J_{M,N} J_{m-M}(\kappa_{|M|,N} R_\alpha)$$
$$+ C^Y_{M,N} Y_{m-M}(\kappa_{|M|,N} R_\alpha) \big]$$
$$\times \left\{ I_3 - r_\alpha^4 \sum_{l=|m|}^{\infty} \frac{(2l+1)[(l-|m|)!]}{2[(l+|m|)!]} \right.$$
$$\left. \times S^{P'M'N',PMN}_{lm,\alpha} \right\}, \tag{124}$$

$$\langle \Psi_{P'M'N'} | \widehat{H} | \Psi_{PMN} \rangle$$
$$= (K_{P'} K_P + \kappa_{|M'|,N'} \kappa_{|M|,N}) \delta_{P'M'N',PMN}$$
$$- \frac{1}{c}(-1)^{M+M'} \sum_\alpha \exp\{i[(K_P - K_{P'})Z_\alpha + (M - M')\Phi_\alpha]\}$$
$$\times \sum_{m=-\infty}^{\infty} \big[C^J_{M',N'} J_{m-M'}(\kappa_{|M'|,N'} R_\alpha)$$
$$+ C^Y_{M',N'} Y_{m-M'}(\kappa_{|M'|,N'} R_\alpha) \big]$$
$$\times \big[C^J_{M,N} J_{m-M}(\kappa_{|M|,N} R_\alpha)$$
$$+ C^Y_{M,N} Y_{m-M}(\kappa_{|M|,N} R_\alpha) \big] W^{P'M'N',PMN}_{\alpha m} \tag{125}$$

5.3. LACW Method for Nanoporous System

The pore LACW method can be developed to study the characteristic electron states of the pores in nanoporous system with cylindrical nanocavities in a bulk material [44, 45]. Again, we use the step cylindrical-MT electron potential. In this case, an impenetrable cylindrical step potential separates an unattainable for electron cylindrical region from the rest of the system.

In this case in the interstitial region, the LACW

$$\Psi_{II,PMN}(Z, R, \Phi) = [\sqrt{\Omega}|Y'_M(\kappa_{|M|,N}b)|]^{-1}$$
$$\times \exp[i(K_P Z + M\Phi)]Y_M(\kappa_{|M|,N}R) \quad (126)$$

is a solution of the Schrödinger equation (84) with the potential $U(R) = 0$ at $R \geq b$ and $U(R) = \infty$ at $R < b$. The condition of the vanishing of the wave function at the impenetrable barrier $\Psi_{|M|,N}(b) = Y_M(\kappa_{|M|,N}b) = 0$ determines the corresponding energy spectrum through the roots of the Bessel functions of the second kind. Here, $\Omega = \pi c b^2$.

In the local spherical coordinate system ρ, θ, and φ, we have

$$\Psi_{II\alpha,PMN}(\rho, \theta, \varphi) = [\sqrt{\Omega}|Y'_M(\kappa_{|M|,N}a)|]^{-1}$$
$$\times \exp[i(K_P Z_\alpha + M\Phi_\alpha)]\exp(iK_P\rho\cos\theta)(-1)^M$$
$$\times \sum_{m=-\infty}^{\infty} Y_{m-M}(\kappa_{|M|,N}R_\alpha)J_m(\kappa_{|M|,N}\rho\sin\theta)e^{im\varphi} \quad (127)$$

When (127) is compared with analogous equations (96) for a nanorod or (122) for a nanotube, the overlap and Hamiltonian matrix elements are readily obtained from (104) and (105) or (124) and (125):

$$\langle\Psi_{P'M'N'}|\Psi_{PMN}\rangle$$
$$= \delta_{P'M'N',PMN} + 2\pi[\Omega|Y'_{|M'|}(\kappa_{|M'|,N'}b)Y'_{|M|}(\kappa_{|M|,N}b)|]^{-1}$$
$$\times (-1)^{M+M'}\sum_\alpha \exp\{i[(k_P - k_{P'})Z_\alpha + (M - M')\Phi_\alpha]\}$$
$$\times \sum_{m=-\infty}^{\infty} Y_{m-M'}(\kappa_{|M'|,N'}R_\alpha)Y_{m-M}(\kappa_{|M|,N}R_\alpha)$$
$$\times \left\{I_3 - r_\alpha^4\sum_{l=|m|}^{\infty}\frac{(2l+1)[(l-|m|)!]}{2[(l+|m|)!]}S_{lm,\alpha}^{P'M'N',PMN}\right\}, \quad (128)$$

$$\langle\Psi_{P'M'N'}|\widehat{H}|\Psi_{PMN}\rangle = (K_{P'}K_P + \kappa_{|M'|,N'}\kappa_{|M|,N})\delta_{P'M'N',PMN}$$
$$- 2\pi[\Omega|Y'_{|M'|}(\kappa_{|M'|,N'}b)Y'_{|M|}(\kappa_{|M|,N}b)|]^{-1}(-1)^{M+M'}$$
$$\times \sum_\alpha \exp\{i[(k_P - k_{P'})Z_\alpha + (M - M')\Phi_\alpha]\}$$
$$\times \sum_{m=-\infty}^{\infty} Y_{m-M'}(\kappa_{|M'|,N'}R_\alpha)Y_{m-M}$$
$$\times (\kappa_{|M|,N}R_\alpha)W_{\alpha m}^{P'M'N',PMN} \quad (129)$$

6. CLUSTER LINEAR AUGMENTED SPHERICAL-WAVE METHOD

In this section, a cluster linear augmented spherical-wave (C-LASW or 0D-LASW) method for spherical nanocrystals or polyatomic clusters such as fullerene C_{60} is presented

[46, 47]. The C-LASW model is based on the 3D-LASW method for crystals [48] and the multiple-scattering model for polyatomic molecules [49–51]. We use the spherical-MT approximation here; that is, we assume that the effective one-electron potential is spherically symmetric with large radial variation in the vicinity of atoms Ω_I and constant in the Ω_{II} space among them up to the impenetrable spherical potential barrier Ω_{III}. In the general case considered here that a molecule such as $\mathscr{C}_{60}$ has an inner spherical hole, there must be two spherical potential barriers with radii a and b, between which the major part of the electron density is located.

6.1. Forming the Basis Cluster LASW Functions

Here, the basis function is called a linear augmented spherical wave (LASW). In the spherical interatomic region, it is a solution of the wave equation with constant potential. In the general spherical coordinates R, Θ, and Φ (Fig. 3), the Schrödinger equation for free electron movement in a spherical layer takes the form:

$$\left\{-\frac{1}{R^2}\frac{\partial}{\partial R}R^2\frac{\partial}{\partial R} - \frac{\Lambda}{R^2} + U(R)\right\}\Psi(R,\Theta,\Phi) = E\Psi(R,\Theta,\Phi) \quad (130)$$

where

$$\Lambda = \frac{1}{\sin\Theta}\left[\frac{\partial}{\partial\Theta}\left(\sin\Theta\frac{\partial}{\partial\Theta}\right) + \frac{\partial^2}{\sin\Theta\,\partial\Phi^2}\right] \quad (131)$$

For a spherical cluster with a spherical hole, $U(R) = 0$ for $a \leq R \leq b$ and $U(R) = \infty$ outside the step potential barriers (110). The solution of (130)

$$\Psi_{II,NLM}(R,\Theta,\Phi) = f_{N,L}(R)Y_{L,M}(\Theta,\Phi)$$
$$\equiv f_{N,L}(R)Y_{L,M}(\widehat{R}) \quad (132)$$

is called the spherical wave. The radial function $f_{N,L}(R)$ is the solution of the equation

$$\left(\frac{d^2}{dR^2} + \frac{2}{R}\frac{d}{dR} + \kappa_{N,L}^2 - \frac{L(L+1)}{R^2}\right)f_{N,L}(R) = 0 \quad (133)$$
Figure 3. General and local spherical coordinate systems and illustration of the theorem of expansion for spherical waves.

where $\kappa_{N,L} = \sqrt{E}$. Any solution of this equation is a linear combination of its partial solutions—spherical Bessel functions of the first j_L and second y_L kinds

$$f_{N,L}(R) = c_{N,L}^j j_L(\kappa_{N,L}R) + c_{N,L}^y y_L(\kappa_{N,L}R) \qquad (134)$$

Using the normalization

$$\int_b^a f_{N,L}^2(R)R^2 \, dR = 1 \qquad (135)$$

and boundary conditions $f_{N,L}(a) = f_{N,L}(b) = 0$, we obtain three equations

$$j_L(\kappa_{N,L}a)y_L(\kappa_{N,L}b) = j_L(\kappa_{N,L}b)y_L(\kappa_{N,L}a) \qquad (136)$$

$$c_{N,L}^y = -c_{N,L}^j \frac{j_L(\kappa_{N,L}a)}{y_L(\kappa_{N,L}a)} \qquad (137)$$

$$\frac{R^3}{2}[(c_{N,L}^j)^2 j_{L-1}j_{L+1} + (c_{N,L}^y)^2 y_{L-1}y_{L+1}$$
$$+ c_{N,L}^j c_{N,L}^y (j_{L-1}y_{L+1} + j_{L+1}y_{L-1})]|_a^b = 1 \quad (138)$$

for $\kappa_{N,L}$, $c_{N,L}^j$, and $c_{N,L}^y$. Here, $j_{L-1} = j_{L-1}(\kappa_{N,L}R)$, $j_{L+1} = j_{L+1}(\kappa_{N,L}R)$, ... To obtain (138) from (135), we used (117) and the relationship between spherical and cylindrical Bessel functions

$$j_L(z) = \sqrt{\frac{\pi}{2z}} J_{L+1/2}(z)$$

$$y_L(z) = \sqrt{\frac{\pi}{2z}} J_{-L-1/2}(z)(-1)^{L+1} \qquad (139)$$

Inside the MT sphere α in the local spherical coordinate system, the basis function $\Psi_{I\alpha,NLM}(\rho, \theta, \varphi)$ is expanded in spherical harmonics according to (21) with the coefficients $A_{lm,\alpha}^{NLM}$ and $B_{lm,\alpha}^{NLM}$ determined by matching the basis function Ψ_{NLM} and its derivative over the boundary of MT spheres.

Using an expansion theorem (Fig. 3) for the spherical wave [49], according to which

$$\frac{n_L(\kappa R)Y_{LM}(\widehat{R})}{4\pi} = \sum_{l'm'}\sum_{l''m''} i^{l'+l''-L} I_{l''}m''(LM, l'm')n_L(\kappa R_\alpha)$$
$$\times Y_{l'm'}(\widehat{R}_\alpha)j_{l''}(\kappa r)Y_{l''}m''(\hat{r}) \qquad (140)$$

where n_L is the spherical Bessel function of the first j_L or second y_L kind and κ is an arbitrary complex number, we express the $\Psi_{II,NLM}(R, \Theta, \Phi)$ function through the general spherical coordinates R_α, Θ_α, and Φ_α of the center of the αth sphere and through the local spherical coordinates ρ, θ, and φ:

$$\Psi_{II\alpha,NLM} = 4\pi \sum_{l'm'}\sum_{l''m''} i^{l'+l''-L} I_{l''m''}(LM, l'm')$$
$$\times [c_{N,L}^j j_{l'}(\kappa_{N,L}R_\alpha) + c_{N,L}^y y_{l'}(\kappa_{N,L}R_\alpha)]$$
$$\times Y_{l'm'}(\widehat{R}_\alpha)j_{l''}(\kappa_{N,L}\rho)Y_{l''m''}(\hat{\rho}) \qquad (141)$$

where the Gaunt integral

$$I_{l''m''}(LM, l'm') = \int_0^\pi \int_0^{2\pi} Y_{l''m''}(\theta,\varphi)$$
$$\times Y_{LM}^*(\theta,\varphi)Y_{l'm'}(\theta,\varphi) \sin\theta \, d\theta \, d\varphi$$
$$= \sqrt{\frac{(2l''+1)(2l'+1)}{4\pi(2L+1)}} C_{l''0l'0}^{L0} C_{l''m''l'm'}^{LM} \quad (142)$$

over triple products or spherical harmonics is easily computed in terms of products of Clebsch–Gordon coefficients $C_{l''0l'0}^{L0}$ and $C_{l''m''l'm'}^{LM}$ [52].

From the equality of the function $\Psi_{I\alpha,NLM}$ of the type (21) and $\Psi_{II\alpha,NLM}$ (141) and of their derivatives at the MT-sphere boundary, we have

$$A_{lm,\alpha}^{NLM} = r_\alpha^2 D_{lm,\alpha}^{NLM} a_{lm,\alpha}(NL) \qquad (143)$$
$$B_{lm,\alpha}^{NLM} = r_\alpha^2 D_{lm,\alpha}^{NLM} b_{lm,\alpha}(NL) \qquad (144)$$

where

$$D_{lm,\alpha}^{NLM} = 4\pi \sum_{l'm'} i^{l'+l-L} I_{lm}(LM, l'm')[c_{N,L}^j j_{l'}(\kappa_{N,L}R_\alpha)$$
$$+ c_{N,L}^y y_{l'}(\kappa_{N,L}R_\alpha)]Y_{l'm'}(\widehat{R}_\alpha) \qquad (145)$$

$$a_{lm,\alpha}(NL) = j_l'(\kappa_{N,L}r_\alpha)\dot{u}_{l,\alpha}(r_\alpha) - j_l(\kappa_{N,L}r_\alpha)\dot{u}_{l,\alpha}'(r_\alpha) \quad (146)$$
$$b_{lm,\alpha}(NL) = j_l(\kappa_{N,L}r_\alpha)u_{l,\alpha}'(r_\alpha) - j_l'(\kappa_{N,L}r_\alpha)u_{l,\alpha}(r_\alpha) \quad (147)$$

6.2. Cluster LASW Hamiltonian and Overlap Matrices

The overlap matrix in this method has the form:

$$\langle \Psi_{N_2L_2M_2} | \Psi_{N_1L_1M_1} \rangle$$
$$= \delta_{N_2L_2M_2,N_1L_1M_1} - (4\pi)^2 \sum_{l'm'}\sum_{l''m''} i^{l'-l''-L_1+L_2}$$
$$\times \sum_\alpha [c_{N_2,L_2}^j j_{l''}(\kappa_{N_2,L_2}R_\alpha)$$

$$

For the special case that there is no inner spherical hole in a cluster, the overlap and Hamiltonian matrices can easily be found from these equations. In this case, $c^y_{N, L} = 0$, $f_{N, L}(R) = c^j_{N, L} j_L(\kappa_{N, L} R)$, $\kappa_{N, L}$ are to be obtained from the equation $j_L(\kappa_{N, L} a) = 0$, and

$$
c^j_{N, L} = \left[\frac{a^3}{2} (j_L^2(\kappa_{N, L} a) - j_{L-1}(\kappa_{N, L} a) j_{L+1}(\kappa_{N, L} a)) \right]^{-1/2} \tag{155}
$$

7. APPLICATIONS

Presently, there are not too many applications of the LAW theory to nanomaterials. The majority of the studies are related to 1D and 2D systems such as nanotubes, nanowires, and films. In terms of the LAW formalism, we studied nanotubes and nanowires, and these data are briefly described below. Here, the applicability of the LAW formalism to nanomaterials will be demonstrated by examples of our calculations of one-dimensional systems: polymers, transition metal nanowires, and pure and $3d$-metal intercalated carbon and boron nitride nanotubes. As to the applications of the LAW theory to nanoporous crystals and spherical and tetragonal clusters, the development of computer codes is in progress.

7.1. Polymers

Carbyne is a linear chain of carbon atoms with alternating bond lengths of 1.34 and 1.20 Å. It is the most simple carbon nanowire. The results of the 1D-LAPW calculations of this system are presented in Figure 4 [27–29]. The calculations are in close agreement with the experimental data for carbyne: the experimental bandgap width is 1–2.2 eV, the width of the valence π band is 5–6 eV, and the width of the σ band is 6–7 eV [53].

Figure 5 shows the 1D-LAPW calculated electron dispersion curves together with the total (N_T) and partial densities of the $1s(H)$, $2s(C)$, and $2p(C)$ states of poly($para$-phenylene) broadened by the gauss with a half-width of 0.25 eV. In this figure, the calculated results are compared with photoelectron spectroscopy (PES) data [54]. In agreement with experiment, the calculated total valence band width equals 18 eV. The three PES bands in the range from 0 to −7 eV are to be assigned to the $2p_\pi(C)$ states. The positions of these peaks virtually coincide with those of the peaks of the total and $2p(C)$ states. The $2s(C)$ and $1s(H)$ states dominate in a structure below −9 eV with peaks at −10, −13, and −16 eV. The $2p_\pi^*(C)$ states dominate in the conduction band in a region between 0 and 4 eV. The energy gap is equal to 1 eV and corresponds to a direct p_π^*–p_π transition. The bands located above 5 eV include contributions of the $2s(C)$ and $2p_\sigma(C)$ states with significant admixture of the $1s(H)$ states at energies exceeding 7.5 eV.

As seen from a comparison of the densities of the valence states and PES [54] of the polyethylene (Fig. 6), the valence band width and positions of the experimental and theoretical peaks near −14 and −21 eV coincide completely. The dip in the experimentally PES is represented by the gap in the band structure in the range from −14 to −11.5 eV. The set of theoretical peaks spreading from the valence band edge to about −11.5 eV with the most intensive maximum at −7 eV is observed experimentally as a band with a peak at the same energy. The energy gap between the conduction and valence bands corresponds to a direct transition near $k = (2/3)(\pi/c)$. The 1D-LAPW band structure of polyethylene seems to reproduce the PES of this system somewhat better than the results of *ab initio* calculations by the molecular orbital linear combination of atomic orbitals (MO LCAO) method [55, 56].

7.2. Carbon Nanotubes

The electronic structure of all-carbon nanotubes was predicted by *ab initio* and Hückel quantum-chemical calculations in the early 1990s [57–60]. This prediction has been later corroborated by electric conductivity measurements and spectra. At the present time, a great body of theoretical and experimental information on the electronic structure of such nanotubes is available [61–65]. Therefore, we believe that they are best suited for testing the LACW method [41, 42, 66].

As is known, all carbon nanotubes with the armchair configuration have a metal-type electronic structure. The Fermi level is located at the intersection of two π bands at the point $k = (2/3)(\pi/c)$. This is also reproduced by the LACW method, as follows from our calculations of the (n, n) nanotubes (Fig. 7).

The carbon $(n, 0)$ nanotubes with a zigzag configuration, depending on their diameter parameter n, can be both semiconductors with a direct gap in the center of the Brillouin zone (at $k = 0$) and semimetals when the top of the valence band and the bottom of the conductivity band touch each other at $k = 0$. If n is a multiple of 3, the nanotubes are semimetals (Fig. 8); otherwise, they are semiconductors (Fig. 9), which is clearly reproduced by the LACW method.

7.3. 3*d*-Metal Atomic Wires

Intercalating different metals inside nanotubes opens the way to producing metal nanowires. Similar superthin metal wires have also been produced upon implanting metal atoms
Figure 6. Electron structure of polyethylene. Reprinted with permission from [29].
Figure 7. Band structure of carbon $(5, 5)$ nanotube. Reprinted with permission from [41].

in zeolite [67, 68]. Metal nanowires were observed on the crystal surfaces and sandwiched between the leads [69–71].

The rod-LACW method was used to calculate the electronic structure of nanowires consisting of third-period atoms from potassium to zinc [35, 36]. The chains $(M)_\infty$ and $(M_2)_\infty$ with, respectively, equal and alternating short and long M–M bonds were calculated.

Figure 10 shows that all the $(M)_\infty$ chains without alternating, except for those formed by Ca and Zn, exhibit the metal-type band structure. The $(K)_\infty$ chain is a one-dimensional metal, since the nondegenerate $4s$ band is half-filled with valence electrons. The $(Ca)_\infty$ chain represents a one-dimensional dielectric with a completely filled nondegenerate $4s$ band, whose top is located at the edge of the Brillouin zone. The band gap is 2.2 eV and corresponds to the indirect transition into the doubly degenerate band dominated by the $4p_x$ and $4p_y$ states.

In the low-energy region, the dispersion curves of all $3d$ transition metals have much in common. As in the case of $4s$ metals, their origin can be interpreted in terms of the MO LCAO method and related to the MOs of the M_2 diatomic molecules of transition metals [72]. In all cases, the nondegenerate $E_1(1)$ and $E_1(2)$ bands in the $(M)_\infty$ chains without bond alternation represent bonding and antibonding combinations of the $4s$- and $3d_{z^2}$-metal states. In all transition
Figure 8. Band structure of carbon $(12, 0)$ nanotube. Reprinted with permission from [41], P. N. D'yachkov and D. V. Kirin, *Dokl. Chem.* 369, 326 (1999).

Figure 9. Band structure of carbon $(16, 0)$ nanotube. Reprinted with permission from [41], P. N. D'yachkov and D. V. Kirin, *Dokl. Chem.* 369, 326 (1999).

metals, the $E_1(1)$ band is completely filled with electrons. An increase in the atomic number of a transition metal is accompanied first by an increase and then by a decrease in the bandwidth. The doubly degenerate narrow band $E_2(1)$, located between the $E_1(1)$ and $E_1(2)$ bands, is formed by the $3d_{x^2-y^2}$ and $3d_{xy}$ functions. Orientation of these functions indicates that this band is a δ-bonding band. In the $(M)_\infty$ chains from Sc to V, the Fermi level intersects this band; hence, conductivity in these chains should occur with participation of δ-type states. The doubly degenerate $E_2(2)$ and $E_2(3)$ bands are higher in energy. One of these bands can be related to the π states formed by the $3d_{xz}$ and $3d_{yz}$ functions of a metal. The origin of the other (higher energy) band is not interpreted in terms of the MO LCAO method. This band can be associated with metallic conducting states with electron transfer over the interspherical region.

Beginning with the $(Cr)_\infty$ chain, the $E_2(3)$ band is gradually filled with electrons. The whole $E_2(2)$ band lies higher than the upper occupied level in all the metal chains, except for the copper one. The $(Zn)_\infty$ chain with the completely filled $E_1(1)$, $E_2(1)$, $E_1(2)$, and $E_2(3)$ bands represents a

narrow-gap semiconductor with a direct gap of 0.19 eV at the edge of the Brillouin zone.

The $(Sc)_\infty$ and $(Sc_2)_\infty$ [73] chains are characterized by a virtually flat upper partially filled band and, correspondingly, by a high density of states at the Fermi level, which can lead to a high conductivity of these nanowires.

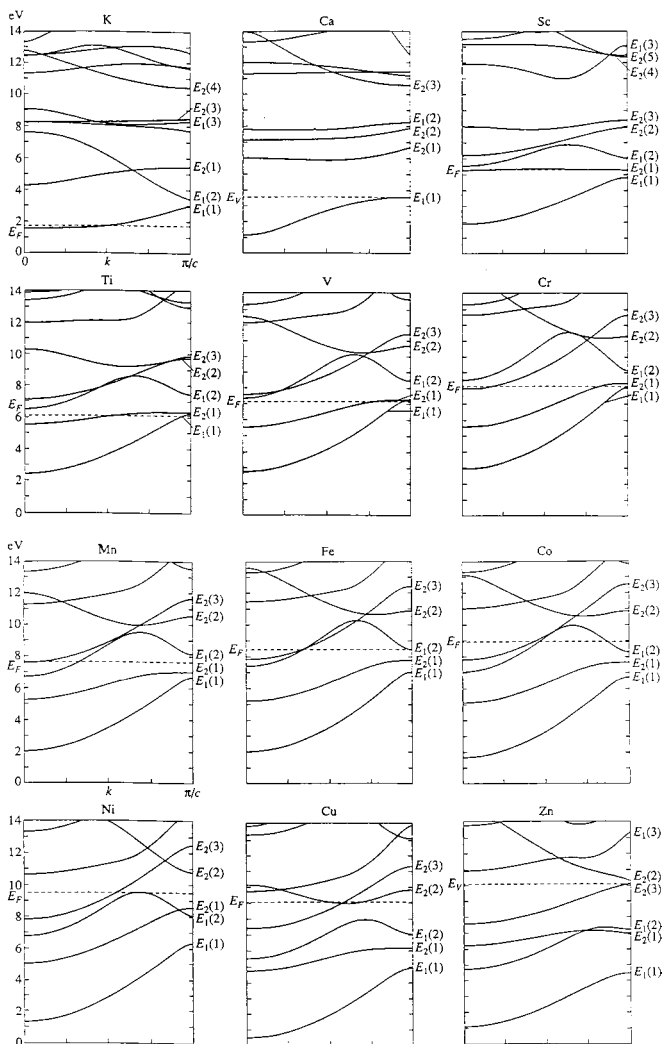
Let us discuss the chemical bond strength in $3d$-metal chains, taking into account the bonding and antibonding character of the bands and their filling with electrons. In all cases, the bonding σ band $E_1(1)$ is completely filled; therefore, its influence leads to the equal stabilization of all the systems. In the series Sc–Ti–V–Cr, the bonding δ band $E_2(1)$ becomes broader and is gradually filled with electrons. The broader the band, the stronger the metal–metal δ interactions; the greater the filling of this band with electrons, the stronger the bond between the atoms in the chain. Therefore, we can predict an increase in stability of the chains to metal–metal bond dissociation in the series Sc–Cr. Beginning with a chain of manganese atoms, the antibonding σ band $E_1(2)$ is filled, which should result in a weakening of the chemical bond. In the chains of Ni, Cu, and Zn atoms, σ antibonding neatly compensates for σ bonding;


Figure 10. Band structure of metal chains without bond alternation. Reprinted with permission from [35].

Figure 11. Band structure of the $(Mn@C_{20})$ nanotube. Reprinted with permission from [35].

hence, these chains should be unstable, since they are stabilized only by weak δ interactions. The chain of copper atoms is additionally destabilized because of a partial filling of the antibonding $d(\pi)$ band $E_2(2)$. The filing of the $E_2(2)$ band, which we associate with predominant electron transfer across the interspherical region, should not result in stabilization of the chains formed by late $3d$ metals. Therefore, upon an increase in the atomic number of a transition metal, the stability of the $(M)_\infty$ chains should first increase and then decrease.

7.4. 3d-Metal Intercalated Carbon Nanotube

Using the LACW method, we calculated the band structures of the $3d$-metal doped carbon nanotube $(M@C_{20})_\infty$ with a (5, 5) armchair carbon network and metal atoms located on the tube axis [35, 37, 42, 74]. Figure 11 shows a typical example of the $(Mn@C_{20})_\infty$ nanotube band structure.

Comparison with the calculation results of the $(C_{20})_\infty$ tube indicates that the bands $E_1(1)$–$E_8(1)$ and $E_1(2)$–$E_{16}(2)$ are

similar to those observed for the pure carbon tube. The bands $E_9(1)$, $E_{10}(1)$, $E_{17}(2)$, and $E_{18}(2)$ are similar to the $4s$ and $3d$ bands of $(Mn)_\infty$. In the vicinity of the Fermi level, the dispersion curves of the carbon and metal subsystems intersect, which points to their considerable interaction and joint participation in conductivity. The most important are the narrow bands that intersect the Fermi level. They can be assigned to the $3d(Mn)$ and $4s(Mn)$ states. In the pure carbon armchair nanotube, the Fermi level is known to be located in the dip of the electron density of states. Intercalation of metals fills the dip (Fig. 12), which results in growth of the electron density of states in the Fermi level and, consequently, in a considerable increase in the conductivity of the carbon nanotube.

7.5. Pure and Intercalated BN Nanotube

Figures 13 and 14 show the influence of Ti atoms located in the tube cavity on the properties of the boron nitride (5, 5) tube [42, 43]. The pure tube is a wide-gap semiconductor in agreement with the LCAO data with parametrization based
Figure 12. Total densities of states of the $(Sc@C_{20})_\infty$ (left) and $(Cu@C_{20})_\infty$ (right) nanotubes. Reprinted with permission from [74].

on the band structure of hexagonal BN [75, 76]. Introducing Ti atoms changes the type of conductivity from semiconducting to metallic. This can be used to create wide-gap semiconductor–metal heterojunctions and various nanoelectronic setups based on them. For example, to design a diode, it suffices to fill one half of the tube with metal, while the other half should remain unfilled. In such a system, the current will only flow in one direction: from the metallic end to the semiconducting one.

GLOSSARY

Augmented wave   Basis function for electronic structure calculations in terms of the LAPW, LACW, LASW, etc. methods.

Cylindrical-MT potential   This term is taken to mean that the one-electron potential is spherically symmetric in the atomic region and constant in the interstitial region up to the cylindrical potential barrier that separates, for example, the nanotube and the vacuum region.

Film-MT potential   This term is taken to mean that the one-electron potential is spherically symmetric in the atomic region and constant in the interstitial region up to the planar potential barrier that separates the film and the vacuum region.

Linear augmented cylindrical-wave method (LACW)   First-principle techniques in the electronic structure theory applicable to cylindrical multiatomic systems such as nanotubes, nanowires, and porous systems with cylindrical nanocavities.

Linear augmented plane-wave method (LAPW)   First-principle techniques in the electronic structure theory applicable to bulk and nanocrystals, nanofilms, polymers, nanowires, and clusters.

Linear augmented spherical-wave method (LASW) First-principle techniques in the electronic structure theory applicable to spherical multiatomic systems such as quantum dots, spherical clusters, and porous systems with spherical nanocavities.

Muffin-tin potential (MT potential) A model one-electron potential spherically symmetric in the atomic region and constant in the interstitial region.

Spherical-MT potential This term spherical-MT potential is taken to mean that the one-electron potential is spherically symmetric in the atomic region and constant in the interstitial region up to the spherical potential barrier that separates, for example, the spherical cluster or quantum dot and the vacuum region.

Bimetallic Ferrofluids

Michael Hilgendorff

Research Center Caesar, 14109 Berlin, Germany

CONTENTS

1. INTRODUCTION

Inorganic colloidal solutions are in the first kinetically stable dispersions of nanoscale clusters or fine particles, which can be crystalline or amorphous, in a solvent [1–4]. If the dispersed material is known to exhibit ferromagnetic behavior in the bulk material, colloidal solutions thereof are generally called ferro fluids or magnetic fluids [5–8]. Magnetorheological fluids are ferrofluids with special hydrodynamic behavior for the colloidal solution [9, 10].

Inorganic colloids are of interest in many applications, primarily as a result of their promising size-dependant electronic properties, known generally as the "quantum-size effect." Moreover, they find applications as the colloidal dispersion itself or for the preparation of assembled particle layers on different substrates by applying inexpensive deposition techniques, that is, Langmuir–Blodgett (LB) [11, 12], layer-by-layer (LBL) assembly [13–16], dip-coating, spin-coating, spraying, or simply drying (for an overview, see, for example, [17–23]).

There have been many reports describing application of mechanical (LB), electrical [24], and magnetic [25, 26] external forces during deposition that influence the symmetry, as well as the properties, of the as-deposited particulate layers. Different deposition techniques demand different properties for the parent colloidal solution, for example, viscosity, and different surface properties for the dispersed nanoparticles, for example, charge. Moreover, each application requires different properties for the dispersed material, for example, biocompatibility for applications in cancer therapy or drug delivery. The availability of different colloidal dispersed

materials for different applications is limited mainly by the surface chemistry of the dispersed materials [27, 28].

It is widely appreciated that the surface-to-volume ratio of nanoparticles increases with the decreasing particle size, for example, the surface chemistry of fine particles dispersed in a solvent becomes more and more important with decreasing particle diameter, thus determining the materials properties. The main properties that are influenced by the size of magnetic nanoparticles are their chemical reactivity, the occurrence of superparamagnetism, and an enhanced magnetic moment per atom [29–33]. Such increased reactivity decreases the oxidative stability of the materials, especially as ferromagnetic materials in general comprise nonnoble metal materials, for example, Fe, Co, Ni. Moreover, the decreasing size causes structural changes compared to bulk materials, which have been well documented in the past [34–37]. In addition, drastically decreased melting points [38, 39] have been observed, as well as the formation of metastable alloy phases of elements (for example, behavior not found for bulk materials) like FeCu [40], FeAg [41], or CoAg [42, 43], which have been theoretically predicted and experimentally verified for nanoscale materials. The latter is not surprising, as inorganic nanoparticles are usually prepared under conditions far from those approaching thermodynamic equilibrium, used to obtain binary alloys of bulk materials [44].

Generally, it is necessary to surface-passivate colloidal nanoparticles with a protecting shell consisting of inorganic and/or organic materials to decrease their reactivity. The important role of the stabilizing organic shell is to overcome the dipole-dipole interactions (magnetic [45–47] and van der Waals [48, 49]) and hinder aggregation and precipitation processes. Solubility and the wetting behavior of such nanoparticles are additionally tailored by the chemical nature of the organic shell material, while the particle properties are mainly determined by their core-shell interaction [50–54]. The increasing reactivity with decreasing size of nanoparticles, as well as the core-shell interaction is of interest in catalysis [55–58]. Of particular interest is the production of extremely small particles covered with chemical compounds which can further enhance the particles catalytic activity.

Single crystals of ferromagnetic nanoparticles, small enough to be a single domain particle, show superparamagnetic behavior above a critical temperature called the blocking temperature T_B [5, 7]. Single domain size and critical temperature are material-dependant properties. The preparation of polycrystalline ferromagnetic nanoparticles (d < single domain diameter) each consisting of several smaller single-crystalline subunits has been reported [59].

Therefore, superparamagnetic behavior limits the number of applications of ferrofluids to those that do not require ferromagnetic behavior for the dispersed material. The determination of the orbital-to-spin ratio of the magnetic moment in fine particle systems via sophisticated characterization methods, for example, studies using synchrotron radiation, may lead to a better understanding of magnetism in the nanoscale. Most properties of inorganic colloids are functions of the particular material(s), particle size, and synthetic procedure due to the different interactions between the nanoparticles and their environment.

In summary, ferrofluids have received much attention in the past several decades for their interesting properties, which can be exploited to develop new technologies such as new refrigerators that employ the magneto-caloric effect [60–63], novel inks for inkjet printers [64, 65], new spin valves [66], or within areas of cancer therapy (such as hyperthermia [67] and apherese [68]), as well as for the investigation of enhanced surface effects and magnetism in these nanoscale materials [29–33]. An extensive list of references and patents describing syntheses of ferrofluids and the investigation of their properties and applications can be found in the magnetic fluid bibliographies [69–74]. It is interesting to note that most articles in the literature concern magnetite (Fe_3O_4) or maghemite (γ-Fe_2O_3). This may reflect the fact that they can both be easily prepared in aqueous solutions and doped with Co, Mn, Zn, or Ni, the latter which allows manipulation of the magnetic hardness of the material.

Many possible applications of ferrofluids necessitate two material prerequisites—high remanent magnetization and high anisotropy at room temperature for the dispersed particles. High remanent magnetization is a characteristic property of soft ferromagnetic materials. Moreover, high anisotropy is a characteristic feature of ferromagnetic three-dimensional elements alloyed with noble metal elements of the platinum group (hard magnetic materials) [75–77]. Soft ferromagnetic materials embedded in a metallic matrix of Cu, Ag, or Au exhibit a technologically important property known as the giant magneto-resistance effect (GMR) [78]. In addition to these properties, the syntheses of colloidal bimetallic magnetic particles may be directed to yield materials with increased stability to oxidative processes. Another desirable feature is the ability to manipulate magnetic particles like noble metal particles upon appreciation of their surface chemistry, and to investigate the combination of optical and magnetic properties. To achieve oxidative stability under applicable conditions is a major problem that has yet to be resolved for nonnoble metal colloidal systems.

The preparation of ferromagnetic/noble metal alloys or core-shell particles is therefore a challenge, as evidenced by the small number of articles (mainly motivated by catalytic applications and ground state investigations of nanomagnetism), which were published in the last century [79–94].

The most important breakthrough came in 2000, through the publication of results by Sun et al. in *Science* on the synthesis and self-assembly of FePt nanoparticle alloys [95]. Since then, interest in the colloidal chemical preparation of bimetallic ferrofluids has been renewed. The as-described syntheses of well-ordered layers of particles are expected to yield novel systems for the preparation of devices with increased data storage capacity, to define a new application of bimetallic ferrofluids [96–129]. Alloys of FeMo [106], prepared by thermal *in-situ* decomposition of zerovalent metalorganic compounds and CoMo alloys [108], prepared in reverse micelles, have been investigated as catalysts for the growth of single- and multiple-walled carbon nanotubes, thus demonstrating a further new application of bimetallic magnetic fluids.

A major issue that remains for bimetallic ferrofluids is a comprehensive investigation of the nanoparticle structure and morphology. Structure and morphology of bimetallic noble metal clusters and colloids alloys—as well as core shell particles, have been unambiguously determined using combinations of ultraviolet/visible/infrared (UV/VIS/IR), X-ray powder diffraction (XRD), high-resolution transmission electron microscopy (HRTEM), energy filtered energy-dispersive X-ray spectroscopy (EDX) and electron energy loss spectroscopy (EELS), X-ray photoelectron spectroscopy (XPS), X-ray absorption near edge spectroscopy (XANES), and extended X-ray absorption fine structure (EXAFS) [19, 56, 130, 131]. By contrast, the determination of structure and morphology of as-prepared bimetallic *ferrofluids* often remain ambiguous, because of the amorphous character of the particles and an increased reactivity of the materials compared to noble metal particles.

2. METHODS

Wet chemical syntheses, based on a bottoms-up approach, of mono- and bimetallic noble metal nanoparticles, alloys, and core-shell particles are well documented and have been thoroughly reviewed in the past [19, 56, 57]. Nonnoble three-dimensional monometallic particles such as Fe [55, 102, 132–134], Co [26, 36, 37, 45, 55, 102, 135–143], or Ni [55, 102, 144–147], have been successfully synthesized by electrochemical reduction [138, 147], chemical reduction by Li [144], hydroborides [55, 137, 141, 142], or alcohols [56] (denoted hereafter as polyols) of metal salts; thermal decomposition (initiated conventionally [26, 36, 45, 132–136, 139, 140, 143–145] or by ultrasound [134]) of zerovalent metal-organic compounds in organic solvents in the presence of bulky stabilizers such as

  (i) fatty acids (in combination with organic amines or phosphines) [26, 37, 102, 141];
 (ii) polymers [36, 56, 133, 139, 140, 143];
(iii) tensides (often called surfactants) [29–31, 45, 55, 56, 59, 133, 137, 142].

In the case of (i), the fatty acids act as stabilizing compounds, i.e., to overcome oxidation and dipole-dipole interactions, while the amines or phosphines control the particle growth. Tensides can be used as stabilizers tetra-octyl-ammonium bromide (TOAB), sodium-bis-2-ethyl-hexyl sulfosuccinate (AOT), sodium-dioctyl sulfosuccinate (MOT),

N-methyl-*N*-(1-oxo)-9-octadecenyl glycine (SO) for inorganic nanomaterials dispersed in organic solvents or as compounds sodium-dodecyl sulfate (SDS) forming stable micelles in heterogeneous oil-in-water systems. Other tensides didodecyl-dimethyl-ammonium bromide (DDAB), cetyl-trimethyl-ammonium bromide (CTAB), (AOT) form a stable emulsion of water droplets in hydrophobic solvents (reverse micelles).

Morphology, size, and size deviation of the particles are controlled by stabilizers. General observations for these systems are increasing particle sizes with decreasing concentrations and decreasing chain length of the stabilizers, and increasing size distributions with increasing particle size. As one challenge of syntheses is to achieve a narrow-size distribution, the reverse micelle technique and the so-called "hot injection" technique have been successfully applied, especially for the preparation of larger particles (diameters > 5 nm–15 nm). Using the latter method, standard size deviations <10% have been experimentally demonstrated (standard size deviations of ca. 5% have been predicted theoretically by choosing a proper combination of solvent and stabilizers [148]). Moreover, the hot-injection technique has been employed to facilitate a further growth of primary prepared particles (seed particles [149–151]) by reactive precipitation of precursors on the surface of seed particles.

The main differences between noble metal and nonnoble ferromagnetic colloidal materials are crystallinity and reactivity. Noble metal colloids are usually highly crystalline and are resolved in their bulk modification or form well-defined polyhedrons [152, 153]. Ferromagnetic colloids, however, are often amorphous, polycrystalline, and/or crystallize in structures not known for bulk materials (depending on the applied synthetic procedure). As a result, determinations of structures by XRD are often ambiguous, except for particles post-treated at high temperatures (at least above 250 °C), which of course results in structural changes and size development of as-prepared particles.

The increased reactivity of nonnoble metal nanoparticles requires the use of chemisorbed rather than physisorbed stabilizers [45], resulting in an increased mass of stabilizers remaining on dried particle surfaces, which further increases the (inelastic) radiation damage in transmission electron microscopy (TEM) investigations and necessitates TEM specific spectroscopy, for example, EDX, in the nanoprobe mode (spot sizes of only a few nm) [154]. The micelle technique, as well as methods producing polymer stabilized particles, results in products with enhanced amounts of organic compounds compared to other techniques. Additionally, the micelle, ferritin, and some polyol reduction techniques (**M**, **R**, **F**, and **P** (see Table 1)) employing aqueous media assist surface oxidation processes. The latter remains a problem for all syntheses and further hinders the determination of structure and morphology. A typical morphology found for nonnoble colloidal particles consists of a core, an inner oxidation layer, and an outer shell of stabilizers, as depicted in Figure 1.

The development of bimetallic ferrofluid syntheses has been based on existing synthetic procedures for monometallic ferrofluids. In general, alloys have been produced by *in-situ* reduction of metal salts or thermal decomposition of zero-valent monometallic metal-organic compounds, or combinations thereof, as well as by decomposition of bimetallic zero-valent metal-organic compounds (see Table 1). *In-situ* reactions require similar reaction kinetics for both metal components, which are mainly determined by the difference in redox potentials. With increasing differences, the reactions will become successive and this is expected to form core-shell particles. Thus, core-shell particles have been produced by the precipitation of metal atoms on the surface of initial seed particles (successive reduction, successive decomposition, or combinations thereof [56]). It has been reported that successive reduction is also dependant on the difference in redox potential between seed particles and successively added metal compounds. With increasing redox potential difference, the reduction of metal salts by seed particles becomes an increasing concurrent reaction, to the metal salt reduction by an additional added reductant. The reaction between preformed particles and added compounds results in the formation of ionic compounds of the seed particles material, which, subsequently, may be further reduced by the reducing agent. This mechanism has been rationalized to explain the formation of bimetallic noble metal alloys produced by successive reduction [56].

Stabilizers are known to change the redox potential of particles and compounds. Thus, the formation of inverse core shell particles, that is, consisting of a core of successively grown compounds covered with a shell of the seed particle material, by an improper (or proper, if desired) choice of surfactants and solvents, cannot be excluded. Comparisons of documented surface tensions of different bulk materials have been taken into account to explore the possibility of formation of Fe, Co, or Ni particles covered with an Au or Ag shell. Reported data of the element surface tensions were usually derived under conditions far from those pertaining to the colloidal syntheses.

A second important parameter determining the formation of bimetallic colloids is the lattice mismatch between both elements. It has been observed to be the main reason for the formation of separated monometallic particles in several syntheses. The possibility of separated particle formation increases with increasing lattice mismatch [56].

In summary, bimetallic noble metal particles form alloys, core-shell particles, or clusters in cluster particles [155], all dependant largely, but not exclusively, on reaction kinetics. Applied methods and comments are summarized in Table 1. Figure 2 provides a schematic overview of possible morphologies. A gallery showing TEM images representing typical results obtained from colloidal systems by various methods is presented in Figure 3.

The Li reduction of metal salts in naphthalene (known as the Rieke method [156]) and the ultrasound decomposition of zero-valent metal-organic compounds (the sonochemical approach developed by Suslick [157]) have been cited as a route to bimetallic ferrofluids. Kirkpatrick et al. has published the preparation of high reactive stabilizer free powders of MgCo alloy [158]. Suslick et al. presented the preparation of Fe-ferrofluids [134], as well as the preparation of bimetallic nanocrystalline FeCo powders [159]. The preparation of bimetallic ferrofluids has not been forthcoming to date. It should be mentioned that Gonsalves and Rangarajan used Suslick's method for the preparation

Table 1. Overview and comments about applied routes to bimetallic ferrofluids.

Synthesis	Materials	Comments	Ref.
D *Decomposition:*			
D$_1$ Thermal decomposition of zero valent bimetallic metal-organic compounds in organic solvents stabilized by the surfactants Duomeen, Solsperse, (FeCo) MOT, or SO (FeNi).	FeCo and FeNi alloys	Noncommercially available compounds; particle composition did not equal compound composition for FeNi; problems of magnetic diameter calculations were discussed.	[79, 80]
D$_2$ Thermal *in-situ* decomposition of zero valent monometallic metal-organic compounds in tetrahydrofuran stabilized by polymer (PVP).	CoRh and CoPt alloys	Noncommercially available, carbonyl free compounds; synthesis under 3 bar H$_2$ pressure; ground-state magnetic surface physics; sophisticated investigation methods.	[101, 115, 126]
D$_3$ Thermal *in-situ* decomposition of zero valent metal carbonyls in octyl ether.	FeMo alloy	Particle size increases with increasing stabilizer amount; carbon nanotube growth.	[106]
E *Electrolysis:* Electrochemical *in-situ* reduction of metal ions in tetrahydrofuran stabilized by tetraoctylammonium ions.	FeCo, FeNi, and NiPd alloys	Metal ions were preformed by oxidation of the desired electrode pair within the same electrolysis cell; tetraoctylammonium bromide was electrolyte; catalysis.	[82]
F *Reduction in apoferritin:* Sodium borhydride *in-situ* reduction of metal salts in the cavities of demineralized ferritin (apoferritin).	CoPt alloy		[100]
R *Reverse Micelles:*			
R$_1$ Sodium borhydride *in-situ* reduction of metal salts in water-in-oil reverse micelles formed by different surfactants (AOT, CTAB, DDAB).	FeCu, CoPt, and CoMo alloys	Aggregated particles for FeCu and CoPt; sophisticated investigation methods for FeCu; carbon nanotubes grown on CoMo.	[84, 90, 116]
R$_2$ As R$_1$ but successive reduction.	Co$_{clusters}$Ag$_{Host}$, Au@Fe@Au, and Fe@Au	H$_2$ reduction of Co in CoAg at moderate 100 °C; Au coating of FeAu particles is ambiguous; different magnetic properties for *similar prepared* FeAu particles were not discussed.	[81, 85, 89, 90, 96–98, 109–112, 125]
R$_3$ Combination of R$_1$ and R$_2$.	FePt@Au and CoPt@Au	The existence of Au at the surface was again not unambiguously verified.	[90, 98, 110, 113]
M *Micelles:* Sodium borhydride co reduction of metal salts in oil-in-water micelles formed by the surfactant sodium dodecyl sulfate (SDS).	FeCu alloy	Elongated and coagulated particles; sophisticated investigation methods.	[86]
O *Organohydroborate Reduction:* Successive reduction of metal salts by tetraoctylammonium triethylborhydride (TOAEt$_3$BH) in tetrahydrofuran.	Fe, Co, and Ni covered with Pd, Ag, Pt, or Au	Mainly noncommercially available reducing compound; principle stabilizer was tetraoctylammonium salt; core-shell morphology is expected but remains ambiguous; catalysis.	[92]
P *Polyol Reduction:*			
P$_1$ *In-situ* reduction of metal salts stabilized by PVP.	CoPt and NiPd alloys	Catalysis; sophisticated investigation methods for NiPd.	[83, 94]
P$_2$ Successive reduction of metal salts stabilized by PVP.	Pd@Ni	"Core-shell" morphology for particles prepared by *in-situ* reduction; catalysis.	[87, 88, 93]
C *Combination:*			
C$_1$ Decomposition of metal carbonyls combined with *in-situ* polyol reduction of metal salts in high boiling solvents.	FePd, FePt, FeCoPt, CoPt, and CoSm alloys	Chen and Nikles used the diol reduction of Co(acac)$_2$ for the synthesis of FeCoPt [120], and the thermolysis of the more expensive Co(CO)$_3$NO for the synthesis of CoPt [121], both instead of the thermalysis of dicobalt octacarbonyl.	[95, 103, 104, 119–123]
C$_2$ Decomposition/transmetallation.	Ag@Co, Co@Pt, and CoPt alloy	Sophisticated investigation methods for AgCo. Co@Pt core-shell morphology remains ambigiuous.	[107, 127–129]
C$_3$ Organoborhydride reduction/ transmetallation.	Fe@Au, Co@Pt, and Co@Au	Noncommercially available compounds; core-shell morphology was expected but remains ambiguous.	[91, 107]

Monometallic particle
Figure 1. Representation of a magnetic nanoparticle prepared via typical colloidal chemical synthesis. The desired core material is covered with an inner oxidation layer of the core material and an outer surfactant layer, necessary to overcome attractive forces. As a result, three interfaces are present, which determine the nanoparticles properties. Adapted with permission from [27], M. Hilgendorff and M. Giersig, "Nanoscale Materials," 2002. © 2002, Kluwer Academic Publishers.

of M50-type steel fluids consisting of 4.0% Cr, 4.5% Mo, 1.0% V, 0.8% C, and 0.3% Mn [160]. The desired crystalline phase could be only obtained after post-treatment of dried particles at high temperatures. Similar results have been reported for the colloid chemical preparation of ternary compounds, such as yttrium iron garnet [161, 162] or barium hexaferrite [163, 164]. The results reflect the fact that "multinary" systems can be well preprepared by colloid chemistry, but the extent of amorphous components in the materials increases with increasing components in the systems. Thus, post-treatments that reduce the particle solubility in aqueous or organic solvents are required to obtain the desired materials.

Bimetallic particles
Figure 2. Schematic of possible results of colloidal **AB** bimetallic ferrofluid preparation. (A) separated particles; (B) small clusters embedded in a nanoparticulate matrix; (C) core-shell particle obtained by either synthesis or segregation; (D) polycrystalline nanoparticle. **B** is denoted to be the heavier element and represented by darker contrast as found typically in TEM investigations.
Figure 3. TEM gallery of bimetallic ferrofluids. (A)–(C) and (E) represent typical micrographs of nanoparticles obtained by different routes; (D) and (F) are special cases (see text for details). Soc.* 124, 11480 (2002). © 2002, American Chemical Society.

Consideration of both the multiple morphology of bimetallic noble metal colloids versus synthetic methods (as mentioned above) and segregation phenomenon of bimetallic bulk alloys prepared under thermodynamic equilibrium conditions [165] leads to the following conclusions. It is clear that bimetallic ferromagnetic nanoparticles, generally prepared under conditions of kinetic control, are rather complicated materials. Thus, the determination of structure and morphology requires the combination of different investigation methods, as well as their careful interpretation.

3. MAGNETISM

The critical discussion of magnetic properties is rather complicated because of a large number of systems and units. In the field of nanoscale magnetic colloids, the confusion is enhanced because of the size dependence of material properties—that is, physical parameters like ε_0, μ_0, ρ, etc.,

defined as constants in descriptions of bulk material properties, become size dependant. In other words, changing the size of nanoscale materials produces new materials. Moreover, different results have been obtained from measurements on different physically conditioned samples, that is, fluids, powders, or assembled layers, because of different degrees of interaction [166, 167].

The first detailed description of magnetism was developed around 1900 using the electromagnetic cgs unit system. Two different systems are still in use—the irrational system, where μ_0 is set to unity (implying that μ_0 does not exist), and the rationalized system, where $\mu_0 = 4\pi$. Both systems rely on different basic equations. Subsequently, the mks-based SI system was developed and is widely employed. The central and unambiguous conversion between cgs and mks in magnetism is based on the relation

$$1\,\text{T} = 10^4\,\text{G}. \tag{1}$$

The translation of the two cgs systems in mks units produced at least two different mks systems, which differ by the factor $4\pi \times 10^{-7}$. The systems and their differences are represented schematically in Figure 4. A more detailed summary and critical discussion of existing systems and units and their relation can be found by Scholten [168]. Misconceptions and misinterpretations of hysteresis curves in textbooks and scientific literature have been reviewed by Sung and Rudowicz [169]. An extensive list of tables describing the transformation between different magnetic units is available via the internet [170].

Nowadays, the SI system is the only legally allowed system that has to be used by engineers and teachers. However, many scientists in the field of magnetism still employ cgs units. The advent of smart materials has led to renewed interest in the investigation and interpretation of magnetic properties. Thorough descriptions of magnetism in textbooks, developed about 30 years ago, increasingly provide descriptions of nanomagnetism. One main difference in contemporary works is the tendency to present magnetic properties in units of energy per atom [171], or in reduced (dimensionless) units, for example, M_R/M_S versus T/T_B, to facilitate the comparison between particle assemblies with different blocking temperatures and saturation magnetizations or to circumvent the confusion of using different systems. In the present review, however, results presented are generally given in cgs units. This holds for M versus H hysteresis loops, as well as for M versus T (or χ versus T)

field cooled/zero field cooled (FC/ZFC) curves. The determination of the susceptibility $\chi \equiv dM/dB$ for $B \to 0$ and χ versus T easily allows one to distinguish between ferro-, para-, and diamagnetic properties of materials. Susceptibilities of diamagnetic materials are negative and temperature-independent. Susceptibilities of paramagnetic materials are positive and decrease with increasing temperature, according to the Curie law. Both susceptibilities are independent of the applied magnetic field strength and very small ($|\chi| \ll 1$). In ferromagnetic materials, the susceptibility is defined differently, since dM/dB is infinite for a single-domain ferromagnet; in other words, there exists a remanent magnetization without an applied magnetic field B. It is generally accepted to use M/B as a measure of the susceptibility which is positive. The "ferromagnetic susceptibility" decreases with increasing temperature, dependant on the applied magnetic field strength, and is orders of magnitudes enlarged (about 100–1000 times) compared to susceptibilities of dia- and paramagnetic materials ($|\chi| \gg 1$). Typical shapes and important parameters obtained from magnetic hysteresis loops and FC/ZFC curves are qualitatively presented in Figure 5.
Figure 5. Qualitative presentation of important parameters obtainable from (A) M versus H hysteresis loops, and (B) ZFC/FC χ versus T plots. Saturation magnetization M_S, remanent magnetization M_R, coercivity H_C, and blocking temperature T_B, are shown. The shape of the dashed lines indicates deviations from the assumption that particles have uniaxial anisotropy.

Figure 4. Schematic drawing of systems and units used in magnetic literature, and how they are related.

Hysteresis loops allow the determination of H_C, M_R, and M_S, which all depend on the applied temperature. One observation in magnetic colloid science is that magnetization remains often unsaturated even at high fields. Furthermore, hysteresis loops sometimes remain unclosed within the range of the applied magnetic field. Values of M_R and H_C obtained from those loops (minor or inner loops) are then decreased, compared to values obtained from closed loops because of incomplete alignment of magnetic domains within the sample. Temperature-dependant ZFC curves are usually determined in order to define the blocking temperature T_B, which decreases with increasing applied magnetic fields. Below T_B, measurements sometimes show a decreased change of the curves shape with decreasing temperature, which often reach a plateau (dashed lines in Figure 5B). The results are rationalized in terms of a failure of the assumption of uniaxial anisotropy. Otherwise, the curves follow the shape of the solid lines in Figure 5B. Quantitative descriptions of these observations are still not available. T_B is commonly determined to calculate the effective anisotropy constant K_{eff} from the Néel equation:

$$K_{eff}V = \ln(\tau/\tau_0)k_B T_B \tag{2}$$

where τ is the relaxation time of magnetization over an energy barrier $\Delta E = K_{eff}V$ (assuming uniaxial anisotropy), τ_0 an attempt time, typically set between 10^{-12} s–10^{-9} s, and V, the magnetic volume. In dc susceptibility experiments over a time range of t = 100 s, $\ln(t/\tau_0)$ has values, therefore, in the 25–32 range. Hence, the magnetization of a material will relax within the measurement time t if $\tau \leq t$. More detailed information is available by Leslie-Pelecky and Rieke [8] and Binns [165]. The following relations between SI and cgs units were found to be valid in the literature reviewed here [79–129]:

$$H \text{ [Oe]} = 10^{-4}H \text{ [T]} \tag{3}$$

$$M \text{ [emu/g]} = M \text{ [Am}^2\text{/kg]} = M \text{ [J/(Tkg)]} \tag{4}$$

$$K_{eff} \text{ [erg/cm}^3\text{]} = 0.1K_{eff} \text{ [J/m}^3\text{]} \tag{5}$$

Critical is the particular term of M given in emu per mass, per unit volume, or as μ_B/atom. Measurements of M by standard methods gives only emu (or 10^{-3} Am^2). The exact determination of magnetic mass or volume is therefore required. The same holds for calculations of K_{eff} requiring V. Magnetic moments can be divided into orbital and spin moments. General observations of nanoscale materials showed enhanced orbital-to-spin ratios of magnetic moments for colloids with increasing degrees of freedom, indicating that the enhanced orbital magnetic moment is mainly effected by the orbital magnetic moment of surface atoms. Thus, one can conclude that the degree of freedom of the orbital magnetic moment of surface atoms is rather influenced by interactions with the particles environment, while the spin moment of colloids is mainly a function of the size of inner core atoms.

It is well known that oxidatively sensitive colloids consist of a magnetic core and a nonmagnetic (that is, dia-, para-, or antiferromagnetic) shell. This is reflected by the fact that particle diameters are always found to be smaller compared to TEM diameters when calculated from magnetic measurements. The first method for magnetic diameter determination of nanoparticles was developed by Chantrell et al. and published in 1978 [172]. More recently, Berkov et al. developed a new method for the determination of the particle magnetic moment distribution in a ferrofluid [173, 174], and Wiedenmann et al. presented magnetic$_{core}$-nonmagnetic$_{shell}$ determinations by small-angle scattering investigations of ferrofluids using polarized neutrons [175, 176].

The shell typically consists of a nonmagnetic outer shell of stabilizers and probably a second inner shell (Fig. 1). The outer shell defines the solubility of the colloid and may impart some stability to oxidation, which increases with increasing binding energy of the stabilizer, that is, chemisorption > physisorption. Existence and composition of the inner shell depends on two factors, the interaction of stabilizers with the particle surface and the extent to which surface oxidation is excluded during syntheses. The interaction between stabilizer and particle surface is mainly determined by the stabilizers electron σ-donation capability, which increases with its increasing electron density. On the other hand, the binding energy between stabilizer and particle is determined by the stabilizers π-electron acceptor ability (electron back donation from the metal particle to the stabilizer), which decreases as the stabilizers electron density increases [177]. It has been reported that electron injection into the colloid surfaces results in quenching of the particle surface atoms orbital magnetic moment [51, 52]. A "dead" magnetic surface layer will be formed if the quenching is complete.

Reduced binding energies between stabilizer and colloid enhance the potential for particle oxidation, that is, the formation of different sized oxide surface layers becomes more and more possible. The oxide surface layer can therefore reveal ferrimagnetic (in the case of iron oxide) or antiferromagnetic (in the case of cobalt oxide) properties, which further enhances the uncertainty of magnetic volume determinations from magnetization curves. Furthermore, the formation of oxide layers changes the interaction with stabilizers (electron back donation) and the occurring oxide$_{hell}$/particle$_{core}$ interaction must be further take into account. Generally, a progress in anisotropy is observed in oxide-covered monometallic ferrofluids, as well as an exchange bias causing a shift of FC hysteresis loops to negative applied fields.

Commonly employed methods for investigations of concentration in colloids are atomic absorption spectroscopy (AAS) and EDX. Volumes are then calculated using TEM diameters, which can be extremely different if the real particle structure is unsolved because of different surface-to-volume ratios (see Fig. 6). The calculation of "dead" surface layers therefore remains ambiguous. The techniques of AAS and EDX do not allow one to distinguish between different oxidation states of elements, thus rendering the exact determination of magnetic volumes.

Different results have been obtained while investigating different physically conditioned samples. The reasons cited are different magnetic dipole-dipole interactions in fluids, powders, or assembled layers. Cooling a liquid to low temperatures produces a frozen liquid, that is, particles embedded in a solid matrix. The degree of interaction is then

Icosahedra: FF = 64 % (five fold symmetry)   **Sphere: FF = 74 %** (close packed)

10 nm Ø Co

V = 317 nm^3,   24737 atoms
S = 239 nm^2,   3610 atoms,
i.e. space for 1195 surface molecules

V = 524 nm^3,   47396 atoms
S = 314 nm^2,   5323 atoms,
i.e. space for 1570 surface molecules
Figure 6. Calculation of the surface-to-volume ratio and the surface area of Co nanoparticles, 10 nm in diameter, for two different geometries with the fill-factor FF. Adapted with permission from [27], M. Hilgendorff and M. Giersig, "Nanoscale Materials," 2002. © 2002, Kluwer Academic Publishers.

dependant on concentration. Available results showed that dipole-dipole interaction is more affected by particle size than by volume fraction, that is, interaction will increase faster with increasing particle size than with decreasing interparticle distance [166, 167].

In conclusion, one has to accept that the magnetic properties presented here are, in principle, only qualitatively comparable for particles prepared by similar methods.

4. RESULTS

A detailed description of different methods applied for the preparation of bimetallic ferrofluids, their catalytic and magnetic properties, and conclusions on determination of structure and morphology of dispersed materials will be given below. The results are discussed separately by applied methods and are summarized in Table 2.

4.1. D: Decomposition

The thermal decomposition of organic compounds provides the advantage of gaseous by-products which are not present in the final fluids. Oxide and carbide formation at the surface of monometallic colloids prepared from metal carbonyls has been observed.

4.1.1. D_1: Decomposition of Bimetallic Metal-Organic Compounds

The first successful route to bimetallic magnetic fluids, prepared in hydrocarbons by thermal decomposition of non-commercially available zero-valent bimetallic metal organic compounds under inert gas conditions, was published by Lambrick et al. FeCo-containing fluid was reported in 1985 [79] and synthesized by thermal decomposition of the binuclear precursor $[(\pi\text{-}C_5H_5)Fe(CO)_2Co(CO)_4]$ in toluene in the presence of commercially available surfactants (Duomeen-T, Duomeen-TDO, or the polymeric hyperdispersant Solsperse 3000). The precursor was prepared by reaction of $[(\pi\text{-}C_5H_5)Fe(CO)_2Cl]$ and $([Co(MeOH)_6]^{2+} [Co(CO)_4]^-)$ at room temperature (RT) over 16 h in methanol (MeOH) [178]. The compounds $[(\pi\text{-}C_5H_5)Fe(CO)_2Cl]$ and

$([Co(MeOH)_6]^{2+} [Co(CO)_4]^-)$ have been prepared by Piper et al. [179] and by the disproportionation of $Co_2(CO)_8$ in MeOH at ~30 °C. Typical starting concentrations of the precursor were 100 g/l and 150 g/l, corresponding to a range where such colloids show magnetorheological behavior. The ratio precursor/surfactant was adjusted to either 1 wt% or 0.5 wt%. Transmission electron microscopy investigations showed particles with diameters between 5 nm and 8 nm with a narrow size distribution. The formation of the ordered 1:1 alloy phase of FeCo has been concluded from HRTEM.

Magnetic investigations have been done under different conditions using a vibrating sample magnetometer. Room temperature measurements show that M_S (in the order of 1–3 JT^{-1}kg^{-1}) varies with the preparative conditions. Magnetic particle diameters obtained by applying the method of Chantrell et al. [172] were smaller than the TEM diameters. Magnetization measurements in the frozen state showed no coercivity and remanence. More generally, it was concluded that Solsperse 3000 provided better, but not complete, protection against oxidation, while Duomeen-TDO provided better protection against sedimentation. Carbide formation was not discussed. It was mentioned that no alloy formation could be observed under similar conditions by *in-situ* decomposition of iron and cobalt carbonyls.

FeNi-containing fluid [80] was prepared by thermal decomposition of the trinuclear bimetallic cluster $[\pi\text{-}(C_2H_5)_2Ni_2Fe(CO)_5]$, which has been prepared, as described by Hsieh and Knight [180]. Methyl naphthalene or petroleum ether were used as solvents. The particles were stabilized by MOT or SO. The weight ratio of compound/surfactant was adjusted between 1.08 and 1.65. Typical concentrations of the bimetallic compounds in the starting solutions were 44–70 g/l. This again is in a range where such colloids show magnetorheological behavior. The structure of the particles was determined from HRTEM investigations (images were not shown). The authors presented average diameters of 7 nm, and concluded from lattice spacings, the formation of the $L1_2$ phase of ordered Ni_3Fe, which was different from the starting composition of the bimetallic precursor (Ni_2Fe). These results were rationalized in terms of the greater reactivity of Fe to oxygen and surfactants, reflecting the fact that oxidation remains a problem in these materials. Carbide formation was not discussed.

Magnetic investigations have been done under a variety of conditions using a vibrating sample magnetometer. Room temperature measurements show that M_S (in the order of 0.3–0.5 JT^{-1}kg^{-1}) varies with the TEM diameter and does not saturate in applied fields up to 1 T. T_B is >4.2 K and <77 K, H_C at 4.2 K is 13 mT. Particle sizes have also been calculated from magnetic measurements using the method of Chantrell et al. [172], showing again the typical result that the magnetic diameter is smaller than the TEM diameter. Problems of the accuracy of this calculation and calculations of K_{eff} (in the order of some 10^6 erg/cm^3) concerning uncertainties in concentration determination were discussed.

4.1.2. D_2: Decomposition of Monometallic Metal-Organic Compounds

CoRh [115, 126] and CoPt [101] alloys have been successfully prepared by *in-situ* thermal decomposition of carbonyl-free, zero-valent, metal-organic compounds $Co[(\eta^3\text{-}C_8H_{13})\cdot$

Comments and results presented as supporting information (supp.) to cited references are given in italics. For details see text.

$(\eta^4\text{-}C_8H_{12})]$ and $Rh[(acac)(\eta^4\text{-}C_8H_{12})]$ or $Co[(\eta^3\text{-}C_8H_{13})\cdot$ $(\eta^4\text{-}C_8H_{12})]$ and $Pt_2(dba)_3$, respectively. Syntheses have been performed using tetrahydrofuran (THF) as the solvent. Particles were stabilized by poly-(N-vinyl-2-pyrrolidone) (PVP) and the precursors were decomposed at room temperature under a H_2 pressure of 3 bar during 15 h–64 h. The motivation for using carbonyl free metal-organic compounds and PVP as a stabilizer was that the surface properties of the final particles remain unchanged.

The compound $Co[(\eta^3\text{-}C_8H_{13})(\eta^4\text{-}C_8H_{12})]$ has been prepared by Otsuka and Rossi [181], while $Pt_2(dba)_3$ has been prepared using the method of Moseley and Maitlis [182], both with minor modifications. Information on the synthesis of $Rh[(acac)(\eta^4\text{-}C_8H_{12})]$ was not given. The final particle compositions reflected the precursor compositions and were adjusted by varying the ratio of the metal-organic compounds, that is, Co_3NM, $CoNM$, and $CoNM_3$ (NM = Rh, Pt). Typical concentrations of the metal-organic compounds in the starting solution were $\sim$8 g/l. Structural investigations were performed by HRTEM and wide-angle X-ray scattering (WAXS). The latter method shows bimetallic bonds within the particles, thus verifying the formation of alloys. The degree of ordering decreased with increasing Co content, and the authors described Co_3NM and $CoNM$ particles as consisting of a crystalline NM rich core surrounded by a disordered Co rich shell. Transmission electron microscopy and HRTEM analysis showed extremely small particles (1 nm–2.6 nm in diameter) with a small size distribution. The presented TEM and HRTEM images were consistent with those expected for small bimetallic colloids prepared by different methods, that is, D_2, E, O, P, and C_2 (for alloy formation). In particular, TEM and HRTEM (insert) of CoRh particles dried from a solution on a carbon-coated Cu-grid, representing morphology and size deviation of several nanoparticles $d < 3$ nm and prepared by various methods, can be viewed in Figure 3A.

Super-conducting interference device (SQUID) measurements showed an increase of T_B for CoPt and a decrease of T_B for CoRh with increasing noble metal (NM) content in a range between 10 K and 20 K. T_B was calculated from ZFC/FC versus T curves. The magnetization for all particles does not saturate at 5 T. H_C and magnetic moments are increased compared to pure Co colloids. H_C and magnetic moments per Co atom of $Co_{1-x}Pt_x$ particles increase with increasing x. Estimated values were 0.518 T, 1.76 T, and 2.057 T of H_C (T = 0) and 1.35 μ_B, 1.5 μ_B, and 1.95 μ_B of the magnetic moments (5 K, 5 T) for $x = 0.25$, 0.5, and 0.75. $Co_{0.5}Rh_{0.5}$ colloids have been estimated to show a magnetic moment per Co atom of 1.9 μ_B (5 T) and K_{eff} was found to be 1×10^6 Jm^{-3}. The differences in fine particle magnetism with the corresponding materials bulk magnetism was discussed.

4.1.3. D_3: Decomposition of Monometallic Metal-Organic Carbonyls

The *in-situ* thermal decomposition of commercially available metal carbonyls has been used for the preparation of FeMo ferrofluids [106]. Synthesis has been achieved by refluxing a solution of $Mo(CO)_6$ and $Fe(CO)_5$ in dioctylether for 30 min, in the presence of equimolar amounts of octanoic

acid and/or ethyl hexyl amine as stabilizers under an inert atmosphere. Typical carbonyl concentrations of the starting solutions were 45 g/l and the Fe/Mo molar ratio was adjusted to 5/1. A structural investigation was conducted by HRTEM and compositional analysis by EDX. The former was consistent with highly crystalline particles. Energy-dispersive X-ray spectroscopy analyses gave a mole-atom ratio for the final particles of Fe/Mo = 96/4. This result was explained in terms of the lower decomposition rate of $Mo(CO)_6$ compared to $Fe(CO)_5$. However, presented EDX spectra showed K- and L-edge signals from Fe and L-edge signals from Mo, although the composition calculations from EDX were not explained. Different particle sizes were achieved by varying the nature and concentration of stabilizers. One surprising result of this work was the fact that the particle size increases with increasing octanoic acid concentration, which represents a reversal of many published results. The authors explained their observations by assuming a lowering of the reaction rate for carbonyl moieties in the presence of octanoic acid, which means a lower number of nuclei were formed initially. Different reaction kinetics for the $Fe(CO)_5$ or $Mo(CO)_6$ decomposition in the presence of stabilizers, which may explain both the observed reversal and the discrepancy between initial precursor composition and the composition found by EDX, were not considered. However, it was agreed that more work was necessary in order to clarify discussion of presented results. Nevertheless, TEM and HRTEM images as shown represent typical images of bimetallic nanocrystals prepared by various methods, that is, D_1, D_3, and C_1. An image of 8.5 nm particulate alloys is given in Figure 3B. Magnetic properties were not investigated. The particles were used as a catalyst for the growth of single-walled carbon nanotubes (SWNT). The results appear to indicate that an upper limit of particle size exists to grow SWNT.

4.2. E: Electrolysis

This novel procedure was developed by Reetz et al. and differs greatly from other conventional techniques [82]. The method is based on the *in-situ* electrochemical reduction of metal salts in THF under inert gas conditions. Metal ions were preformed by oxidation of the desired metal electrode pair in the presence of 0.1 M TOABr, which acts as a stabilizer and electrolyte. Oxidation of the electrodes and reduction of the preformed metal salts occurs in a commercially available electrolysis cell (volume of 80 mL). By employing this configuration, Ni_xPd_y ($x/y = 0.25$, 0.32, and 5.25), $Fe_{74}Co_{26}$, and $Fe_{72}Ni_{28}$ particles have been prepared, which may be redispersed in THF (concentrations of 1 M [82]). Typical particle sizes as determined by TEM were 2.5–3.5 nm for NiPd and 2.5–3.0 nm for FeCo and FeNi. Alloy formation was expected.

4.3. F: Reduction in Apoferritin

A further unusual approach for preparation of bimetallic ferrofluids has been developed by Warne et al. (NanoMagnetics Ltd.) [100]. The synthesis is based on the *in-situ* reduction of metal salts by $NaBH_4$ within the empty cavities of the demineralized protein ferritin (apoferritin). Demineralization has been done according to the method of

Funk et al. [183]. The synthesis allows for the preparation of monodisperse, biocompatible, aqueous, magnetic fluids, and post-annealing of assembled layers thereof, in reductive atmosphere, result in carbon protected nanoparticulate films. Carbon protection is the result of reductive protein decomposition. NanoMagnetics Ltd. hold the patent for the preparation of a large range of materials prepared via this method [184]. In the case of bimetallic ferrofluids, only the preparation of CoPt has been published.

CoPt was prepared by *in-situ* reduction of ammonium tetrachloroplatinate and cobalt acetate-loaded, aqueous protein solution by $NaBH_4$. The as-prepared particles (d $\sim$ 3.5 nm) were amorphous, as could be revealed by electron diffraction. Further investigations have only been done after the annealing of dried powders in hydrogen at 650 °C for 1 h.

4.4. R: Reverse Micelles

The water-in-oil reverse micelle technique is very popular and has been applied for the preparation of a large number of colloidal materials. Importantly, this technique has provided well-separated colloidal particles with diameters up to 15 nm or more with narrow size distributions. Figure 3C is representative of typical images of particles prepared via this method. A further advantage of the procedure is the possibility of controlling the size of colloids by controlling the size of micelles, which is dependant on the H_2O/surfactant ratio.

4.4.1. R₁: In-Situ Reduction

FeCu alloys have been prepared by Duxin et al. [84] by $NaBH_4$ *in-situ* reduction of $Fe(AOT)_2$ and $Cu(AOT)_2$ in isooctane under inert atmosphere. Initial compositions were reported as 30% (70%) $Fe(AOT)_2$ and 70% (30%) $Cu(AOT)_2$. The total concentration was maintained at 0.1 M. Structural characterization was achieved by XRD, TEM, EDX, EELS, and Mössbauer experiments. Transmission electron microscopy showed aggregated particles, 5–15 nm in diameter, with a broad-size distribution for both starting compositions. This observation is not typical for this method. The final composition obtained from EDX (spectrum not given) was similar to the starting composition for Cu-rich samples and different for Fe-rich samples. The former gave rise to alloy formation, the latter to the formation of pure Fe and alloy composites. These assumptions have been confirmed by XRD, showing a single reflection for α-Fe for Fe-rich samples and by EELS. Results from EELS on the $L_{2,3}$-edges of Fe and Cu and the K-edge of B of dried samples revealed a homogeneous distribution of the three elements in Cu-rich and a heterogeneous distribution in Fe-rich samples. The authors concluded from this investigation that the procedure led to the formation of FeCuB alloys. Mössbauer spectra were consistent with a metallic alloy. Fe^{3+} and Fe^{2+} in the Cu-rich sample and mainly α-Fe and Fe^{3+} in Fe-rich samples could be detected. It was expected that Fe^{3+} is derived from iron oxide and Fe^{2+} results from incomplete reduction. Super-conducting interference device magnetometry of Cu-rich (Fe-rich) samples at RT showed M_S, and H_C of 1.1 emu/g (51 emu/g), and 24 Oe (531 Oe), respectively.

CoPt colloids have been prepared by $NaBH_4$ reduction of the metal chlorides in reverse micelles formed by CTAB in octane under inert atmosphere [90]. The Co concentration was chosen to be 10 mM. Initial compositions were CoPt and $CoPt_5$ and final compositions were not published. The colloids were investigated by XRD and TEM; the former revealed good crystallinity and no formation of ordered alloys. The size distribution cannot be deduced from the as-presented results. Boride formation is not discussed. A SQUID magnetometer was used for magnetization measurements. T_B was obtained from ZFC plots in a field of 1 kG. H_C was determined from M versus H curves recorded at 2 K. Values of T_B, H_C, and μ_{eff} for CoPt ($CoPt_5$) were reported as 140 K (130 K), 2700 Oe (2000 Oe), and 0.0598 emu/g (0.0357 emu/g), respectively.

CoMo colloids have been prepared by $NaBH_4$ reduction of the metal chlorides in reverse micelles formed by DDAB in toluene under inert gas conditions [116]. Typical concentrations were 60 g/L. The initial metal composition was equimolar and only slightly changed during reaction (determined by XPS; spectra not given). Transmission electron microscopy data presented well-separated particles (the typical image of colloids prepared by this technique (see Fig. 3C)), possessing an average diameter of 8.5 nm. The colloids were used for the growth of SWNTs and it was pointed out that nanoparticles as small as the diameter of SWNTs are not necessary for the nanotube growth.

4.4.2. R₂: Successive Reduction

The formation of Co@Ag core-shell particles [81, 85, 89] has been realized by a process involving successive reduction of a 10-fold molar excess of Ag^+ ions on the surface of Co nanoparticles, in reverse micelles formed by AOT in n-heptane. The reduction of Ag^+ was carried out by UV irradiation or $NaBH_4$ treatment. A typical starting concentration of cobalt salt was 0.1 M. Transmission electron microscopy investigations show well-separated monodisperse particles of about 10 nm in diameter. Only fcc Ag reflections were recorded in the XRD pattern.

Super-conducting interference device magnetometry and electron paramagnetic resonance (EPR) measurements were applied for investigation of magnetic properties. The as-prepared particles remain superparamagnetic down to 2 K measured in a field of 50 Oe. M_S and K_{eff} were calculated from high-field magnetization data (H > 30 kOe) at different temperatures and determined to be 646 emu/g and 2×10^7 erg/cm³, respectively. The formation of CoO was extrapolated from the obtained inverse susceptibility data which indicated antiferromagnetic interactions. Calculation of the magnetic volume resulted in a Co cluster size of only 10 atoms, that is, the synthesis has produced small Co clusters embedded in a nanoparticulate Ag matrix (see Fig. 2B). After moderate post-treatment of the particles in H_2 at 100 °C for 2 h, values for M_S and K_{eff} increased to 1700 emu/g and 8.5×10^7 erg/cm³, respectively, indicating the reduction of CoO to metallic Co. It is worthy to note that the value of M_S was higher than the bulk value for Co. The observation is well known for small Co clusters. However, the question remains as to whether the reduction is limited to Co clusters near the surface of the Ag matrix, as depicted in Figure 2B.

The successful synthesis of Fe@Au core-shell particles has also been reported. The procedure involves successive $NaBH_4$ reduction of $HAuCl_4$ on the surface of Fe particles, in reverse micelles formed by CTAB in octane [98, 110–112, 125]. Metal concentrations of 0.1 M were typically employed. Investigations of structure and morphology were performed using UV/VIS, XRD, HRTEM, and later XANES (2002) [125]. X-ray powder diffraction data revealed good crystallinity. The results of TEM were indicative of aggregated particles with a core-shell structure. Surprisingly, the core had a dark contrast, while the shell was shiny. This observation was contrary to existing theory and in published results of core-shell particles, the disparity was not discussed by the authors. Conventional wisdom would expect a darker contrast for the heavier Au shell and a lower contrast for the lighter Fe core. Such observations have been made and published for bimetallic noble metal core-shell colloids. Moiré patterns, visible in HRTEM investigations, verify a core-shell structure [112]. Interpretations of XANES experiments revealed that the Fe in these particles consisted mainly of iron oxide, demonstrating unsuccessful protection of the Fe core by the Au shell. The authors suggested that the Fe core was not centered in the Au shell and thus parts of the core were not covered by a protective Au layer. Incomplete coverage through Au island formation on the Fe surface, as well as alloy formation of FeB, FeAu, and FeAuB that is possible under these preparation conditions, were not discussed.

Due to these many factors, different magnetic properties must be expected for different samples prepared in a similar way. Values for T_B (1 kOe), H_C (2 K), and M_R (2 K) have been reported as 50 K, 400 Oe, and 13.67 emu/g, respectively.

Formation of Au@Fe@Au core-shell particles has been achieved using similar strategies to those used for the Fe@Au particles presented above. Au@Fe particles were first prepared vice versa to Fe@Au particles in similar concentrations in reverse micelles formed under identical conditions. Subsequently, these have been used as the core material for the preparation of Au@Fe@Au onions [96, 97, 109, 110, 125]. The techniques of TEM, XRD, and EDX have been applied for structural investigations. Again, XRD demonstrated only crystallinity (diagram not presented). Transmission electron microscopy showed aggregated particles with an untypical broad-size distribution. The particles consisted of a dark core of Au and a shiny shell of Fe, as expected from theory. The outer second shell of Au could not be resolved. Results from EDX measurements in the nanoprobe mode (spot size = 2 nm) were consistent with Au enrichment at the surface (spectra not available). The authors did not discuss their results with respect to the XANES investigations of Au@Fe@Au colloids, as well as the possible alloy formation of FeB, FeAu, and FeAuB. Similar rationales were not discussed with reference to magnetic properties. Values for T_B (1 kOe), H_C (10 K), and M_R (10 K) were reported as 50 K, 420 Oe, and 3.6 emu/g, respectively.

Co@Au particles [90, 110] were prepared in a similar fashion to Fe@Au, although detailed investigation of structure, morphology, and composition were not revealed. T_B (100 Oe) and H_C (10 K) were determined by SQUID magnetometry to be 60 K and 20 Oe.

4.4.3. R_3: Combination of In-situ and Successive Reduction

FePt@Au and CoPt@Au have been prepared by reduction of $HAuCl_4$ on the surface of preformed bimetallic particles, prepared similarly to CoPt particles presented in Section 4.4.1 and by the same group [90, 98, 110, 113]. Initial compositions of the core particles were CoPt and $CoPt_3$, and Fe_2Pt, FePt, and $FePt_3$. Final compositions were stated to be similar to the starting composition. $FePt_3$ was characterized as a homogeneous alloy and as an intermetallic compound. Transmission electron microscopy images showing core-shell particles were not presented. Oxide and boride formation was not discussed.

A detailed discussion of magnetic properties requires a detailed knowledge of structures. The results of magnetic measurements of references [90, 96–98, 109–113] presented in Table 2, will therefore only be given for completeness.

4.5. M: Micelles

Syntheses of ferromagnetic colloids by $NaBH_4$ reduction of metal salts in oil-in-water micellar solutions have been reported. The synthesis of elongated FeCu alloys (alloy formation in bulk materials is not known under conditions of thermodynamic equilibrium) published by Duxin et al. is the only example of bimetallic ferrofluids prepared by this method [86].

FeCu alloys have been synthesized by *in-situ* $NaBH_4$ reduction of 30% $Fe(DS)_2$ and 70% $Cu(DS)_2$, forming ellipsoidal shaped micelles of 2.7 nm hydrodynamic diameter at critical micellar concentrations of 1.34 mM (synthesis under inert atmosphere). Typical structure, morphology, and composition of the resulting particles have been investigated by XRD, HRTEM, EDX, EELS, and Mössbauer experiments. Transmission electron microscopy showed coagulated networks of elongated particles of 6.6 nm average diameter (Fig. 3D). X-ray powder diffraction (XRD), electron diffraction (ED), and fast fourier transformation (FFT) of HRTEM revealed good crystallinity, and calculations thereof were in good agreement with the [111] lattice spacing for bulk fcc Cu. Neither an oxide phase nor the α-Fe phase could be detected. Alloy formation was concluded from Mössbauer experiments. The average composition was determined by EDX, employing a 35 nm spot (spectra not shown), giving compositions of 14% Fe and 86% Cu. The authors explained this result in terms of incomplete reduction of $Fe(DS)_2$. Electron energy loss spectroscopy (EELS) on the $L_{2,3}$ edges of Fe and Cu showed Fe enrichment at the surface of the particles. The pattern of results was consistent with the formation of a heterogeneous FeCu alloy. Moreover, the presence of interstitial boron, well known for colloid preparations by $NaBH_4$ reduction of metal salts in the presence of water and investigated in detail by Glavee et al., [137, 185] was expected.

Magnetic properties have been determined by SQUID magnetometry. The magnetization at 1.8 K did not saturate in applied fields up to 50 kOe. M_S was calculated by extrapolation to zero at 40 emu/g. A value for H_C of 250 Oe was determined. T_B was determined from ZFC curves at various applied fields, showing a decrease of T_B with increasing H. The values were 9.5 K, 8.5 K, and 7.5 K for applied

fields of 20 Oe, 50 Oe, and 100 Oe, respectively. K_{eff} has been estimated from the Neel equation and reported as $\sim 10^5$ erg/cm^3. Uncertainty in the value was explained in terms of the colloidal particle shape, which makes the determination of the particle volume rather difficult.

4.6. O: Organohydroborate Reduction

This method has been developed by Bönnemann more than 10 years ago for the preparation of highly dispersed mono- and bimetallic particles, with typical diameters <5 nm, in organic solvents [55]. This nonaqueous method additionally produces boron-free final product materials. Typical starting concentrations for the metal salt were ~ 25 mM. The method's success based on the preformation of novel, noncommercially available reducing agent TOAEt$_3$BH (synthesized in THF by the reaction of KEt$_3$BH with TOABr). KEt$_3$BH was used rather than the more commonly employed Li analogue (super hydride), because KBr is insoluble in THF and can be separated from the product. As a result, the synthesis leads to products free of impurities derived from the reducing agent. Parallels to the approach are found in work developed by Reetz (**E**).

Fink et al. [186] provided evidence that both the tetraoctyl-ammonium (TOA) cation, as well as the counterion from the reduced metal salt, comprise the stabilizing shell on the surface of noble metal nanoparticles. The inner shell consists of counterions and the outer shell is formed by TOA$^+$. These investigations were later confirmed by Bucher et al. [187] using XANES and metastable impact electron spectroscopy (MIES), correcting earlier assumptions by Bönnemann and Reetz of a vice versa stabilizing shell composition.

The preparation of nanoparticulate Fe, Co, and Ni passivated with a protecting layer of Ag, Au, Pd, and Pt has been reported in the patent literature [92]. The procedure involves addition of solutions of noble metal salts in THF to mixtures of preprepared Fe, Co, or Ni nanoparticles and excess strong reducing compounds (e.g., superhydride, modified superhydride, or trialkyl aluminium hydride) in THF or toluene over a period of several hours (14 h–16 h). The particles thus obtained showed an increased stability of magnetization compared to both unpassivated seed particles and particles covered with Au by successive transmetallation ([91], see **C$_3$**). The decreased stability of particles prepared via **C$_3$** was ascribed to island formation of the protecting noble metal shell. Detailed structural and morphological investigations, as well as differences in magnetic properties of different compositions were not presented.

4.7. P: Polyol Reduction

Polyols have been used as moderate reducing compounds for the preparation of colloids for several years [188]. One advantage of this method is that alcohols with one, two, or more hydroxyl groups are oxidized to aldehydes or ketones during reaction, that is, they do not form ionic by-products. Moreover, this method allows for the preparation of colloids in hydrophilic, as well as hydrophobic media, by choosing alcohols with corresponding properties. The polyol method

has been modified for the preparation of bimetallic micronsized particles [189]. The modification is based on the hydrolysis of mixed metal salts prior to reduction, resulting in the formation of hydroxides.

4.7.1. P$_1$: In-situ Reduction

CoPt   The modified polyol process has been applied to produce CoPt alloy colloids [83]. Cobalt chloride and hexachloroplatinic acid were dissolved in a 4/1 mixture of ethylene glycol/diethylene glycol, hydrolyzed by adding aqueous NaOH, and heated to reflux for 2 h under N$_2$ in the presence of poly-(N-vinyl-2-pyrrolidone) (PVP). A typical starting concentration of 0.4 M in Pt was employed, the Pt/Co ratio adjusted to 3 and the PVP concentration (as monomeric residue) maintained at ~ 50 mM.

The final colloidal dispersion has been investigated by TEM and XRD. Transmission electron microscopy exhibits isolated particles of ~ 1.7 nm average diameter. X-ray powder diffraction showed rather broad reflections due to the small size of the particles. The authors concluded from XRD that the colloid consisted of CoPt$_3$ particles or a mixture of CoPt and Pt. An unambiguous structural determination from XRD was not possible because of overlapping reflections for CoPt$_x$ and Pt, further complicated by the broadening effect due to the small particle size. Magnetic properties were not investigated. The colloid was applied as catalyst for the hydrogenation of cinnamaldehyde showing high selectivity and conversion. The particles were found to withstand the hydrogenation reaction at 333 K and 4 MPa.

NiPd   A minor modification to the (modified) polyol process has been found to be suitable for the preparation of NiPd alloy colloids [94]. Palladium acetate and nickel sulfate were chosen instead of hexachloroplatinic acid and nickel acetate; Pd acetate was dissolved in dioxane prior to use. Initial reaction concentrations were 4 mM (total concentration of metal salts at various Ni/Pd ratios). Synthesis was performed by refluxing the hydrolyzed metal salts in ethylene glycol for 3 h under N$_2$ in the presence of 14.3 times molar excess of PVP (as monomeric unit). Investigations by TEM and HRTEM revealed well-separated crystalline particles with an average diameter of about 2 nm. Interpretation of XPS, XANES, and EXAFS measurements resulted in a Pt-rich random alloy structure of the particles. The colloids have been found to be an excellent catalyst for the hydrogenation of nitrobenzene. Maximum activity was found for a composition of Ni$_2$Pd$_3$.

4.7.2. P$_2$: Successive Reduction

A successive polyol method was described in 1999 for the preparation of Pd@Ni core-shell particles stabilized by PVP [93]. It is necessary to point out that the authors published the procedure previously, but the work concerned the formation of alloys while applying the same investigation methods (TEM, XRD, XPS) [87, 88]. The synthetic procedure is based on the prepreparation of PVP-stabilized Pd particles and involves reflux of 0.16 mmol H$_2$PtCl$_4$ and 1.6 mmol PVP (as a monomeric unit) in a mixture of 640 ml H$_2$O and 160 ml ethanol for 3 h. The preformed Pd particles (initial concentration of ~ 8 mM Pd (atoms); d = 2.5 nm) were then

refluxed in 1-propanol, together with various amounts of Ni acetate for 3 h under N_2. As a result, monodisperse colloids possessing particle diameters in the range 2.5–2.8 nm were formed by using a Ni/Pd ratio up to 1 (the theoretical thickness of the Ni shell for a ratio of 1 is about 1.5 layers). Further increases in the Ni/Pd ratio led to an remarkable increase of the particles diameter along with a broadening of their size distribution. Super-conducting interference device measurements at 1.8 K showed a remarkable increase of the magnetic moment above a Ni/Pd ratio of ∼0.07. It is concluded that the anomalous increase of the magnetization may correspond to the giant magnetic moment effect in ultrafine Pd particles [190].

4.8. C: Combination

Thermal decomposition of zerovalent metalorganic Fe or Co compounds, combined with polyol reduction or redox transmetallation [191] of Ag, Sm, Pd, or Pt salts, have been reported to be suitable methods for the preparation of bimetallic ferrofluids. The transmetallation, first adapted by Paulus et al. for the preparation of Co@Au and Fe@Au colloids [91], is based on the reduction of noble metal salts by surface atoms of preformed colloids (C_3) of nonnoble metal elements.

4.8.1. C_1: Decomposition/Polyol Reduction

FePt   A notable success in this field of research was the seminal report in *Science* by Sun et al. on the preparation of bimetallic FePt ferrofluids [95]. The authors combined the polyol reduction of a noble metal salt, described by the 1,2-hexadecanediol reduction of Pt(acac)$_2$, with the thermal decomposition of Fe(Co)$_5$ at high temperatures in the presence of two stabilizers (vis oleic acid and octylamine). As a result, monodisperse alloy particles were fabricated. Initial concentrations of 25 mM Pt(acac)$_2$ were employed. The particle size distribution could be narrowed by applying the hot injection technique using a high boiling solvent (octyl ether or phenyl ether) followed by a size-selective precipitation using, for example, ethanol as the nonsolvent [192]. The reaction was initiated by adding Fe(CO)$_5$ to a solution of Pt(acac)$_2$ at 100 °C (hot injection) and continued under reflux conditions for 30 min under N_2. The composition could be adjusted by varying the starting Fe/Pt ratio. Primary particle diameters were 3 nm, which could be increased to 10 nm by successive addition of desired precursor ratios to a solution containing the 3 nm seed particles.

Investigations by TEM of as-prepared 4 nm particles revealed a typical fcc structure of the particles which were substantiated by XRD. Super-conducting interference device measurements showed superparamagnetic behavior for those particles at room temperature and blocking temperatures between 20 K and 30 K in a field of 10 Oe. Further investigations have been only applied on sintered films of self-assembled particles, showing a transformation to the L1$_0$ phase above 500 °C, which was concomitant with an increase of coercivity.

The method of Sun et al. has been reproduced [103, 119] and adapted for the preparation of FePd [122], Fe [103, 104, 117] (Yamamuro, Farrell, and Chamberlin et al. used seed Pt clusters to obtain monodisperse Fe particles by

successive growth. The Pt concentration was less than 1%), FeCoPt [121], CoSm [123], and CoPt [122] ferrofluids, and modified for the synthesis of CoPt$_3$ [120] by several groups. The work by Shevchenko et al. [119] showed a blocking temperature of 14 K in a field of 200 Oe for as prepared 4.5 nm particles. Applying the Néel equation by assuming $\ln(\tau/\tau_0)$ to be 25, leads to a value for the anisotropy constant $K_{eff} = 1 \times 10^6$ erg/cm^3.

FePd   Chen and Nikles adapted the described method by substituting Pt(acac)$_2$ with Pd(acac)$_2$ [122]. The resultant particles showed an average diameter of 11 nm, which is increased in comparison to FePt, in addition to a relative broad-size distribution. Both observations are indicative of different reaction kinetics. The particles were found to be ferromagnetic at RT (H_C = 12 Oe). Further investigations have been performed only on annealed self-assembled films, showing that FePd particles do not transform to the L1$_0$ phase within the applied temperature range up to 700 °C.

FeCoPt   Chen and Nikles have adapted Sun's method for the synthesis of ternary FeCoPt alloys by adding Fe(CO)$_5$ to a mixture of Pt(acac)$_2$ and Co(acac)$_2$ in dioctyl ether [121]. Investigations have only been done on sintered self-assembled layers. The main result from these studies was that the measured coercivity of the annealed particles decreases with increasing Co content.

CoSm   Ono et al. adapted Sun's method using Sm(acac)$_3$ and Co$_2$(CO)$_8$ instead of Pt(acac)$_2$ and Fe(CO)$_5$, respectively [123]. The final particles had an average diameter of 9 nm as determined by TEM and showed a decreased Sm content, compared to the starting composition of the metal salts (determined by EDX). This result may be due to an incomplete reduction of Sm^{3+} as was discussed by Pileni for iron in FeCu particles. Magnetic measurements indicated a coercivity of 50 Oe and a saturation magnetization M_S = 2 emu/g at RT. These values are different from pure Co particles prepared in a similar way indicating a 3d–4f electron interaction. A discussion of electronic interaction is still outstanding.

CoPt   CoPt$_3$ and Co$_{48}$Pt$_{52}$ have been synthesized by substituting Co(CO)$_3$NO for Fe(CO)$_5$ [122]. Issues concerning the use of Co(acac)$_2$ or Co$_2$(CO)$_8$, instead of Co(CO)$_3$NO, were discussed. Investigations have been focused on Co$_{48}$Pt$_{52}$. The colloids showed an average particle diameter of 7 nm and were superparamagnetic at RT. Further investigations were only applied on annealed films.

CoPt$_3$ A modified procedure has been developed by Shevchenko et al. for the preparation of CoPt$_3$ colloids by thermolysis of Co$_2$(CO)$_8$ and polyol reduction of Pt(acac)$_2$ [120]. The modifications were as follows: (i) use of mixtures of highly coordinating solvents, that is, diphenyl ether/hexadecylamine, diphenyl ether/tetradecylphosphosphonic acid, or hexadecanol/hexylamine; (ii) replacement of oleic acid by adamantanecarboxylic acid or adamantanacetic acid. Use of different hot injection temperatures and reaction times for solutions of Co$_2$(CO)$_8$ in dichlorbenzene have also been thoroughly investigated. The best results concerning size distribution, crystallinity, and reproducibility were obtained for

syntheses involving mixtures of diphenyl ether/HDA (hexadecylamine) and diphenylether/TDPA (tetradecylphosphonic acid) in the presence of ACA (adamantanecarboxylic acid). A typical starting concentration of 8 g/l $Pt(acac)_2$ was employed. Primary particle sizes were in the range of 3 nm–5.5 nm. The success of procedures using ACA as a stabilizer was explained in terms of protection of free surface sites from coordination by ligand molecules. This would be expected to increase the free surface energy of the particles, leading to growth and larger dimensionality compared to systems using fatty acids. Moreover, this method allowed the further growth of alloys without remarkable changes in size distributions for one and two additional precursor injections. However, experiments with pure $Co_2(CO)_8$ were not successful when using ACA as a stabilizer.

High-resolution transmission electron microscopy and XRD investigations showed well-separated single crystalline particles consisting of the $CoPt_3$ intermetallic $L1_2$ phase. A (HR)TEM image of the particles, representing a micrograph typical for successive-growth colloids prepared via C_1, is presented in Figure 3E. The authors emphasized that segregation and core-shell formation could not be excluded, but was not expected from their results. Some explanations concerning their expectations were given.

Results of magnetic measurements on ~6.2 nm particles are available as supporting information to [120]. M versus H curves were measured at 5 K and 300 K, and ZFC/FC M versus T plots measured in a field of 100 Oe. Exact values of characteristic magnetic properties were not given. The presented curves reveal that the colloids are superparamagnetic at RT. T_B, M_S (5 K), and H_C (5 K) can be estimated from the figures to be ~35 K, ~10 emu/g, and ~1200 Oe, respectively.

4.8.2. C_2: Decomposition/Transmetallation

Ag@Co A procedure has been described to produce Ag@Co colloids, involving the thermal decomposition of $Co_2(CO)_8$ in the presence of anhydrous $AgClO_4$ (reduced *in-situ* by $Co_2(CO)_8$ via transmetallation) in toluene, using oleic acid and tridodecylamine as stabilizers [127–129]. A typical starting concentration of 25 mM $AgClO_4$ is employed. The thickness of the Co shell could be increased by increasing the amount of $Co_2(CO)_8$ from 24 mM to 56 mM, while keeping the Ag concentration constant. As a result, Ag particles of a diameter of 8 nm and covered with a Co shell of lower TEM contrast were found (see insert in Figure 3F), in addition to some unpassivated pure Ag particles of a smaller size. The final compositions have been determined from corresponding edges by EDX.

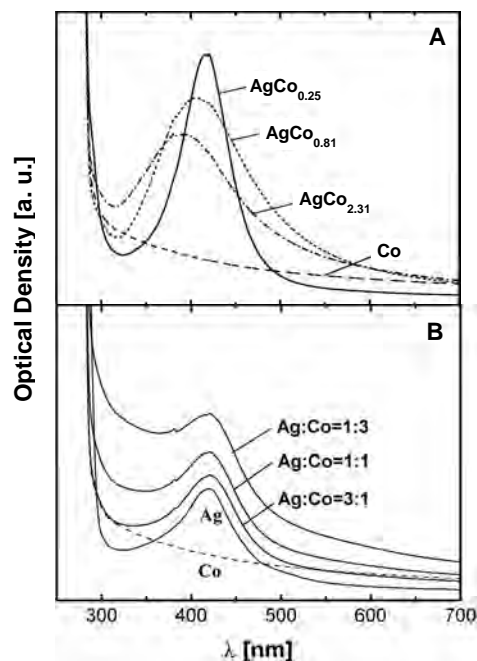
Ultraviolet/VIS spectrometry showed an increasing blue shift and quenching of the Ag surface plasmon band with increasing Co content, that is, increasing shell thickness, indicating a strong electronic interaction for both elements in these composite particles (Fig. 7A). Similar observations have been reported for Ag particles coated with an Au shell [193]. A comparison with the optical spectra for mixtures of pure Co and Ag colloids (Fig. 7B) indicated neither a Ag/Co-ratio dependant blue shift nor a broadening of the Ag plasmon wavelength. Structural investigations by (HR)TEM revealed a multiple twinning or "polycrystalline" structure


Figure 7. (A) Blue shift and quenching of the Ag plasmon band with increasing Co content for composite particles of constant Ag concentration in solution. The stoichiometric ratio is given as $AgCo_x$. (B) Optical density of different mixtures of pure Ag and Co particles. The size of the Ag particles (8 nm) is the same as in (A). Reprinted with permission from [127], N. S. Sobal et al., *Nano Lett.* 2, 621 (2002). © 2002, American Chemical Society.

of particles consisting of fcc phase subunits of both elements. Energy-filtered EELS analysis on the Ag $M_{4,5}$ and Co $L_{2,3}$ edges verified that Ag was present mainly in the center, while Co was preferentially located in the particles shell. Calculations from EELS measurements on Ag@Co particles having a thin shell (<2 nm) suggest no surface oxidation of the Co shell. It was concluded that the latter result again reflects a strong electronic interaction of both elements in the nanocrystals. Super-conducting interference device [127, 128] and X-ray magnetic circular dicroism (XMCD) [129] measurements were applied to obtain information concerning magnetic properties of the material. Available magnetization experiments showed superparamagnetic behavior at RT and ferromagnetic behavior at 90 K. H_C (90 K), and M_R/M_S (90 K) were found to be 0.07 T and 0.32, respectively. X-ray magnetic circular dicroism difference spectra on the $L_{2,3}$ edge of Co allowed the calculation of the orbital-to-spin ratio of the magnetic moment after ion etching of a deposited film under grazing incident conditions (to remove the stabilizers from the surface). The ratio was found to be 0.24, that is, a threefold increase compared to bulk fcc Co (0.08). Detailed discussions of these results were not given.

CoPt Park and Cheon reported on the preparation of CoPt and $CoPt_3$ alloy colloids by *in-situ* thermal decomposition of $Co_2(CO)_8$ in the presence of platinum hexafluoroacetylacetonate, $Pt(hfacac)_2$ (that is, transmetallation) in toluene, using oleic acid as stabilizer [107]. Hot injection

of a $Co_2(CO)_8$/toluene dispersion was used to obtain a narrow particle size distribution. The expensive, commercially available $Pt(hfacac)_2$ has been prepared by the method of Okeya and Kawaguchi [194]. A typical initial concentration of 50 mM $Pt(hfacac)_2$ was used. The procedure resulted in the formation of well-resolved crystalline particles having an average diameter of ~1.9 nm, determined by (HR)TEM. Lattice spacing was found to be in the range of known data for the corresponding bulk materials. Different compositions for the colloids were obtained by changing the ratio of starting compounds. Energy dispersive X-ray spectroscopy investigations revealed a final particle composition close to compositions expected from the starting ratio of metal compounds. Super-conducting interference device magnetometry was used for magnetization experiments. For $CoPt_3$ (CoPt) colloids, as powders incorporated in gelatin capsules, blocking temperatures T_B of 75 Oe at 20 K (15 K) and coercivities H_C at 5 K of 6900 Oe (5300 Oe) were determined.

Co@Pt   The synthesis of Co@Pt core-shell nanocrystals, by reduction of $Pt(hfacac)_2$ in a redox transmetallation reaction on Co nanoparticle surfaces, has been published by the same authors [107]. The reaction was carried out in nonane solvent in the presence of (noncommercially available) dodecane isocyanide as a stabilizer. The stabilizer was prepared by the method of Weber and Gokel [195]. As a result, well-defined particles with an average diameter of 6.4 nm and a relatively broad-size distribution ($\sigma = 0.54$) were obtained. Micrographs from HRTEM investigations showed two particles with a homogeneous contrast throughout, having lattice fringes whose distances correspond to typical distances of bulk Pt. A core-shell structure was not visible. Magnetic measurements were done using a SQUID magnetometer. T_B (75 Oe) and H_C (5 k) were determined to be 15 K and 330 Oe, respectively. The authors mentioned that these values are close to values for pure Co particles, having diameters similar to those estimated for the Co core in Co@Ag colloids (T_B and H_C values of pure Co can be found in [12]). The possible formation of disordered alloys or a mixture of Pt and PtCo or Co particles was not discussed.

4.8.3. C_3: Organoborohydride Reduction/Transmetallation

Fe@Au particles have been formed by successive reductive transmetallation of $AuCl_3$ on the surface of preformed Fe particles [91]. Measured diameters of prepared particles, determined by TEM (images not shown), were determined to be 2 nm and 5 nm. Structure and morphology, inferred from SQUID magnetometry and Mössbauer experiments, were consistent with those expected for FeAu alloy formation. Magnetization curves showed an increase of T_B compared to pure Fe particles. Applying the Néel expression, K_{eff} was found to be increased to 8×10^6 erg/cm^3. An Au coating would be predicted to yield a reduced anisotropy.

Co@Au   particles were prepared and investigated similarly to Fe@Au particles described above [91]. Transmission electron microscopy diameters of the particles were close to 3 nm. Alloy formation was not concluded from magnetization measurements. Super-conducting interference device

magnetometry showed a saturation magnetization M_S (5 K, 5 T) of 1.77 μ_B/atom, which is close to the bulk value of Co. T_B (100 Oe) was decreased compared to pure Co particles. K_{eff}, calculated from the Néel equation, was reduced to 2.6×10^6 erg/cm^3, the bulk value of Co. The authors concluded that the additional surface anisotropy, usually found in small Co particles, was reduced by Au coating.

5. CONCLUDING REMARKS

The presented results showed that colloid chemistry is rather complex. The complexity enhances with the number of parameters, which, in general, comprise the number of elements. Small changes in preparative conditions have been shown to lead to completely different results. The main reason for this observation is the enhanced surface-to-volume ratio of nanoparticles. Thus, the properties of nanoparticles are mainly determined by the interaction of surfaces and interfaces. In particular, in the case of nonnoble materials, the enhancement of the surface-to-volume ratio means an increased reactivity that ensures that such materials are comparatively difficult to handle. Moreover, the increased reactivity highlights the discrepancies that exist between the environments of basic research (high expense, for example, ultra-high vacuum) and industrial scale development (low capital costs are desirable).

The development of materials for new applications is clearly a dynamic process. Investigations in novel colloid syntheses for technological applications often rise to serendipitous developments and new applications. In summary, work on bimetallic ferrofluids will be a challenge for many scientists from different fields for at least the next decade.

GLOSSARY

Colloidal nanoparticles   Kinetically stable dispersion of nanoparticles in a solvent.

Electron energy loss spectroscopy (EELS)   Electron energy loss spectroscopy analyses the inelastically scattered electrons present in the beam of a TEM after it has been transmitted through the sample. The spectra can be used to obtain information about the chemical composition and electronic structure of the sample.

Electron paramagnetic resonance (EPR)   Specttroscopic technique that relies on the detection of microwave-induced transitions between the split sublevels of a certain paramagnetic defect.

Energy dispersive X-ray spectroscopy (EXDS)   Generally used in conjunction with the electron microscope and allows relative concentrations of particular elements within a sample to be measured.

Extended X-ray absorption fine structure (EXAFS)
XAFS measurements in the region up to 1000 eV past the absorption edge to yield information about bond lengths, coordination numbers, and structural disorder.

Ferrofluid   Ferrofluids or magnetic liquids, are colloidal ferromagnetic nanoparticles.

Metastable impact electron spectroscopy (MIES)   Based on the energy analysis of electrons originating from collisions of metastable He* (2^3S) atoms with the surface, and

can be used for probing the spatial distribution of surface species.

Micelle A spherical assembly of appropriate surfactants in solution.

Microemulsion A stable dispersion of two immiscible liquids containing appropriate amounts of different surfactants.

Nanoparticle A material with dimensions in the lower nm (10^{-9} m) region.

Superconducting quantum interference devices (SQUID) The most sensitive devices available for magnetometry. The detector consists of a superconducting loop and one or two Josephson junctions.

Superparamagnetism Paramagnetic behavior of low dimensional ferromagnetic materials (nanoparticles) above a size dependant temperature T_B but with giant magnetic moments compared to paramagnetic materials.

Surfactants Are organic molecules, which have two ends with different polarities, and can serve as a capping or protecting agent for nanoparticles against external forces.

Transmission electron microscopy (TEM) Used to obtain images of nanoparticles for shape and size analysis. Electron diffraction patterns provide structural information, while chemical analysis is possible by EDX or EELS.

X-ray absorption fine structure (XAFS) An XAS analytical technique that uses the small variations in absorption (fine structure) above the absorption edge to extract information regarding oxidation states and coordination symmetry (XANES) or bond lengths, coordination numbers, and structural disorder (EXAFS).

X-ray absorption near-edge fine structure (XANES) XAFS measurements in the region near the absorption edge (within several 10 eV) to determine the oxidation states and the coordination symmetries of the elements in the sample.

X-ray absorption spectroscopy (XAS) Measures the degree of X-ray absorption of a sample as a function of X-ray energy. XAS energy spectra are characteristic of both the elements and their electronic energy levels.

X-ray diffraction (XRD) An X-ray beam can be diffracted by the lattices planes of atoms in samples of sufficient crystallinity.

1. INTRODUCTION

The investigation range of life science has reached the level of single cells, subcells, and even single molecular (such as nerve glia) and single base pairs of nucleotide acid, as shown in Figure 1. Traditional analysis methods and techniques such as optical fiber sensors or electroanalytical sensors, even submicrometer optical fiber sensors or micromachined electroanalytical sensors for obtaining biological and chemical information [1–3], are confronted with great challenges. How to analyze and detect trace analytes of life science in the microlevel, *in-situ*, *in vivo*, and in real time to understand the relationship between biological molecule structure and its function is the focus of the challenges. With the fast development of nanotechnology in 1990s, new thoughts and opportunities have appeared for deep research of biomedicine and resolution of the aforementioned key problem. As the revolutionary effect of the microelectronic

integrating technology on the electronics industry, the development of nanotechnology has had considerable impact on biotechnology and biomedicine systems [4, 5]. Because particle size approaches the molecular dimension, all properties of the materials will change to some extent; however, some of them are wonderful for use in particular biological applications [6]. The fact that the nanoparticles are similar to many common bimolecules with respect to size magnitude permits them to have widespread use in biotechnological systems. The broad fields of biotechnology and medicine, such as diagnosis of disease, drug delivery, gene repair, dispensing, gene therapy, and so on, are all correlative with the nanotechnology [7–11].

Especially with the implementation and accomplishment of the human genome project, it becomes much more crucial to resolve the abundant data to find the pivotal genes that control or dominate the versatile functions of life through nanotechnology techniques than before. Nanoparticles, with high surface-to-volume ratio and ultrasmall in size, are potential alternative materials to obtain biological information inside or outside of living specimens, and provide an excellent analysis system for biotechnology and biomedicine. Given the particularity of living life, biocompatible core–shell nanoparticles have been developed and attracted much attention from all over the world. And a new growth point of modern analytical chemistry has been formed under the combination of nanotechnology, analytical chemistry, materials science, and biotechnology. Especially carrying out research and application of bionanotechnology and developing modern analytical methods and techniques for obtaining related biochemical information *in-situ*, *in vivo*, in real time, and in nanolevel is one of the new research directions of current chemistry and biology.

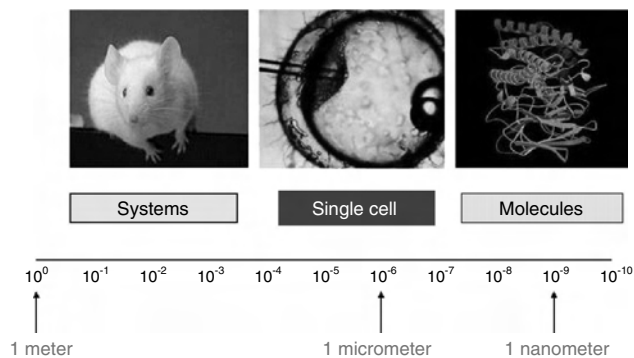
In this chapter, we will first introduce the general configuration and the synthesis of biocompatible core–shell nanoparticles. The unique properties of biocompatible core–shell nanoparticles for bioanalytical chemistry,


Figure 1. The size of our research objects is from big to small in the life science.

Figure 2. The schematic diagram of the biocompatible core–shell nanoparticles.

bioseparation, and bioimaging have been summarized. At the same time, several successful examples of biocompatible nanoparticles that have been integrated with biomolecular species and applied to relevant problems in biotechnology have been introduced. The use of biocompatible nanoparticles as biological labels will be discussed. The novel bioseparation method based on biocompatible nanoparticles, the novel delivery for genes and drugs based on biocompatible nanoparticles, will also be described. The objective of this chapter is to introduce the magical and extremely valuable biocompatible core–shell nanoparticles to biologists and analytical chemists and to encourage them to consider biocompatible core–shell nanoparticles in their own research and projects.

2. CONFIGURATION OF THE BIOCOMPATIBLE CORE–SHELL NANOPARTICLES

Universally particles with at least one dimension (d) $\leq$ 100 nm can be considered nanoparticles; the biocompatible core–shell nanoparticles are of course a kind of nanomaterial with diameter of 1 nm $< d <$ 100 nm. In contrast to normal nanoparticles, the outstanding advantage of the biocompatible core–shell nanoparticles lies in the typical core–shell structure and favorable biocompatibility. Generally speaking, biocompatible core–shell nanoparticles are composed of a functionalized core, a modifiable shell, and the biomolecules modified on the surface of the nanoparticles [12], as shown in Figure 2. The three parts all make prominent contributions to their application of biomedicine.

2.1. Biocompatible Core–Shell Nanoparticles with Different Cores

The different functionalized biocompatible core–shell nanoparticles can be prepared by using different core materials. There are many kinds of materials that can be used as core materials, such as luminescent, electronic, magnetic, and thermal materials and so on. Prepared core–shell nanoparticles with different core material possess various properties and functions and so play an important role in a wide range of biotechnology and nanotechnology, especially
in biomedcine. For example, core–shell fluorescent nanoparticles encapsulating fluorescent dyes, like the inorganic dye [tris(2,2′-bipyridyl) dichlororuthenium(II) hexahydrate (Rubpy)] [13–15] have been widely studied in fluorescent labeling of biomolecules and tissue because their intensified fluorescent signals are agreeable and their fluorescence characteristics are protected due to the high degree of insulation from the environment. Core–shell semiconductor nanoparticles, also called quantum dots (QDs) with CdSe as core material [16, 17], are used for the preparation of sensors with multidimensional response signals, because QD labels exhibit size-tunable, narrow-band luminescent emission and high resistance to photodegradation. Core–shell magnetic nanoparticles with Fe_3O_4 as core [18], according to their peculiar superparamagnetism (i.e., magnetized in the presence of a magnetic field while nonremanent in the absence of a magnetic field), can easily be operated in magnetic or electromagnetic fields, so they are commonly utilized in the separation and enrichment of biological analytes. Core–shell drug nanoparticles [19] can perform the targeted delivery of drugs and avoid the side effects of drugs as much as possible, because drugs are encapsulated in the core of nanoparticles, which can be concentrated around the suffering tissues under the exterior guide and greatly increase therapy efficiency. Core–shell gene nanoparticles [20] make the higher efficient transfection realized compared with other materials or tools for the same usage and present great promise in gene therapy and related application.

There is another interesting structure [21] which widens our views on nanoparticles. In this model, the core is a single living yeast cell. It has been encapsulated by the alternate adsorption of oppositely charged polyelectrolytes. Its fluorescent images showed the integrity of the core and shell structure after the coating procedure (Fig. 3). The most significant result is that after encapsulation, cells preserve their metabolic activities and are still able to divide (Fig. 4), which provides evidence of its interesting foreground for biophysical studies.

Sometimes, single and simple core material is not sufficient to form completely perfect nanoparticles with core–shell structure, for they may leach through netlike shells with pores. Hence, many researchers attempted to encapsulate the conjugates of desired material with other macromolecules, thus protecting useful core material from
Figure 3. Confocal images of fresh by coated shells. Vignette of the encapsulation process, consecutive adsorption of the polycation PAH (red) and the polyanion PSS (blue) onto a single living cell. To provide evidence of a successful coating, one or two layers are FITC-labeled PAH (green). Reprinted with permission from [21], A. Diaspro et al., *Langmuir* 18, 5047 (2002).© 2002, American Chemical Society.

bleaching. In normal conditions, free fluorescine isothiocyanate (FITC) and rhodamine are difficult to entrap into silica shells. These situations can be dramatically improved by forming fluorescent dye complexes. Our studies have found that the FITC–IgG complexes could be encapsulated into silica nanoparticles with a much higher entrapment efficiency, greatly increased compared to that of free FITC [22]. The entrapment efficiency of FITC–dextran conjugate has also been studied, but it did not offer as good results as that of FITC–IgG, maybe because of the different structures of dextran and IgG, and their different effects on FITC. To control permeability, polydextran aldehyde, incorporated into the particle core, was used to enable physiologic cross-linking and long-term retention of substances that would otherwise rapidly leak out of the nanoparticles [23]. Results of cross-linking experiments clearly demonstrated that the release rate could be substantially reduced, depending on the degree of cross-linking.

In addition, complex core materials can be utilized for more functions and better performance. Lai et al. reported [24] the preparation of novel two-photon dye encapsulated silica nanobubbles with enhanced luminescent

properties and pleasing bioimaging applications. It is a zinc sulfide-ASPI-SH dye (homemade)–silica layered heterostructure. As they showed, two-photon processes have drawn considerable interest for thorough application in two-photon laser scanning microscopy. Mitra et al. [19] have conjugated the anticancer drug Doxorubicin (OXR) with dextran (the latter was found to minimize the undesirable side effects of the drug while making the drug retain its antitumor activity in the conjugate) and then encapsulated this drug conjugate in hydrogel nanoparticles for tumor targeted delivery.

2.2. Biocompatible Core–Shell Nanoparticles with Different Shells

A number of shell materials exist nowadays. Generally, nanoparticles are classified according to the shell materials into inorganic nanoparticles, organic nanoparticles (polymer nanoparticles), metal nanoparticles, and semiconductor nanoparticles. Silica shell as inorganic material is extensively studied for the reason of its superiorities. Compared with liposomes, it is not subject to microbial attack and will be resistant to bile salts and lipases encountered in the gastrointestinal tract and physical stress during aerosolization, and it should also withstand autoclaving in principle. In contrast to polymers, there is little concern about its toxicity [25]. Moreover, silica is chemically inert and therefore does not affect the redox reaction at the core surface. This shell is optically transparent too. Organic nanoparticles of cholesterol, rhovanil, and rhodiarome have been synthesized [26]. And the common organic shell material is chitosan, a polysaccharide known to be a favorable pharmaceutical material and a kind of ideal hydrophilic material because of its biocompatible and biodegradable properties. Coating chitosan on a magnetite nanoparticle surface will render the nanoparticles water soluble, more stable, and biocompatible and will provide the nanoparticles with functional amino and hydroxyl groups on their surfaces. There is also broad interest in semiconducting matrixes. Han et al. prepared ZnS-capped CdSe quantum dots [27] whose emission colors varies from blue to red with the change of nanoparticle size, excited by the same excitation wavelength (as shown in Fig. 5).

Figure 4. Transmission image (A) of a duplicating cell. This is confirmed by the fluorescence image (B) where the lack of green fluorescence in the mother cell coating reveals where the bud has formed. The DAPI-labeling of the DNA distribution allows the imaging of both mother and uncoated daughter cell. Reprint with permission from [21], A. Diaspro et al., *Langmuir* 18, 5047 (2002). © 2002, American Chemical Society.

From left to right (blue to red), the emission maxima are located at 443, 473, 481, 500, 518, 543, 565, 587, 610, and 655 nm. Reprinted with permission from [27], M. Y. Han et al., *Nat. Biotechnol.* 19, 631 (2001). © 2001, Macmillan Magazines Ltd.

2.3. Biocompatible Core–Shell Nanoparticles Modified with Different Biomolecules

Core–shell nanoparticles may still lack adequate biocompatibility to be applied in biomedicine or cannot perform the required bioanalysis exclusively. Through the design of the biomolecule linked to the nanoparticles (biological modification on the surface of nanoparticles), the biocompatibility of the nanoparticles will be strikingly heightened and their application will be widely expanded. In particular, the biomolecules modified always play an indispensable part in biological applications.

Well-studied single strand DNA or RNA-complementary DNA or RNA, biotin–streptavidin, antibody–antigen, and other ligand–receptor reactions are commonly used to realize biological chemical detection and related studies. Therefore, DNA or RNA and proteins including antibody or antigen and enzymes are usually conjugated with nanoparticles. Other biomolecules like hormone, growth factor, and agglutinin are suitable in specific experiments. The most beneficial aspect of the modification of biomolecules lies in the specific recognition and targeting effect. The biocompatible core–shell nanoparticles with Fe_3O_4 as core and different materials as shell and modified with different biomolecules prepared in our lab are shown in Table 1.

3. SYNTHESIS OF BIOCOMPATIBLE CORE–SHELL NANOPARTICLES

The synthesis and preparation of biocompatible core–shell nanoparticles is crucial for applications in biomedicine. Because of the complexity of the biological system, the dimension of the nanoparticles might as well be controlled in the range of 1 nm $\leq (d) \leq$ 100 nm and with narrow distribution. At the same time, the functionalized biomolecules should be easily immobilized on the surface of nanoparticles with high bioactivity. Thus, it is required to carefully choose effective methods to synthesize biocompatible core–shell nanoparticles. There are three key techniques for the preparation of the biocompatible core–shell nanoparticles [28].

3.1. Nucleation of the Core–Shell Nanoparticles

Selection of appropriate method to prepare the core of the nanoparticles is of first importance. The size and the distribution of the nanoparticles will be mainly affected by using different methods of nanoparticle preparation. The preparation techniques of nanoparticles are usually classified into gas phase, liquid phase, sol–gel, etc., methods. Among these methods, the microemulsion method that belongs to the liquid phase method has played a vital part in the preparation of nanoparticles [29–31]. A microemulsion is an isotropic and thremodynamically stable single-phase solution formed with least three components: two of them immiscible, such as oil and water, and a surfactant with amphiphilic behavior. As for the water-in-oil microemusion, the water core of the microemulsion is akin with a nanocontainer for core materials and a nanoreactor for the formation of shell (Fig. 6). The dimension of the nanoreactor can straightly control the size and the distribution of the nanoparticles through selection of an appropriate microemulsion system. The nanoparticles are uniform in size and well dispersed when prepared by this method. Many nanoparticles with different cores such as fluorescent dye, magnetic material, drug, and gene have been successfully prepared by this method and are widely used in biomedicine.

3.2. Shell Coating of the Nanoparticles

The shell coating technique is also important to realize the conformation of the core–shell nanoparticles. A coating shell is built up around the core materials to increase their chemical stability, intensify their functions, improve their biocompatibility compared with bare core materials, confer specific properties, such as optical, magnetic, or mechanical properties on the core material, and so on. Organic material and inorganic material can both used as shell material. One typical example of such nanoparticles is a silica coated biocompatible nanoparticle. The synthesis of silica nanoparticles with controlled diameters and size distribution has been extensively studied by Osseo-Asare and Arriagada [32, 33]. The technique involves the base-catalyzed controlled hydrolysis of tetraethoxysilane (TEOS), with short-chain nonionic surfactants as stabilizer and ammonia as catalyst. Following a synthetic procedure similar to that of Osseo-Asare and Arriagada, a silica coating can be also performed in the nanoreactor of a water-in-oil microemulsion, as shown in Figure 7. We have prepared a series of silica coated functionalized nanoparticles

Table 1. Core–shell magnetic nanoparticles with different shell materials and surface modification.

Batch	Shell material	Surface modification	Applications
1	SiO_2	DNA	separation of DNA
2	gelose	antibody	enrichment of liver cells
3	dextran	sorbent	purification of enzymes
4	chitosan	enzyme	immobilization of enzymes
5	polylactic acid	antineoplastic drugs	targeting therapy of cancer cells
6	polystyrene	concanavalin A	environmental protection

Figure 6. Schematic diagram of nucleation of the nanoparticles.
Figure 7. Shell coating of nanoparticles.

through the hydrolysis of TEOS in the nanoreactor of the microemulsion. But we found that not all water-soluble material can be doped in the silica shell. A great breakthrough in the synthesis theory and techniques of core–shell nanoparticles has been obtained. The results have testified that the charges of the shell materials and core materials will dominate whether the stable core–shell structure forms or not, by employing the silica shell formed through the hydrolysis of TEOS and the core formed by microemulsion. Figure 8 shows transmission electron microscope (TEM) images of silica coated nanoparticles that we have prepared.

On the other hand, a variety of trialkoxysilane molecules with vinyl, thiol, amino, or methacryloxy functionalities were introduced into the nanoreactor of the microemulsion along with TEOS to produce functionalized silica shell coated nanoparticles, which will be engaged for further application in biomedicine [34]. Based on this theory, a synchronous technique for preparation of amino-modified silica nanoparticles has been developed in our study.
Figure 8. TEM images of silica coated nanoparticles. (a) RuBPY doped silica nanoparticles, (b) silica coated magnetic nanoparticles, (c) TRITC doped silica nanoparticles, (d) RuBPY doped silica nanoparticles.

Amino-modified silica nanoparticles are directly synthesized using the synchronous hydrolysis of tetraethoxysilane and *N*-(*β*-aminoethyl)-*γ*-aminopropyltriethoxysilane in water-in-oil microemulsion [35].

3.3. Biological Modification of the Nanoparticles

The surface properties of core–shell nanoparticles play outstandingly significant roles from both a theoretical and a practical point of view. For instance, modified quantum dots are capable of purifying and binding to the targeted chemical or biological agents. At the same time they provide visible evidence of the binding event, such as a change in color or light diffraction capabilities of the sample, and represent a promising alternative to organic dyes for a variety of fluorescence-based applications in biosensing. However, bare quantum dots are difficult to apply in biological assay due to their poor biocompatibility. Biological modification of the nanoparticles is generally rated as an absolutely necessarily step to reduce cytotoxicity and immunogenicity both *in vitro* and *in vivo*. Functionalization of the surface makes it possible to obtain the fine biocompatibility of nanoparticles. By selecting the desirable functional modification, the application of nanoparticles is expanded and extended extensively in many biological fields such as gene transfection and therapy immunoassay, enzyme immobilization, cell recognization, biological separation, and biosensing.

Modifying biomolecules onto the ultrasmall surface of nanoparticles while least affecting their activities is a prime goal for the nanoparticles used in biomedicine. At the present time, modification of the surface can be done via three methods. One is performed *in-situ* during the nanoparticle synthesis. As described, amino-modified silica nanoparticles are prepared by the synchronous hydrolysis of TEOS and AEAPS. The simple synthesis process provides the formation of silica nanoparticles and the modification of the amino group as well. The other two first synthesize the nanoparticles and then treat them with adequate biomolecules. One is physical absorption such as electrostatistic binding. In this case the modified biomolecules are susceptible to removal from the surface under certain conditions such as high salt and high temperature and so are restrained in a relatively narrow application areas. The other is widely used chemical modification. Chemical modification is mainly done by a variety of covalent coupling the activated functional group on the nanoparticle surface, such hydroxyl, carboxyl, amino groups, and so on, with that of biomolecules, the same as the modification of microsphere [36], as shown in Figure 9. Biotin–streptavidin, antibody–antigen, and other ligand–receptor reactions are commonly selected to realize the biological chemical modification. This modification is not necessarily finished in one step. Multistep modification has been reported. Following are some modification methods of silica nanoparticles. The first is achieved by using a cyanogen bromide (CNBr) method [18]. Dried silica coating nanoparticles were suspended with sodium carbonate solution of appropriate concentration by ultrasonication for 15 min. Solution of CNBr in acetonitrile (2 mg/ml) was then added dropwise to the nanoparticle suspension under stirring for 10 min at

room temperature. The active particles then were washed twice with iced water and twice with PBS buffer (pH 7.6) and resuspended in PBS buffer. In this way, modified nanoparticles were prepared for the experiments. In the second method [15], silanization was performed by immersion in freshly prepared 1% (v/v) solution of distilled DETA and 1 mM acetic acid for 30 min at room temperature. The DETA modified silica nanoparticles were thoroughly rinsed with deionized water to remove excess DETA and then were treated with 10% succinic anhydride in dimethylformamide solution under an argon atmosphere and stirred for 6 h. The resulting carboxylate modified nanoparticles were washed with water and centrifuged several times; then the whole modification procedure for pure silica nanoparticles was finished.

4. CHARACTERISTICS OF THE BIOCOMPATIBLE CORE–SHELL NANOPARTICLES

Because of the unique core–shell structure, biocompatible core–shell nanoparticles are more superior in biocompatibility, photochemical stability, and ultrasensitivity in detection in comparison with other materials.

4.1. Least Toxicity

Many nanoparticle materials with optic, electric, thermal, and magnetic properties have been widely used in optics, catalysis, microelectronics, and so on. However, their application in biomedicine is restrained because of their lack of biocompatibility. When they are applied in biological fields, they may disturb the normal metabolism and functions of biological system or cells, due to some side effects occurring by the physical and chemical properties of themselves. Finally, they present toxicity to some extent. The problem is remarkably solved using these functional materials as core. When these materials are encapsulated as functional core materials, the biocompatible shell forms an excellent barrier. The side effects will be reduced because the core materials are separated from the cellular environment and do not have contact with the system or cell directly. Anticancer drugs for cancer therapy are good examples, because when the anticancer drugs are taken by the system, the drugs will also play their role in the normal tissues, and anticancer drugs presently are widely limited for use in clinic therapy. However, there are many reports focusing on drug delivery and disease therapy by use of core–shell nanoparticles. By encapsulation of drugs in biocompatible nanoparticles, one can not only protect the integrity of drugs during their transport in blood circulation but also protect the normal nontarget tissues from the toxicity of drugs. In our study, we have studied the biocompatibility of the silica coated fluorescent nanoparticles *in vivo* and *in vitro*. The fluorescent nanoparticle was injected into the tail vein of a mouse and incubated with different times. The result indicated that the fluorescent silica nanoparticles could be eliminated quickly, as shown in Figure 10. We also have studied the biocompatibility of the silica coated fluorescent nanoparticles with cells. The HNE1 cells were seeding in the cell-dish with medium. For biocompatibility, the cells were incubated with nanoparticles and cultured for a time. Then the cells were subcultured four times. The results showed that the cells could endocytosize the nanoparticles effectively and were biocompatible with the nanoparticles. The cell-endocytosized silica nanoparticles not only grow well but also have normal shapes. There is no obvious difference with the cells in the control experiment [35], as shown in Figure 11.

4.2. Photochemical Stability

Because of the protection of the shell, another special advantage of the core–shell structure is its photochemical stability. The shell acts as a stabilizer, limiting the effect of the outside environment on the core material, such as photo-bleaching, oxidation, biodegradation, and so on. This is particularly
Figure 10. Images of the blood. (a) Optical image of blood cells taken at 15 min. (b)–(h) Fluorescence images of blood cells taken at 15, 30, 45, 60, 75, 90, and 105 min.

important for dyes, genes, and drug nanoparticles. For example, there are many quenching substances such as oxygen that may affect the fluorescence of the fluorophore [37]. And genes can be digested or degraded by enzymes before they reach the desired organs or tissues. For drugs, they are affected as far blood clearance and immnogenicity are concerned. The shell provides a protective obstacle to penetration of external substances, thereby not only making the dyes more photostable [37, 38] (Figs. 12 and 13) but also making

the genes and drugs more stable in biological milieu before they are released at target sites.

4.3. Ultrasensitivity in Detection

Increased surface area caused by the size effect of nanoparticles results in two advantages, more biomolecules modified onto the surface of core–shell nanoparticles and the amplification characteristic derived from the encapsulation of functionalized core materials by the core–shell structure. Both lead to highly increased sensitivity when core–shell nanoparticles are used for biomedicine detection and determination.

In our research, the emission intensity of the labeled cell by the fluorescent nanoparticles and FITC label was recorded [39]. The results indicate that the fluorescent nanoparticle label provided more sensitivity in comparison with the FITC label method. We think the number of dye molecules coupled to the antibody is the most important reason for this. There are only a few dye molecules coupled to one antibody through the amine group in the FITC label method [40]. However, the fluorescent nanoparticle label was achieved by coupling the antibody to the shell of the fluorescent nanoparticles. We have roughly estimated there
Figure 13. Photostability comparison of (1) the fluorescent nanoparticles labeled target cells and (2) the FITC labeled target cell. The cell images were taken every 10 minutes. were about 8000 dye molecules in a single nanoparticles of 30 nm. In this way, one antibody can be coupled to about 8000 dye molecules. The detection sensitivity was thus greatly improved. See Figure 14.

5. APPLICATIONS OF THE BIOCOMPATIBLE CORE–SHELL NANOPARTICLES IN BIOMEDICINE

Biocompatible core–shell nanoparticles emerged under the combination of nanotechnology and biotechnology and have already exhibited potential applications as nanosensors in cell imaging and biochemical information determination, biological separators, drug and gene carriers, or other types of analysis measurements. Biocompatible core–shell nanoparticles have been proven to be efficient and effective tools for biomedical research. Details are described as follows.

5.1. Biochemical Information Obtained Based on Biocompatible Nanoparticles

The development of highly sensitive nonisotopic detection systems for obtaining biochemical information has received considerable attention in biology and medicine research fields. At present, nonisotopic detection methods, such as organic reporter molecules that undergo enzyme-linked color changes, and luminescent, electrochemical, and fluorescent methods, have been applied in these fields [41–43]. Among these methods, the fluorescence is an important nonisotopic detection method. The fluorophores as fluorescent biological labels play an important role in the field of biomedicine, such as the detection of materials inside or outside of the cell [44, 45], hybridization and sequencing of the nucleic acid [46, 47], clinic diagnostics at the early stage,
and so on [48]. But the conventional fluorescent labels may be restricted in some fields of biological application because of the following limitations. Some fluorophores are easy to photobleach, which will affect the emission intensity. The toxin of some fluorophores is harmful to living things or cells. The detection sensitivity is not very high because only a few fluorophores can be coupled to one biomolecule in the conventional fluorescent label methods. Recently, significant progress has been achieved in fluorescent labeling by the use of core–shell nanoparticles that are induced by analyte binding as the sensing mechanism, as shown in Figure 15.

5.1.1. Bioconjugate Quantum Dots as Fluorescent Biological Labels

Semiconductor quantum dots are highly light absorbing, luminescent nanoparticles whose absorbance onset and emission maximum shift to higher energy with particle size, due to quantum confinement effects [16]. These nanoparticles are in the size range of 2–8 nm in diameter. Unlike molecular fluorophores, which typically have very narrow excitation spectra, semiconductor quantum dots absorb light over a very broad spectral range, as shown in Figure 5. This makes it possible to optically excite a broad spectrum of quantum dot colors using a single excitation laser wavelength, which enables one to simultaneously probe several markers. Bruchez et al. [17] and Chan and Nie [16] reported the synthesis of highly luminescent semiconductor quantum dots (zinc sulfide-capped cadmium selenide), which can be covalently coupled to biomolecules for use in ultrasensitive biological detection. In comparison with organic dyes such as rhodamine, this kind of luminescent label is 20 times as bright, 100 times as stable against photobleaching, and one-third as wide in spectral linewidth. After biological modification on the QDs, formed nanometer-sized conjugates are water soluble and biocompatible. Results showed that quantum dots that were labeled with the protein transferrin underwent receptor-mediated endocytosis in cultured Hela cells, while those dots that were labeled with immunomolecules recognized specific antibodies or antigens. Their further research was to use two luminescent QDs emitting red and green lights separately for simultaneous detection of murine actin fibers and cell nuclei (Fig. 16) [17]. In order to analyze a large number of molecules at the same time, Han et al. have invented a way to barcode DNA using tiny light-emitting quantum dots to obtain molecular ID codes [27]. By embedding such quantum dots in polystyrene microbeads bearing short strands of DNA, these created labels can recognize particular DNA molecules of interest

by tagging them with a unique identification code (Fig. 17). Uniquely coded beads are built using different combinations of colors and intensity levels and visualizing various fluorescent signals. Ultimately, it is expected that the codes should be easily be tagged onto both nucleic acids and proteins–facilitating research in many areas of biomedical research, including drug screening, gene expression studies, and clinical diagnostics.

Similarly, Chen et al. [49] presented fluorescent markers made from semiconductors only 5 nanometers in size, which could help detect tumor cells. This particular semiconductor is manufactured with a core of cadmium and selenium crystals, encapsulated in a shell made from a zinc-sulfur compound. These materials all have properties conducive to semiconductors. At 5 nanometers, the structure can display varied fluorescent coloring depending on the size when binding with other molecules. The QDs have demonstrated good ability at targeting specific molecules on tumor cells and provide an enhanced method of detecting cancer and other diseases. They have previously developed an approach to conjugate biotinylated or nonbiotinylated antibodies to CdSe–ZnS core shell QDs via molecular adaptor proteins that have been electrostatically bound to nanocrystals capped with dihydrolipoic acid ligands.

Mattoussi et al. [50] showed results of studies that employed QD–protein conjugates in immuno- and fluorescence-based quenching assays to detect low levels of toxin analytes and explosives in solution environments. In particular they showed that these QD–antibody conjugates exhibit high specificity and stability in both surface and
flow displacement immunoassays. These QD bioconjugates are used in live cell labeling and show that QD–antibody conjugates can selectively label cells and regions within cells that express proteins of interest. These approaches enable us to use luminescent QDs for simultaneously studying growth and development of multiple cells over extended time periods.

In short, combining the advantages of capped CdSe–ZnS or other kinds of quantum dots, such as photochemical stability and narrow band tunable emission through the visible, with the simple binding approach, these hybrid bioinorganic conjugates represent a very promising tool for use in biotechnological applications especially in biosensing and biolabeling.

5.1.2. Fluorescent Dye Doped Nanoparticles as Biolabels

At present time, rapid and sensitive molecular techniques for the detection of particular microorganisms (e.g., pathogens and biological warfare agents) in environmental sources serve as an important means of warning and prevention. Fluorescence sensing systems are the most commonly used means for the current methods but are limited to the availability of specific targets and the number of targets simultaneously examined. The use of fluorescent dye doped nanoparticles as the sensing system has emerged as a promising approach since it provides better specificity than fluorescence dyes, can be seen under visible light (low equipment cost), and allows specific targets to be examined.

Tan et al. [51, 52] reported the development of novel luminescent nanoparticles composed of inorganic luminescent dye, tris(2,2′-bipyridyl) dichlororuthenium (II) hexahydrate, doped inside a silica network. These dye doped silica (DDS) nanoparticles all are suitable for biomarker application since they are much smaller than cellular dimension. The luminophores are well protected from the environmental oxygen because they are doped inside the silica network. These nanoparticles are highly photostable in comparison to most commonly used organic dyes. Generally speaking, the silica surface of DDS nanoparticles is available to covalently bind with biomolecules for surface modification and bioconjunction. For demonstration as a biomarker, the DDS nanoparticle surface has been biochemically modified to attach membrane-anchoring groups and applied successfully to stain human leukemia cells. As an example, they used an antibody for leukemia cell recognition. The antibody was first immobilized onto the luminophore-doped nanoparticle through silica chemistry and then was used for leukemia cell identification by a fluorescent microscopy imaging technique. The leukemia cells were identified easily, clearly, and with high efficiency using these antibody-coated nanoparticles.

In our research, a method for cell recognition of system lupus erythematosus (SLE) patients using photostable luminescent nanoparticles as biological labels was reported too [38]. The luminescent silica nanoparticles are prepared and are covalently immobilized with goat antihuman immunoglobulin G (IgG), which can recognize SmIgG$^+$ B lymphocytes. Using antibody-conjugated nanoparticles, target SmIgG$^+$ B lymphocytes isolated from the circulating

Figure 17. Fluorescence micrograph of a mixture of CdSe/ZnS QD-tagged beads emitting single-color signals at 484, 508, 547, 575, and 611 nm. Reprinted with permission from [27], M. Y. Han et al., *Nat. Biotechnol.* 19, 631 (2001). © 2001, Macmillan Magazines Ltd.

blood of SLE patients were recognized. It has been observed that the bioassay based on fluorescent nanoparticle labeling can identify target cells selectively and efficiently (Fig. 18). According to these experimental results, this cell recognition method based on fluorescent nanoparticle labeling was an effective diagnosis of the SLE diseases. Based on the same technology, HepG liver cancer cells have been recognized selectively.

Soukka et al. [53–55] introduced a detection technology improving sensitivity in miniature that relies on the use of europium (III) nanoparticles and time-resolved fluorometry to improve the detection limit of biochemical assays and to visualize individual molecules in a microtiter plate format. Streptavidin was covalently coated on 107 nm nanoparticles containing >30,000 europium molecules entrapped with P-diketones. In a model assay system, these nanoparticles were used to trace biotinylated prostate-specific antigen in a microtiter plate format. As a conclusion, the universal streptavidin-coated europium (III) nanoparticle label is suitable for detection of any biotinylated molecule either in solution or on a solid phase. The europium (III) nanoparticle labeling technology is applicable to many areas of modern biochemical analysis, such as immunochemical and multianalyte DNA-chip assays as well as histochemistry and cytochemistry to improve detection sensitivities.

5.1.3. Colorimetric Assay Based on Gold Nanoparticles

The use of gold colloid in biological applications began in 1971, when Faulk and Taylor invented the immunogold staining procedure. Since that time, the labeling of targeting molecules, especially proteins, with gold nanoparticles has revolutionized the visualization of cellular or tissue components by electron microscopy [56] because the high density of gold makes them appear dark in a transmission electron microscope image. Site-specific staining is obtained by labeling the nanogold particles with antibodies directed against a protein in the region of interest. Recently, gold nanoparticle conjugation was applied to polynucleotide detection based on a colorimetric method. The characteristic red of gold colloid has long been known to change to a bluish-purple color upon colloid aggregation. When a single-stranded target oligonucleotide was introduced into solution, a polymer network was formed consisting of the target

oligonucleotide and the conjugated nanoparticles. This condensed network brought the nanoparticles into close enough vicinity to induce a dramatic red-to-blue macroscopic color change. Mirkin et al. [57–60] have developed selective colorimetric detection of DNA, scanometric DNA array, and array-based electrical detection of DNA by the use of gold nanoparticles.

5.1.4. Other Nanoparticles as Biolabels

Biological binding reactions play a key role in biology and medicine. Their detection is usually achieved by labeling one of the reaction components with radioisotopes, enzymes, or fluorescence dyes. In particular, assays, using the specificity of the reaction between antibodies and antigens, are of outstanding importance. Most of these assays are hampered by the drawback that the label generates a signal that is not influenced by the binding reaction. Therefore, separation procedures between bound and unbound reaction components are mostly inevitable. The use of superconducting quantum interference device (SQUID)-based magnetic nanoparticle relaxation measurement has been [61] presented as a novel tool for the quantitative determination of biological binding reactions, where magnetic nanoparticles are used as labels to antibodies. The rotational diffusion of the label is hindered by the binding of the antibody to the antigen, which is adsorbed to the sample tube wall. As a result, the observed relaxation of its magnetization is driven by the internal reorientation of the magnetic moment of the nanoparticles. The measured signal is specific for the magnetically labeled antibody bound to the antigen. It was shown that already at a very early stage of technical development SQUID-based magnetic nanoparticle relaxation shows a higher sensitivity than a comparable standard assay technique, enzyme linked immunosorbent assay.

5.1.5. Nanosensor Probe Single Living Cells Based on Biocompatible Nanoparticles

Rapid advances in the biomedical field pose new challenges to analytical chemistry in the field of chemical and biological sensors and real-time, noninvasive analysis of biochemical processes inside live cells and their suborgans. In recent years, the submicrometer-sized sensors have widely been used for getting biochemical information, with applications including pH, Ca, Na, K, O, Mg, glucose, glutamate, and so on [62–71]. However, the submicrometer optical fiber or a micropipet tip was still limited in biological research, particularly in the field of single cell analysis where the sensor has to be inserted into a single cell through the cell membrane. Then the measurement technique is as not as invasive as conventional cellular fluorescence labeling. Furthermore, this technique is not feasible when a large population of cells needs to be detected at the same time. Recently sensors based on biocompatible nanoparticles have been in development. Nanosensors based on biocompatible nanoparticles can overcome these problems. Clark et al. have reported a kind of nanosensor which is called PEBBLEs (probes encapsulated by biological localized embedding). They introduced a unique approach for

the fabrication of nanosized optochemical probes in which the fluorescent dye is entrapped in nanosized phospholipid vesicles. The PEBBLEs can be delivered to viable cells and these cells can be observed in a time resolved manner, responding to changes in their environment [72–74]. Rosenzweig et al. have developed the dye-encapsulating liposome as a fluorescence-based oxygen nanosensor, and for the first time one can quantify an analyte-molecular oxygen [75].

We have synthesized a novel fluorescent core–shell nanoparticle which has been developed by encapsulating the conjugation of FITCs modified with protein IgG into a silica shell for use as fluorescent pH-sensitive nanoparticles, and we carried out its application in intracellular pH measurements in real time [76]. These nanoparticles can measure the change of intracellular pH value after phagocytosis by murine macrophages, and they show excellent stability and high reproducibility when used as pH optical sensors, as shown in Figure 19.

5.2. Separation of Biomolecules or Cells Using the Nanocapturer

The separation of biological cells and life active species is a basilic technique in biomedicine, such as the separation of fetal cells, separation of disease cells, classification of cells, and so on [77–80]. Biocompatible core–shell nanoparticles offer a novel tool and means for the separation of cells and biological species. Magnetic bioseparation, for example, is a powerful and versatile diagnostic technique in biology and medicine. The basic concept in magnetic bioseparations is to selectively bind the biomaterial of interest (e.g., a specific cell, protein, or DNA sequence) to a magnetic particle and then separate it from its surrounding matrix using a magnetic field. They could find a large range of applications for the separation of DNA and other intermediate-size objects such as cells, proteins, organelles, and so on. Nanoparticles of Fe_3O_4 with diameters in the 5–100 nm range are typically used for such separations. These particles are "superparamagnetic," meaning that they are attracted to a magnetic field but retain no residual magnetism after the field is removed [80]. Then the superparamagnetic nanoparticles coupled with specific analytes can be easily and rapidly isolated from the original sample solution. A common use of superparamagnetic nanoparticles is for immunospecific cell separations. Exploiting coating protein A on the surface of magnetic nanoparticles, followed by modifying the specific antibody to the antigen on the surface of cells, Sonti and Bose realized the immunoseparation of chick red blood corpuscles [81]. One hospital in London applied magnetic polystyrene nanoparticles (50 nm) with the modification of antinerval cellular tumor monoclonal antibody to cure cancer by successfully separating cancer cells from human marrow [82].

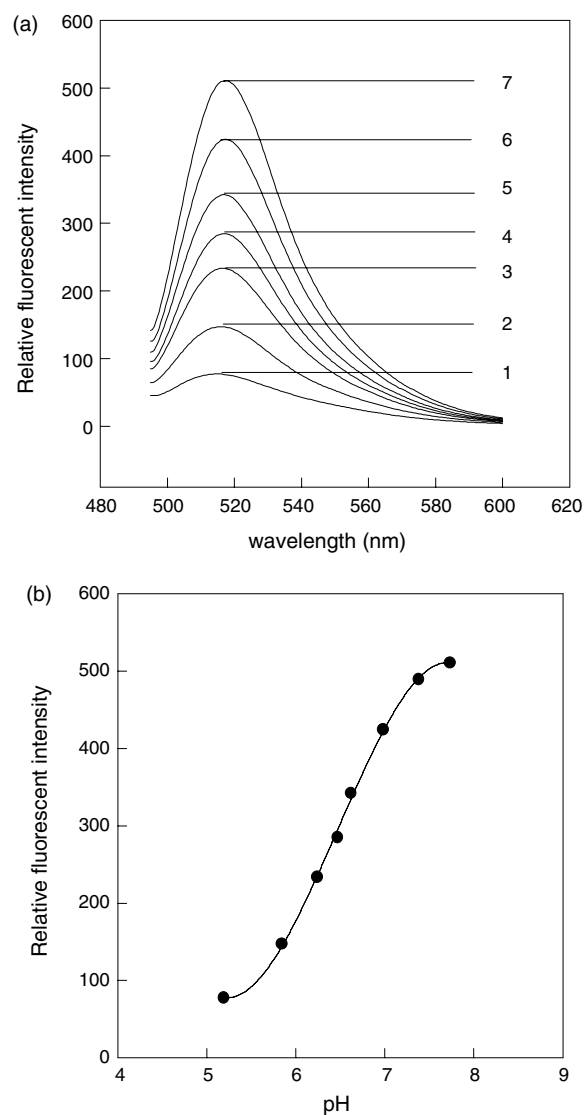
In our research, silica coated magnetic nanoparticles, employing Fe_3O_4 as core and silica as shell, have been prepared by using a water-in-oil microemulsion technique. The procedure was first done using synthesis of aqueous magnetic ferrofluid with the precipitation of the chloride mixture with the base. Then the silica coating was done using a


Figure 19. (a) pH sensitivity of fluorescent core–shell nanoparticles, (1) pH = 5.19; (2) pH = 5.84; (3) pH = 6.24; (4) pH = 6.47; (5) pH = 6.62; (6) pH = 6.98; (7) pH = 7.73. (b) Fluorescence pH response of fluorescent core–shell nanoparticles.

water-in-oil microemulsion technique. The magnetic nanoparticles are also superparamagnetic, as shown in Figure 20. A nanocapturer has been developed using the superparamagnetic [18]. Based on the special recognition and combination between the biomolecules modified on the magnetic nanoparticles and analyzed substances, superparamagnetic nanocaptures have been developed for biological separation. Zhao et al. report the development of a genemagnetic nanocapturer using magnetic nanoparticles functionalized with MBs [83]. The high sequence selectivity and excellent detection sensitivity of MBs are combined with the superior separation capability of the magnetic nanoparticles for the separation of trace amounts of DNA/mRNA strands with a single base difference. Single base mismatched DNA has been easily separated, collected, and determined from perfectly matched complementary DNA by applying a magnetic field and controlling the temperature.

Under the special combination of biotin and avidin, a superparamagnetic DNA nanoseparater has been built through modification of single strand oligonucleotide probes labeled with biotin onto the surface of these nanoparticles. Complementary oligonucleotide labeled with streptavidin was efficiently separated (Fig. 21) with high selectivity and the characteristics of the separated DNA were not affected (Fig. 22) [84].

The biological separation method based on superparamagnetic particle captures has also been developed to separate trace biological active substances [85, 86]. Guo et al. prepared the superparamagnetic particle and modified it with rhIL-2 monoclonal antibody and further purified and

enriched rhIL-2 with a purity of 93%, thus providing a simple and rapid separation method for proteins [87].

A flow-through quadrupole magnetic cell separater [88, 89] has been designed and built using a cell model system of human peripheral T lymphocytes [CD4(+), CD8(+), and CD45(+) cells]. It was accomplished using a sandwich of mouse antihuman monoclonal antibody conjugated to fluorescein isothiocyanate and rat antimouse polyclonal antibody conjugated to colloidal magnetic nanoparticles for the immunomagnetic labeling. The magnetically labeled cells could be separated from the nonlabeled. The maximum throughput of the quadrupole magnetic cell separator was 7040 cells/s (CD45 cells, initial purity of 5%). Theoretical calculations showed that the throughput could be increased to 10^6 cells/s by a scale-up of the current prototype. Paramagnetic nanoparticles conjugated to antibodies that target specific cell surface molecules are consequently commonly utilized as an excellent cell separation method.

5.3. Drug Delivery Based on Nanoparticles

With development of biotechnology and genomics, many new chemical drugs have been synthesized. Among the drugs being synthesized, proteins and peptides represent the major part. But these drugs are often poorly permeable, poorly soluble, and unstable in physiological fluids, with rapid drug metabolism *in vivo* and unfavorable pharmacokinetics. Biocompatible core–shell nanoparticles are promising technologies that can be used to overcome most of the problems of protein/peptide delivery and stability. These delivery systems offer numerous advantages compared to conventional dosage forms, including improved efficacy, reduced toxicity,

Figure 21. Schematic diagram of separation of oligonucleotide by use of superparamagnetic DNA nanocapturer. Reprinted with permission from [84], K. M. Wang et al., *Chem. J. Chinese Univ.* 24, 40 (2003). © 2003, Chem. J. Chinese Univ.

uptake by the cells through the cell membrane, and the ability to cross the blood–brain barrier and to target specific cells.

Furthermore, most anticancer drugs have difficulties and limitations in clinical administration due to their poor solubility and/or other unfavorable properties. They usually require the aid of an adjuvant, which often causes serious side effects. Moreover, intravenous injection and infusion are unavoidably associated with considerable fluctuation of drug concentration in the blood. Therefore, the drugs can only be administered over a limited dosage and time period. Their efficacy is far from satisfactory and the diseases of the patients greatly deteriorate. By microencapsulating drugs in nanosphere matrices to form biodegradable and/or biocompatible core–shell nanoparticles, the release of drugs can be controlled without reaching toxic levels. By further targeting the drugs to be concentrated in the tumor tissue, toxicity can be selectively reduced with a concurrent increase in therapeutic index. The nanoparticle delivery systems offer the advantage of targeted or site-specific delivery of chemotherapeutics and other drugs to affected cells over an extended period, thereby increasing efficacy while reducing toxic side effects.

5.3.1. Polymeric Nanoparticles as Drug Carriers

Many carrier systems for the treatment of brain tumors and nervous system disorders have been developed using polymeric nanoparticles recently. Nanosphere drug targeting systems allow any drug to cross the blood–brain barrier (BBB). Advectus Life Sciences, Canada, has completed the first phase of a study to determine the effectiveness of its Nanocure nanoparticles (P80DOX-NP) for delivering cancer-fighting drugs to brain tumors, which is a novel method for delivering the drug doxorubicin across the blood–brain barrier—a network of blood vessels and cells that protect the brain and prevent certain molecules from passing through. This nanocure consists of a nanoparticles of poly(butylcyanoacrylate) (PBCA) polymer coated with a layer of doxorubicin and a layer of polysorbate-80. Once nanocure enters the bloodstream, the polysorbate-80 coating attracts apolipoproteins. These proteins coat the nanoparticles and, as a result, the blood–brain barrier treats the particles. Results showed there was an excellent dose–response curve for all cancer cell lines tested and that doses delivered as doxorubicin and doses delivered as nanoparticles were equally effective, indicating that the drug did not lose its effectiveness during nanoparticle formulation or shipping.

It has recently been suggested that the PBCA nanoparticle drug delivery system has a generalized toxic effect on the BBB and that this effect forms the basis of an apparent enhanced drug delivery to the brain. Kreuter et al. [90] explored more fully the mechanism by which PBCA nanoparticles could deliver drugs to the brain. Both *in vivo* and *in vitro* methods have been applied to examine the possible toxic effects of PBCA nanoparticles and polysorbate-80 on cerebral endothelial cells using human, bovine, and rat models. It is confirmed that at concentrations of PBCA nanoparticles and polysorbate-80 that achieve significant drug delivery to the brain, there is little *in vivo* or *in vitro* evidence to suggest that a generalized toxic effect on the BBB is the primary mechanism for drug delivery to the brain.

Paclitaxel, one of the best antineoplastic drugs found from nature in recent decades, will be used as a prototype drug due to its excellent efficacy against a wide spectrum of cancers and its great commercial success in the world market. American Pharmaceutical Partners has developed a protein-based paclitaxel nanoparticle currently in clinical studies for metastatic breast cancer. Their product, dubbed ABI-007, leverages the attributes of nanotechnology by encapsulating paclitaxel in an albumin-based paclitaxel nanoparticle approximately a hundredth of the size of a single red blood cell. It poses drug-delivery challenges to solid tumors without using the solubilizing reagent which can be very toxic.

As mentioned, an increasing amount of attention to the use of polymeric nanoparticles as drug carriers is arising both in academia and industry. The development of suitable delivery systems for protein drugs with high molecular weights and short half-lives is of current interest. In conclusion, nanoparticles have a number of potential applications in drug and vaccine delivery.

Prokop et al. [23] featured a new production technology for nanoparticles comprised of multicomponent polymeric complexes that are candidates for delivery vehicles of biological molecules such as proteins and drugs. This novel technology is extensively discussed in contrast to other technologies, primarily those that are water- and organic solvent-based. The usefulness is demonstrated using several examples, evaluating protein and small drug delivery.

Kim and Kim [91] reported polymeric nanoparticles synthesized from a sugar-containing conjugate for liver-specific drug delivery. The conjugate was composed of lactobionic acid, diamine-terminated poly(ethylene glycol), and cholic acid. In aqueous media, the conjugate can self-assemble to form core–shell type nanoparticles. Clonazepam (CNZ) was used as a model hydrophobic drug and was incorporated into the hydrophobic core of the nanoparticles. CNZ was released more slowly at a higher drug loading due to drug crystallization, so these polymeric nanoparticles can be used as drug carriers.

5.3.2. Chitosan Nanoparticles as Drug Carriers

Chitosan (CS), an aminopolysaccharide, has extensive applications as a new drug or gene delivery carrier because it is nontoxic, bioabsorbable, and biodegradable. Recently it has become of consequence to develop hydrophilic nanoparticle carriers for water-soluble natural macromolecules, such as peptides, proteins, and polynucleotides. Calvo and Remunan-López [92] reported a new approach for the preparation of nanoparticles based on an ionic gelation process between CS and a diblock copolymer of PEO–PPO and polyanion sodium tripolyphosphate. These new nanoparticles have great protein loading capacity and provide a continuous release of the entrapped protein for up to 1 week.

Poly(ethylene glycol)-grafted chitosan (PEG-g-chitosan) was found [93] to form nanoparticles through intermolecular

hydrogen bonding in an aqueous solution. PEG-g-chitosan nanoparticles can be expected to incorporate water-soluble, polar, or anionic molecules, which can then interact with chitosan by hydrogen bonds or electrostatic interactions. Therefore Ohya et al. investigated the incorporation of a peptide hormone, insulin, as a model peptide drug into PEG-g-chitosan nanoparticles. PEG-g-chitosan nanoparticles incorporated a certain quantity of insulin molecules spontaneously which depended on the degree of introduction of PEG chain on chitosan, as did the release rate. PEG-g-chitosan nanoparticles have much possibility to be applied as delivery vehicles for peptide drugs.

Polymeric vesicles based on glycol chitosan have been prepared to encapsulate drugs and control the release of drugs, making them suitable for use as drug carriers. Wang et al. [94] reported that the size of the polymeric vesicles might be controlled by the polymer molecular weight. This is not possible with the existing nanoparticles and liposome carriers. The chitosan amphiphile used to make the liposome encapsulating polymeric vesicles is also capable of increasing the transport of drugs across mucous membranes [95]. The incorporation of targeting ligands into polymeric vesicles increases the specific uptake of a drug by mammalian cells [96]. A simple carbohydrate polymer glycol chitosan has been investigated for its ability to form polymeric vesicle drug carriers [97]. Glycol chitosan modified by attachment of fatty acid pendant groups assembles into uniform polymeric vesicles with a mean size of 200 nm in the presence of cholesterol. These polymeric vesicles are found to be biocompatible and capable of entrapping water-soluble drugs, such as bleomycin, which can be efficiently loaded on to these polymeric vesicles to yield a bleomycin-to-polymer ratio of 0.5 units mg^{-1}.

Some anticancer drugs such as doxonrubicin (DXR) produce undesirable side effects such as cardiotoxicity. To minimize these, attempts have been made to couple the drug with dextran (DEX) and then to encapsulate this drug conjugate in chitosan nanoparticles [98]. The size of nanoparticles, found to be 100 ± 10 nm diameter, favors the enhanced permeability and retention effect as observed in most solid tumors. The tumor targeted delivery of encapsulated DEX–DXR conjugate using chitosan nanoparticles not only reduces the side effects but also improves its therapeutic efficacy in the treatment of solid tumors.

A novel delivery system based upon chitosan has obtained increasing attention for nasally administered vaccines due to its enhancement to the immune response of nasally administered vaccines. Illum and co-workers [99–103] have exploited the chitosan concept for the delivery of a variety of pharmacological agents, to include peptide and protein drugs such as insulin, calcitonin, etc. Chitosan-based formulations can greatly improve the absorption of drugs from the nasal cavity and products for the treatment of migraine and cancer pain have reached Phase II clinical evaluation. Investigations in cell culture (CaCo-2) as well as in animal models have demonstrated that chitosan is due not only to improved adhesion between the formulation and the nasal tissues, but also to a transient effect of chitosan on paracellular transport process [104].

5.4. Nonviral Gene Carrier Based on the Nanoparticles

Nonviral gene delivery systems based upon plasmid DNA/chemical complexes have gained increasing attention for their potential in avoiding problems inherent in viral gene vectors. With the development of nanotechnology, nanoparticle gene vectors brought about new hope to safely and efficiently transfer foreign DNA into cells. In view of biocompatible and biodegradable natures and flexibility in design and fabrication with chemical or molecular biology methods, biocompatible core shell nanoparticles provide an excellent and relevant material to form DNA nanoparticles while endosomal lysis and nuclear uptake domains may be included for further improvement in the efficiency of DNA based gene therapy.

At present, nonviral gene therapy has been growing rapidly in two directions. One concerns the synthesis of DNA-encapsulated nanoparticles. The other deals with the DNA modification of the core–shell nanoparticles with diverse functions. Nevertheless, both delivery systems are designed to provide opportunities for DNA targeted delivery.

5.4.1. DNA-Doped Nanoparticles as Gene Carriers

Cui and Mumper [20] reported a pDNA-nanoparticle delivery system developed by entrapping hydrophobized pDNA inside nanoparticles engineered from oil-in-water microemulsion precursors. *In vitro*, hepatocyte transfection studies in Hep G2 cells showed that pullulan (a hepatocyte targeting ligand) coated DNA nanoparticles resulted in enhanced luciferase expression, compared to both pDNA alone and uncoated nanoparticles. Preincubation of the cells with free pullulan inhibited the transfection. Finally, 30 min after tail vein injection to Balb/C mice to monitor *in vivo* biodistribution of the nanoparticles containing I-125 labeled pDNA, only 16% of the "naked" pDNA remained in the circulating blood compared to over 40% of the entrapped pDNA. Due to the apparent stability of these pDNA-entrapped nanoparticles in the blood, potential of these nanoparticles for systemic gene therapy applications requiring cell and/or tissue-specific delivery is assumed.

Ultralow size, highly monodispersed DNA doped calcium phosphate nanoparticles reported by Roy et al. [105] presented a unique class of nonviral vectors, which can serve as efficient and alternative DNA carriers for targeted delivery of genes too. The DNA encapsulated inside the base is protected from the external DNaseI environment and could be used safely to transfer the encapsulated DNA under *in vitro* and *in vivo* conditions after suitably modifying these nanoparticles by adsorbing a highly adhesive polymer like polyacrylic acid followed by conjugating the carboxylic groups of the polymer with a ligand such as *p*-amino-1-thio-beta-galactopyranoside using 1-ethyl-3-(3-dimethylamino-propyl)-carbo diimide hydrochloride as a coupling agent. The modified calcium phosphate nanoparticles have been used *in vivo* to target genes specifically to the liver.

Kabbaj and Phillips [106] demonstrated a possible material for mycobacterium phlei (M. phlei) DNA delivery.

Although M. phlei DNA inhibits cancer cell division but is susceptible to degradation by DNaseI, incorporation of DNA within chitosan nanoparticles significantly decreases the degradation of DNA. They have characterized chitosan-DNA based formation, determined DNaseI susceptibility, and evaluated their antiproliferative activity. In their results, the ability of M. phlei DNA-chitosan nanoparticles to inhibit melanoma cell division was determined relative to M. phlei DNA and a cationic Liposomal M. phlei DNA formulation. M. phlei DNA had antiproliferative activity (MTT reduction, IC50 = 0.9 mg/ml) without intrinsic cytotoxicity (LDH release, ED50 > 50 mug/ml). Cationic polyphosphate chitosan nanoparticles were inert (antiproliferative IC50 > 1 mg/ml, ED50 > I mg/ml). M. phlei DNA-chitosan nanoparticles were 20-fold more potent than M. phlei DNA. Cationic DOTAP/DOPE liposomes were cytostatic (IC50 = 49 mug/ml) and cytotoxic (ED50 = 87 mug/ml), and complexation of M. phlei DNA resulted in a significant reduction of antiproliferative activity. Chitosan nanoparticles may therefore be appropriate delivery vehicles for M. phlei DNA.

Extensive studies examining the interaction between chitosan and DNA were conducted [107, 108] and it was found that it is possible to produce a range of nanoparticles of size from 20 to 500 nm, carrying different surface charges. These nanoparticles have been proven to be appropriate for *in vitro* cell transfection as well as for optimal performance *in vivo*.

5.4.2. DNA-Conjugated Nanoparticles as Gene Carriers

Besides DNA-encapsulated nanoparticles as nonviral gene carriers, there are many reports about DNA-nanoparticle conjugates used in gene delivery.

In the research of Zhu et al. [109], silica nanoparticles (SiNP) were synthesized first in a microemulsion system, polyoxyethylene nonylphenyl ether (OP-10)/cyclohexane/ammonium hydroxide, and then poly-L-lysine (PLL) was linked on the surface of SiNP by nanoparticle surface energy and electrostatically bound. Lastly a novel complex nanomaterial—poly-L-lysine-silica—was prepared to conjugate with DNA. Their cell transfection showed that PLL-SiNP could efficiently transfer PEGFPC-2 plasmid DNA into HNE1 cell lines, which indicated that PLL-SiNP was a novel nonviral nanoparticle gene vector and would probably play an important role in gene structure and function research as well as gene therapy.

Recently we have developed a novel DNA enrichment technology based on the amino-modified silica nanoparticles which have been prepared by the controlled synchronous hydrolysis of tetraethoxysilane and N-(β-amimoethyl)-γ-aminopropyl-triethoxy silane in water nanodroplets of water-in-oil microemulsion. Due to the presence of amino groups on the surface of the nanoparticles, nanoparticle–plasmid DNA complexes (DNA–NP) can easily form through electrostatical binding between the positive charges of the amino-modified silica nanoparticles and the negative charges of the plasmid DNA. As shown in Figure 23, lanes 2 and 4, plasmid DNA moved in the electric field, and amino-modified silica nanoparticle–plasmid DNA complexes
Figure 23. Agarose gel electrophoresis of plasmid DNA and DNA–NP complexes. Lane 1 is DNA marker (λ DNA is cleaved by HindIII). Lane 2 is undigested free plasmid DNA. (a) Superhelix DNA, (b) linear DNA, and (c) open circular DNA are the three forms of the plasmid DNA. Lane 3 is digested free plasmid DNA. Lane 4 is plasmid DNA–NP complexes. Lane 5 is pure silica NP after incubation with plasmid DNA. Lane 6 is plasmid DNA–NP complexes digested with DNaseI. Lane 7 is the DNA released from the DNA–NP complexes that have been digested with DNaseI. Lane 8 is DNA marker (λ DNA is cleaved by HindIII). Reprinted with permission from [110], X. X. He et al., *J. Am. Chem. Soc.* 125, 7168 (2003). © 2003, American Chemical Society.

were retained around the sample well. The reason the DNA–NP complexes did not move toward the positive electrode lies in the charge and the large size of the complexes. In a control experiment, pure silica nanoparticles with negative zeta potential at neutral pH could not enrich plasmid DNA. As shown in lane 5, there was no DNA shown in the lane after the incubation of the pure silica nanoparticles with plasmid DNA. This clearly shows that it is necessary to have amino-modified NP for DNA binding. And the results also suggested the plasmid DNA enriched on the nanoparticles could be protected from DNaseI cleavage and keep its integration function, due to the large surface and pore structures of the nanoparticles. As shown in Figure 23, lanes 3 and 6, free plasmid DNA was degraded completely when incubated with DNaseI, while plasmid DNA–NP complexes were visualized around the sample pore after the same digestion process, and the intensity is quite similar to the plasmid DNA–NP complexes without digestion of DNaseI (lane 4). And the properties of the plasmid DNA in the DNA–nanoparticle complexes were not changed after digestion with DNaseI. It was clear that the DNA released from the DNA–NP complexes gave the same three bands (lanes 2 and 7) as those from the free plasmid DNA. The relative intensities of the bands are different for lanes 2 and 7, and the possible reason is that not all the plasmid DNA is released from the nanoparticles. These results have shown that DNA–NP complex formation was indeed efficient to provide protection against enzymatic cleavage [110].

Based on the aforementioned advantages of the amino-modified silica nanoparticles, a nonviral protective gene carrier has been developed. By using these nanoparticles, the plasmid DNA can successfully cross various systemic barriers to COS-7 cells as well as mediate high expression of the green fluorescence protein gene in cells (Fig. 24).
Figure 24. Transfection of plasmid DNA in COS-7 cells based on (a) amino-modified silica nanoparticle gene carrier, (b) amino-modified silica coated magnetic nanoparticle gene carrier.

Keneuer et al. developed a nonviral DNA delivery system also based on surface modified silica nanoparticles which can efficiently transfect genes into cells *in vitro* [111]. In their study, the galactosidase expression plasmid DNA pCMV/β was immobilized on the nanoparticle surface and efficiently transfected COS-1 cells. The transfection activity was accompanied by very low cytoxicity, with LD_{50} values in the milligrams per milliliter range.

Efforts to influence the biology of blood vessels by gene delivery have been hampered by a lack of targeting vectors specific for endothelial cells in diseased tissues. Hood et al. [112] aimed to solve this and their results showed that a cationic nanoparticle (NP) coupled to an integrin alphavbeta3-targeting ligand could deliver genes selectively to angiogenic blood vessels in tumor-bearing mice. The therapeutic efficacy of this approach was tested by generating NPs conjugated to a mutant Raf gene, ATP(mu)-Raf, which blocks endothelial signaling and angiogenesis in response to multiple growth factors. Systemic injection of the NP into mice resulted in apoptosis of the tumor-associated endothelium, ultimately leading to tumor cell apoptosis and sustained regression of established primary and metastatic tumors.

5.4.3. Significant Factors in Gene Delivery

During the gene delivery process, some factors predominantly contribute the transfection of biocompatible core–shell nanoparticles.

The size of the nanoparticles may be considerably related to transfection efficiency. As for nanoparticles formulated from biodegradable polymers [113], such as poly(lactic acid) and poly(D,L-lactide-co-glycolide), extensively investigated as nonviral gene delivery systems due to their sustained release characteristics and biocompatibility, the smaller sized nanoparticles showed a 27-fold higher transfection than the larger sized nanoparticles in the COS-7 cell line and a 4-fold higher transfection in the HEK-293 cell line.

Different DNA–nanoparticle complexes as well as nanoparticles conjugated with different biomolecules may result in better or worse transfection efficiency. The transfection efficiency of chitosan–DNA nanoparticles prepared using a complex coacervation process was cell-type dependent [114]. Typically, it was three to four orders of magnitude, in relative light units, higher than the background

level in HEK293 cells, and 2–10 times lower than that achieved by LipofectAMINE(TM)–DNA complexes. The present study also developed three different schemes to conjugate transferrin or KNOB protein to the nanoparticle surface. The transferrin conjugation only yielded a maximum 4-fold increase in their transfection efficiency in HEK293 cells and HeLa cells, whereas KNOB conjugated nanoparticles could improve the gene expression level in HeLa cells 130-fold.

6. CONCLUSIONS

In this chapter, we have described the structure, synthesis, characteristics, and applications in biomedicine of biocompatible core–shell nanoparticles. Different core material and different shell material can be used to construct varieties of core–shell nanoparticles. Biomolecules immobilized on the surface of nanoparticles make them more biocompatible for the application in biomedicine. By exploiting the nucleation and coating techniques, nanoparticles can be synthesized with a typical core–shell structure. Further biological modification on their surface in one-step or multistep reactions extend the range of functions and provide access to a new sort of smart functional nanoparticle for particular applications.

Due to their marvelous core–shell structure, nanometric size, and high surface to volume ratio, these core–shell nanoparticles are least toxic, highly stable, and highly sensitive compared with conventional materials or tools used in biological analysis. Based on these excellent characteristics, core–shell nanoparticles have been used in biosensing, cell recognization, bioseparation, drug delivery, gene transfection, and so on. Desirable results have been obtained and so much attention has focused on their further research.

Although the core–shell nanoparticle research has veritably exploded over the last few years and a few remarkable attempts have already been made, there is no doubt that ever-increasing advancements of science and technology, such as nanotechnology, biotechnology, materials science, medicine, and the combination of them, should allow the development of new core–shell nanoparticles with amazing properties and offer bright prospects that the applications of core–shell nanoparticles are almost unlimited.

GLOSSARY

Biocompatibility The property of being biologically compatible by not producing a toxic, injurious, or immunological response in living tissue.

Bioimaging Visualization of internal bodily organs, tissues, or cavities using specialized instruments and techniques, such as fluorescent microscopy, for diagnostic purposes.

Biomedicine The branch of medical science that deals with the ability of human beings to tolerate environmental stresses and variations and detects trace analytes of life science to understand the relationship between biological molecule structure and its function.

Biosensing Detecting a specific biological molecule, system of biological molecules, or biologically produced signal with a device.

Bioseparation Develops new and improved technologies for isolation of biomolecules or cells (e.g., proteins).

Core–shell nanoparticles A kind of nanomaterial with diameter of $1 \text{ nm} < d < 100 \text{ nm}$ and possessing typical core–shell structure.

DNA A nucleic acid that carries the genetic information in the cell and is capable of self-replication and synthesis of RNA. DNA consists of two long chains of nucleotides twisted into a double helix and joined by hydrogen bonds between the complementary bases adenine and thymine or cytosine and guanine. The sequence of nucleotides determines individual hereditary characteristics.

Drug delivery A device or material to transport drugs actively directed to the target cell, actively translocated across the cell membrane, and specifically to intervene with a particular function in the cell.

Gene delivery A device or material introducing DNA or RNA into cells, tissues, or organisms, in order to study regulation and function of genes and proteins.

Nanocapturer A nanodevice designed to obtain or separate the desired materials and information.

Nanosensor A nanodevice designed to detect specific biological molecules, chemical molecules, system of biological molecules, or biologically produced signal or other chemical process and so on.

Nucleation A process in which some material condenses into clusters or particles in settlements of increasing size and density.

Quantum dot A nanoscale crystalline structure made from cadmium selenide that absorbs white light and then reemits it a couple of nanoseconds later in a specific color. The quantum dot has been around since the 1980s when scientists were looking into the technology as a way to build nanoscale computing applications where light is used to process information. More recently, however, the technology is being used in medicine. The crystals are one ten-millionth of an inch in size and can be dissolved in water. When illuminated, they act as molecule-sized light-emitting diodes and can be used as probes to track antibodies, viruses, proteins, or DNA within the human body.

Real time The actual time in which a physical process, chemical process, or a biological process under control occurs.

Ribonucleic acid (RNA) A naturally occurring polymer composed of ribonucleotides. Although commonly found in its single-stranded form, it can adopt two- and four-stranded forms having a variety of shapes.

Bioconjugated Silica Nanoparticles for Bioanalysis

Xiaojun Zhao, Lisa R. Hilliard, Kemin Wang, Weihong Tan

University of Florida, Gainesville, Florida, USA

CONTENTS

1. INTRODUCTION

Nanotechnology in combination with biomedical and other biotechnological developments promises to produce major breakthroughs and revolutionary tools in bioanalysis. One of the best ways to link biomolecules and nanotechnology is through the generation of bionanomaterials. Recently, nanoparticles have been rapidly developed and show great potential for use as efficient bionanomaterials [1–10]. Among them, luminescent nanoparticles have demonstrated great promise as optical probes in bioanalysis due to their unique optical properties and high surface-to-volume ratio [11–20]. In comparison with traditional fluorescence labeling techniques, which usually use fluorescent dye molecules to signal target bioconjugation and other biological interactions, the luminescent nanoparticle labeling method provides enhanced detectable signal and reproducibility. This advancement in luminescent techniques makes direct and rapid detection of trace amounts of biomolecules possible. To effectively use nanoparticle probes in various bioassays, conjugation of biomolecules to the luminescent probes is critically important. The most convenient and effective surface bioconjugation can be done using well established silica surface chemistry if the nanoparticle has a silica surface. As a result, silica nanoparticles can be routinely modified to bionanomaterials suitable for various bioanalytical studies. Thus, this chapter focuses on luminescent silica nanoparticles for biomedical applications and begins with a brief review of the recent developments in the field of luminescent nanomaterials.

Several important nanoluminescent materials, including quantum dots [21–27], gold and silver nanoparticles [28, 29], and dye-doped nanoparticles [30], have demonstrated excellent signaling capabilities in the detection of trace amounts of target biomolecules. Quantum dots are remarkable luminescent nanocrystals that show great promise for simultaneous detection of multiple analytes, with a single excitation wavelength, as a result of their narrow emissions based on size. Basically, the emission energies of quantum dots shift to higher energies as the size of the quantum dots (QDs) decreases due to quantum confinement. A clear difference in emission peaks is observed with a 1–2 nm difference in QD size. Some efforts have been made to improve the solubility of quantum dots in aqueous solution in order to use them in biological environments. The recent development of water-soluble silica coated quantum dots shows promise in the bioconjugation of QDs with biomolecules [31, 32]. So far, quantum dots have been employed to label several biomolecules including proteins and oligonucleotides for cell recognition, anisotropy studies, and DNA detection. Nie and others have achieved great success in the development and applications of quantum dots [33–39]. The unique advantage of QDs with narrow emissions offers new capabilities for multicolor optical coding in gene expression studies, high-throughput screening, and medical diagnostics.

Gold nanoparticles are another attractive nanomaterial for merging nanotechnology with biotechnology due to the high affinity of the gold atom toward thiol modified molecules. Ultrasensitive analyses of oligonucleotides, proteins, and other bioanalytes have been achieved using gold nanoparticles as biomarkers [40–46]. Mirkin et al. have done extensive work in this area [47–60], especially in DNA analysis using gold nanoparticles as signaling probes. Principally, as the target biomolecules bind to the

probe molecules linked to gold nanoparticles, the formation of polymeric gold nanoparticle/polybiomolecule aggregates leads to changes in the sample's emission wavelength. The resultant fluorescence intensity reflects the amount of target molecules. Gold nanoparticles have also been extended to biomolecule detection in the solid phase. In a sandwich-based array method, a DNA-labeled gold nanoparticle hybridizes with a target sequence that has also formed a duplex with a capture sequence immobilized to a solid support. Signal is obtained from the bound gold nanoparticle probe and is further amplified by silver reduction of the gold nanoparticle probe. By utilizing different light scattering properties of oligonucleotide-capped particles, a method has also been developed for multicolor labeling and imaging of DNA arrays, which shows an ability to distinguish two different DNA targets.

Dye-doped nanoparticles provide highly luminescent signals due to the very high quantum yield of dye molecules as compared to other luminescent materials. Various organic dye-doped polymer microparticles have been developed [61–64]. Due to their hydrophobic properties, organic dye molecules are easily incorporated inside polymer matrices to form luminescent polymer particles. Some commonly used fluorophores in traditional fluorescence labeling techniques, such as fluorescein isothiocyanate and rhodamine isothocyanate, have been applied to generate luminescent polymer particles. Polystyrene and poly(tert-butylacrylate) are polymer materials that are frequently employed to produce uniform polymer particles through the microemulsion method. The resultant particles emit high luminescence intensity. However, most biomolecule reactions take place in aqueous solutions, making polymer nanoparticles unsuitable for bioanalysis due to their hydrophobicity and bioincompatibility. Core–cell luminescent microparticles, including organosilicon microgels [65–67], have also been reported [68–71].

To develop highly effective nanoluminescent probes, we have produced dye-doped silica nanoparticles for easy bioconjugation, significant signal amplification, and excellent

reproducibility. The dye-doped silica nanoparticle contains thousands of dye molecules in a matrix of water soluble silica [30, 72–74]. Due to the large number of dye molecules (with a high quantum yield), the dye-doped silica nanoparticles provide highly luminescent signals when used as optical probes. Also, the silica matrix protects the dye molecules from environmental oxygen, and thus the dye-doped nanoparticles give highly photostable fluorescent signals. Moreover, silica is an excellent biocompatible and versatile substrate for the immobilization of biomolecules. In this chapter, we will discuss the synthesis, characterization, bioconjugation, and applications of various silica nanoparticles [61–80], including core–shell fluorescent silica particles and microgels, silica coated metal nanoparticles and quantum dots, and dye-doped silica nanoparticles. Polymer fluorescent particles and magnetic silica nanoparticles will also be briefly discussed [81–84].

It is our intent in this chapter to mainly focus on dye-doped silica nanoparticles and their utilization in biomedicine. We believe that each one of the biolabeling reagents listed in Table 1 has its own advantages and can be preferably used in unique applications in order to best exploit the strengths of each probe.

2. SYNTHESIS AND CHARACTERIZATION

There are two major silica nanoparticle synthesis methods, Stöber [83] and reverse microemulsion [94–96], which provide a silica matrix by hydrolysis and polymerization of tetraethylorthosilicate (TEOS). The Stöber method requires a shorter synthesis time than the microemulsion method but results in relatively large, nonuniform nanoparticles. In contrast, the reverse microemulsion method provides monodisperse and smaller sized silica nanoparticles. Thus, the majority of the silica nanoparticles discussed here is synthesized using the reverse microemulsion method.

The reverse microemulsion method, also called water-in-oil (W/O) microemulsion, is based on an isotropic and thermodynamically stable, single-phase system that consists

Table 1. Comparison of fluorescence labeling reagents for bioanalysis.

Characteristics	Dye-doped NP	Fluorophores	Quantum dots
Signal amplification	Extremely high, up to 100,000 × 1 Fluorophore	Low	<20× of 1 Fluorophore
Photostability	Excellent without photobleaching	Poor	Excellent with minimal photobleaching
Ability to bioconjugate	Easy and universal	Easy, but nonuniversal	Still under investigation and progress being made
Aqueous solubility	Excellent	Mostly excellent, but some low	Low
Multiplex analysis capability	Possible and under investigation	Difficult	Excellent
Toxicity	None	Severe	Minimal
Environmental influence	None	Severe	Minor
Manufacturing	Easy and batch production possible	N/A	Difficult
Compatibility with existing detection system	Excellent	Excellent	Very good
Overall feasibility for bioanalysis	Great potential	Good	Great potential, still under investigation

of small amounts of water, a large volume of oil, and a surfactant. The surfactant molecules lower the interfacial tension between water and oil, resulting in the formation of a transparent solution. Water nanodroplets (also called water pools) are formed in the bulk oil phase and serve as nanoreactors for the synthesis of nanoparticles from various materials (Fig. 1). The size of the water pool influences the size of the nanoparticles. By changing the molar ratio of water to surfactant (W_0 value), the size of the spherical nanoparticles is controllable. In general, the higher the value of W_0, the larger the particle size will be. The excess base in the microemulsion initiates the polymerization reaction through hydrolysis of TEOS and finally forms the network silica matrix [97]. The rate of the polymerization is much slower in the microemulsion in comparison to that in a bulk aqueous solution. Therefore, as the polymerization reaction proceeds, monodisperse silica nanoparticles are formed.

The Stöber method is based on hydrolysis and polymerization of TEOS using either base or acid in a bulk ethanol solution. Using this method, different sizes of silica particles are obtained ranging from 100 nm to 1 μm in diameter. The size of the particles can be tuned by changing the experimental conditions, such as temperature, polymerization time, and silica precursor (TEOS) concentration. Although this method is relatively simple and easy to carry out in only a few hours, it is limited by the nonuniformity of the produced nanoparticles. Consequently, this method is usually used as an alternative procedure for the preparation of large silica nanoparticles.

Using the W/O microemulsion method, the produced silica nanoparticles have very uniform size, which is characterized by scanning electron and transmission electron microscopy (SEM and TEM) (Fig. 2). Inorganic and organic dye-doped silica nanoparticles show the same size distribution. Given the different applications for bioanalysis, various sized silica nanoparticles can be obtained by controlling the W_0 value and using different surfactants. For example
at $W_0 = 10$, the nanoparticle size is 60 ± 3 nm in diameter; RuBpy-doped silica nanoparticles of this size have been used in applications for cell recognition and bacteria detection [76, 78].

2.1. Pure Silica Nanoparticles and Core–Shell Silica–Polymer Particles

To take advantage of the high surface to volume ratio of the nanoparticles, pure silica nanoparticles were synthesized for application as effective solid supports in bioanalysis. Both Stöber and reverse microemulsion methods were used as will be described.

Very uniform pure silica nanoparticles were synthesized using the W/O microemulsion method. In an organic solvent solution, cyclohexane, surfactant (Triton X-100), and a co-surfactant (n-hexanol) were mixed. A small volume of water (amount dependent upon the desired nanoparticle size) was then added to the system to form an isotropic and thermodynamically stable single phase. In the presence of TEOS, a polymerization reaction was initiated by adding a small amount of NH_4OH (28–30 wt%). The reaction was allowed to proceed for 24 hours with continuous stirring. After the reaction was completed, the silica nanoparticles were isolated from the solution using acetone to break the single phase of the microemulsion system, followed by washes in ethanol and acetone to remove any surfactant molecules. The resultant nanoparticles were air-dried at room temperature.

The Stöber method was also used to obtain pure silica nanoparticles [80]. The synthesis process was carried out in a bulk of ethanol solution with various amounts of TEOS. The solution was cooled to 0 °C in an ice cooled ultrasonicator. Ammonium hydroxide (NH_4OH, 28–30 wt%) was added to the solution with ultrasonicating. After reacting for 1 hour, the nanoparticles were separated from the solution, washed 5–6 times with water and acetone, and air-dried.

The pure silica nanoparticles obtained from the W/O microemulsion method were small and uniform while the nanoparticles from the Stöber method were relatively large. Both pure silica nanoparticles demonstrated good support when used as a solid substrate for DNA detection and enzyme catalyzed reactions in aqueous solutions [79, 80].

The silica particles can be further coated with various polymers to form core–shell silica–polymer particles that may have different applications in material science and biomedicine [84], such as the stabilization of pigments in

paints and drug delivery. So far, several core–shell particle synthesis methods have been reported, including copolymerization of hydrophobic monomer core–hydrophilic shells [85], and different self assembly approaches [86–90]. Among various assembly methods, a colloidal assembly of polystyrene shell on the silica particle surface is simple and attractive [84]. As shown in Figure 3, the colloidal assembly process was controlled by either specific chemical or biochemical interactions. For the chemical reaction, the amine-modified particles were first activated by glutaraldehyde followed by chemical binding with amine-modified polystyrene nanoparticles. For the biochemical reaction, the glutaraldehyde-activated silica particles were coated with avidin; then biotin-labeled polystyrene nanoparticles were assembled onto the silica particle surfaces. The assembled polymer particles on the silica particle surface were subsequently heated at temperatures above the glass transition of the polymer nanoparticles, allowing the polymer to flow over the silica particle surface and resulting in a uniform core–shell composite (Fig. 4). Due to the stability of the

Mater.* 13, 2214 (2000). © 2000, American Chemical Society.

bonds between the polymer and silica, a wide range of pHs, ionic strengths, and solvents can be applied in the assembly process.

2.2. Core–Shell Fluorescent Silica Particles

To obtain highly fluorescent, photostable, and biocompatible nanoparticles for bioanalysis, several fluorescent silica nanoparticles were developed [30, 72–74]. The basic idea was to entrap a large number of dye molecules inside a single nanoparticle so that each individual nanoparticle would emit a strong fluorescent signal and thus serve as a highly fluorescent probe.

A core–shell fluorescent silica particle is one type of highly fluorescent material that consists of an organosilica fluorescent core and a silica shell, which was developed by van Blaaderen et al. [68–70] and recently reviewed by Schärtl [71]. The fluorescent molecules, such as fluorescein isothiocyanate and rhodamine isothiocyanate, were covalently attached to the silane coupling agent 3-(aminopropyl)triethoxysilane (APS). The reaction product between APS and fluorescent dyes was incorporated into a silica core via polymerization of the TEOS (Stöber method). The resultant fluorescent silica core was further coated with another silica shell by a second polymerization of TEOS. The nonfluorescent shell of the particles did not block the fluorescence of the core. Moreover, with efficient shell thickness, the fluorescence signals of the individual particles were clearly separated in the fluorescence images even though the concentration of the particles was very high. This property makes the core–shell fluorescent particles very useful for generating a highly concentrated colloidal system for bioanalysis.

Figure 3. Reaction scheme for assembling composite materials via both glutaraldehyde chemistry and biospecific interactions. The top section illustrates assemblies starting with amine-labeled silica. Glutaraldehyde treatment of the labeled silica is followed by reaction with amine-modified polystyrene nanoparticles. The resultant material is heated to melt the polystyrene and form the polymer shell. The bottom section illustrates assembly of biotin-labeled polystyrene nanoparticles onto avidin coated silica microspheres. Reprinted with permission from [84], M. S. Fleming et al., *Chem. Mater.* 13, 2213 (2000). © 2000, American Chemical Society.

Organosilicon microgels with a dye-labeled core and a protective nonfunctionalized shell are a novel type of core–shell fluorescent particle developed by Schärtl et al. [71]. This particle has larger porosity and a lower density than other core–shell silica particles. The synthesis process is schematically illustrated in Figure 5. A reactive core was first formed by condensation of trimethoxymethylsilane (TMOMS) and chlorobenzyltrimethoxysilane. The core was then coated with a nonfunctional shell of pure TMOMS. To avoid chemical aggregation, the particle surface was reacted with monosilane. Finally, the produced core–shell particles were converted to functional dye-labeled microgels by dissolving the particles in tetrahydrofuran, and using the —CH$_2$Cl groups for esterification with the carboxylate group of a dye molecule, which diffuses through the micropores of the TMOMS shell into the reactive core. Several fluorescent dye molecules containing COO$^-$ groups, such as coumarin 343 and pyrene, have been incorporated into the microgels. The dye molecules remained inside the microgel network without leakage, making the fluorescent microgels a stable optical tracer for bioanalysis.

2.3. Dye-Doped Silica Nanoparticles

2.3.1. Inorganic Dye-Doped Silica Nanoparticles

Inorganic dye-doped silica nanoparticles were first developed using the W/O microemulsion method. The synthesis method is effective because of the electrostatic attraction between the positively charged metal ions in the inorganic dye molecules and the negatively charged silica matrix of the nanoparticles. Due to the hydrophilic property of inorganic dye molecules, they are easily dissolved in aqueous solution and retained in the water pool during the TEOS polymerization reaction. Thus, after the negatively charged silica matrix forms, the inorganic dye molecules are trapped inside by electrostatic interactions, resulting in inorganic dye-doped silica nanoparticles.

A commonly used inorganic dye molecule, tris(2,2′-bipyridyl) dichlororuthenium (II) (RuBpy), was employed

as a dopant in the W/O microemulsion [30]. The synthesis procedure was similar to the pure silica nanoparticle synthesis method using the W/O microemulsion system described earlier. Instead of the pure water, dye in aqueous solution was added to the water pool. The resultant dye-doped nanoparticles contain tens of thousands of dye molecules. However, the luminescence intensities of the dye-doped nanoparticles were not proportional to the amounts of loaded dye molecules. As the loaded dye amount increases, the luminescence intensity of the nanoparticles increases up to a certain dye concentration limit. Approximately 20 wt% loading of dye molecules is an optimal amount, indicated by maximum luminescence intensity of the nanoparticles. Further dye loading reduced the luminescent signal due to self-quenching of the dye molecules. To make the nanoparticle size compatible with biomolecules for more effective use in bioanalysis, much smaller sized nanoparticles, ranging from 10 to 90 nm in diameter, were prepared using different surfactant types and W_0 values (Fig. 6).

2.3.2. Organic Dye-Doped Silica Nanoparticles

Given the higher quantum yield of organic dyes than inorganic ones, the doping of organic dyes inside silica nanoparticles is an improved alternative for obtaining highly fluorescent probes. Inspired by the success of the inorganic dye-doped silica nanoparticle synthesis, we then focused on the development of organic dye-doped silica nanoparticles. However, it was difficult to trap organic dye molecules inside the silica matrix using either the W/O microemulsion or the Stöber method. Two factors hindered the retention of the organic dye molecules inside the silica matrix in the synthesis process of the silica nanoparticles. One is the hydrophobic property of the organic compounds. Some organic dye compounds cannot dissolve in aqueous solution; some partially dissolve in the water solution but their solubility in organic reagents is much higher than in the aqueous solution. Thus, even though they first dissolve in the water pool in the W/O microemulsion system, they quickly transfer to the
Figure 5. Preparation of organosilicon microgels with dye-labeled and nonfunctional protective shell (HMN = hexamethyldisilazane). Reprinted with permission from [71], W. Schärtl, *Adv. Mater.* 12, 1903 (2000). © 2000, Wiley.
Figure 6. TEM images of various sizes of RuBpy-doped silica nanoparticles synthesized with different types of surfactants and water to surfactant ratios.

organic phase, resulting in pure silica nanoparticles. The second reason is the lack of attraction force between organic molecules and the silica matrix. Unlike RuBpy, most organic dye molecules have neutral charges, and thus there is no electrostatic attraction to retain the dye molecules inside the silica matrix. Thus, water solubility and positive charge are two essential requirements for obtaining dye-doped silica nanoparticles using the W/O microemulsion and Stöber methods. All the methods to be described for the synthesis of organic dye-doped silica nanoparticles focus on the exploration of novel approaches based on these two requirements.

Rhodamine 6G (R6G) and tetramethylrhodamine (TMR) are commonly used organic fluorophores in bioanalysis due to their high quantum yield and suitable excitation and emission wavelengths for most conventional optical sources and instrumental detection systems. Therefore, these two dye molecules were chosen to explore new synthesis methods for organic dye-doped silica nanoparticles.

R6G-Doped Silica Nanoparticles The goal of this Stöber-based synthesis approach was to reduce the hydrophilicity of the silica matrix so that the highly hydrophobic R6G molecules would be trapped inside the nanoparticle matrix [72]. TEOS was still used as a hydrophilic silica precursor in the system. In addition, a relatively hydrophobic silica compound, phenyltriethoxysilane (PTES), was also added to the system as a second precursor to aid in trapping the organic fluorophores. Since the matrix was changed to a mixed medium of hydrophilic and hydrophobic components, R6G was more retained in this matrix, resulting in R6G-doped silica nanoparticles. This method was previously used for the synthesis of hydrophobic-dye-doped microspheres [88]. The silica nanoparticle formation was a three-step process: (a) hydrolysis of the silica precursors TEOS and PTES to silanols, (b) polymerization, and (c) nanoparticle formation. For the preparation of the R6G-doped nanoparticles, a dye solution in ethanol was mixed with PTES. Hydrochloric acid or ammonium hydroxide was added to the resulting solution to start the hydrolysis of the PTES. The completion of the reaction was indicated by the formation of a one-phase system after a few hours. TEOS, which also hydrolyzes in the presence of ammonium hydroxide, was then added to the system. The reaction proceeded for 1 hour at 0 °C with continuous sonication and frequent vortexing. An excess amount of acetone was then added to stop the growth of the nanoparticles. The size of R6G silica nanoparticles can be controlled by the polymerization time.

The amount of PTES was an important factor for the entrapment of R6G in the silica nanoparticles. An increase in the amount of PTES resulted in a corresponding increase in the amount of doped dye molecules. The assumed driving force for the entrapment of the dye molecules is the affinity between the hydrophobic dye molecules and PTES. At high PTES concentrations, the produced nanoparticles possess a high degree of hydrophobicity and thus hinder subsequent nanoparticle surface biomodification.

Nanoparticles obtained through this approach exhibited high fluorescent intensity, excellent photostability, and minimal dye leakage after prolonged storage in aqueous solution. Applications of the R6G-doped silica nanoparticles

illustrated their utility as fluorescent probes for ELISA-like assays in BSA determination and as biosensors in glutamate analysis [72].

TMR-Doped Silica Nanoparticles The obtained R6G-doped silica nanoparticles are relatively large and nonuniform due to the employment of the Stöber-based method. To obtain a better organic dye-doped silica nanoparticle, a different synthesis approach was explored. The new design for the synthesis of TMR-doped silica nanoparticles was based on the W/O microemulsion method. Unlike the scheme of the synthesis of R6G-doped silica nanoparticles which altered the composition of the silica matrix, the aim of this approach was to change the property of the water pool in the microemulsion system to make the TMR molecules meet the two requirements for the synthesis of organic dye-doped silica nanoparticles [73].

Since TMR molecules are neither positively charged nor hydrophilic compounds, more than one modification procedure was initially needed to trap TMR molecules inside the silica matrix. To avoid complicated synthesis procedures, a novel approach was designed to complete the two objectives within one step using the W/O microemulsion method. The basic idea employs a special binary compound to form the bulk of water pool; this compound has both organic and inorganic properties and acts as an aqueous solvent to dissolve and retain the TMR molecules inside the water pool. Moreover, this compound also provides enough protons to induce positive charges on the TMR molecules. Acetic acid (HAc) is an ideal compound that meets all the requirements. First, acetic acid acts as an organic reagent capable of dissolving the TMR molecules. Second, TMR-HAc remains in the water pool in the W/O microemulsion system because in the presence of both water and oil, HAc has a greater affinity for the water phase than the oil phase. Third, acetic acid provides protons for the TMR and makes it positively charged. Thus, TMR molecules can be trapped inside the silica matrix using acetic acid as a solvent to form TMR-doped silica nanoparticles; this approach is simple and easy to carry out. Compared to inorganic dye-doped nanoparticles, the TMR-doped silica nanoparticles provide much higher fluorescent signals. Preliminary results show that these TMR-doped silica nanoparticles, despite the formation of aggregates, can be used as highly fluorescent biomarkers for cancer cell recognition and detection.

TMR–Dextran Doped Silica Nanoparticles An alternative approach for the synthesis of TMR-doped silica nanoparticles was also developed using a TMR–dextran complex [74]. By linking a highly hydrophilic dextran molecule to a TMR molecule, the TMR was converted to a hydrophilic molecule and thus could be trapped inside the water pool in the microemulsion system. However, due to the lack of a combination force between the TMR-dextran complex and the silica matrix, the TMR-dextran easily leaked out from the silica matrix when it was used in an aqueous solution. To efficiently trap TMR molecules inside the silica, TMR-dextran complex needed to become positively charged. By adding a low pH hydrochloric acid solution to the water phase in the microemulsion system, the TMR molecules were firmly entrapped in the silica matrix,

resulting in highly fluorescent TMR-doped silica nanoparticles (Fig. 7). TMR–dextran-doped silica nanoparticles showed excellent capability as a highly fluorescent probe for detection of DNA molecules [77].

2.3.3. Signal Amplification and Photostability of Dye-Doped Silica Nanoparticles

To evaluate the effect of the signal amplification of three types of dye-doped silica nanoparticles described, a series of comparisons of the fluorescent intensities between the dye-doped nanoparticles and the corresponding dye molecules was carried out in aqueous solution using a spectrofluorometer. The results showed that the fluorescence intensity of one dye-doped nanoparticle was approximately 10^4 times higher than that of one dye molecule when each dye-doped nanoparticle is observed at its maximum fluorescence intensity. For TMR–dextran-doped silica nanoparticles, the dextran molecules did not affect the nanoparticle fluorescence intensity as compared to TMR-doped silica nanoparticles because excessive loading of TMR molecules reduces fluorescent intensity of the nanoparticles due to TMR molecule self-quenching effect. Thus, one dye-doped nanoparticle contains approximately 10^4 effective dye molecules. This result is the foundation for the extremely high signal enhancement provided by dye-doped nanoparticles when they are used as fluorescent probes for bioanalysis (Fig. 7).

The excellent photostability of dye-doped silica nanoparticles was proven by the following comparisons. Solutions of three types of dye-doped silica nanoparticles and corresponding dye molecules were prepared. For each comparison, a pair of samples with the same fluorescent intensity, a dye solution and a dye-doped nanoparticle solution, were continuously irradiated with excitation light for 1000 seconds. The fluorescence intensity of the pure RuBpy molecules was reduced by 81%, while the fluorescence intensity of RuBpy-doped silica nanoparticles remained constant (Fig. 8).

To further verify the RuBpy-doped silica nanoparticle's optical stability, a different experiment was carried out by varying the oxygen level during excitation. It is known that oxygen greatly quenches RuBpy, and thus RuBpy is used as an oxygen sensing reagent. However, RuBpy-doped silica nanoparticles showed great stability to oxygen at high oxygen concentrations up to 8 psi. The reason for the high
Figure 8. Comparison of photostability of dye-doped silica nanoparticles vs pure dye molecules. Reprinted with permission from [72], R. Tapec et al., *J. Nanosci. Nanotech.* 2, 3–4, 405 (2002). © 2002, American Scientific Publishers.

photostability of dye-doped silica nanoparticles is the protective function of the silica matrix, which acts as a shield to isolate dye molecules from environmental oxygen, thus allowing the dye molecules inside silica to provide a constant fluorescence signal in various environments. This high photostability of the nanoparticles provides a foundation for precise and reproducible analytical measurements when nanoparticles are used as fluorescent probes.

2.4. Silica Coated Metal Particles

2.4.1. Silica Coated Luminescent Metal Nanoparticles and Quantum Dots

As discussed in the Introduction, quantum dots and metal nanoparticles, such as gold and silver, are attractive luminescent nanomaterials. To use these nanomaterials in different systems, silica shell coated gold clusters and quantum dots were developed [91, 92]. The shell of the silica does not change the optical and electrical properties of the metal particles. Moreover, the silica shell stabilizes the individual particles by reducing metal particle aggregation (Fig. 9) [93]. The synthetic principle is to provide a silane coupling agent for the metal surface and then the agent is used as an anchor point for chemical deposition of active silica [84]. The development of this sort of silica coated metal material has been systematically reviewed by Schärtl [71].

2.4.2. Silica Coated Magnetic Nanoparticles

Magnetic nanoparticles are very important in the separation of a variety of biomolecules [99, 100]. However, the inherent property of nanoparticle aggregation and the biodegradation of biomolecules restrict magnetic nanoparticle's bioapplications. A suitable coating prevents these limitations and makes the magnetic nanoparticles more practical for bioanalysis. Based on this idea, silica coated magnetic nanoparticles were developed using the W/O microemulsion method [82].

Figure 7. Fluorescence image of TMR–dextran-doped silica nanoparticles.
Figure 9. TEM micrograph of silica coated gold clusters. Reprinted with permission from [93], M. Giersig et al., *Adv. Mater.* 9, 572 (1997). © 1997, Wiley-VCH.

Two separate microemulsions (ME1 and ME2) were prepared using each surfactant, Brij-97, Igepal CO-520, and Triton X-100, respectively. ME1 contained the iron salts, $FeSO_4$ or $FeCl_2$ and $FeCl_3$, whereas ME2 contained the base, either NaOH or NH_4OH. All aqueous solutions were prepared with deoxygenated pure water. ME2 was allowed to stir for an hour and then was added to ME1. The resultant microemulsion was further reacted for 12 hours, and the water droplets collided and coalesced to form the nanoparticles. Nitrogen gas was used to continuously purge the mixture when NaOH was used. The formation of pure magnetic nanoparticles was visually recognized by a change in color of the microemulsion mixture to dark brown [101]. To form a silica coating layer outside the magnetic core, TEOS was added to the system. The base-catalyzed hydrolysis of TEOS produced silica acid, which undergoes polymerization to produce the silica coating layer. Resultant silica coated magnetic nanoparticles were isolated after 24 hours of aging using acetone and ethanol washes.

The produced magnetic nanoparticles were characterized using TEM, X-ray electron diffraction, and superconducting quantum interference device magnetometry. The results showed that the size of the nanoparticles was ultrasmall and the magnetic property was very strong, close to that of pure superparamagnetic materials. The silica coating layer provided a convenient biocompatible surface that allowed the conjugation of various biomolecules to the magnetic nanoparticles. These silica coated magnetic nanoparticles have the potential to be useful in biomolecule separation and drug delivery.

2.5. Polymer Fluorescent Particles

Synthesis techniques for polymer fluorescent particles have been widely developed. Various commercial polymer fluorescent particles, which are loaded with different dye molecules, are available. [Molecular Probes (Eugene, OR) is one of the biggest suppliers of a wide variety of polystyrene fluorescent beads [102].] The fluorescent intensity of the polymer beads is sufficient to allow visualization of single particles. Meanwhile, the polymer particles show good photostability when they are excited with the intense illumination required for fluorescence microscopy. So far, the

smallest size of polystyrene fluorescent beads produced by Molecular Probes is 20 nm in diameter. In order to apply the fluorescent beads to bioanalysis, several different functional groups have been linked to the bead surface, including carboxylates, sulfates, aldehyde-sulfates, amines, and avidin/biotin.

Fluorescent polymer particles are synthesized with different polymers. Polymerization of methyl methacrylate (MMA) loading dye molecules to form fluorescent particles is one example. Passirani et al. [103] prepared such fluorescent nanoparticles by random copolymerization of MMA and *N*-vinyl carbazole (NVC). The NVCs were covalently linked to PMMA, resulting in fluorescent nanoparticles that can be used as *in vivo* monitor targets.

3. BIOCONJUGATION

Simple and reliable bioconjugation is very important for nanoparticle applications. The silica-based nanoparticles can be useful in bioanalysis only when they are conjugated to recognition biocomponents which contain special elements that selectively interact with target analytes. Silica surface chemistry has been well established for bioconjugation of various molecules when used as a solid support. Most of these surface modification methods are easily adapted to attach biomolecules to the silica nanoparticle surface. The bioconjugation methods to be discussed are based on previously reported silica surface immobilization knowledge [104–109].

Using various biochemical binding approaches, the nanoparticle surface can be modified to contain functional groups that are useful for subsequent surface modification and biomolecule immobilization. Some commonly used functional groups biochemically added to the silica nanoparticle surface include amines, carboxyls, and thiols. The most frequently used biomolecule linking bridge, the avidin–biotin linkage, was also adapted for bioconjugation of probe molecules onto the silica nanoparticles. Various biomolecules including oligonucleotides, enzymes, antibodies, and other proteins have been immobilized onto the nanoparticles using this method, clearly demonstrating the advantage of the silica matrix in providing bioversatility.

3.1. Avidin–Biotin Linking Bridge

The affinity constant between avidin and biotin is 10^{15} l/mol, which is 10^5–10^6 times higher than that of regular antibody–antigen. Therefore, the avidin–biotin linkage is a great conjugation approach to bind biomolecules onto the silica nanoparticles, which has been used for immobilization of biomolecules on the glass substrate [108]. Usually, biotin easily links to biomolecules to form recognition agents, and thus many biotinylated biomolecules are commercially available. As long as avidin molecules are immobilized to the nanoparticles, upon avidin–biotin binding, the recognition biomolecules steadily remain on the nanoparticle surface for subsequent binding and identification of target biomolecules.

This avidin immobilization process is very simple mainly based on electrostatic attraction. The silica surface of the

nanoparticles is negatively charged, which allows the positively charged avidin to passively adsorb on the silica surface. By incubating appropriate concentrations of avidin with the silica nanoparticles for 12 hours at 4 °C, the avidin is adsorbed on the nanoparticle surface. To stabilize the adsorption, a cross-linking step is followed using 1% glutaraldehyde solution, which has two carboxyl groups at both ends of the molecule. The remaining unbound carboxyl groups can be blocked by reacting them with a buffer containing primary amine groups (Tris-HCl) for 3 hours. The resulting avidin-coated silica nanoparticles conjugate to biotinylated molecules via a strong avidin–biotin affinity (See Fig. 10).

3.2. Disulfide-Coupling Chemical Binding

Disulfide-coupling chemistry has proven to be an efficient methods for the immobilization of oligonucleotides to a substrate [109]. Unlike most of the other covalent attachment processes, this method does not require preactivation or reduction of the disulfide groups to generate more reactive, however, unstable thiol species. The disulfide-modified oligonucleotides are directly coupled to the silane-activated silica surface without any pretreatment. Potential side reactions are minimized due to the specificity of the thiol/disulfide exchange reaction.

To covalently attach oligonucleotides, the silica nanoparticles were silanized with 1% 3-mercaptopropyltrimethoxy-silane in 95% ethanol and 16 mM acetic acid (pH 4.5) for 30 minutes at room temperature and rinsed with ethanol and acetic acid. Then, the nanoparticles were cured for approximately two hours in a vacuum oven at 150 °C, forming functional thiol groups on the silica nanoparticle surfaces. A disulfide-modified oligonucleotide was used as a probe DNA attached onto the nanoparticle surface through disulfide-coupling. This process was performed by directly adding disulfide-modified oligonucleotide to the silane-activated silica nanoparticles and incubating for 15–21 hours in a humid chamber. The immobilized nanoparticles were then washed in a buffer containing 0.05% Tween 20. Using this process, a probe DNA sequence was bioconjugated to the silica nanoparticles through disulfide-coupling chemical binding [79].

3.3. Amino-Group Derivatization Linkage

An effective bioconjugation approach for the immobilization of proteins, such as enzymes and antibodies, onto the silica nanoparticles is to chemically link amino groups on the nanoparticle surface. Then, the amino groups on the surface of the proteins can replace the same group on the nanoparticle, leading to chemically bound proteins on the silica nanoparticles. The procedure used in this method is more complicated than the other two methods described. The advantage of this approach is a more stable binding between the silica nanoparticles and proteins that can last until the proteins become inactive [80].

The silica nanoparticles were silanized by immersion in 1% (v/v) solution of distilled trimethoxysilylpropyldiethylenetriamine (DETA) and 1 mM acetic acid for 30 minutes at room temperature (23 °C). The DETA modified silica nanoparticles were thoroughly rinsed with deionized water to remove excess DETA. The silanized particles were then treated with 10% succinic anhydride in dimethylformamide solution under an argon atmosphere and stirred for 6 hours [110]. The resulting carboxylate modified particles were washed with deionized water. Two different approaches were used, based on Bangs Labs [111] protocols, to further modify the nanoparticle. The first approach used carbodimide hydrochloride in an activation buffer to produce o-acylisourea intermediate on the nanoparticle surface. Then, the proteins with available amine groups were bound to the modified silica nanoparticles through amine bonds by immersion of the nanoparticles in a suitable concentration of protein solution. The nanoparticles were subsequently washed and ultrasonicated to remove any physically adsorbed protein molecules on the silica surface. The second approach was to add a water-soluble N-hydroxysuccinimide along with carbodimide hydrochloride to the carboxyl modified silica nanoparticles. The active ester intermediate formed by the N-hydroxy compound replaced the o-acylisourea intermediate, which was more stable for hydrolysis, and thus the coupling efficiency of proteins to the nanoparticles was increased. After probe protein immobilization on the nanoparticle surface, 1% BSA was used to block unreacted functional groups to prevent nonspecific binding in later reactions with target biomolecules.

An alternative approach also provided effective bioconjugation of proteins to the silica nanoparticles by activating the nanoparticles with sodium carbonate [111]. A solution of cyanogen bromide in acetonitrile was added to the nanoparticle suspension to yield –OCN groups on the nanoparticle surface. The produced modified nanoparticles can directly bind to the biomolecules containing free amino groups [78]. Using the aforementioned conjugation methods, the produced bioconjugated silica nanoparticles well retain the original activity of the biomolecules.

4. APPLICATIONS

Several significant bioapplication areas have been exploited using the three types of developed silica nanoparticles, including pure silica nanoparticles [79, 80], dye-doped silica nanoparticles [30, 72–78], and magnetic nanoparticles [81].

This section focuses on how dye-doped silica nanoparticles have shown great signal amplification as fluorescent biomarkers for trace bioanalysis. In addition, silica coated magnetic nanoparticles have been used for biomolecule separations, and pure silica nanoparticles have served as solid support substrates for bioanalysis.

4.1. Cell Recognition

Luminescent nanoparticles are novel labeling probes that offer highly enlarged detectable signals in bioanalysis. Generally, identification and detection of bioanalytes are carried out with labeling technologies that use fluorescent dyes to provide a detectable signal [112]. Of the various available fluorescent materials, organic dye molecules are frequently used due to their high quantum yield [113]. However, the sensitivity of methods using organic dyes is limited by a low number of recognizable components in trace amounts of biosamples; thus, there are not enough detectable fluorescent signals. In addition, all dye molecules suffer from rapid photobleaching [114], resulting in unstable and inaccurate fluorescence signals. In contrast, newly developed dye-doped silica nanoparticles contain a large number of dye molecules for signaling targets and have excellent photostability due to the silica matrix protection. Therefore, dye-doped silica nanoparticles are ideal fluorescent probes because they provide significantly amplified and photostable signals. The following three applications of dye-doped silica nanoparticles have shown this promise in bioanalysis and biotechnology.

RuBpy-doped silica nanoparticles were first used in bioanalysis to identify leukemia cells with antibody–nanoparticle conjugates through fluorescent imaging [78] (see Fig. 11). A special antibody, mouse antihuman CD10 antibody, was used as a recognition element in the system, which was covalently immobilized onto the nanoparticle surface using CNBr pretreated nanoparticles. The mononuclear lymphoid cells with a round shape were incubated with CD10-immobilized nanoparticles. Unbound nanoparticles were washed away with PBS buffer. The cell suspension was then imaged using both optical microscopy and fluorescence microscopy (Fig. 11). The leukemia cells were well recognized as bright fluorescent areas in the fluorescence images, which correlated well with the optical images. Control experiments were done using bare RuBpy-doped silica nanoparticles without labeling probe antibody and with PTK2 cells, cells that do not have a surface antigen on the
cell membrane for CD10 antibody. The resulted fluorescent images showed no fluorescent signals, indicating that the nanoparticle conjugate is able to selectively identify cells when using a fluorescence imaging system.

4.2. Bacteria Determination

A rapid bioassay for the precise determination of a single bacterium was developed using bioconjugated nanoparticles. Rapid and sensitive detection of pathogenic bacteria is extremely important for food safety, clinical diagnosis, and the inactivation of bioterrorism agents. Traditional methods for the detection of trace amounts of bacteria require amplification or enrichment of the bacteria in the sample. These methods tend to be laborious and time-consuming due to complicated assay procedures [115–120]. Recently, many attempts have been made to improve the sensitivity of bacterial detection without the need for target amplification and pre-enrichment [121–123]. However, rapid bacterial detection at the single cell level in a large volume sample has not been possible.

Using the nanoparticles and their conjugation with bacterium specific antibody, a novel bionanotechnology has been developed for fast, ultrasensitive, and accurate detection of single bacterial cells without any amplification or enrichment. The antibody conjugated nanoparticles offer significant signal amplification in bacterium bioanalysis [76]. A potentially lethal bacterium, *E. coli* O157:H7 [124–126], was selected as the object for detection. The antibodies against *E. coli* O157:H7 were conjugated to the RuBpy-doped silica nanoparticle to form a nanoparticle–antibody complex that was used to bind the antigen on the *E. coli* O157:H7 surface and thus give fluorescence signals. In comparison with a conventional immunoassay, where an antibody–antigen binding event brings only a few dye molecules for signaling, dye-doped nanoparticles contained approximately 10^4 dye molecules to signal one antibody–antigen binding event and provided significant signal amplification. Meanwhile, there were many *E. coli* O157:H7 surface antigens for the antibody specific recognition. Thus, thousands of nanoparticles bound to one bacterium to greatly amplify detectable signals. This bioassay is rapid (<20 minutes from sampling to detection and analysis), convenient, and highly selective. Furthermore, since multiple samples can be analyzed simultaneously, this assay is adaptable to high-throughput bioanalysis. This study clearly demonstrates the excellent utility of biologically conjugated nanomaterials in biological studies and biotechnology.

4.3. Probing Single Strand DNA Sequences

TMR-doped silica nanoparticles have much higher fluorescent intensity than RuBpy-doped silica nanoparticles [72, 73]. For cell or bacteria analysis, there are many surface binding sites on each target and that means many nanoparticles can link to one target; thus, the RuBpy nanoparticles are good enough for signal amplification [76, 78]. However, for DNA detection based on hybridization, each probe sequence can bind to only one target, and a much stronger fluorescent probe is needed

Figure 11. Recognition of target cells using RuBpy-doped silica nanoparticle probes. Fluorescent image (A) and optical image (B). Reprinted with permission from [78], S. Santra et al., *Anal. Chem.* 73, 4992 (2001). © 2001, American Chemical Society.

to achieve excellent detection limits. TMR-doped silica nanoparticles can overcome this limitation.

An ultrasensitive DNA analysis has been developed using TMR–dextran-doped silica nanoparticle probes [77]. Usually, a fluorophore labeled probe DNA sequence hybridizes to the target DNA in conventional DNA analysis, the fluorescence intensity is detected, and then it reflects the amount of the target DNA. Each target DNA molecule is represented by only one dye molecule. In comparison with the dye molecule labeled method, dye-doped nanoparticle labeled assay can give approximately 10^4 dye molecules to represent one target DNA sequence, which means that the signal is enlarged by 10^4 times. Therefore, a single hybridization event is highly indicated, making the trace amount of target DNA detection possible. Based on this principle, using a highly fluorescent TMR-doped silica nanoparticle probe and a high resolution confocal microscope, an ultrasensitive DNA analysis was achieved.

This DNA analysis assay was carried out using a typical sandwich method in which a capture DNA sequence was immobilized on a glass substrate [59], a probe DNA sequence was attached to a dye-doped silica nanoparticle, and a target DNA sequence was complementary to the capture sequence and the probe sequence. In a two-step hybridization procedure wherein the target DNA hybridizes to the capture DNA and the probe DNA, the target DNA was recognized and signaled by the fluorescent nanoparticle probe. An imaging system was used to measure the fluorescence signal of the surface-bound nanoparticle probes. The number of fluorescent particle spots, proportional to the concentration of the target DNA, was counted on the images. A detection limit of 5 fM was achieved in this assay.

Polymer fluorescent nanoparticles have also been covalently linked to DNA binding proteins to probe specific sequences on single DNA molecules [16] as shown in Figure 12; 20 nm latex fluorescent nanoparticles were used as biomarkers. The results showed that attached proteins maintain specific DNA binding and cleavage activities, while the nanoparticles emit intense and stable fluorescent signal. The use of fluorescent nanoparticle bioconjugates solves the problems associated with single fluorophores, such as rapid photobleaching and blinking. The results of target specific sequences on single DNA molecules suggested that it is possible to observe real-time DNA-protein binding and enzymatic dynamics.

4.4. Biomolecular Separation

Magnetic separation has been widely used in bioanalysis and biotechnology for purification and separation of various biomolecules [127–129]. Based on newly developed silica coated magnetic nanoparticles [82], a novel genomagnetic nanocapturer (GMNC) was designed for the collection and detection of trace amounts of DNA/mRNA molecules from a complex matrix such as a mixture or cells [81].

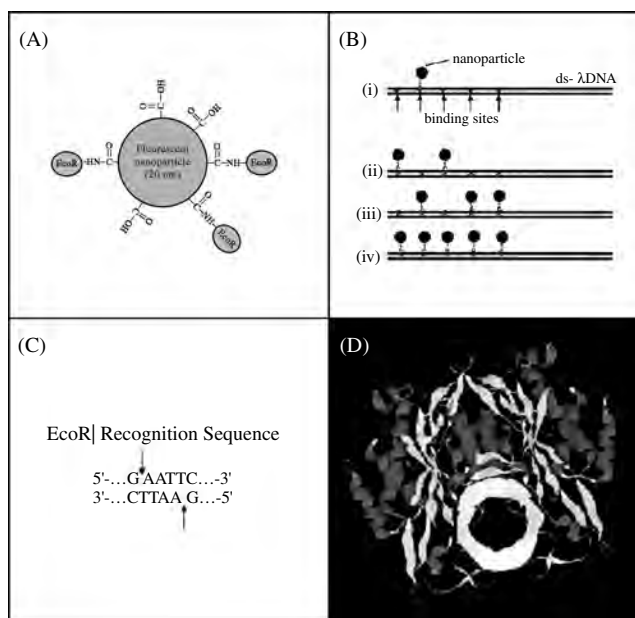
The GMNC was constructed with a magnetic nanoparticle core, a silica coating layer, a biotin–avidin linking bridge, and a biotinylated molecular beacon DNA probe (Fig. 10). The two key elements, the magnetic nanoparticle


Figure 12. Illustration of (A) EcoRI molecules covalently conjugated to a 20 nm fluorescent nanoparticle. (B) Single DNA molecules with nanoparticles bound at specific sites. Chem.* 72, 1982 (2000). © 2000, American Chemical Society.

and MB, provide the GMNC with unique properties; the nanocapturer acts as an effective molecule separator and carrier and serves as a highly selective and sensitive gene probe for the recognition and detection of specific DNA sequences. The excellent sequence selectivity of the GMNC is a result of the MB's special stem-loop structure [130–135], which is critical for single base mismatch discrimination. Meanwhile, the nanoparticles in the GMNC structure further enhance the utility of the MB by altering the MB's melting temperature curve. The melting temperature profiles of the MB on the GMNC surface shift to a higher temperature when the MBs are immobilized onto the GMNC surface, resulting in an optimal temperature for separation of the different target DNA sequences with high collection efficiency.

The GMNC's strong target collection ability was demonstrated by specific hybridization and collection of trace amounts of perfectly complementary DNA vs a single base mismatched DNA sequence in the presence of nontarget DNA sequences and proteins. By subjecting the mixture to a magnetic field, the GMNC was removed from the system, resulting in separation of the target DNA from the rest of the matrix. In addition, a specific mRNA sequence in living cells was selectively collected using the GMNC. The capture ability of the GMNC was also showed in the trace amount of DNA/RNA collected from a large sample volume. With adequate hybridization time, the GMNC collected as low as 0.3 pM target sequences in aqueous solution with high specificity and collection efficiency. Moreover, real-time monitoring of the DNA hybridization can be performed by recording fluorescent signals of the GMNC as the hybridization takes proceeds.

5. CONCLUSIONS

The development of various luminescent silica nano-particles has been summarized in this chapter. Among them, dye-doped silica nanoparticles demonstrate great signaling ability when they act as fluorescent probes in trace bioanalysis. Three major advantages of dye-doped silica nanoparticles—high fluorescence intensity, excellent photostability, and good biocompatibility—make the dye-doped silica nanoparticles ideal fluorescent biomarkers for use in bioanalysis and biotechnology. The bioconjugation approaches provide simple ways to modify the silica nano-particles for biomolecule recognition and detection. The examples of real applications for fluorescent silica nano-particles described in this chapter show great promise in the advancement of fluorescent labeling techniques.

Many theoretical and technical problems still have to be solved—from understanding the contrast mechanisms and the nanofabrication of smaller sized particles, to the control of bioconjugation for applications with biologically active molecules. We believe that bionanotechnologies will be highly useful for bioimaging of cells and cellular components, bioassays targeted at biologically relevant diseases, detection probes used in neurochemical monitoring, and mRNA/DNA detection techniques based on nanoparticle arrays.

GLOSSARY

Bioconjugation Immobilization of biomolecules onto a substrate or solid support.

Dye-doped silica nanoparticle A silica nanoparticle in which a large number of dye molecules are trapped inside a silica matrix.

Nanoparticle A spherical particle with a diameter in the range of 1–100 nanometers.

Polymer fluorescent particle A polymer sphere in which a number of dye molecules are trapped inside a polymer matrix.

Silica coated magnetic nanoparticles A silica nanoparticle in which the core of the particle is made from magnetic materials and the shell is a layer of silica.

Biodoped Sol–Gel Polymer Nanocomposites

Iqbal Gill

BioSynTech, Nutley, New Jersey, USA

CONTENTS

1. NANOTECHNOLOGY AND BIOLOGICALS

1.1. Nanotechnology

The last two decades have witnessed spectacular advances in the biological, chemical, and materials sciences, with rapid progress being made in the elucidation of the functioning of living systems and the organization of natural and synthetic materials and the development of physicochemical techniques for the study and manipulation of matter. In the vanguard of these advances is nanotechnology, a highly interdisciplinary science which seeks to comprehend and control phenomena at the atomic to macromolecular scale (1–100 nm) and therein create nanostructures and assemble them into larger architectures with the aim of devising materials, devices, and systems that have novel properties and functions by virtue of their nanoscale size and/or organization [1–5].

Areas that are receiving particular attention in this respect are the understanding of the nanoscale organization and functioning of biosystems and the application of this knowledge to the construction of bio-inspired systems and the interfacing of biological macromolecules and assemblages with synthetics to create hybrid materials with novel properties [1–12]. This interest derives from a number of unique properties of biological molecules [13–16]:

(a) Biomolecules, especially polymers such as nucleic acids (DNA and RNA), proteins, and oligosaccharides, are typically highly functionalized and spatially organized, and this gives rise to defined molecular structures with unique properties, such as chirality, amphiphilicity, and aggregation behavior.

(b) Biomolecules such as oligosaccharides, proteins, and nucleic acids exhibit hierarchical structural organization by virtue of their modular form and precise intra- and intermolecular interactions.

(c) Functionality, hierarchical structure, and chirality enable highly specific molecular recognition interactions, such as the binding of ligands by antibodies and nucleic acids, and catalysis by enzymes and catalytic RNA.

(b) Biological molecules and macromolecules can assemble into two-dimensional (2D) and three-dimensional (3D) architectures and form multifunctional assemblies, for example, vesicles, membranes, 2D and 3D crystals, colloids, fibers, and networks.

As a result, biomolecules such as lipids and macrocyclics, macromolecules including natural, engineered, and synthetic proteins, polypeptides, oligosaccharides, DNA and RNA, as well as macromolecule assemblies have found unique nanotechnical applications in areas as diverse as catalysis, sensors, diagnostics, medical imaging, electronics, optics, drug discovery, controlled delivery, and high-performance coatings [6–25].

1.2. Nanostructured Bioencapsulated Solid-State Materials

The realization of the aforementioned applications depends critically on enabling technologies, of which the production of solid-state materials in which the requisite biosystems are

organized onto synthetic surfaces or incorporated into polymers to form composites have gained a special significance [17–26]. The need for such solid-state biomaterials derives from several factors:

(a) Biological materials are often characterized by their lability—thus, proteins and nucleic acids are readily degraded by various biotic and abiotic processes and are sensitive to a host of environmental perturbances (pH, temperature, salts, solvents, pressure, etc.), all of which can result in the partial or complete loss of biological properties. Immobilization onto/within a rigid polymer matrix often substantially stabilizes the biological by anchoring the molecular structure and protecting it from bio/chemical attack, and the ability to engineer the physicochemistry of synthetic materials enables the tailoring of the immobilization method to the biological and its application.

(b) Although many biological materials can be obtained in the solid state, for example 2D/3D protein crystals and DNA/RNA colloids and thin films, these materials tend to have poor physicochemical attributes (solubility in water, resistance to solvents, storage stability, mechanical properties, etc) and cannot be utilized in their native form. Immobilization allows for the fixation of biologicals on or encasement within robust synthetic polymers that endow the resultant materials with their distinctive physicochemical properties which can be readily engineered.

(c) Many applications require the isolation of biological components, their interfacing with other biosystems and/or with synthetic polymers, and/or their spatial organization in a reproducible manner. Immobilization addresses all these issues, since it allows for the matrix isolation of biologicals in defined physicochemical environments, enables the simultaneous or sequential immobilization of multiple biosystems, and by virtue of the controllable functionality of synthetic surfaces and polymers also permits the site-specific and ordered anchoring of biologicals.

The importance of bio-immobilization is clear from the many commercial technologies and research fronts that rely on immobilized biologicals for molecular assembly, recognition, catalysis, and transduction functions [13–26]. Thus, the production of many lipids, amino acids, peptides, mono- and oligosaccharides, antibiotics, and numerous food ingredients, cosmetics, pharmaceuticals, agrochemicals, and fine chemicals depends on heterogeneous biocatalysts that can function efficiently under a variety of operating conditions and are stable to long-term usage [13–19]. Similarly, biosensors for detecting and monitoring analytes such as sugars, hydroxyacids, amino acids, sterols, nitric oxide, mycotoxins, pesticides, antigens, antibodies, and pathogenic organisms in clinical, environmental, industrial, and consumer settings depend critically on bioimmobilizates, which must be highly discriminating and responsive, operate reliably for extended periods, and be amenable to miniaturization and mass fabrication [20–35]. Likewise, bioarrays employing peptides, proteins, and nucleic acids anchored on/within polymers for the detection and profiling of ligands, proteins, DNA and RNA, and biooptics and bioelectronics devices utilizing chromatic,

photoactive, and electroactive proteins encapsulated within polymers require biologicals immobilized in defined and reproducible orientations/conformations and materials that can be readily microfabricated [33–46].

Many of the above applications are served by biocomposite materials comprising the biological entrapped at the nanoscale level within a polymer framework, the latter being a purely inorganic lattice, an organometallic material, an organic polymer, or a combination thereof [47]. The result is a material that marries at the nanoscale level the molecular structures of the biological and the host polymer to form a hybrid material endowed with the functional, recognition, organizational, and/or catalytic attributes of the biological together with the bulk functional, physicochemical, and mechanical properties of the host polymer [47].

In the field of bio-nanocomposite materials, the technique of sol–gel encapsulation has achieved pre-eminence as a generic platform for the production of bionanocomposites.

2. SOL–GEL TECHNOLOGY AND BIONANOCOMPOSITES

2.1. Classical Sol–Gel Technology

Classic sol–gel technology is based upon the striking observation early in the last century that silica glasses can be produced via a simple room temperature synthetic process [47–53]. In it's simplest form, the protocol consists of the following:

(a) A silica precursor, namely an ester of orthosilicic acid such as tetramethyl orthosilicate (tetramethoxy silane, TMOS) or tetraethyl orthosilicate (tetraethoxysilane, TEOS) is mixed with water and methanol or ethanol as cosolvent.

(b) The addition of a strong organic or mineral acid catalyst results in the rapid hydrolysis of the orthosilicate ester to form a solution containing partial esters such as trimethyl orthosilicic acid and dimethyl orthosilicic acid, which upon extended reaction ultimately afford fully hydrolyzed orthosilicic acid.

(c) The partial silicic acid esters and silicic acid can undergo condensations to form soluble oligomeric species, reactions that are catalyzed by acids and especially by bases such as fluoride, amine, and hydroxide.

(d) The soluble oligomers condense to form colloids composed of macromeric species, and this is accompanied by a sharp increase in viscosity of the reaction mixture.

(e) Further condensation of collidal macromers results in the formation of a polymer network and bulk phase separation, which is observed as gelation of the reaction mixture and the formation of a friable and transparent hydrated gel, the hydrogel.

(f) Upon standing, the hydrogel undergoes further condensation and crosslinking, resulting in contraction of the hydrated polymer and the extrusion of interstitial liquid from the pore network, a phenomenon known as syneresis.

(g) Drying of the aged hydrogel results in further shrinkage (up to 80%) and pore collapse and furnishes a rigid and transparent nano- to mesoporous silica glass, the xerogel.

By substituting metal alkoxides and organofunctional silicon alkoxides for simple silicic acid esters, it has proven possible to prepare a wide range of main group and transition metal oxides, metallosilicates, organically modified silicates (Ormosils), various composite materials, and highly structured nano- to macroporous inorganic and hybrid organic–inorganic polymers with an astounding range of chemical characteristics [48–56].

2.2. Sol–Gel Bioencapsulation

A critical feature of sol–gel technology that was discerned at an early stage is that small molecules, such as transition metal complexes and organic dyes, could be encapsulated within sol–gel polymers to form doped materials. Research has shown that the entrapped molecules largely retain their native chemical characteristics within the polymers, and this combined with high optical transparency and porosity to low molecular weight molecules enables their use as optical materials, chemical sensors, or catalysts [47–56]. In view of the the aqueous chemistry of the sol–gel method, efforts were undertaken to extend sol–gel encapsulation to biological molecules. Thus, in 1984 Venton et al. [57] showed that antiprogesterone antibodies could be immobilized within silica-poly(3-aminopropylsiloxane) xerogels and, crucially, that they therein retained to a large degree their binding affinity for progesterone, thus demonstrating for the first time that sensitive biologicals could be encapsulated via silicon alkoxide sol–gel chemistry. One year later, Glad et al. [58] expanded upon these observations with the disclosure that the enzymes glucose oxidase, horseradish peroxidase, trypsin, and alkaline phosphatase could be immobilized within silica-poly[N,N-bis(2′-hydroxyethyl)-3-aminopropylsiloxane) sol–gels and that the resulting nanocomposites efficiently catalyzed oxidation and hydrolysis reactions typical of the native enzymes. These groups utilized aminoalkyl- and aminohydroxyalkyl-substituted alkoxysilanes rather than tetraalkoxysilanes as precursors, thus forming organically modified silicates (Ormosils) rather than pure silicas, in the belief that alkoxysilanes bearing functional organic ligands were requisite for efficient bioencapsulation and that simple precursors such as TMOS and TEOS were not suitable.

Although these two groups proved the fundamental concept underpinning bioencapsulation, perhaps the most significant advances leading to its establishment as a mainstream research field derived from the efforts of Avnir et al. [59], who in 1990 reported that the proteins alkaline phosphatase, chitinase, aspartase, and α-glucosidase could indeed be encapsulated into pure silica sol–gels using modified protocols with TMOS and TEOS as precursors. This was followed in 1992 with the disclosure by Ellerby et al. [60] that the metalloproteins copper–zinc superoxide dismutase, cytochrome c, and myoglobin could similarly be entrapped within silica xerogels [60]. Reinforcing the findings of Avnir et al., this group showed that the bioencapsulated

nanocomposites displayed the catalytic, metal-exchange, oxidation–reduction, and ligand-binding reactions typical of the free, soluble proteins.

These investigations unequivocally demonstrated that labile biological molecules with catalytic, recognition, and transduction functions could be incorporated into sol–gel materials with minor modifications in protocols [47, 61–75]. Explorations of the arena since then have proven the broad applicability of the technique, and to date proteins, polypeptides, antibodies, antigens, DNA, RNA, cell fractions, organelles, and whole cells have been encapsulated in a range of inorganic, organic, and hybrid polymers [47, 61–75]. The focus of bioencapsulation is mainly on highly selective, sensitive, and robust biosensor platforms for industrial, biomedical, and environmental analysis [47, 67–75], but there is also increasing awareness of the applicability of the approach to generating high-performance biocatalysts and materials for bioelectronics [47, 74].

3. BIOLOGICAL MATERIALS AND BIOENCAPSULATION

3.1. The Properties of Proteins

Before discussing the practical aspects of sol–gel bioencapsulation, it is instructive to review some relevant features of biological materials, in particular proteins [76–79]:

(a) Proteins are typically linear polymers composed of amino acids with a variety of pendant functionalities and with molecular weights ranging from $\sim$5,000 to >400,000, corresponding to sizes of $\sim$1–15 nm [76], which is in the pore size range of mesoporous materials [61–66].

(b) The constituent amino acids of proteins possess neutral, hydrophilic, hydrophobic, basic, and acidic functionalities, and these are typically organized in a hierarchical fashion to form ordered assemblies that are critical to binding, catalysis, dynamics, and stability [76–79]. A variety of physicochemical factors, such as pH, solutes, solvents, and liquid or solid interfaces that interact with these assemblages can influence the ionization state, hydration and hydrophobicity, dynamics, and ligand partitioning and have an impact upon biomolecule structure, solubility, aggregation, and activity [76–79].

(c) Proteins are hierarchical nanostructures: the primary structure (amino acid sequence) is ordered into a topologically defined secondary structure (β-turns, β-sheets, α-helices, etc.), which is itself spatially organized into a (monomeric) tertiary structure (α-α packed helices, β-β-β barrels, etc.) which may further associate with other monomers to form homo- or hetero-oligomeric assemblies (cylinders, toroids, sheets, etc.) that comprise quaternary structures [76, 77]. Critical to molecular recognition and catalysis is the binding site, a specific spatial and functional arrangement of amino acids, which is complemented by complexed metal centers and/or photo-/redox-active cofactors in more complex proteins. The components of the active site interact

among themselves as well as the surrounding protein residues and solvent environment in a precise fashion to create a topologically and physicochemically defined chiral microenvironment, the structure and dynamics of which dictate the selectivity and efficiency of recognition and catalysis [76, 77]. Therefore, the maintenance of the various levels of short- and long-range structural order is a perquisite to protein functioning, and pH, solutes, solvents, polymers, and interfaces that interact with organization can dramatically influence biomolecule function [76–79].

(d) Proteins are highly dynamic systems: local and/or global conformational motions impart a high degree of local and/or global conformational flux, and this feature is central to the dynamic processes which accompany ligand channelling, orientation, and binding and the resulting cascade of recognition, transduction, and catalytic event(s) [76, 77]. Such dynamics can range from relatively small structural changes restricted largely to the binding site and its immediate surroundings as in proteases, to the movement of secondary structures such as α-helices and β-sheets as observed in lipases and cutinases, and the large-scale concerted supramolecular movements of oligomeric assemblies that characterize multicomponent photoactive and membrane protein systems. Here again, any environmental factors (solvents, interfaces, etc.) that impact upon the kinetics and/or thermodynamics of such structural transitions can profoundly impact protein functioning.

3.2. Considerations for the Bioencapsulation of Proteins

When one considers the above attributes of proteins, one can identify several critical aspects that must be factored in when the sol–gel bioencapsulation of such biomolecules is contemplated [47, 61–67, 74]:

(a) The encapsulation of proteins must proceed in conditions resembling their native environments—that is, aqueous solutions, crystalline products, or some suitably "protected" forms: (i) aqueous solutions or suspensions, assemblies with synthetic surfactants, natural lipids, membranes or protein arrays, or solid-supported nano-sized dispersions [47, 74, 79]; (ii) pure protein crystals or co-crystals with suitable protein or polymer dopants; (iii) proteins which are modified by conjugation to surfactants, polyethylene glycol (PEG), functional siloxanes, silica or acrylates [80].

(b) The bioencapsulation procedure and any subsequent processing must be biocompatible—that is [47, 61–74]: (i) aqueous protocols must employ ambient/sub-ambient temperatures, in the biological pH and redox and ionic strength range, and with the minimal use of solvents or other organic species which can cause protein unfolding/denaturation, aggregation, or precipitation; (ii) nonaqueous media permit the use of more aggressive conditions due to the increased stability of the biomolecule conjugates employed therein, and solvents, surfactants, and polymerization initiators can be used.

(c) The encapsulating polymer structure must allow sufficient access to the entrapped protein as well as freedom for conformational mobility to enable efficient protein functioning, while also preventing the solubilization and leaching of protein molecules from the matrix [47, 61–74]. A 3D continuous mesoporous structure with unrestricted entry to the protein is clearly essential for realizing native protein–target molecule interactions, as is a spacious entrapment cavity to permit the requisite molecular movements. However, this must be balanced against sufficient constraint, in the form of gross physical embedding and/or more specific physicochemical protein–polymer interactions, to prevent the escape of the protein from the polymer matrix.

These types of considerations are especially critical for multimeric proteins and those that are part of larger-scale assemblies such as bilayers, vesicles, and membranes, because the gross structural integrity and hierarchical structural transitions of these structures are especially sensitive to perturbation and require careful preservation [79, 81, 82].

4. PRACTICAL ASPECTS OF SOL–GEL BIOENCAPSULATION

The first publications in the arena of sol–gel bioencapsulation established some critical features that form the basis of the present day technology [47, 61–75]:

(a) Classical aqueous sol–gel protocols can be modified and used to encapsulate biomolecules to form bioencapsulated nanocomposites.

(b) The careful selection of experimental conditions enables bioencapsulation under conditions that are mild enough to permit proteins to largely retain their native structure, dynamics, and molecular recognition and catalytic functions, in both hydrogels and xerogels.

(c) The mesoporous structure and high pore volume of sol–gel matrices enable the diffusion of low to medium molecular weight species (up to 20,000 depending upon sol–gel type) and their free interaction with entrapped biomolecules.

(d) The mesoporosity, physical rigidity, functionality, and specific host matrix-entrapped protein interactions prevent the leakage of entrapped biomolecules, while also stabilizing their structure.

When one considers these attributes, it becomes apparent that the technology offers some singular benefits in the immobilization of proteins [47, 61–75]:

(a) Sol–gel bioencapsulation offers the only truly generic route discovered to date for efficiently incorporating biomolecules into polymers to form nanocomposite materials.

(b) The great flexibility of sol–gel chemistry allows bioencapsulation in a very diverse range of inorganic, hybrid organic–inorganic, and composite materials.

(c) Many bioencapsulated sol–gel polymers can be produced as ultraviolet (UV)–visible(VIS) transparent materials suitable for optical applications.

(d) Conducting, redox-active, and photoactive sol–gels can be accessed by utilizing transition metal (Mo, W, Zn, Ti, and Sn) oxides as bulk sol–gels or as dopants and/or by incorporating graphite, noble metals (Au, Pt, and Pd), metallocenes (ferrocene, nickelocene, titanocene, etc), biological redox cofactors (nicotinamide, flavins, plastoquinones, etc.), photoactive proteins (rhodopsin, phytochromes, etc.) and others, therein allowing the fabrication of electrochemical and optochromic devices.

(e) Standard sol–gel fabrication methods can be used to produce bioencapsulates as monolithic materials, nano-, micro-, and macroparticulates, and deposited, spun, screen-printed, and stamped thin and thick films.

4.1. The Technique of Sol–Gel Bioencapsulation

The practical procedure used for bioencapsulation parallels that of the sol–gel entrapment of abiotic materials in many respects, except that protocols must be adapted to ensure that encapsulation and ensuing processing operations are conducted under biocompatible conditions (Fig. 1) [47, 61–75]:

(i) An aqueous solution (sol) containing partially or fully hydrolyzed alkoxysilanes is prepared as follows:

- Alkoxysilanes such as TMOS, TEOS, or methyltrimethoxysilane (MeTrMOS) are 50–100% hydrolyzed under acid and/or surfactant catalysis in water or water–alcohol (ethanol or methanol) mixtures to furnish solutions of poly(alkoxysiloxanes), poly(alkyl silicates) or poly(silicic acids), which may be partially or fully evaporated to reduce or remove alcohols [47, 61–75].

- Alkoxysilanes are subjected to 50–75% hydrolysis with the stoichiometric amount of water in an alcoholic solvent (ethanol or methanol) and then transesterified (one pot) with glycerol under acid, basic, or alkoxide catalysis to form water-soluble and isolable poly(glyceryl silicates) and poly(glyceroxysiloxanes), which can be isolated and dissolved in water to furnish aqueous solutions [47, 74].

The identity of the precursor sol can range from a mixture of linear, branched, and cyclic poly(silicates)/poly(siloxanes) with degrees of polymerization of 3–16 for partially hydrolyzed sols to colloidal solutions of nano-sized macromers for fully hydrolyzed and aged sols. The exact composition depends upon the structure of the precursor silane (number and types of alkoxy groups, functionality of nonhydrolyzable moieties, whether the silane is monomeric or a disiloxane, etc.), its concentration, the catalyst, cosolvent, water content, and temperature used for hydrolysis, and how the sol is stored/aged [61, 64, 65, 74].

(ii) The precursor sol obtained is mixed with a buffered (typically pH 5–9, 10–200 mM buffer) solution or suspension of the biological. Fluoride, hexafluorosilicate, or amine catalysts, and drying control additives such as formamide and glycerol. Poly(vinyl alcohol) (PVA), PEG, and alginate, and fumed silica, clays, glass powder, and graphite can also be included as structure modifiers and reinforcing fillers, respectively. The catalysts and/or elevated pH of the buffer initiate a series of condensation and crosslinking reactions which lead to the formation, growth, and aggregation of oligomeric species and in an increase in viscosity, culminating in the observed sol–gel transition (that is, viscous solution transforming into a stiff gel) and bulk gelation, all this occurring within a time frame of seconds to hours.

- Exogenously added catalysts as well as surface amine, amide, hydroxy, thiol, and carboxy residues of the protein and any functional additives accelerate the hydrolytic, condensation, and crosslinking reactions.

- The adsorption of sol–gel oligomers onto biomolecule surfaces via ionic, H-bonding, and/or hydrophobic interactions results in soluble protein–macromer complexes and the biomolecule-directed evolution of oligomer/polymer growth and morphology. Functional additives such as PEG and PVA can act in a similar fashion.

- This biomolecule surface-templated development of the polymer framework results in the physical embedding of the protein via the overgrowth of biomolecule–macromer complexes and/or their coalescence to form colloidal nanoparticles.

- The further growth and coalescence results in phase separation of the nanoparticles to form nano-sized aggregates which fuse to form large-scale nano- or microparticle frameworks, this transition coinciding with bulk gelation and the formation of the hydrated mesoporous polymer framework.

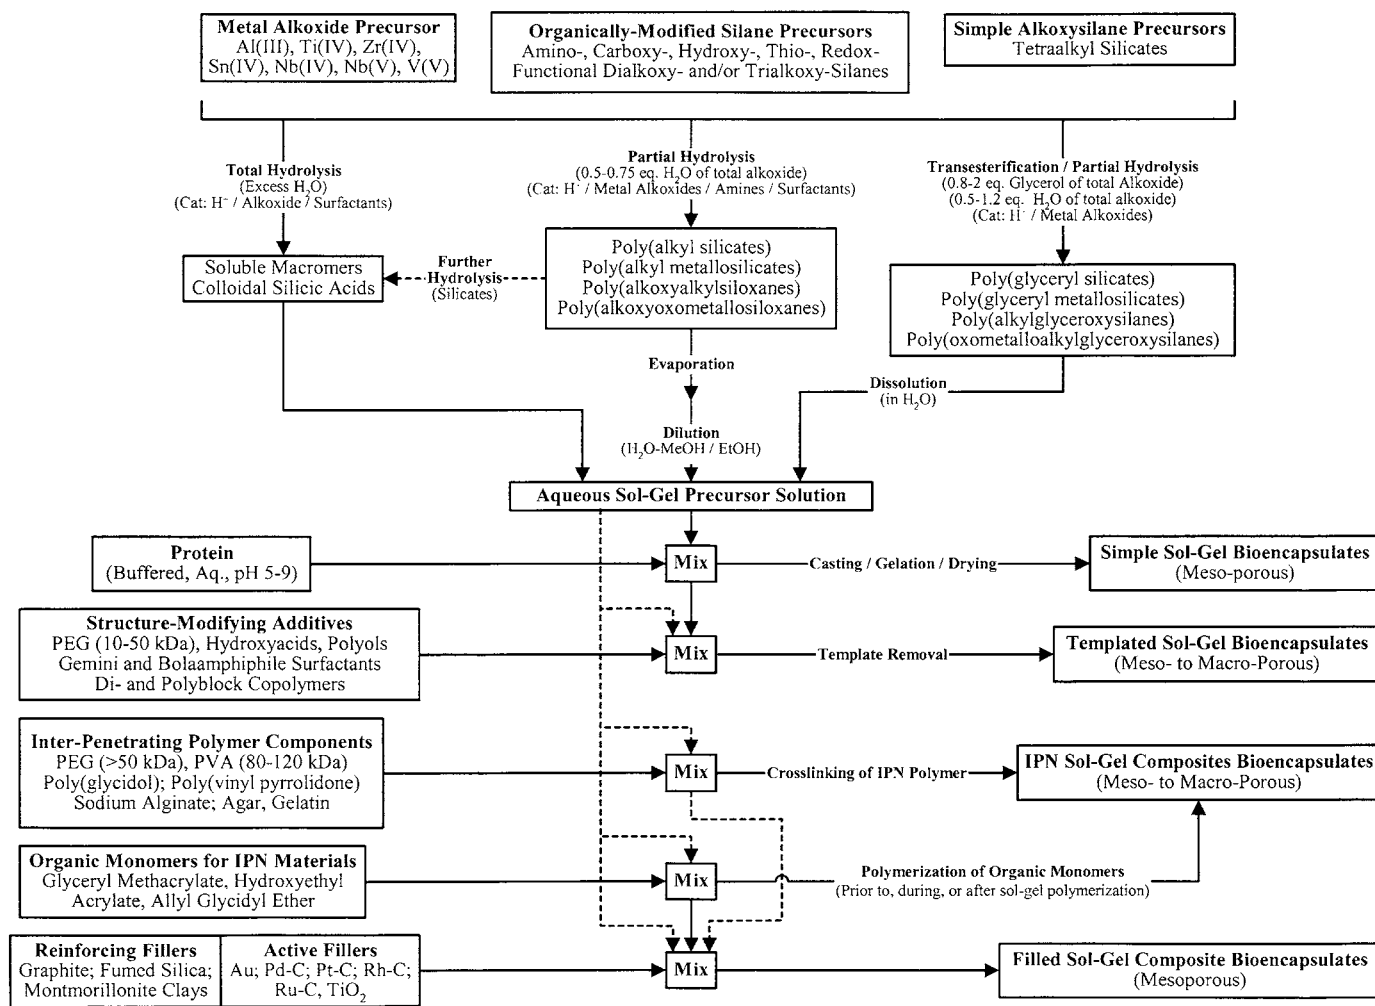
It is critical to minimize the use of cosolvents in this stage: 0–30% v/v of lower alcohols and ketones can lead to reversible aggregation and inhibition of proteins, while higher concentrations often cause irreversible denaturation and precipitation with corresponding losses in biological activity [61–65, 74]. The hydrogels produced are typically brittle or semi-flexible, compressible gels that contain some 50–80% interstitial solvent, with pore volumes of 0.9–3.4 mL g^{-1}, pore distributions of 4–200 nm, and surface areas of 600–2,100 m^2 g^{-1}. The extent of protein encapsulation depends upon the nature of the biomolecule, the type of sol–gel precursor used, and the gelation conditions: generally, silicates and hydrophilic siloxanes give near-quantitative immobilizations (80–100%), whereas the corresponding figures for hydrophobic siloxanes can be as low as 30%


Figure 1. Standard protocols for the sol–gel bioencapsulation of proteins.

due to phase separation effects, resulting in substantial entrainment of the protein in the interstitial solvent phase. Due to the high degree of hydration and elevated porosity of these materials, biomolecules typically display 60–100% of their native activities within such freshly prepared hydrogels [47, 61–65, 74].

(iii) The hydrogel is then typically aged in the wet state for 12–72 h to allow for the completion of condensation reactions, particle growth/fusion, and the maturation of the polymer framework. This results in bulk shrinkages of 5–30% and the contraction of the pore network and resultant expulsion of entrained liquid (syneresis). Aged hydrogels range from brittle glassy gels (silicates and hydrophobic siloxanes) to semiflexible hydrogels (hydrophilic siloxanes and composites with PVA, PEG, alginate, etc.), with typical pore volumes of 0.4–3.1 mL g^{-1}, pore sizes of 3–150 nm, and surface areas of 600–1,700 m^2 g^{-1}. Aging can reduce biomolecule activities by 0–20% from those observed in fresh hydrogels [47, 61–65, 74].

(iv) The aged hydrogel is conditioned by washing with buffer and then dried, resulting in the loss of most of the remaining water, further crosslinking

and structural consolidation, pore collapse, and bulk shrinkage. Controlled dehydration, via freeze-drying or pinhole drying, may be required to avoid the structural collapse that accompanies the removal of the interstitial solvent and the ensuing loss of porosity, an occurrence that can result in a severe loss of biomolecule viability. The incorporation of drying control additives or the use of glyceroxysilane precursors can substantially reduce pore collapse effects and speed up the drying process and therein enable the recovery of high levels of biomolecule activity [47, 74]. The final xerogels can range from optically clear brittle silicate glasses to rigid or semiflexible siloxane plastics and rubbers, which contain up to 30% of bound water, show pore volumes of 0.3–2.7 mL g^{-1}, pore sizes of 0.5–100 nm, and surface areas of 400–1,300 m^2 g^{-1}. Due to their dehydrated state and resulting pore collapse and matrix compression, up to 80% of biomolecule viability can be lost in the final xerogel. Rehydration of xerogels can result in a considerable expansion of the pore framework and the recovery of up to 30% of biomolecule activity, especially in the case of materials derived from hydroxylated siloxanes, and composites containing

hydrophilic modifiers such as PVA, PEG, alginate, gelatin and poly(hydroxyethyl acrylate).

5. SOL–GEL PRECURSORS AND MATRICES

Although most studies of sol–gel bioencapsulation have utilized silica matrices derived from tetraalkyl silicates such as TMOS and TEOS because of their facile preparation, reasonable physicochemical robustness, and good optical transparency, a variety of other more exotic sol–gel polymer chemistries have been explored (Tables 1–3, Fig. 1) [47, 61–75, 83]:

(a) *Inorganic oxide/hydroxide sol–gels.* These include aluminum, titanium, zirconium, tantalum, niobium, tin, vanadium, iron and molybdenum oxides, their mixed oxides with silica, as well as polyoxomolybdate–silicas. The hydrogels are friable and compressible gels while the corresponding xerogels are hard transparent glasses that are micro- to meso-porous and chemically robust, have good optical clarity, but are limited by their inherent brittleness, limited porosity, and lack of modifiable chemical functionality.

(b) *Organically modified silica sol–gels (Ormosils).* In this case, the precursor silanes are monomeric or dimeric and bear one or two organic groups attached by hydrolytically stable Si–C bonds, and furnish poly(organosiloxanes) upon hydrolysis/polymerization. The resultant polymers marry an inorganic siloxane backbone with pendant organic moieties, the attached functions ranging from simple alkyl, alkenyl, and aryl moieties to those additionally bearing functional amino, amido, carboxy, hydroxy, thiol, and mixed groups, as well as redox-active metallocenes, nicotinamides, flavins, quiniones, and phthalocyanines. These matrices are very utilitarian because they offer tailorable hydrophilic, hydrophobic, ionic, and H-bonding capacities, as well as specific functionalities such as electrochemical activity. Although the hydrogels and xerogels display a broad mesoporosity, they are relatively fragile, of limited optical transparency, and less robust than the inorganic matrices.

(c) *Hybrid sol–gels.* These materials are derived from amino- and/or hydroxy-functional homopolymers and di-block copolymers, such as polymethylsiloxane, polydimethylsiloxane, poly(alkene oxide), polyurethane/polyurea, polyacrylate, polyphosphazene, and polydimethylsiloxane-*co*-poly(alkene oxide), which are modified on the main chain or termini with alkoxysilanes [47, 74, 83]. Polymerization leads to siloxane-crosslinked dendritic or comb architectures, which combine the physicochemical attributes of the contributing polymer components. This leads to rigid, semirigid, rubber, and plastic materials with good mechanical properties, variable hydrophobic-hydrophilic balances, and a wide range of porosities, but with poor optical properties.

(d) *Interpenetrating polymer network* (IPN) *composite sol–gels.* These composite polymers are obtained by the

following methods [47, 74, 83]. (1) A solution of sol–gel precursor is combined with that of a water-soluble polymer such as alginate, carrageenan, gelatin, agar, PVA, PEG, poly(vinylpyrrolidone), or poly(glycidol), followed by initiation of sol–gel polymerization, which is often followed by phase separation of the organic component by ionotropic crosslinking (alginate or carageenan) or cryo-phase separation (PVA, gelatin, agar, or gelatin). (2) Solutions of nonhydrolyzed or partially hydrolyzed sol–gel precursors are infused into organic hydrogels, such as calcium alginate, potassium carageenan, agar, gelatin, PVA cryogels, poly(glyceryl methacrylate), poly(hydroxyethyl acrylate), poly(acrylamide), and polyurethane, and sol–gel polymerization is allowed to proceed therein. (3) Organic monomers such as glyceryl and hydroxyethyl acrylates are infiltrated into preformed sol–gels, and the organic component is polymerized via standard free radical, UV, or redox initiation processes. Whichever method is used, the resultant composites contain 20–80% w/w of organic component and display varying degrees of phase separation, thereby forming rigid plastics, elastic hydrogels and flexible rubbers with meso- to macro-pore networks. A unique attribute of these materials is that they combine the respective attributes of the component polymers—thus, the sol–gel phase transforms otherwise soft organic hydrogels that readily imbibe water and/or are liquefied by chelating agents or elevated temperatures into rigid glassy materials that are resistant to swelling and structural collapse, due to the supporting action of the supporting sol-gel framework. Such composites are notable for their high biocompatibility and are highly suited to the entrapment of very labile biologicals such as multicomponent enzymes and membrane proteins;

(e) *Reinforced/filled composite sol–gels.* All of the aforementioned materials can be reinforced with inert nano- or microparticulate materials such as native and oxidized graphite powder, hydrophilic and hydrophobic fumed silicas, clays, zeolites, cellulose, and esters thereof [47, 61–75, 83]. The fillers may be incorporated at levels of up to ~75% w/w and substantially improve the mechanical properties and processing attributes of the sol–gel polymers. In addition, active fillers such as gold, palladium, and platinum, and palladium–graphite can be used where conducting and redox-active materials are required.

(f) *Templated sol–gels.* The simple sol–gel systems (a–b) can be templated with a variety of compounds which act to direct the evolution of the pore structure and the supporting structural framework [84–96]. Templating agents include polyols, hydroxyacids, PEG, monovalent surfactants, multivalent gemini and bolaamphiphile surfactants and surface-active di- and polyblock copolymers. These compounds form nanostructured assemblies such as microemulsions and vesicular and liquid crystalline phases that act as chemical and topological templates for guiding the sol–gel process. Removal of the templates after aging

Table 1. Sol–gel oxide polymers used for bioencapsulation and their precursors.

Sol–gel oxides	Precursors	Bulk properties	Chemical attributes
Silica (SiO_2)	Tetraalkyl silicates: $Si(OMe)_4$; $Si(OEt)_4$; $Si(OiPr)_4$ Poly(alkyl silicates): $[SiO_{1-1.4}(OMe)_{1.2-2}]_n$ Poly(glyceryl silicates): $[SiO_{0.8-1}Glc_{0.8-1}]_n$	Hard, brittle Clear, transparent UV-VIS	Hydrophilic to semihydrophobic Stable to pH 2–9 Degraded by fluorides
Alumina ($Al_2O_3 \cdot xH_2O$) Alumina–silica	Aluminium(III) alkoxides: $Al_2(OEt)_6$; $Al_2(OiPr)_6$; $Al_2(OtBu)_6$ Aluminium(III) alkoxides + poly(alkyl silicates), etc.	Hard, brittle Clear, transparent UV-VIS	Hydrophilic Stable to pH 2–14
Zirconia ($ZrO_2 \cdot xH_2O$) Zirconia–silica	Zirconium(IV) alkoxides: $Zr(OEt)_4$; $Zr(OiPr)_4$; $Zr(OtBu)_4$ Zirconium(IV) alkoxides + poly(alkyl silicates), etc.	Hard, brittle Clear, transparent UV-VIS	Hydrophilic Resistant to pH 2–14
Titania ($TiO_2 \cdot xH_2O$) Titania–silica	Titanium(IV) alkoxides: $Ti(OEt)_4$; $Ti(OiPr)_4$; $Ti(OtBu)_4$ Titanium(IV) alkoxides + poly(alkyl silicates), etc.	Hard, brittle Clear, transparent UV-VIS	Hydrophilic Photoactive Stable to pH 2–14
Niobia ($NbO_2 \cdot xH_2O$) Niobium(V) oxide (Nb_2O_5)	Niobium(IV) alkoxides: $Nb(OEt)_4$ Niobium(V) alkoxides: $Nb(OEt)_5$	Hard, brittle Clear, transparent UV-VIS	Hydrophilic Chromic, photoactive Stable to pH 2–11
Tin(IV) oxide ($SnO_2 \cdot xH_2O$)	Tin(IV) alkoxides: $Sn(OEt)_4$; $Sn(OiPr)_4$; $Sn(OtBu)_4$ Tin(IV) alkoxides + poly(alkyl silicates), etc.	Hard, brittle Clear, semitransparent UV-VIS	Hydrophilic Conductive, redox-active, photoactive Stable to pH 4–10
Vanadium(V) Oxide (V_2O_5)	Vanadium(V) oxide trialkoxides: $VO(OEt)_3$; $VO(OiPr)_5$ Vanadium(V) oxide trialkoxides + poly(alkyl silicates), etc.	Hard, brittle Clear, colored, opaque UV-VIS	Hydrophilic Conductive, redox-active, photochromic Stable to pH 3–9
Molybdenum(V) oxide (Mo_2O_5)	Molybdenum(V) alkoxides: $Mo(OEt)_5$; $Mo(OiPr)_5$; $Mo(OtBu)_5$	Hard, brittle Clear, colored, opaque UV-VIS	Hydrophilic Conductive, redox-active, photoactive Stable to pH 4–10
Polyoxometallates–silicates–siloxanes	Phosphomolybdic acid and phosphotungstomolybdic acids + tetraalkyl silicates, poly(alkyl silicates), etc.	Hard, brittle Clear, colored, opaque UV-VIS	Hydrophilic to semihydrophobic Redox-active, photoactive Stable to pH 3–9

Table 2. Organically modified silicate sol–gels used for bioencapsulation and their precursors.

Sol–gel	Precursors	Bulk properties	Chemical attributes
Alkylsiloxanes	Trialkoxyalkylsilanes: $SiR'(OR)_3$ Dialkoxydialkylsilanes: $Si(R')_2(OR)_2$ Tetraalkoxydialkyldisiloxanes: $[OSiR'(OR)_2]_2$ Bis(trialkoxysilyl)alkanes: $(C_nH_{2n})[Si(OR)_3]_2$ (R' = CH_3 to $C_{18}H_{37}$, cyclohexyl; R = Me, Et, Pr, glyceryl)	Soft, semiflexible, hard, brittle Clear, translucent, opaque Semitransparent UV-VIS	Hydrophobic Stable to pH 2–10
Alkenylsiloxanes Alkylalkenylsiloxanes Alkynylsiloxanes	Trialkoxyalkenylsilanes: $SiR'(OR)_3$ Dialkoxyalkylalkenylsilanes: $SiR'R''(OR)_2$ Tetraalkoxydialkenyldisiloxanes: $[OSiR'(OR)_2]_2$ N-Acryloylaminoalkyltrialkoxysilanes: $CH_2CHCONHC_3H_6Si(OR)_3$ (R' = vinyl, allyl, propargyl; R'' = Me, Et; R = Me, Et, glyceryl)	Soft, semiflexible, hard to brittle Clear, translucent, opaque Semitransparent UV-VIS	Semihydrophobic Stable to pH 2–10
Arylsiloxanes Arylalkylsiloxanes	Trialkoxyarylsilanes: $SiAr(OR)_3$ Bis(trialkoxysilyl)arenes: $Ar[Si(OR)_3]_2$ (Ar = Ph, $PhCH_2$, C_6H_4, $C_6H_4(CH_2)_2$; R = Me, Et)	Soft, semiflexible, hard, brittle Clear, translucent, opaque Semiopaque UV-VIS	Hydrophilic Stable to pH 2–11
Aminosiloxanes	Aminoalkyltrialkoxysilanes: $NH_2C_3H_6Si(OR)_3$ N,N-Bis(aminoalkyl)aminoalkyltrialkoxysilanes: $(NH_2C_2H_4)_2NC_3H_6Si(OR)_3$ N-(Aminoacyl)aminoalkyltrialkoxysilanes: $AAc\text{-}NHC_3H_6Si(OR)_3$ (Aac = 2-aminoacyl; R = Me, Et, Pr, glyceryl)	Semiflexible Clear, semitransparent UV-VIS	Hydrophilic Basic, zwitterionic Stable to pH 6–11
Amidoalkylsiloxanes	N-Acylaminoalkyltrialkoxysilanes: $R'CONHC_3H_6Si(OR)_3$ Ureidoalkyltrialkoxysilanes: $NH_2CONHC_3H_6Si(OR)_3$ (R'CO = Ac, TFAc, higher acyl; R = Me, Et, Pr, glyceryl)	Semiflexible, brittle Hydrogels Clear, semitransparent UV-VIS	Hydrophilic to hydrophobic Basic, neutral Stable to pH 4–11
Carboxyalkylsiloxanes	Carboxyalkyltrialkoxysilanes: $HO_2CC_3H_6Si(OR)_3$ N-(Carboxyalkylacyl)aminoalkyltrialkoxysilanes: $HO_2CCH_2CONHC_3H_6Si(OR)_3$ (R = Me, Et, Pr, glyceryl)	Semiflexible, brittle Hydrogels Clear, semitransparent UV-VIS	Hydrophilic Acidic Stable to pH 2–11
Hydroxyalkylsiloxanes	Dihydroxyalkyltrialkoxysilanes: $HOCH_2(HOCH)OC_3H_6Si(OR)_3$ N,N-Bis(hydroxyalkyl)aminoalkyl: $(HOC_2H_4)NHC_3H_6Si(OR)_3$ N-(Polyhydroxyalkyl)aminoalkyltrialkoxysilanes: $R'CONHC_3H_6Si(OR)_3$ Hydroxyalkylureidoalkyltrialkoxysilane: $HOC_2H_4NHCONHC_3H_6Si(OR)_3$ (R'CO = δ-gluconyl, pantoyl; R = Me, Et, Pr, glyceryl)	Flexible, semiflexible, rigid Hydrogels Clear, semitransparent UV-VIS	Hydrophilic Neutral to Basic Stable to pH 4–11
Mercaptoalkylsiloxanes Sulfidoalkylsiloxanes	Thioalkyltrialkoxysilanes: $HSC_3H_6Si(OR)_3$ Bis(trialkoxysilylalkyl)disulfides: $[SC_3H_6Si(OR)_3]_2$ (R = Me, Et, Pr, glyceryl)	Flexible, semiflexible, rigid Hydrogels Clear, semitransparent UV-VIS	Hydrophilic Neutral, slightly acidic Redox-active Stable to pH 4–9
Redox-active siloxanes	Ferrocenylalkyltrialkoxysilanes: N-ferroceneacetyl-$NHC_3H_6Si(OR)_3$ Nicotinamidoalkyltrialkoxysilanes: $[NAD\text{-}/NADP\text{-}CONH]\text{-}COC_3H_6Si(OR)_3$ Flavinamidoalkyltrialkoxysilanes: $[FAD\text{-}NH]\text{-}COC_3H_6Si(OR)_3$ (R = Me, Et, Pr)	Flexible, semiflexible, rigid Clear, colored Semitransparent UV-VIS	Hydrophilic Redox-active Stable to pH 5–9

Table 3. Composite sol–gels used for bioencapsulation and their precursors.

Sol–gel	Precursors	Bulk properties	Chemical attributes
Polydimethylsiloxanes–silicates–siloxanes	Bis(alkoxyalkylsiloxy)polydimethylsiloxane: $[SiR'(OR)_2O]_2[Me_2SiO]_n$ Bis[poly(alkoxyalkylsiloxy)]polydimethylsiloxane: $\{[(SiO_xR'(OR)_y)]_m\}_2[Me_2SiO]_n$ (R' = aminoalkyl, hydroxyalkyl, etc; R = Me, Et, Pr, glyceryl)	Flexible, semiflexible to rigid Translucent, opaque Semitransparent UV-VIS	Hydrophobic Stable to pH 4–11
Polymethylsiloxane–silicates–siloxanes	Poly[(trialkoxysilylethylene)methylsiloxane]: $\{[(OR)_3SiC_2H_4]Si(Me)O\}_n$ (R = Me, Et, Pr, glyceryl)	Flexible, semiflexible, rigid Translucent, opaque Semitransparent UV-VIS	Hydrophobic to hydrophilic Surface-active Stable to pH 4–11
Poly(alkene oxides)–silicates–siloxanes	Bis(alkoxyalkylsiloxy)poly(ethylene oxide): $[Si(OR)_2C_3H_6NHCH_2(CHOH)]_2$-PEO Bis(alkoxyalkylsiloxy)-(PEO-co-PDMS): $[Si(OR)_2C_3H_6NHCH_2(CHOH)]_2$-(PEO-co-PDMS) (R = Me, Et, Pr, glyceryl)	Flexible, semiflexible, rigid Translucent, opaque Semitransparent UV-VIS	Hydrophobic, hydrophilic Surface-active Stable to pH 4–10
Poly(acrylates)–silicates–siloxanes	Poly[(trialkoxysilylalkylaminocarboxy)ethylmethacrylate]: $[Si(OR)_3C_3H_6NHCO_2C_2H_4O_2C(Me)CH]_n$ (R = Me, Et, Pr, glyceryl)	Flexible Hydrogels Clear, Semitransparent UV-VIS	Hydrophilic Stable to pH 4–10
Polyurethanes–silicates–siloxanes	Bis(trialkoxysilylalky)-[poly(propylene glycol)-diurea]: $[Si(OR)_3C_3H_6NHCONH(MeC_6H_3)NHCO(CH(Me)CH_2)_n]_2$ (R = Me, Et, Pr, glyceryl)	Flexible Hydrogels	Hydrophilic Stable to pH 4–10
Polyureas–silicates–siloxanes	Tris[(trialkoxysilylalkyureido)poly(propylene glycol)]glycerol: $[CHO-(CH_2O)_2-]-[(CH_2CH(Me)O)_nCONHC_3H_6Si(OR)_3]_3$ (R = Me, Et, Pr, glyceryl)	Clear, translucent Semiopaque UV-VIS	
Poly(phosphazenes)–silicates–siloxanes	Poly[bis(trialkoxysilylalkylamino)phosphazenes]: $[NP(NHC_3H_6Si(OR)_3)_2]_n$ (R = Me, Et, Pr, glyceryl)	Flexible Clear, translucent Semitransparent UV-VIS	Hydrophilic Stable to pH 4–10

Note: PEO, poly(ethylene oxide); PDMS, poly(dimethyl siloxane).

and drying provides meso- to macroporous materials with highly structured pore frameworks, which despite the dearth of bioencapsulation applications, hold great promise for accessing highly ordered and porous bioencapsulated sol–gels [83, 96].

In general, the physicochemical properties of hybrid and composite sol–gel materials are often significantly improved over those of the constituent sol–gel polymers due to the reinforcing action of the partnering phase [74, 83]. In a similar vein, xerogels are usually superior in terms of mechanical properties and chemical resistance to hydrogels by virtue of greater crosslinking and densification [61–65]. However, the drying of hydrogels inevitably reduces porosity and increases steric compression effects and diffusional limitations, thereby resulting in reduced protein functionality, especially in the case of oxide-based sol–gels [61–65].

6. THE STRUCTURE AND FUNCTIONING OF SOL–GEL BIOENCAPSULATES

On the surface, the (gross) morphology of bioencapsulated sol–gels can appear very similar to that of undoped materials, but this belies that fact that the entrapped biomolecules can substantially affect sol–gel nanostructure by modifying the development of the polymer network. Thus, as outlined above, acidic/basic and charged residues influence the mechanism and rates of alkoxysilane hydrolysis and condensation, and charged, hydrophilic, hydrophobic, and H-bonding domains can act as interfacial templates to direct the branching pattern, functionality, growth, topology, and aggregation of developing polysilicate/polysiloxane colloids [65–74, 84–92].

The avenue via which large oligomeric proteins (>100,000 molecular weight) and micron-sized biologicals such as membrane fragments that are larger than the pore structure can be readily explained by bulk capture by the developing polymer framework. However, the mechanism of entrapment and retention of smaller biomolecules whose dimensions are smaller than the pore size of the sol–gel is less obvious. For example, proteins with molecular weights as low as ~8,000 (globular size ~1 nm) can be irreversibly encapsulated in sol–gels with mesopore networks spanning 2–6 nm, which otherwise allow the infiltration of molecules with masses of 2000–200,000. Thus, polylysine with a molecular weight 150,000 can penetrate into silica and metallosilicate xerogels and therein inhibit trypsin [89, 97], and cytochrome *c* and myoglobin are able to diffuse through *N,N*-bis(3-siloxypropy)ethylenediamine xerogels [98]. Similarly, RNase enzymes can penetrate silica xerogels and bind to encapsulated dinitrophenyl (DNP)-poly(adenylate) [99], and immunoglobulin antibodies can diffuse into silica hydrogels and bind to encapsulated antigenic proteins and cells [100]. Intriguingly, high-porosity sol–gels prepared via special gelation and templating procedures to display pore sizes of 2–20 nm (xerogels) and 4–100 nm (hydrogels) have been used to fractionate proteins with molecular weights of 14,000–77,000 [101]. Even more more striking, it has been shown that intact 50–100 nm influenza virus particles can access and bind to sialic acid-coated liposomes encapsulated in silica hydrogels [102].

The few investigations undertaken to date on this aspect of sol–gel bioencapsulation suggest that entrapment derives from a combination of physical embedding of the protein within sol–gel nanoparticles and strong binding interactions between the biomolecule and surrounding (templated) sol–gel surfaces. Studies indicate that small to midsized biomolecules (5000–100,000 molecular weight) are fully or partially encased by sol–gel surfaces that substantially conform to the topology of the hydrated biologicals, thereby essentially halting their large-scale lateral diffusion [61–74]. However, while global biomolecule dynamics are restricted as a result of this confinement, it appears that the encapsulating sol–gel structures of most hydrogels and xerogels are sufficiently loose to allow for local rotational and translational motions [61–63].

UV-VIS, fluorescence, Fourier transform infrared, Raman, circular dicroism, electron spin resonance, and nuclear magnetic resonance studies of proteins encapsulated in sol–gels have provided some insights into biomolecular dynamics in these restricted environments. Thus, investigations on myoglobin, hemoglobin, cytochrome *c*, cytochrome *c* peroxidase, catalase, monellin, oncomodulin, glutamate dehydrogenase, glucose oxidase, and nitrobenzoxadiazole- and acryloidan-labeled bovine and human albumins entrapped in a variety of silica and siloxane hydrogels and xerogels suggest that the proteins are confined to 3–10 nm pockets wherein they substantially retain nanosecend and subnanosecond dynamics and at least partial rotational and translational mobility, akin to the species in solution [103–124]. For instance, fluorescence studies of silica-entrapped glucose oxidase demonstrate that the rotational mobility of the enzyme is ~50% of that in solution, that the folding kinetics of the flavin (redox) moiety are greatly reduced, but surprisingly, that the local motions of the active site pocket are similar to those in solution [113, 122]. Similarly, UV-VIS probing of ferricytochrome *c* encased in silica sol–gels indicates that active site dynamics are not repressed per se, but that sol–gel confinement does modify them in the sense of creating local heterogeneity [125]. Similarly, the photoactive proton pump bacteriorhodopsin shows decreased dynamics as reflected in a drop in the rate of decay of the excited M state, but retains sufficient global mobility to change its conformational state and therefore function in silica hydrogels and xerogels [126–130].

In addition to modifying biomolecular motions, the polymer surface can also physically block recognition/catalytic sites. For example, studies with myoglobin, albumins, and glucose oxidase have demonstrated that the active sites of subpopulations of the silica-entrapped proteins reflect highly restricted environments that are essentially not-accessible to their corresponding substrates/ligands [104–108, 122]. Not surprisingly, the chemical functionality of the enveloping sol–gel surface can also strongly affect protein function [61–74], as demonstrated by the observation that glucose oxidase retains most of its activity when entrapped in silica, while glycolate and lactate oxidases lose most of their functioning [131, 132]. It has been suggested that the structures of the active sites as well as redox functioning of the flavin cofactor in the latter enzymes are disrupted via electrostatic interactions between their positively charged binding channels and the anionic silica matrix, while the zwitterionic nature of the

binding cleft in glucose oxidase protects the former protein from such effects.

From the above, one can envisage the following structure for bioencapsulated sol–gels [61–74]:

(a) The biological is embedded within the body of the polymer matrix and/or its pore structure, the two defining a bicontinuous framework of fused nano- or microparticles.

(b) Depending upon the biological and the composition and mode of preparation of the sol–gel, the biomaterial is distributed homogeneously as matrix-isolated molecules, may self-associate/precipitate during gelation to form aggregates, or may be nano- or microcompartmentalized at the surface of sol–gel particles or into the pore structure due to interfacial/phase separation effects.

(c) The biological is in contact with a partially of fully enclosing polymer shell, and the contact surface is templated to conform topologically and chemically to the hydrated surface of the biomolecule.

(d) A low-mobility H-bonded layer of water molecules is trapped between the biomolecule and polymer surface.

(e) Global biomolecule mobility and segmental motions are diminished, depending upon the degree of compliance of the biomolecule and polymer surfaces, the type and magnitude of their interactions, and the amount and mobility of the water layer.

(f) There is sufficient accessibility between the recognition sites of a portion of the biomolecule population and the surrounding pore structure and enough freedom for local conformational transitions to enable the entry and recognition/reaction of ligands.

7. APPLICATIONS OF SOL–GEL BIOENCAPSULATES

7.1. Sol–Gel Biosensors

By far the most investigated area of application of sol–gel bioencapsulates has been the realm of biosensors [47, 61–74]. This has resulted from the pressing need for rugged, miniaturized, and portable biosensing devices for applications such as clinical medicine, diagnostics, bioprocess monitoring, food and environmental analysis, food and drug quality control, drug discovery, genomics, and proteomics [133–144]. The great attraction of sol–gel biosensing platforms lies in the generic nature of the technology together with the ability to readily produce materials with diverse chemistries and fabricate them in a variety of formats.

Most work on sol–gel biosensors has focused on glucose sensors based around the flavoprotein glucose oxidase (GOx), which mediates the air oxidation of glucose to gluconolactone with concomitant generation of hydrogen peroxide (Table 4) [145–183]. In this context it should be noted that despite 30 years of development work, robust biosensor platforms for glucose determination in consumer and clinical settings have as yet to be devised. The enzyme has been encapsulated in silica, metal oxides, metallosilicates, Ormosils, and composite sol–gels and the materials

fabricated as monolithic, passive-deposited thin and thick film and spin-coated optical sensors, and monolithic and passive-deposited thin and thick–film electrodes and electrode coatings. Optical biosensors function via the UV-VIS or fluorescence monitoring of the redox state of the chromophoric flavin cofactor, while amperometric platforms measure oxygen levels via Clarke electrodes or oxygen-sensitive rhodium(II)/(III) complexes, or monitor the redox cycling of the active site of GOx via electrochemical coupling to the electrode surface using suitable electron transfer mediators. Interestingly, the active site of GOx can also be directly "wired" to an electrode by modification of the enzyme with a ferrocene derivative or via the co-dispersion/co-polymerization of dye, transition metal complex, or metallocene redox mediators in the sol–gel, and the activity monitored amperometrically [146, 147, 155, 160, 163–166].

A significant development in amperometric GOx biosensors has been the advent of carbon composite electrodes wherein graphite together with mediators is incorporated into GOx–Ormosil sol–gels, thereby furnishing highly sensitive and robust wired configurations, which can be mass produced by screen printing [146–148, 156, 157, 160, 166, 171, 175–177]. In these materials, the carbon phase provides electrical conductivity, porosity, and mechanical reinforcement, while the Ormosil sol–gel framework provides modifiable chemical functionality for fine tuning the catalytic properties and stability of GOx, as well as controlling the hydrophobicity and wetting behavior of the composite. This configuration enables the surface of monolithic and thick film electrodes to be renewed as required by simple polishing to exposing fresh biosensor surface, once sensor performance declines due to surface fouling and/or enzyme inactivation. In a further modification, the inclusion of electrocatalytically active graphite-supported palladium, platinum and ruthenium, or gold nanocrystals in place of graphite provides mediator-free electrodes that are highly sensitive, selective, and stable [147, 149, 155, 169, 172, 174]. Mediator-free amperometric configurations can also be constructed by coupling GOx with horseradish or soybean peroxidases, which mediate the reduction of hydrogen peroxide [145, 147, 155–157, 171].

The generic applicability of sol–gel biosensor platforms has been amply demonstrated with its extension to a wide variety of oxidoreductases ranging from peroxidases, alcohol, amine, polyol and hydroxyacid oxidases and dehydrogenases, phenol oxidases, and hydroxylases to nitrite and nitrate reductases (Table 5) [184–210]. These biosensors have been applied to the determination of hydrogen peroxide, aliphatic alcohols and aldehydes, sugars, lactate, amines, phenols, organophosphates, competitive enzyme inhibitors such as cyanide and organophosphates, nitrates, nitrites, and polar organic solvents.

Whereas optical and amperometric configurations are readily constructed for chromoproteins and oxidoreductases, other proteins can also be applied, providing that the substrate/product can be monitored optically/electrochemically. Thus, the sol–gel entrapped hydrolases cholinesterase, acetylcholinesterase, butyrylcholinesterase, phosphodiesterase, urease, and penicillinase have been used as direct and inhibition-based biosensors for the optical and potentiometric monitoring of acetylcholine, organophosphate

pesticides, penicillin, and urea (Table 6) [221–228]. Of particular interest is the construction of coupled optical sensors using bacteriorhodopsin together with urease, acetylcholine esterase, or penicillinase—the action of the hydrolase alters the pH and thus the protonation state of and hence the rate of decay of the photoactive M state of bacteriorhodopsin [230].

A variety of noncatalytic proteins that selectively bind metal ions and gaseous oxygen and oxides have also been utilized for optical sol–gel biosensing (Table 6). Thus, the luminescent protein has been used to construct sol–gel sensors for calcium, and the chromophoric metalloproteins hemoglobin, myoglobin, cytochrome *c*, and superoxide dismutase have been applied to the solution- and gas-phase detection/quantification of oxygen, carbon monoxide, carbon dioxide, and nitrogen monoxide. In particular, the heme proteins have proved to be excellent model systems for sol–gel bioencapsulation, because the proteins are chromophoric and can be de-readily metallated and metal-exchanged, and their conformation, molecular motions, and ligand binding

can be easily monitored via spectroscopic probing of the active centers [83, 157, 231–240].

There is particular interest in the medical, food, drug, and environmental sectors for developing biosensors for the detection and quantification of antibody–antigen interactions, and sol–gel materials have been explored with some success on this front. Thus, monoclonal and polyclonal antibodies to fluorescein, nitroaromatics, and organophosphates have been encapsulated in silica sol–gels and used for the optical, electrochemical, and coupled enzyme-linked immunosorbent assay (ELISA) detection of the corresponding antigens (Table 6) [241–246]. The reverse configuration, that is, the entrapment of antigens in sol–gels has been used for constructing optical biosensors for detecting the presence of antibodies to disease-causing parasites in human blood [248, 249].

Photoactive proteins, which are of interest for photocatalyst and optoelectronics applications, have also been entrapped for envisaged application as solid-state optical devices and transducers. Thus, the membrane-associated proteins bacteriorhodopsin, phycocyanin, allophycocyanin,

and phycoerythrin have been entrapped in silica hydrogels and xerogels and shown to retain their proton pumping and photoactive properties [149–154].

7.2. Sol–Gel Biocatalysts

A sphere of application that has received rather less attention but that also offers considerable commercial promise is sol–gel biocatalysts (Table 7). With the increasing application of biological catalysts to synthetic chemistry and industrial processes has come the growing need for high-performance immobized biological catalysts that are efficient, are stable to long-term operations under a variety of operating conditions, and can be fabricated on a large scale [13–15, 257–260]. Initial work in this arena was restricted to the encapsulation of model hydrolases such as trypsin and acid phosphatase with little prospect for industrial applications, but more attention has been focused on this arena recently. Thus, Reetz et al. [261–267] established the general practical utility of sol–gel immobilized biocatalysts with their studies on the encapsulation of lipase enzymes in Ormosils and composite sol–gels. The maximal activity of many lipases, as well as that of phospholipases and cutinises, requires the operation of a lid mechanism, whereby the contact with a hydrophobic interface displaces a mobile section of the tertiary structure to expose the binding site, thereby "activating" the enzyme toward its substrate [108]. Reetz et al. [261–267] reasoned that it might be possible to use hydrophobic Ormosils to both encapsulate and activate lipases and showed that a variety of lipases could indeed be stably activated and entrapped in micro-phase-separated poly(alkylsiloxanes), hybrid poly(alkylsiloxane)–polydimethylsiloxane sol–gels, and magnetite–Ormosil composites. The method has since been extended to functional Ormosils and filled composite sol–gels, and it appears that the technique is generically applicable to many lipases, phospholipases, and cutinises [268–277]. The technique provides particulate and thick film materials that display aqueous and organic-phase activities of 60–130% and 140–1,400% of those of the soluble enzymes. The biocatalysts have been used to catalyze the regio-, chemo- and enantio-selective hydrolysis, esterification, and transesterification of carboxylic acids, alcohols, and esters and the acylation of amines in aqueous and aqueous–

organic media and organic solvents. Fluka offers these catalysts for laboratory-scale trials, and Novo Nordisk markets several poly(alkoxysiloxane)–lipase immobilizates for industrial catalysis.

Various other hydrolases have also been encapsulated in inorganic, Ormosil, hybrid, filled, and IPN sol–gels (Table 7). Esterase, serine, cysteine, and metallo-proteases, α- and β-glycosidases, acid and alkaline phosphatases, phospholipases, and organophosphorus hydrolases have been successfully entrapped in hydrogels and xerogels and applied to the hydrolysis of model compounds and the synthesis of bioactive peptides, glycosides, oligosaccharides, lipids, etc. [83, 226, 279–283].

Sol–gel biocatalysts have also been fabricated for lyase enzymes, which are of great interest for asymmetric synthesis by virtue of their ability to stereospecifically form C–C bonds [13–15, 257–260]. Enzymes such as aldolases, aldolase catalytic antibodies, oxynitrilase, and ketoacid decarboxylases have been successfully entrapped in oxide and siloxane sol–gels and applied to the asymmetric aldol condensation, hydrocyanation, and addition of aldehydes and ketones [83, 284, 285]. Similarly, sol–gel immobilized oxidoreductases, including lipoxygenases, tyrosinases, the heme proteins, cytochrome *c*, hemoglobin, myoglobin, and horseradish peroxidase, and alcohol and polyol oxidases and dehydrogenases have likewise been used for the synthesis of polyunsaturated fatty acid hydroperoxides, the hydroxylation of aromatics, oxidative polymerization of phenolics, the *S*-oxidation of sulfides, and the regio- and enantio-selective oxidation of alcohols [83, 286, 287].

The power of sol–gel encapsulation is perhaps best demonstrated with its application to the preparation of multienzyme biocatalysts (Table 7) [83, 288]. Thus, it has been clearly demonstrated that the co-entrapment of enzymes that catalyze consecutive reactions in sol–gels can lead to an enhancement in overall catalytic efficiency and productivity, presumably due to the proximity of catalytic centers resulting in the efficient transfer of reaction intermediates between enzymes, effectively enhancing their local concentration. Thus, a system of the six proteins—sialic acid aldolase, myokinase, pyruvate kinase, pyrophosphatase, CMP-sialate synthase, and α-(2,6)-sialyl transferase—has been trapped in Ormosil–metallosilicate matrices and applied to the continuous synthesis of the

Rice α-galactosidase	PMS	[Enz]–alginate-silica hydrogels and xerogels	Synthesis of alkyl and hydroxyalkyl α-galactosides	
Almond β-glucosidase	PGS		Synthesis of sterol β-glucuronides	
Sulfolobus β-glucosidase	PGS + GAPS			
Bovine β-glucuronidase	PDMS-PGS			
Phospholipase D	PMeGS + PGZrS	[Enz]–siloxane hydrogels and xerogels	Hydrolysis and transesterification of phospholipids	[83]
Acid phosphatase	PMS PGS	[Enz]–silica hydrogels and xerogels	Hydrolysis of phenyl phosphate	[83]
Pseudomonas atrazine	TMOS	[Enz]–siloxane hydrogels and xerogels	Hydrolysis of atrazine	[282, 283]
Chlorohydrolase	TMOS + MeTMOS			
Organophosphorus hydrolases	TMOS	[Enz]–siloxane hydrogels and xerogels	Hydrolytic detoxification of paraoxon and parathion	[83, 226]
Pseudomonas paraoxonase	PGS			
Pseudomonas parathion	PDMS-PMS			
Hydrolase	PDMS-PGS			
Aldolase catalytic antibodies (abzymes)	TMOS	[Antibody]-silica xerogel	Aldol condensation of aldehydes and ketones	[284]
Aldolases	PMS	[Enz]–silicate hydrogels and xerogels	Aldol condensations of aldehydes and ketones	[83, 285]
Rabbit muscle aldolase	PGS			
Sialic acid aldolase	PGTiS			

Table 7. Continued

Proteins	Precursor(s)	Bioencapsulated sol–gel	Reaction catalyzed	Ref.
Almond α-hydroxynitrile Lyase (oxynitrilase)	PMS GAPS + PGS GAPS + PGS + MeGS	[Enz]–siloxane hydrogels and xerogels	Hydrolysis of α-hydroxynitriles Asymmetric hydrocyanation of aldehydes	[83]
Pyruvate decarboxylase	PGAIS	[Enz]–silicate hydrogels and xerogels	Synthesis of phenylacetyl carbinol	[286]
Soybean lipoxygenase I	TMOS PMS MeGS + PGS	[Enz]–siloxane hydrogels and xerogels [Enz]–alginate-silica hydrogels and xerogels [Enz]–phyllosilicate-silica xerogels	Hydroperoxidation of linoleic and linolenic acids	[83, 286]
Mushroom tyrosinase (polyphenol oxidase)	PMS PGS + GAPS	[Enz]–siloxane hydrogels and xerogels	Hydroxylation of phenols and tyrosine derivatives	[83]

Heme proteins
  Cytochrome c
  Hemoglobin
  Myoglobin
 	
  Horseradish peroxidase
	TMOS
	PMS
	PGS
		[Enz]–silica hydrogels and xerogels	Oxidative polymerization of phenols
			S-Oxidation of dibenzothiophene
			S-Enantioselective sulfoxidation of sulfides
				[83, 287]

Alcohol oxidoreductases
  Glucose oxidase
  Glycerol-3-phosphate oxidase
  Alcohol dehydrogenase
	PMS
	PGS
	PGZrS
	PMeMS + PMS
	
	PMeGS + PGS
		[Enz]–siloxane hydrogels and xerogels	Oxidation of glucose to gluconate
			Oxidation of glycerol-3-phosphate to glyceraldehyde-3-phosphate
			Enantioselective oxidation of primary alcohols
			Asymmetric reduction of aldehydes
				[83]

Sialic acid aldolase + sialyl transferase + myokinase + pyruvate kinase + CMP sialate synthase + pyrophosphatase	3-APGS + PGZrS	[Enzymes]–siloxane xerogels	Synthesis of the bioactive sialylated trisaccharide α-(2,6)-sialyl-N-acetyllactosamine	[83]
Formate dehydrogenase + formaldehyde dehydrogenase + alcohol dehydrogenase	TMOS	[Enzymes]–silica hydrogels	Conversion of carbon dioxide to methanol	[288]

Note: 3-APGS, 3-aminopropylglyceroxysilane; 3-APTMOS, 3-aminopropyltrimethoxysilane; BuTMOS, butyltrimethoxysilane, 3-GAPS, 3-gluconamidopropylsiloxane; 3-HEAGS, 3-(1′-hydroxy-2′- (2″-hydroxyethylamino)ethoxy)propylglyceroxysiloxane; HxTMOS, hexyltrimethoxysilane; MeGS, methylglyceroxysilane; MeTEOS, methyltriethoxysilane; MeTMOS, methyltrimethoxysilane; 3-MPTMOS, 3-mercaptopropyltrimethoxysilane; OcTMOS, octyltrimethoxysilane; ODcTMOS, octadecyltrimethoxysilane; PDMS, silanol-terminated polydimethylsiloxane; PGAIS, poly(glyceryl aluminosilicate); PGS, poly(glyceryl silicate); PGZrS, poly(glyceryl zirconosilicate); PMS, poly(methyl silicate); PMeGS, poly(methylglyceroxysilane); PMeMS, poly(methylmethoxysilane); PMZrS, poly(methyl zirconosilicate); PrTMOS, propyltrimethoxysilane; TEOS, tetraethoxysilane; TMOS, tetramethoxysilane; VnGS, vinylglyceroxysilane.

bioactive oligosaccharide α-(2,6)sialyl-N-acetyllactosamine [83]. Similarly, formate dehydrogenase, formaldehyde dehydrogenase, and alcohol dehydrogenase, have been co-encapsulated in silica and used for the remarkable conversion of carbon dioxide to methanol [288].

8. FUTURE DEVELOPMENTS IN SOL–GEL NANOBIOENCAPSULATION

The last decade has witnessed an increasing interest in sol–gel bio-nanocomposites, and studies to date have uncovered some remarkable features of these materials [47, 61–74]:

(a) Sol–gel bioencapsulation is generic—a remarkably diverse range of enzymes, noncatalytic proteins, DNA, RNA, organelles, and even live cells have been encapsulated.

(b) Although, as expected, encapsulation within a sol–gel polymer matrix modifies the functioning of the biological, the native activity can be largely retained therein.

(c) Inorganic, hybrid, and composite materials with exotic physicochemical properties can be utilized for bioencapsulation.

(d) Bioencapsulation enables the conversion of labile biological materials into reusable and physicochemically robust nanocomposites, which can be fabricated and manipulated using conventional sol-gel processing procedures.

(e) Biomolecules encapsulated in sol–gel polymers are protected from biological degradation, and are often considerably stabilized to chemical and thermal inactivation.

(f) Sol–gel bioencapsulates can be interfaced with spectroscopic, optical, and electrochemical platforms to generate biosensing devices.

However, studies have also exposed substantial hurdles that need to be overcome for the widespread adoption of the technology [47, 61–74]:

(a) The biocompatibility of sol–gel protocols needs to be refined: although advances have been made with

alcohol-free solutions and glyceroxysilane precursors, difficulties are still encountered with certain classes of biologicals, especially oligomeric biomolecules, membrane proteins, organelles, and live cells.

(b) Pore collapse during xerogel preparation remains a major issue: as well as being the single most important cause of bioactivity decline upon encapsulation, this can also lead to structural defects in films and monoliths and complicate fabrication procedures. Although some amelioration can be achieved via the application of special drying regimens, drying control additives, templating and pore-forming compunds, and glyceroxysiloxane precursors, a generic, practical, and scalable method for minimizing structural collapse has as yet to be devised.

(c) The porosity of current generation bioencapsulates is not optimal: low pore size and volume and the presence of a disordered/semicontinuous pore structure give rise to biomolecule subpopulations, which are inaccessible to analytes, reduce biomolecule dynamics and inhibit functioning, and cause internal diffusional limitations. The availability of ordered mesocellular materials with large pore dimensions above 10 nm would considerably ease the fabrication of efficient materials for fast-biosensing and high-throughput biocatalysis. Most likely, this could be achieved via the application of structure-directing surfactants and polymers, and the use of self-templating precursors.

(d) Present day bioencapsulates generally show poor mechanical attributes: brittleness and a low resistance to mechanical stress are typical, and this poses a limit on many bulk applications. Unfortunately, here one is at odds with porosity—in general, the greater the pore size and volume the more fragile and deformable the polymer is and vice versa. A possible partial solution is the synthesis of sol–gels with ordered mesopore or heirarchical pore assemblies, the honeycomb structures of which are known to enhance mechanical stability. Alternatively, mechanical properties can be improved by using dendritic- or comb-type macromeric precursors, IPN composites, and the use of reinforcing fillers.

In spite of the many substantial hurdles facing sol–gel bioencapsulation, the rapid advances that have been made in the past decade in improving encapsulation protocols and diversifying applications have been remarkable. Indeed, sol–gel nanoencapsulation offers the single most facile, generic, and promising methodology for the entrapment and stabilization of biological materials. With this in mind, one can forsee some future directions for sol–gel nanocomposite bioencapsulates:

(a) *Combinatorial discovery.* Recently developed methods for generating sol–gel polymer and heterogeneous catalyst libraries will be applied to the discovery of novel matrices, the optimization of sol–gel compositions, and the screening of sensor and catalyst libraries for particular applications [289, 290].

(b) *Bioencapsulation in transition metal alkoxides.* The use of bulk transition metal oxides and co-encapsulated oxometallates and metal oxide colloids with conducting, catalytic and/or chromic properties may pave the way to novel bioencapsulated electro- and photocatalytic and electrochromic devices for novel biosensors, photobioelectronics, etc. [291–297].

(c) *Engineering of Ormosils.* The appendage of moieties that can be directly wired to the active centers of oxidoreductases and photoproteins and interfaced with co-encapsulated conducting or photoactive polymers would enable the construction of integrated electrosensor and optical devices. Similarly, the adaptation of strategies for the co-entrapment of transition metal catalysts will allow the execution of multicatalytic reaction cascades [298–300].

(d) *Advanced hybrids and composites.* Novel organic–inorganic sol–gels, IPN and filled composites, and multilayered architectures are expected to contribute to the development of highly responsive and rugged biosensors and biocatalysts that can be used in extreme environments, and self-supporting catalytic membranes, as well as enable the use of novel fabrication methods [301, 302].

(e) *Templated sol–gels.* The development of biocompatible templating methods based upon self-assembling mercaptosiloxanes and long-chain alkyl siloxanes, polyblock siloxane copolymers, and exogenous pore-forming additives should give access to encapsulates with highly ordered pore morphologies and chemical functionalities. Furthermore, the deployment of molecular imprinting techniques should allow the addition of highly specific recognition functions to sol–gel biosensors and thereby improve selectivity, response and resistance to interference and fouling [303–308].

(f) *Microfabrication methods.* Recently developed microstamping, soft lithography, microspotting, and ink-jet printing technologies [309–311] are expected to be applied to sol–gel bioencapsulates to the fabrication arrays for drug screening, genomics, proteomics, and combinatorial synthesis [312–316] and the production of microsensors, microreactors, and bioelectronic devices [317–321].

Although still in its infancy, sol–gel bio-nanocomposites should significantly advance a range of disciplines that interface with biology, from the production of biosensors, biocatalysts, and bioartificial organs to the fabrication of high-density bioarrays and bioelectronic devices. Indeed, it is expected that the coming years will witness the realization of a variety of research and industrial applications, especially those aimed at the catalysis, sensing/monitoring, diagnostics, biotechnology, and biocomputing sectors.

GLOSSARY

Biological or biosystem A material of biological origin, for example, a protein, deoxyribonucleic acid (DNA), living cell, or some part thereof.

Biocatalyst A biological material, typically an enzyme (protein) or collection of enzymes, that is able to catalyze a chemical reaction in a highly specific manner.

Bioencapsulation The process whereby a biological such as a protein is physically entrapped within a polymeric material, for example, a sol–gel, during the synthesis of the latter.

Biosensor A sensor that utilizes a biological molecule such as protein as a highly specific material for the recognition of the target analyte.

Electrochemical (bio)sensor A (bio) sensor that generates an electrical signal in the presence of the corresponding analyte. The signal is typically measured and quantified using an electrochemical cell.

Nanocomposite A solid-sate material that consists of two or more components, at least one of which is polymeric, and the structure of which is derived from the nanoscale (typically 1–50 nm) interaction and organization of the contributing components.

Optical (bio)sensor A (bio)sensor that generates an optical signal in the presence of the corresponding analyte, typically in the ultraviolet-visible region. The signal is usually measured and quantified by visual or spectroscopic methods.

Sensor A solid-state material that can specifically recognize one or more chemical compounds (analytes) in its environment and generates a response which can be measured and used to determine the concentration of the analyte(s).

Siloxane A polymer of silicon or a precursor thereof, which is characterized by the presence of stable covalent Si–O–Si bonds as well as Si–C bonds.

Sol–gel An inorganic silicon or metal oxide-based polymer or a derivative thereof that is produced using a unique room-temperature aqueous protocol (sol–gel technology) based upon the controlled hydrolysis of specific chemical precursors.

Biogenic Nanoparticles

Joseph M. Slocik, Marc R. Knecht, David W. Wright

Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

1. INTRODUCTION

Biological systems offer an unparalleled level of molecular control over the biosynthesis of inorganic materials, either as a means of metal detoxification (Ag^0, Au^0, ZnS, CdS, and Ag$_2$S) or cellular integration of a functional component (Fe$_3$O$_4$, Fe$_3$S$_4$, and SiO$_2$). Detoxification processes include the bioreduction and/or precipitation of toxic metal ions into insoluble nontoxic nanoclusters. Alternatively, the controlled biosynthesis of magnetite and silica involves oxidative and condensative associated processes. As a result, the collection of biogenic particles display exquisite structural assemblies (diatom frustules), morphologies (tetragonal Ag^0 particles), functionality (Fe$_3$O$_4$ as an internal magnet and SiO$_2$ as a protective barrier), quality (24 carat bacterioform gold), crystallinity, and monodispersity.

2. BIOSYNTHESIS OF ZERO-VALENT NOBLE METALS (Ag^0 AND Au^0)

Noble metals are naturally present in the environment at various abundances in sea water (ng amounts), rock (ng amounts), the atmosphere (ng amounts), and soil (μg amounts). A wealth of documented examples of microbial-metal interactions and bioaccumulation of noble metals in everything from unicellular organisms to animals and even in humans has been documented [1]. At trace amounts, noble metals are toxic to many organisms. Consequently, the survival of the organism is dependent upon the detoxification of noble metal ions by either bioreduction and/or mineralization processes. For example, bacterial cells detoxify Ag$^+$ by evolving silver resistant encoded plasmids that enable Ag^0 production in exquisitely shaped particles [2–4]. Interestingly, it is believed that microbial-metal based interactions involving gold deposits by bacteria date back to over 2.8 billion years [5]. The following examples provide a detailed survey of the organisms and mechanisms of biogenic synthesis of gold and silver nanoparticles (summarized in Table 1).

2.1. Biomineralization of Ag^0 Nanocrystals

2.1.1. Classification of Silver Resistance by Organisms

Several bacterial cultures of *Pseudomonas stutzeri* [2–4], *Escherichia coli* [6, 7], *Enterobacter cloacae* [8], and *Citrobacter intermedius* B6 [9, 10] are resistant to the antimicrobial effects of silver. Silver ions primarily act by poisoning respiratory enzymes and electron transport components through interference with DNA and/or in combination by blocking the permeability of the outer membrane, thereby inhibiting growth [7]. Organisms have developed mechanisms to compensate for this toxicity via precipitation of less toxic silver salts (Ag$_2$PO$_4$, AgCl, or Ag$_2$S), possession of silver resistant plasmids (silver ion efflux or other energy dependent process), and/or bioreduction of silver ions to nanocrystals [6, 12].

Genetically encoded silver resistance is common to all of these organisms and is the most likely silver detoxification mechanism. However, with the exception of *Pseudomonas stutzeri*, studies of most species of bacteria have only reported the biological ramifications of silver and not the physical characterization of these deposits. The resistance of *Citrobacter intermedius* B6 [9, 10] and *Escherichia coli* [6, 7] was conferred by an ion efflux pump and a lack of an outer membrane permeability barrier [7].

Pseudomonas stutzeri A259 was the first bacteria shown to produce silver nanocrystals [3]. Isolated near a silver mine in Utah, silver resistance in *Pseudomonas stutzeri* was linked directly to the DNA plasmid of pKK1 (molecular weight 49.4 MD), one of three known plasmids (pKK1, pKK2, and

Table 1. Summary of biogenic particles.

Name	Organism	Product	Size	Conditions	Ref.
Pseudomonas stutzeri	Bacteria	Ag^0	<200 nm	Grown in $AgNO_3$	[2]
Medicagos sativa	Alfalfa plant	Au^0	2–20 nm	Active uptake Au^0	[18, 19]
Pedomicrobium-Like	Budding bacteria	Au^0	~1 μm	Natural mineralization	[5, 21]
Verticillium sp.	Fungus	Au^0	20 nm	Intracellular reduction	[17]
Verticillium sp.	Fungus	Ag^0	25 nm	Intracellular reduction	[15]
Lactobacillus strains	Bacteria (buttermilk)	Au^0	25–50 nm	Exposure to $HAuCl_4$	[14]
Lactobacillus strains	Bacteria (buttermilk)	Ag^0	15–500 nm	Exposure to $AgNO_3$	[14]
Fusarium oxysporum	Fungus	Au^0	20–40 nm	Extracellular reduction	[22]
Cylindrotheca fusiformis	Diatom	SiO_2	500–700 nm	Exposure to $Si(OH)_4$	[70, 71]
Coscinodiscus granii	Diatom	SiO_2	Undefined	Exposure to $Si(OH)_4$	[69]
Aquaspirillum	Bacteria	Fe_3O_4	25–55 nm	2–7 μM oxygen	[44]
A. Magnetotacticum	Bacteria	Fe_3O_4	Undefined	2–7 μM oxygen	[47, 48]
Undesignated	Magnetotactic bacteria	Fe_3S_4	69 nm	Anaerobic	[56]
Schizosaccharomyces pombe	Yeast	CdS	1.8 nm	Peptide mediated/Cd^{2+}	[86]
Candida glabrata	Yeast	CdS	2.0 nm	Peptide mediated/Cd^{2+}	[86]
Fusarium oxysporum	Yeast	CdS	5–20 nm	Extracellular reduction	[89]
Klebsiella aerogenes	SO_4^{2-} reducing bacteria	CdS	20–200 nm	Exposure to Cd^{2+}/SO_4^{2-}	[90]
Pseudomonas stutzeri	Bacteria	Ag_2S	Undefined	Grown in $AgNO_3$	[2]
Desulfobacteriaceae	Bacterial biofilm	ZnS	2–5 nm	pH 7.2–8.6/(0.1 ppm Zn)	[107]

pKK3) [3]. The existence of pKK1 in the resistant strain was substantiated by its omission in a silver-sensitive bacterial colony, forming the basis for a comparative study. However, this interpretation is controversial.

Slawson et al. [4] first described the accumulation of silver between the resistant and sensitive strains as occurring rapidly within the first eight minutes of exposure and with comparable amounts of silver (300 mg of silver per gram of dry weight of bacteria) through an energy dependent pathway. Similarly, both the resistant and sensitive strains exhibited silver binding and deposition localized predominantly at the cell surface. The silver was deposited at the surface in the insoluble form of Ag_2S as dense conglomerates in response to high levels of H_2S produced by the cell [4]. The release of H_2S was observed to occur at higher concentrations in the Ag-resistant strain than in the Ag-sensitive ones, thus accounting for differing degrees of resistance to silver [4].

In an alternate mechanism for silver resistance, Haefeli et al. [3] speculated that a molecule analogous to metallothionein forms an inert complex with Ag^+, thereby protecting the bacteria. This was supported by the lack of silver reduction upon exposure to light. Additionally, Haefeli et al. [3] reported the reduction capabilities of *Pseudomonas stutzeri* A259 and the silver resistant strain A256 with the common reagents of methylene blue and resazurin, establishing a plausible bioreduction mechanism for Ag^+. They emphasize that this reductive capacity may or may not have a connection to silver resistance as evidenced by similar results with A256 and A259 [3].

2.1.2. Biomimetic Approaches to Microbial-Induced Ag^0 Nanocrystals

Characterization of Ag^0 Particles by Pseudomonas stutzeri Another microbial pathway of detoxification involves the production of silver nanocrystals by *Pseudomonas stutzeri* under laboratory conditions and cultured

in media enriched with $AgNO_3$. Recently, Klaus et al. [2] characterized these particles by TEM, EDX, and electron diffraction. The majority of silver was deposited as particles in vacuole-like granules (ranging from a few to 200 nm in diameter) between the outer and plasma membranes, with higher concentrations located at the cell poles (Fig. 1) [2]. At these cellular binding/accumulation sites, different crystal morphologies displayed in the TEM micrographs were distributed throughout the periplasmic space of the cell in the form of triangular, hexagonal, and spheroidal silver containing particles [2]. The shape selectivity of the triangular and hexagonal forms was presumed to result from the confined space available for plate-like morphology, in addition to the crystallographic plane bearing the highest atomic density [12]. It is known that plate morphology is preferred
Figure 1. TEM image of whole uncontrasted cell enriched with Ag^+. Reprinted with permission from [2], T. Klaus et al., *Proc. Natl. Acad. Sci.* 96, 13611 (1999). © 1999, National Academy of Sciences, U.S.A.

during crystal growth due to the faster rate of accumulation relative to spherical growth. This results from a high aspect ratio (edge size to thickness) of about 100/1 for a flat crystallite, which provides a surface to volume ratio two orders of magnitude larger than at equilibrium for plates versus spheres [12].

From electron diffraction measurements, three different crystal phases were observed within the cell's boundary: a face-centered cubic structure for metallic silver, a monoclinic crystalline α-form of Ag_2S, and an undeterminable phase [2]. From a representative sample, the metallic form was present in the highest abundance followed by a small number of Ag_2S particles. The third crystal type was unidentified crystallographically [2].

Joerger et al. [13] have further developed a biomimetic approach of transforming biocomposites of nanocrystalline silver and bacteria into optically functional thin-film coatings. The films were simply produced by thermally treating the composites to yield a functional carbonaceous material [13]. The optical properties were characterized by strong wavelength selective absorption in regions where the matrix weakly absorbed, and strong reflectance in spectral regions where the matrix strongly absorbed [13].

***Formation of Ag⁰ Particles by* Lactobacillus** Bacterial strains of *Lactobacillus* isolated from buttermilk produced Ag^0 clusters *in-situ* when treated with $AgNO_3$ and whey within 12 hours of exposure [14]. The harvested silver deposits exhibited a bimodal distribution in sizes centered around 15 nm and 500 nm, with the larger particles resulting from coalescence [14]. The subsequent coalescence of the larger particles inside the bacterium forced a structural change observed by a protrusion of particles into the cell wall lining [14]. The crystallinity of these Ag^0 products was inconsistent with metallic silver and Ag_2S by XRD, but likely represented a composite with a silver-rich core externally shielded by various organic species at the surface [14].

2.1.3. Fungal-Mediated Ag⁰ Biosynthesis

Verticillium fungal cells exhibited intracellular surface reduction of silver [15]. Mukherjee et al. [15] cultured cells for 72 hours at concentrations of 10^{-4} M Ag^+, producing silver nanoparticles that were uniformly distributed on the cell surface with average sizes of 25 ± 12 nm. The specific location of the silver deposits was confined to both the cell wall (external boundary) and cytoplasmic membrane (internal boundary), thus providing credence for the biosynthetic mechanism [15]. The mechanism controlling nanocluster formation was dominated by surface trapping of the Ag^+ ions through electrostatic interactions between the Ag^+ and the negatively charged carboxylate groups of cellular enzymes (not specified) [15]. After trapping the silver ions, they are reduced by enzymes in the cell wall to silver nuclei, which further nucleate to clusters [15]. The authors also reported the successful multiplication of cells over a week in the presence of Ag^+ showing no detrimental effects on cell growth. In contrast to the *Pseudomonas* biosynthesized Ag^0 nanoparticles, the crystal morphologies were primarily spheroidal shapes [15].

2.2. Biomineralization of Au⁰ Deposits and Nanoclusters

Gold ions in general are less toxic than silver ions. Consequently, an array of examples of organisms which can effectively biomineralize metallic gold particles has been observed. As a result of gold's properties (lower toxicity), organisms do not require essential resistance encoded plasmids as they did for Ag^+, but in turn must be more robust (physical features of the cell) to counteract the increased density of mineralized gold. *Bacillus cereus* [16], *Verticillium sp.* [17], *Medicago sativa* [18, 19], and *Pedomicrobium*-like bacteria [5, 20], have the ability to biomineralize gold.

2.2.1. Mechanism and Characterization of Microbial-Produced Gold

Pedomicribium-like bacteria are commonly associated with the oxidation of iron and manganese. They represent the first known system to biologically produce gold particles (termed bacterioform gold) at a quality of 24 carats [5]. They have been discovered anchored on gold placer deposits at several geographical sites including Alaska, northwestern China, and regions of South Africa [21]. Common among all three sites are locally high concentrations of Au^+ and Au^{3+} complexes of $Au(CN)_2^-$, $Au(OH)Cl_3^-$, and $AuCl_4^-$ amenable to bioaccumulation processes [5]. Additionally, the bacteria exhibited characteristics suitable for deposition processes such as a direct budding behavior and an inclination towards colonization advantageous to the continuous mineralization of gold [5, 21].

The mineralization of gold begins with accumulation in the cell wall through electrostatic binding of the anionic gold complexes with positively charged residues (RNH_3^+, R_4N^+) and/or ligation with coordinating ligands (RSH, R_2S) of polypeptides [5]. Aggregates of these sulfur-rich/cationic peptides then serve as nucleation sites for gold. Upon binding at the surface, electron transfer processes induce sufficient reduction to metallic Au^0 and crystal growth occurs [5]. This suggests that the high purity (24 carats) isolated from gold deposits are consequences of both highly selective binding and the redox properties of the cell.

The formation of gold particles is controlled and limited by the morphological characteristics of the cells. These bacteria lack spatially delineated compartments that can restrict the dimensions of crystal growth, so the mineralized gold products result in structurally ill-defined, physically heterogeneous, and spatially disorganized forms [5]. This structural incontinuity is clearly apparent in the SEM images obtained from representative samples of bacterioform gold [5, 21]. Additionally, coatings of open diffuse colonies of *Pedomicrobium* produced gold deposits that are described as ranging in appearance from extended lacelike networks to oval, spheroidal, and/or kidney shaped structures approximately 1 μm in size [21]. Samples imaged by SEM also showed a core region that was significantly compacted, indicative that the gold layers episodically grew outwards [21]. This intricate architecture of thin gold layers develops from the complex growth patterns of budding cells, their symbiotic role in the colony, and possibly a hierarchy order. These colonies consisted of branching, axial, and lateral direct budding cells

capable of mineralizing gold in all directions to different extents, evident in the micrographs in which budding assemblages are joined by slender gold metallized stalks and hollow tubules [21]. It is the budding nature of these cells that enables the colony to remain a step ahead of irrevocable entombment by the gold shell.

Watterson [21] confirmed the involvement of *Pedomicrobium*-like bacteria in bacterioform gold by using electron-beam heating experiments. The incident electron beam causes pyrolytic swelling and other textural changes in the substrate material identifying its composition [21]. From the experiments, the results established that the deposits were not solid gold objects, but they possessed an organic substrate interior [21].

The strain of *Lactobacillus*, already shown to produce Ag^0 particles, analogously crystallized Au^0 under the same experimental conditions [14]. Parallel to Ag^0, the growth of Au^0 crystals pushed and/or possibly ruptured the cell wall, but preserved the integrity of the bacterial contour [14]. The Au^0 products belonged to the two size domains of 20–50 nm and greater than 100 nm [14]. The TEM micrograph (Fig. 1) illustrated these two distinct sizes along with the cellular distribution. An abundance of Au^0 clusters resided clearly outside the delineation of the bacterial contour; however within the defined contour were predominantly large Au^0 crystals resulting from coalescence [14].

2.2.2. Eukaryotic Biomineralization of Au^0

Eukaryotic organisms are also a source of biologically derived gold particles. The synthesis of gold particles was recently achieved with the silver bioreducing fungus, *Verticillium sp.*, under the same laboratory conditions utilized for Ag^0 [14, 17]. Upon exposure of $AuCl_4^-$ to *Verticillium* fungal cells and after an incubation period of 72 hours, monodispersed gold nanoparticles successfully formed [17]. The isolated nanoparticles, averaging 20 nm in size, were characterized by a distinguishable plasmon absorption resonance at 540 nm and intense diffraction peaks for the (111), (200), and (220) crystal planes of face-centered cubic gold [17].

The fungal cells bioprocess gold by surface trapping $AuCl_4^-$ ions at the cell wall and through cytoplasmic membrane binding interactions analogous to Ag^+ [17]. The bound gold ions are subsequently reduced by enzymes within the cell wall, resulting in the aggregation of metal atoms and formation of nanoparticles [17]. Mukherjee et al. [17] arrived at this conclusion by examining the sugars in the cell wall and the surrounding media for extracellular reduction of Au^{3+}. A survey of the cell shows a distribution of nanoparticles between the two boundaries, with a higher abundance of gold nanoparticles on the cytoplasmic membrane than the cell wall. Through examination of the TEM micrographs, a few but large gold particles were also present in the cytoplasm with random triangular and hexagonal shaped particles observed.

Contrary to the intracellular synthesis of Au^0 by *Verticillium*, Mukherjee et al. [22] demonstrated the extracellular reductive capacity of an atypical genera of fungus, *Fusarium oxysporum*. In solution, the fungal cells released agents which reduced $AuCl_4^-$ to nanoclusters of Au^0 [22]. Four proteins (molecular masses 10 kDa–66 kDa) were identified as

being released in the solution according to gel electrophoresis [22]. One of the proteins was speculated as being responsible for the Au^{3+} reduction, while the other proteins might bind and stabilize the Au^0 nanoclusters against aggregation [22]. The gold products were characterized by FTIR and TEM. The results from FTIR spectroscopy revealed unchanged amide I and II bands relative to native proteins, suggesting that the secondary structure was not affected by reacting with the gold ions nor binding the gold nanocluster surface [22]. The TEM images showed particles 20–40 nm in size with spherical and triangular morphologies [22]. The implications of extracellular gold reduction impact a proposed harvesting process and affords commercial viability [22].

2.2.3. Phytosynthesis and Remediation of Au^0 Particles

The active uptake and mineralization of gold by plants was first described by Anderson et al. [23] with *Brassica juncea* or common mustard plant. It was shown to hyperaccumulate gold as high as 57 μg of gold per gram of dry biomass when complemented with different concentrations of thiocyanate [23]. More recently, gold biomineralization was reported with *Medicago sativa* alfalfa plants [18, 19, 21]. Previously, Gardea-Torresdey et al. showed that inactivated alfalfa biomass can reduce Au^{3+} ions to Au^0 nanoparticles in solution [18, 20]. In more recent studies, live alfalfa plants grown in a gold enriched agar were examined for nanocluster formation. The experiments were carried out at different concentrations of gold (0, 5, 10, 20, 40, 80, 160, and 320 ppm) and harvested after two weeks of growth [19]. The harvested plants were characterized by EXAFS (X-ray absorption fine structure) measurements and TEM analysis [19]. From EXAFS, it was determined that the Au^{3+} was reduced to Au^0 in the agar solid media prior to active uptake by the alfalfa [19].

Analysis of the plant components by TEM (Fig. 2) revealed areas of aggregated gold nanoparticles in the plant
Figure 2. Low magnification TEM micrograph of alfalfa shoot showing aggregates of gold nanoparticles. Reprinted with permission from [19], J. L. Gardea-Torresday et al., *Nano Lett.* 2, 397 (2002). © 2002, American Chemical Society.

shoots and roots with a negligible concentration in the stems. This suggested that nucleation of the gold atoms inside the plants occurred in preferential zones [19]. The plant samples displayed a broad distribution of nanoparticles with sizes ranging from 2 to 20 nm in diameter [19]. Gardea-Torresdey et al. [19] claimed that the difference in sizes is a consequence of nanoparticles being formed at different times during the transport of gold atoms through the roots and shoots network. This particle size then affected the final crystal phase of the gold, such that an icosahedron structure was adopted by a 4 nm gold particle and a face centered cubic twinned structure crystallized for particles 6–10 nm in size [19]. The icosahedron structure was the most common, as it represents the lowest energy configuration for gold [19].

The bioreduction of noble metals is a viable mechanism utilized by biological systems to control the formation of zero-valent metal particles resulting from the stress of toxic metal ions present in the environment. Specific organisms process metal particles differently; however the exact function that metal particles serve for the organisms besides that of a detoxification product remains elusive. It is speculated that silver particles may possibly function in cellular activity with parallel multifunctionality to magnetite [12]. Additionally, it is alleged that bacteria could use silver ions as part of an electron transport process in its reduction to metallic silver [12].

3. BIOMINERALIZATION OF METAL OXIDES (Fe$_3$O$_4$ AND SiO$_2$)

3.1. Magnetite Bioproducing Bacteria

3.1.1. Discovery and Classification of Bacterium

In 1975, aquatic bacteria were discovered to have the ability to biomineralize the magnetically responsive mineral magnetite (Fe$_3$O$_4$). The bacterium was originally seen in the light of its magnetotaxis during cell culturing. The cells in the culture were able to translocate inside the culture based upon the orientation of the magnetite crystals with respect to the earth's geomagnetic field [24]. Since then, biogenic magnetite has been discovered in a wide variety of organisms, including algae, insects, mollusks, fish, birds, and in the human brain [25–30]. Recent research has focused on improving the understanding of the uptake of iron and formation of magnetite, and its bioapplications will be reviewed.

The largest group of organisms that biologically produce magnetite are bacteria. While there exists an extremely broad range of bacteria that can produce biogenic magnetite, all are gram-negative prokaryotes [31]. Isolated freshwater magnetotactic bacterial strains include *Magnetospirillium gryphiswaldense* (Fig. 3), *Magnetospirillum* sp. AMB-1, *Magnetospirillum magnetotacitcum* MS-1, and *Magnetospirillum* sp. MGT-1 [32–35]. These organisms generally reside in river sediments and/or in low oxygen concentrated aquatic environment. Specifically, Bazylinksi et al. [36] have discovered live magnetotactic bacteria in the Pettaquamscutt River Estuary from depths of 2.25 m to a total depth of 6.5 m. Other populations of bacteria were discovered at
Figure 3. Electron micrograph of *Magnetospirillum gryphiswaldense.* Bar = 0.5 μm. Reprinted with permission from [102], D. Schüller and R. B. Frankel, *Appl. Microbiol. Biotechnol.* 52, 465 (1999). © 1999, Springer-Verlag.

depths between 3.5 and 4.7 m below sea level in a region known as the Oxic-Anoxic Transition Zone (OATZ) with a maximum number of living motile cells located between 4.4 and 4.7 m [36]. The OATZ is a region of the estuary in which both molecular oxygen and hydrogen sulfide exist, but at minimal concentrations. Below the OATZ region is the anoxic zone where concentrations of hydrogen sulfide exist, but molecular oxygen does not. Schüller et al. [37] elucidated that the oxygen concentration range for which bacterial magnetite formation occurs is between 2 to 7 μM, although cells are able to proliferate at higher concentrations of molecular oxygen [37].

Bacterial cells are able to use the magnetite to wade through their native aquatic environments with respect to the earth's magnetic fields [24]. The crystals are single-domain in nature and form chains along the interior of the cell wall [24]. The orientation of the chains aids the cell in direction and motion, which is termed magnetotaxis. Researchers have capitalized on this mobility to isolate magnetite-producing cells from samples by using a magnet to extract these specific cells to an area separate from the other cells [38, 39].

The internalized compass that the bacterial cells possess allows them to determine which direction to move and for what reason. The motility of the cells is directly linked to other environmental factors, especially the concentration of transition metals in the ambient surroundings. Studies have been conducted of cell motility in aqueous environments to understand the effects of the metal concentrations. Concentrations of 1, 10, and 100 parts per million were used as a factor in the study. Copper, cobalt, and zinc were shown to completely inhibit the motility of the cells at any concentration, while other transition metals showed no inhibition of the cell motility [41].

3.1.2. Iron in Bioprocessing

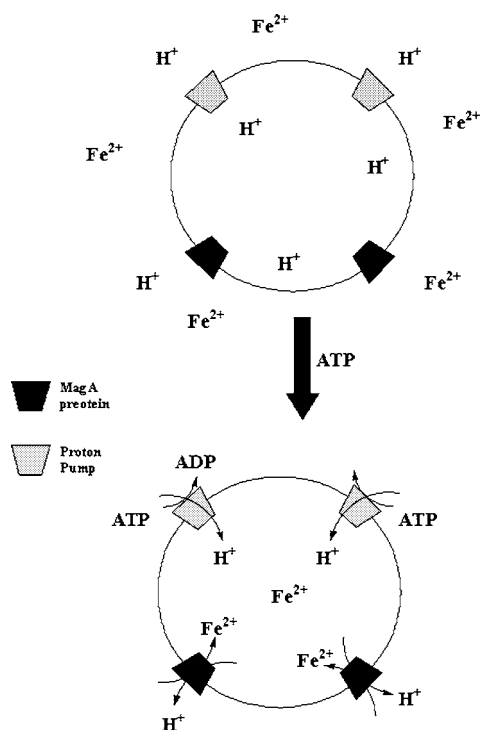
Iron uptake is the first step in the formation of magnetite as illustrated in Figure 4. Matsunaga and Takeyama [42] discovered and cloned the MagA transport protein from the magnetotactic bacterium *Magnetospirillum* into *E. coli* cells using previously employed techniques [49]. This protein exhibits a high degree of hydrophobicity and is oriented in


Figure 4. Dynamic scheme of Fe uptake by magnetotactic bacteria.

the phospholipids bilayer with both the N and C terminals directed towards the interior of the cell. Interestingly, MagA does not possess the ATPase gene and binding site for ATP, thereby supporting the theory of it being used as a transporter protein for iron. Iron uptake is directly linked to ATP consumption away from the MagA site. Upon addition of ATP to the cloned *E. coli* cultures isolated with the proteins, the cloned cells immediately began uptake of ^{59}Fe, which was terminated upon the addition of CCCP (carbonyl-cyanide *m*-chlorophenyl-hydrazone), a metabolic phosphorylation inhibitor [42].

Inside the cell, the iron is used as a substrate for the building of magnetic particles. While the detailed mechanism of biomineralization has not been elucidated, two different modes have been proposed. Round et al. [48] have speculated that iron is taken up by the cell, and chemically adjusted to hydrous ferric oxide (Fe_2O_3) as a precursor to magnetite (Fe_3O_4). The cell utilizes the magnetosome, a highly developed lipid and protein layer that envelopes the magnetite crystal [38], to direct the crystallization and/or precipitation of the aqueous ferric oxide precursor to a specific location in the bacterial cell. Mann observed under high resolution transmission electron microscopy (HRTEM) in *A. magnetotacticum* that nucleation of the precursor occurs at many locations in the cell. There existed a primary site of nucleation for the single domain crystals to grow. Since precipitation of the precursor occurred outside the primary site, he speculated that this precipitated precursor needed to be dissolved and reprecipitated at the primary site. Mann et al. [47] also observed that the amorphous precursor is kinetically more stable than the final product of magnetite crystals. Consequently, once crystallization has begun the magnetite (Fe_3O_4) will be the more thermodynamically stable product relative to the ferric oxide precursor [38].

The second method of controlled growth is envisioned as a solid state rearrangement at a solution front between the amorphous precursor and the crystalline magnetite. As crystals of magnetite grow in the bacterial cell, they form large conglomerates of the amorphous ferric oxide that is used to form the crystal phase magnetite. It has been speculated that the amorphous phase encounters a solution front causing the solid state rearrangement of the substrate of ferric oxide to form the magnetite. In the *A. magnetotacticum* cell, amorphous material has been observed in high association with the Fe_3O_4 crystals, suggesting that the rearrangement of the amorphous ferric oxide occurs to form the magnetite crystals. It is unlikely that precipitation of the precursor occurs in the second method of solid state rearrangement to form the crystal because of this high degree of associativity between the precursor and crystalline phases [38].

3.1.3. The Magnetosome

While studying magnetite in *Aquaspirillum*, Balkwill et al. conjectured that the magnetite particles are probably enveloped by a lipid bilayer, known as the magnetosome [49]. They were, however, unable to visualize the lipid bilayer because of the high electron density of the magnetite core that the bilayer surrounded. Gorby et al. [38] attempted to prove the existence of the lipid layer by removing it using standard biochemical techniques and characterizing the composition of the layer. Magnetotactic cells were cultured and lysed so that the magnetite particles were able to be magnetically separated. Once separated, the lipid layer of the magnetosome was extracted and analyzed [35]. The composition was determined to consist of three components. The first fraction made up of neutral lipids and free fatty acids amounted to eight percent of the total structure. The second fraction, consisting of thirty percent of the lipid layer, was made of glycolipids, sulfolipids, and phosphatides, while phospholipids accounted for sixty-two percent of the lipid layer by weight was the third fraction. None of the neutral lipids, fatty acids, or glycolipids were identified, while the phospholipids were identified as either phosphotidylenthanolamine or phosphotidylserine by thin layer chromatography [38].

Further research by Okudu et al. [45] has led to the isolation of three unique proteins associated with the magnetsome. These proteins include a 12 kDa protein (MAM12), a 22 kDa protein (MAM22), and a 28 kDa protein (MAM28). Interestingly, MAM22 shows a significant degree of homology with numerous proteins of the tetratricopeptide repeat protein family. MAM22 is believed to be located on the surface of the magnetosome and electrostatically interacts with the cytoplasm [45]. Although there has been some speculation that the MAM 22 protein may have a receptor-like function, to date there has been no evidence to support this theory.

3.1.4. Crystal Dimensions and Morphology

In magnetotactic cells, there exist many different morphologies of magnetite crystals that are based specific to different species of magnetotactic bacteria (Fig. 5). The main technique for identifying the structures is HRTEM. Through this
Figure 5. Morphologies of bacterially produced magnetite. Morphologies include (a) cubo-octahedral, (b, d, e, f) elongated hexagonal prismatic, and (c) bullet shaped. Reprinted with permission from [104] D. Schüller and R. B. Frankel, *Appl. Microbiol. Biotech.* 52, 466 (1999). © 1999, Springer-Verlag.

method, researchers have been able to identify a wide variety of structures including parallelpipeds ($40 \times 40 \times 60$ nm) [46], hexagonal prisms truncated by the {111} plane [40], and octahedral with faces truncated by the {111} and {100} faces [47].

Along with varying shapes of the crystal structures, the crystals themselves have defined size values that are species dependent. The overall space constraints within the cell probably dictate the final size of the crystals of magnetite [48]. For instance, Balkwill et al. [44] studied the dimensions of the magnetite mineralized in cells from the genus *Aquaspirillum.* These cells possessed magnetite with a monomodal size range of 25 to 55 nm in diameter (average of 42 nm) and 39 to 49 nm in length [44]. This particular genus of bacteria has a distinct cell size that is determined through mitotic division. When any cell is reproduced, size constraints are dictated by the genetic makeup of that particular cell. Due to this rigid cell size, the biological magnetite can only be produced to a size that can actually fit within the physical space of the cell, leading to crystal size conformity of the magnetite in individual cells of any genera.

3.2. Biological Production of Magnetite in Salmon

While bacterial cells are the most abundant sources of biogenic magnetite, other organisms are able to mineralize magnetite and use it as an internal compass. A notable example is salmon, which employs magnetotaxis to "hone in" on a specific location to spawn without celestial recognition [49]. Biogenic magnetite has been discovered deep in

the recesses of the salmon (*Oncorhynchus nerka*) brain in the ethmoid region [50, 51]. Mann et al. [50] studied the composition and orientation of these magnetite crystals. The chains were straight and continuous, disrupted, or folded upon themselves and looped around other magnetite chains [50]. Previously, other chains were found in bacterial magnetite sources that are typically straight and continuous. In Mann's analysis, sample preparation could have caused the discrepancies in the salmon chains [50]. Overall, the chain makeup contained between 13 and 45 magnetite crystals with modal length groups of 21 to 25 crystals and 35 to 40 crystals. The median of the chain groups fell within a range of 21 to 25 particles in length [50].

The chain arrangements and lengths are not as significant as the morphology of the crystals. As stated earlier, bacterial magnetite has always been highly associated with an amorphous iron layer that surrounds the crystallized material. In salmon, the magnetite is not associated with any amorphous material and in fact has no structural irregularities or edge dislocations [50]. All of the crystals studied were cubo-octahedral and had the [111] face of the adjacent crystals perpendicular to the axis of the crystal chain. The average size of the crystals studied was 25 to 60 nm with a mean value of 48 nm. Elemental analysis showed iron as the only inorganic source in the crystals [50].

The ethmoid region of the adult salmon brain shows an intense magnetic moment. The intensity of the magnetization of the ethmoid tissue was 130 ± 75 pT while the ethmoid cartilage had an intensity of 281 ± 77 pT [52]. This high level of magnetization enables the salmon to translocate using earth's geomagnetic field. The magnetite that is found in the salmon increased throughout the entire lifespan of the fish (fry, yearling, smolt, and adult) [52]. From theoretical calculations, it is believed that salmon in the fry stage of life are able to respond to magnetic changes. Salmon in the smolt stage of life have been shown to be able to detect small magnetic changes in a magnetic field and use this information as a magnetoreceptor [52]. The brain is not the only source of magnetic material for the salmon. Magnetic material, not characterized as magnetite, has been found in other tissues, of salmon such as eye, skin, and olfactory tissues, which do not function in magnetoreception [52].

3.3. Biological Production of Magnetite in the Human Brain

Magnetite has also been found in human brain tissues [30]. Kirschvink [52] exposed magnetite crystals in human cadaver brain tissue 12 to 24 hours post mortem. They found trace amounts of ferromagnetic material homogeneously throughout the meninges and entire brain, including all cerebral lobes, the cerebellum, basal ganglia, and the midbrain [30]. In the meninges, the magnetite crystal concentration was around 70 ng of magnetite per 1 g of tissue, while in brain tissue concentrations were approximately 4 ng of magnetite per 1 g of tissue. Dobson and Grassi [52] have also studied the distribution of magnetite in the brain, observing higher concentrations of 3.0 to 7.2 ng/g for human brain tissue and 54 to 109 ng/g for meninges tissue. The primary difference between the studies is that Dobson and Grassi's were obtained from living samples and frozen in liquid nitrogen

immediately, while Kirschvink's samples were attained post mortem [53]. It seems possible that post mortem degradation or fragmentation from sample preparation of the overall crystal structures may explain the difference in particle concentration and size.

Cerebral magnetite crystals have an oddly prismatic morphology, unlike the more typical octahedral crystals found in geological samples. This bolsters the argument that magnetite formed in the brain is of biogenic origin [30]. The grain sizes of the magnetite are bimodal with a population of crystals between 10 to 70 nm in length, and another population between 90 and 200 nm in length [30]. Due to this large distribution of sizes, the crystals are not likely to be used as a magnetic field detector in humans [54]. Currently, a physiological use for these crystals is unknown. In the study of the human brain crystals, they are remarkably similar to other biogenic crystals of magnetite from other organisms in shape and morphological content [30].

An interesting aside is the fact that there does exist a difference between magnetite crystal bioproduction in human males and females. Male subjects have shown an increased concentration of neural magnetite crystals with age. The data trend has a slope of positive 1.48 for the increase of magnetite as the male ages. In fact, the data is significant at the 90% confidence interval [55].

3.4. Greigite Bioproducing Bacteria

3.4.1. Discovery of Bacterium

While the organisms mentioned above are able to mineralize magnetic particles of Fe_3O_4, other bacterial organisms are able to biomineralize a different magnetic iron particle. Bacteria that reside in anaerobic environments are able to biologically produce crystals of greigite, Fe_3S_4. This bacterium commonly resides in sulphidic rich, brackish water and river sediments [56].

3.4.2. Crystal Composition

Originally, Mann et al. [56] discovered these undesignated magnetotactic bacteria with a mixture of particles containing greigite (Fe_3S_4) and pyrite (FeS_2). The samples that were used were collected from marine environments with high sulphidic concentrations. Upon separation of the crystals, powder patterns returned d-spacings for pyrite from this magnetic material that was irregular in structure. This finding gives support to the fact that in these samples, greigite was a minor component. Greigite was certainly in the sample, though, because strong diffraction contrasts indicated a crystalline structure consistent with Fe_3S_4 [56].

3.4.3. Crystal Morphology and Distribution

Since this initial finding of greigite, more structurally pronounced crystals have been uncovered from bacterial specimens. From sulphidic environments, two different unclassified rod-shaped, single-cell, greigite-producing bacteria have been shown to synthesize highly regulated crystals of greigite. The first bacterial strain is able to produce highly organized chains of rectangular prismatic greigite, up to 57 crystals in length, with crystal dimensions of 69×50 nm. The second strain of bacteria is able to biomineralize chains

of 26 well-defined cubo-octahedral crystals with an average length of 67 nm. All particles analyzed contained only iron and sulfur with no oxygen atoms present [57].

Bazylinksi et al. [36] continued this research of greigite producers to find the environment that they inhabited. Researchers located magnetotactic griegite producing bacteria in the OATZ (Oxic-Anoxic Transition Zone) region and in the anoxic region below the OATZ that is completely sulfidic in nature. These organisms are logically found in this region because of their need of sulfur sources for the biogenic production of greigite. From the OATZ and anoxic regions, magnetotactic bacteria were uncovered that contained both greigite (Fe_3S_4) and magnetite (Fe_3O_4). The deeper into the OATZ region that the samples were procured, the more likely the crystals were to be solely griegite. Finally, once the anoxic region was reached, the bacteria contained only griegite crystals [36].

3.5. Silica Bioproduction

Biogenic silica, SiO_2, has been found in a vast array of creatures in the plant kingdom. Stunning examples of these organisms include single celled diatoms (of the order *Bacillariophyceae*) [58]. These fascinating creatures can bioproduce an estimated 240 ± 40 teramoles of silicon per year in breathtaking arrays of siliceous structures resulting from the uptake and conversion of silicic acid present in dilute concentrations of the earth's oceans [61].

3.5.1. Diatoms

Diatoms, classified under generas *Nitzschia* or *Hantzachia*, are single-celled organisms that biogenically produce amorphous silica as structural elements of their cell wall, commonly referred to as a frustule [59]. Diatoms have two different cell structures, which give rise to different cell shapes. The pinnate diatoms are long and narrow with an axis that spans the length of the diatom and parallel to the plane of symmetry. The centric diatoms have radial symmetry around an axis that is located through the center of the cell lengthwise [60]. Figure 6 provides an example of a centric diatom.
Figure 6. The diatom *P. sulcata*. Reprinted with permission from [59], F. E. Round et al., "The Diatoms: Biology and Morphology of the Genera," Cambridge Univ. Press, New York, 1990.

Recently, studies have begun to focus on the biochemical pathways that give rise to biogenic silica. The likely precursor of biogenic silica is silicic acid ($Si(OH)_4$), which exists in concentrations of 70 μM throughout the world's oceans [61]. Transport proteins from the cell walls of the diatom *Cylindrotheca fusiformis* have been putatively identified as active silicic acid transporters [62]. To date, five different transporter proteins have been found. Active uptake of silicic acid is coupled with sodium ion transport [63, 64]. For frustule formation, the cell must have enough silicic acid for complete formation of the frustule. If there is not enough precursor, the frustule cannot be completely formed. Consequently, it is believed that uptake of silicic acid by the diatom is completed just before frustule formation is performed [62].

Diatom Cell Division   The rigid and amorphous silica cell wall of the diatom causes cell formation to undergo different steps of morphogenesis, different than cells with a phospholipid bilayer cell wall. This specialized cell division actually causes the biodeposition of silica to form this unique diatom cell wall. The silica frustule forms a Petri dish like structure that encapsulates the interior of the cell and protects it from external forces. The top portion of the frustule is the epitheca, which overlaps the bottom portion known as the hypotheca. With cell division, each newly formed cell must develop a new portion of the frustule, either the epitheca or hypotheca. The new cells are able to retain the opposite theca from the original cell from which cell division began [60, 65, 66].

Once the cell begins the division process, a specialized valve is developed in association with each daughter cell. This valve, known as the silica deposition vesicle (SDV), is used for the biodeposition of silica to form the new frustule half. The SDV is used in exocytosis of the silica held within it to form a hypovalve on the exterior of the two daughter cells where the silica frustule is not located. This eventually is turned into the hypotheca of new cells [60, 65, 66].

With the hypovalve developed, the daughter cells separate from each other to form two new cells. The girdle bands, the overlapping bands of the Petri dish like structure, continue to develop fully into the frustule. During this point of division, each newly formed cell uses two SDVs to form the overlapping girdle bands, completing the cell division process [60, 65, 66]. Ironically, such a specialized cell division process eventually reaches a point of diminishing terms. Each resulting daughter cell is smaller than the original cell from which it was derived. Due to this mitotic division, the size distribution of the cell over time will become smaller. Eventually, when mitotic reproduction reaches a 30% to 40% reduction in cell size proportions, the diatoms will engage in sexual reproduction, leading to the return of the larger sized diatomic cells [67, 68].

Diatom Frustule   Each species of diatom has a different silica frustulitic structure leading to an astounding variety of morphologies. Noll et al. [69] have studied the frustulitic morphological structure of the diatom *Coscinodiscus granii* using scanning electron microscopy (SEM), as seen in Figure 7, and atomic force microscopy (AFM). From these micrographs, the inner surface of the sample appeared smooth and featureless between the craters in the silica formation. The right side of the image has been disrupted
Figure 7. SEM micrograph of the valves from the diatom *C. granii*. The right side of the image has been disrupted by the purification process. Reprinted with permission from [69], F. Noll et al. *Nano Lett.* 2, 91 (2002). © 2002, American Chemical Society.

by the purification process. The diameter of the craters is approximately 400 nm [69].

The surface of the *C. granii* diatomic frustule took on new definition when it was analyzed using an AFM. While the gross morphologies of the frustule were similar in both AFM and SEM, more defined structures were revealed by AFM. Granular structures, on the order of tens of nanometers, were clearly observable between the craters as well as on the rim of the craters shown in Figure 8. The crater heights were measured to be on the order of 80 nm from the surface of
Figure 8. AFM image of the valves from the diatom *C. granii*. Reprinted with permission from [69], F. Noll et al., *Nano Lett.* 2, 91 (2002). © 2002, American Chemical Society.

the valve [69]. It is interesting to note that these individual spherule sizes were similar to those observed in experiments with the silica precipitating peptides, the silaffins.

3.5.2. Silica Precipitating Peptides

During frustule formation, silicic acid that has been transported to the SDV must be hydrolyzed to silica and deposited. In their pioneering study, Kröger et al. [70] demonstrated that diatoms have specific peptides associated with the biogenic synthesis of silica. Extracted from the frustle of *C. fusiformis,* the silaffin peptide was shown to mediate the direct precipitation of silica from silicic acid solutions [70]. Terminal amino acid sequencing indicated a high degree of homology between all of the silica precipitating peptides. The primary amino acid sequence was ultimately determined to be SSKKSGSYSGSKGSKRRIL with extensive post-translational modifications of the lysine residues by polyamines. Additionally, the application of more mild purification methods coupled with ^{31}P NMR studies revealed that the serines were post-translationally modified as phosphoserines. This interpretation was confirmed by mass spectrometry, which definitively demonstrated that all of the serines were in fact phosophoserines [71].

Post-translational modifications of the lysine and serine residues of the R5 peptide are of particular interest (Fig. 9). These modifications include phosphorylation of the serine residues and long chain polyamine derivatives of the lysine residues [70, 71]. Studies from different species have shown these modifications to be species-specific [70, 71]. The polyamines are highly associated with the frustule and have been shown to precipitate silica *in vitro* from solutions of silicic acid [72]. The process by which these polyamines generate silica remains unknown. A likely process would occur via interactions of the amine moieties with the silicic acid driving the hydrolysis of the precursor into the formation of silica. Kröger et al. have shown in comparisons between silaffin and the R5 peptide from *C. fusiformis* (with lysines not chemically modified) that there exists a significant difference in the pH profiles for silica deposition. While the nonmodified R5 peptide precipitated silica with a maximum activity at pH 7.0, silaffins have been shown to have optimal silica precipitation activity at pH 5.0 (Figure 10).
Figure 10. pH dependence of silaffin vs. R5 peptide.

This suggests that the polyamine modifications are important in the biologically relevant precipitation of silica [70]. Recently, it has been suggested that the phosphorylation of the serine residues allows for the formation of supramolecular peptide assemblies with locally high concentrations of polyamine moieties to drive silica formation [71].

3.5.3. Biogenic Silica Morphology

Biogenic silica from silaffins and the related R5 peptide is of interesting morphology. *In vitro* precipitated silica forms tiny nanospheres of amorphous silica that aggregate together to form larger particles with a size distribution of 500–700 nm [69, 71] These nanospheres of amorphous silica are the building blocks of the cell wall frustule.

The morphology of silica precipitated from amine containing polymers has also been investigated. Noll et al. [69] studied the effects of using tripropylenetetramine (**I**) and pentapropylenehexamine (**II**) on silica precipitation. These polyamines partially mimicked the post-translational modifications made to the silaffin peptide lysine side chains. Upon addition of these linear chain polyamines to silicic acid solutions, precipitation of silica was immediate. Interestingly, the amorphous silica that was produced had similar aggregate spherical morphology to that produced by silaffins but yielded different sizes. The spheres produced by the polyamine (I or II) possessed a diameter of only 400 nm [69], which is smaller than those produced from silaffins. Poly-L-lysine has also been shown to be active in the precipitation of silica. The nucleophilic amine of each side chain showed similar precipitation activity to the nucleophilic lysine of the R5 peptide. The resultant silica had a particle size distribution of 40–600 nm with a majority of the particles between 200–400 nm [73]. This wide variation in particle size can be attributed to the statistical distribution of amine moieties within the polymer's composition.

Figure 9. Silaffin with modified lysine residues.
4. BIOMINERALIZATION OF METAL SULFIDE NANOCLUSTERS (CdS, ZnS, AND Ag$_2$S)

The biomineralization of cadmium sulfide and zinc sulfide nanoparticles is well known in plants, certain fungi, yeasts, and sulfate reducing bacteria. As with many metal ions, Cd^{2+} and Zn^{2+} are toxic to these organisms at high levels [74]. In response to these metals, organisms have developed a variety of specific detoxification mechanisms: (1) alteration of membrane transport systems reducing entry of Cd^{2+} into cell, (2) intracellular or extracelluar sequestration and precipitation, (3) an energy-dependent ion efflux process, and (4) enzymatic oxidation or reduction of metal ion to a less toxic form [75]. An example of CdS biomineralization utilized by plants and yeasts is a biotransformation mechanism consisting of a metal triggered biosynthetic pathway, metal ion sequestration by small selective peptides, and then coprecipitation with inorganic sulfide to form nontoxic metal sulfide clusters (Figure 11) [74]. A description of the mechanisms will be provided as well as examples of characterized metal sulfide clusters mineralized from different organisms.

4.1. Metal Detoxification by Chelating Peptides

The main feature of metal detoxification (plants and yeast) is the incorporation of small thiol-rich peptides of the general form of (γ-Glu-Cys)$_n$-Gly called phytochelatins (PC$_n$), which can strongly bind Cd^{2+} or Zn^{2+} ions [74, 76–80]. Conversely, a minor function of these peptides is associated with maintaining the homeostasis of the organism by balancing its essential micronutrients [80]. The importance of the peptide, however, originates from the unique binding capacity utilized by the organism in controlling the metal toxicity. These sequences can contain anywhere from 2 to 11 repeating units, n, depending upon concentration, duration of metal exposure, and species [81]. Usually, organisms possess a heterogeneous mixture of peptides of various lengths [82]. This peptide has been identified in a number of biological systems such as *Silene cucubalus* [76], *Pisum sativum* L. [81], *Schizosaccharomyces pombe* [74, 77], *Candida glabrata* [77], and in all plants.

The utility of the phytochelatin peptides results only after a metal induced trigger mechanism of a specific biosynthetic pathway is initiated. Exposure of Cd^{2+} ions induces cellular synthase of an enzyme of γ-glutamylcysteine dipeptidyl transpeptidase, termed phytochelatin synthase [82]. It was observed that Cd^{2+} is the strongest inducer of this pathway requiring only low concentrations to trigger the enzyme, whereas Cu^{2+}, Zn^{2+}, Pb^{2+}, and Ni^{2+} are less effective and must be present at higher external levels for induction [84]. Binding of Cd^{2+} into a metal recognition domain induces a conformational shift of the protein to assemble the active site. The activated enzyme catalyzes the transpeptidation of γ-glutamylcysteine moieties of GSH onto another GSH molecule of the growing phytochelatin peptide [78]. This catalyzed reaction terminates when the newly synthesized phytochelatin peptide reaches an intracellular concentration such that free phytochelatin removes Cd^{2+} bound to PCs.

After synthesis of the peptide template, the available metal ions coordinate to the peptide, forming a metal-phytochelatin complex in accordance with an S$_4$ coordination environment [79]. Johanning and Strasdeit [79] studied the dynamic nature of this complex in terms of thermodynamic stability and its subsequent equilibria by implementing a model system of $Cd^{2+}/(PC_2)$ to ascertain its biological significance. PC$_2$, **(III)**, was chosen since it represents the simplest phytochelatin and a pentabasic acid [79]. Two categories of complexes were observed: complexes with the same number of ligands and Cd^{2+} ions (log K^{Cd} = 9.9–13.3) and those with more ligands than metal ions (log K^{Cd} = 16.3–19.3) [79]. They reported at a plant physiological pH of 7.3, typical of the pH in the cytoplasm of higher plants, the complex of $[Cd_2(H_2L)(HL)_2]^{7-}$ predominates [79]. Additionally at this pH, at least 0.5% of the cadmium was uncomplexed and in the free +2 ionic state indicating that these complexes are by no means extremely stable [79]. Meanwhile, at a pH of 5.4 in the vacuoles of higher plants, the $Cd^{2+}/(PC_2)$ system liberates 62% of the cadmium [79]. Thus at a basic pH, Cd^{2+} is chelated by the peptide, but in the acidic environment of the vacuole, the complexes entirely dissociate to cadmium. This is reminiscent of a storage/transport mechanism, such that the peptide temporarily binds and stores the Cd^{2+} metal ions in the plant cytosol until transported into the vacuole whereby the complexes dissociate and the peptide releases unbound Cd^{2+} [79]. It is suggested that this complex dissociation also allows the plant to recover the phytochelatin peptides [79].

(III)
An additional component of the metal-phytochelatin complex is the integration of acid labile sulfide into the resultant nanocluster. Reactive sulfide ions are believed to originate via one of two biochemical pathways—either from a cadmium-induced mechanism that leads to cellular sulfide generation (source of sulfide is unknown) or as a consequence of the functionality of sulfate reducing bacteria. It is known, however, that the generated S^{2-} ions and H$_2$S readily react with the $Cd^{2+}/(PC_n)$ complex to form insoluble CdS particles coated with the phytochelatin peptides. The sulfide content of the cell invariably increases the binding capacity of the peptide, controls the size of crystallites, and also can
Figure 11. Biotransformation mechanism to CdS involving phytochelatin synthesis, formation of metal-phytochelation complex, incorporation of labile sulfide, and mineralization of CdS with a surface coat representative of PC$_3$ and PC$_4$ peptides.

vary the composition of the peptide coat. The binding capacity was shown to increase for PC_2 from 0.5 mole equivalents of Cd^{2+} in the absence of sulfide to 5 mole equivalents of Cd^{2+} per peptide when the sulfide level was increased [85].

4.2. Biosynthesis of CdS Crystallites by Plants and Yeasts

As recently as 1989, CdS crystallites produced in yeasts were discovered by Dameron and Winge [86]. The importance of the discovery established a method of preparing small monodisperse CdS clusters that offer unique semiconductor properties (high discrete excited electronic states and optimal quantum yields) and are stable against Ostwald ripening and oxidation as compared to synthetic crystals [87]. For example, the yeasts *Schizosaccharomyces pombe* and *Candida glabrata* produced intracellular 1.8 nm and 2.0 nm CdS clusters respectively, with approximately 85 CdS units encapsulated with 30 PC_2 peptides [86]. The presence of a peptide coat was a significant observation in the biological formation of CdS, as it protected and passivated the surface. Also extracellular production of 2.9 ± 0.5 nm sized CdS crystallites yielded clusters of undefined stability [86].

Williams et al. studied the batch cultivation of CdS by *Schizosaccharomyces pombe* during different growth phases for optimal crystallite production. They reported that during early-exponential growth, cellular metabolism is affected and there is an increased efflux of Cd^{2+} ions from the cell, resulting in minimal formation of CdS. The addition of cadmium during the mid-exponential growth phase produced a maximal amount of CdS. Williams et al. concluded that the timing of cultivation harvest and the saturation factor of the biomass are critical for batch production, but production would also be feasible with a fed-batch culture of increased biomass cells [88].

4.2.1. Extracellular Enzymatic Formation of CdS

In a separate study, exposure of aqueous Cd^{2+} and SO_4^{2-} to the fungus *Fusarium oxysporum* (see Section 1.2) resulted in the first reported case of extracellular fungal synthesis of CdS by a purely enzymatic process [89]. The active mechanism operating in the CdS crystallization was the extracellular secretion of sulfate reductase enzymes, which slowly reduced the sulfate over 12 days and formed CdS nanoclusters 5–20 nm in size [89]. Analysis of the fungal mediated synthesis by UV-vis and polyacrylamide gel electrophoresis (PAGE) confirmed the presence of proteinaeous material consisting of the active enzyme and auxiliary proteins (PAGE indicated 4 protein bands) [89]. These auxiliary proteins possibly afforded a degree of stability to the CdS nanoparticles by binding to the cluster surface and preventing aggregation of the colloidal solution [89].

Anaerobic sulfate reducing bacteria presents another enzymatic source of labile sulfide, which has been recognized for years and implicated in the biomineralization of CdS particles. Examples include *Klebsiella aerogenes* [90] and *Clostridium thermoaceticum* [91] type bacteria. *Klebsiella aerogenes* grown in the presence of Cd^{2+} was documented to mineralize extracellular CdS crystallites (20–200 nm) on the cell surface with a total cellular content of labile sulfide and cadmium between 0.5–2.0 molar ratio of Cd:S [90]. For *Clostridium thermoaceticum*, CdS synthesis was energy dependent and driven by the ability of a cysteine desulfhydrase enzyme to catalyze the release of H_2S from cysteine [91]. In order for CdS precipitation to occur, an essential source of cysteine and Cd^{2+} was required. In cultures containing Cd^{2+}, it was observed that the total sulfide increased fourfold and twofold with respect to the amount of extracted protein [91].

4.2.2. Biomimetic Approaches to Encapsulated CdS Clusters

As expected, it is not surprising that different species process and synthesize CdS crystallites to differing degrees and sizes over a range of conditions. The composition of the CdS peptide coat is therefore also likely to be modified. Barbas et al. [91] and Dameron et al. [92] studied the surface coat of *Candida glabrata* derived CdS clusters under different growth and nutrient conditions. They reported a time/sulfide content dependent conversion of an entirely glutathione-coated cluster to a phytochelatin coated surface [91]. The preference of higher order and more elongated phytochelatin peptides offering a multidentate binding mode to the surface are undoubtedly more stable [91]. When cultured in rich nutrients, the CdS particles had a heterogeneous surface composition of both glutathione and γ-glutamylcysteine. In synthetic minimal medium, clusters formed with only polymerized γ-glutamylcysteine peptides as the coating surface [92].

The phytochelatin driven biomineralization of CdS *in vivo* has directed the progression towards new biomimetic approaches. These involve mimicking the phytochelatin peptide template with synthetic analogues. The native CdS crystallites isolated from *Candida glabrata* were systematically compared with clusters formed *in vitro* with synthetic phytochelatin peptides ($n = 2$–4) and a metallothionein hexapeptide [82]. Results indicated that the synthetically produced CdS crystals (coated with phytochelatin peptides or metallothioneins) exhibited a red-shifted electronic transition to 318 nm in the UV-Visible absorption spectrum analogous to the properties of the native CdS formed *in vivo* [82].

Spreitzer et al. [93] and Whitling et al. [94] have recently developed a spatially addressable combinatorial library based on an n_3 phytochelatin skeleton structure, $\underline{X}$-Cys-$\underline{Y}$-Cys-$\underline{Z}$-Cys-Gly, to investigate the stabilization of CdS nanoclusters. Five possible natural and non-natural amino acids of α-Glu, γ-Glu, γ-aminobutyric acid (GABA), SerGly, and ε-aminohexanoic acid (ε-Ahx) were permutated over the X, Y, and Z spacer positions, thus generating a library consisting of 125 peptidomimetic ligands [94]. Results from screening the library showed peptides that stabilized discrete populations of CdS clusters ranging from 1.9 to 2.6 nm in diameter [93]. Spreitzer et al. [93] attributed the difference in sizes to the number of spacer bonds between cysteine residues.

Bae and Mehra [95] synthesized CdS-(GSH) clusters under laboratory conditions to yield a homogeneous GSH surface. They reported size distributions of CdS-(GSH)

ranging from 2.14 nm to 4.06 nm upon varying the Cd^{2+}/GSH ratio and the S^{2-}/Cd^{2+} molar ratio [95]. In contrast, the pytochelatin-stabilized CdS clusters at various sulfide/Cd^{2+} ratios resulted in a uniform crystallite distribution with similar optical properties. The optical properties of CdS-(GSH) were highly affected by the GSH content, whereby the largest sized particles formed at the highest sulfide concentration generated the least GSH capping material and showed a reduced fluorescence (λ_{max} emission = 490 nm) [95]. The extreme case representing clusters with the highest GSH content also exhibited low fluorescence [95]. Additionally, the CdS-(GSH) clusters were shown to reduce methylviologen accounting for its semiconductor properties.

In a parallel experiment, Mehra and coworkers [81], examined the stability of surface bound glutathione ligands around the CdS core. They effectively demonstrated that the titration of phytochelatin peptides with CdS-(GSH) nanoclusters led to a complete ligand exchange on the CdS surface with the phytochelatin peptides and no apparent change in cluster size [82]. This exchange reaction was monitored and detected by following the emission at 480 nm, fractionated on a Sephadex G-25 column, and then analyzed by a cyclic assay [82]. The displacement of GSH conclusively established the higher affinity of CdS for phytochelatin peptides.

Aside from peptide template controlled CdS synthesis, a divergent biomimetic approach is involved in the implementation of an organic matrix mediated process to CdS biosynthesis. Nayar et al. [96] exploited the quaternary structure of bovine serum albumin for its role in CdS mineralization. The applicability of bovine serum albumin resulted from the 35 available cysteine moeities for binding Cd^{2+} and a spherical protein cage with a 5–10 nm cavity suited for crystal growth [96]. According to the SEM image, particles of CdS precipitated out in the appearance of a branched star structure and were arranged in a helical manner along each branch indicative of a denatured protein structure [96]. The CdS crystal sizes were representative of the protein structure and confined to the dimensions of the cavity (5–10 nm CdS clusters).
(IV)

Similarly, a peptidomimetic matrix **(IV)** above was designed to nucleate CdS clusters along the {01.0} crystal face by Bekele et al. [97]. The ligand was chosen because of its propensity to nucleate β-hairpin folding (bracketed structure) and inclination to self-assemble into β-sheet monolayers [97]. The resultant peptidomimetic two-dimensional monolayer effectively nucleated the crystal growth of CdS

(2.5–5.0 nm in width and length) in a wurtizite lattice structure oriented roughly in the same direction on the monolayer [97]. The driving force for the site specific nucleation was predominantly a consequence of the monolayer organization and the {01.0} CdS crystal plane [97]. In the ⟨001⟩ direction of CdS, the Cd-Cd distance was 6.72 Å, which correlated with the atom separation distance of glutamic acid C_α-C_α of 6.9 Å within a single β-strand [97].

4.3. ZnS Biomineralization and Biomimetic Design

Biogenic ZnS nanoparticles are analogous to CdS particles with respect to the crystal lattice structures that they can accommodate (wurtzite and zinc blend), photophysical properties, semiconductor properties, bioprocessing/mineralization mechanism, and, to a lesser extent, their binding behaviors and affinities. For these reasons, the examples of biomineralized ZnS crystallites are limited in contrast to CdS produced clusters. However, the biological production of ZnS crystals are by no means less important. The following examples will be focused on biomimetic techniques and unique aspects to the stabilization and control of ZnS particles.

Mehra and colleagues studied a collection of metal-chelating bioligands of cysteine [98, 99], glutathione [100, 101], and histidine [102] in the formation of ZnS crystals. All of the ZnS nanoclusters were synthesized under a variety of conditions based on a modified colloidal synthetic procedure that mimicked the *in vivo* biomineralization of eukaryotic organisms. Essentially, the strategy involved preforming a Zn-(ligand)$_n$ complex and then subsequently reacting the complex with inorganic sulfide [98]. The presence of inorganic sulfide along with the stabilizing ligand prompted a competition for metal binding, thus promoting ligand displacement and cluster formation entirely controlled and tailored by the amounts of reactants added and various binding affinities of ligands/S^{2-} for Zn^{2+} [98–102]. For example, the dissociation constant of a zinc-cysteine complex is 1.5×10^{-18} and the K_d for ZnS is 1.1×10^{-24} confirming the preference to form ZnS [99].

According to this bio-inspired synthesis, cysteine capped ZnS nanoclusters were successfully produced on a gram quantity scale [99]. The isolated ZnS clusters exhibited many highly desired characteristics such as a large shelf life (stable for more than 30 months as a powder and against Ostwald ripening), an average particle size of around 6.08 ± 0.76 nm determined from TEM, photocatalytic activity with *p*-nitrophenol, enhanced optical properties (absorbance $\lambda_{max} = 257$–277 nm), and cost effectiveness [99].

The analogue to cysteine is the cysteine containing tripeptide of glutathione, already reported for the stabilization of CdS nanocrystals. The biosynthesis of ZnS-(GSH) crystals was carried out by the above procedure and characterized by a cluster size of 3.45 ± 0.5 nm (TEM) [100]. Absorbance maxima ranging from ~250–290 nm were reported for ZnS-(GSH) clusters synthesized from ratios of sulfide varying from 0.25 to 5.0 [95, 98]. In comparison to ZnS-(Cys),

the glutathione stabilized clusters were more disperse in size possibly as a result of the higher stability of the Zn^{2+}-(Cys) complex [98].

The use of histidine as a capping agent yielded hexagonal ZnS-(His) clusters (average size 4.2 nm from TEM) stabilized through surface coordination of the imidazole moiety [102]. Characterization of the resultant clusters by UV-visible spectroscopy revealed a dual peak absorption at ~260 nm and ~290 nm indicative of two ZnS populations. A significant enhancement in the fluorescence of the histidine encapsulated clusters by tenfold was achieved relative to the ZnS-(Cys) clusters, likely due to the charge delocalization within the imidazole ring [102]. It was suggested that histidine may serve as a more efficient ligand than cysteine or glutathione in surface passivation by preventing deep trap surface states from nonradiative recombination [102].

4.4. Biosynthesis of Ag$_2$S Particles

The previously described bacterial strain of *Pseudomonas stutzeri* was documented to produce intracellular zero-valent silver nanoclusters, but also was capable of biogenically producing complementary silver sulfide particles [2, 4]. The extent of silver sulfide precipitation by the bacterial cell varied between reported examples, but Klaus et al. suggested that the difference in results was due to the experimental conditions [2].

Brelle et al. [103] have used the ligands of cysteine and glutathione once again in the biomimetic synthesis of silver sulfide particles. For both glutathione and cysteine capped Ag$_2$S clusters, the average particle diameter was determined to be around 9 nm (TEM) [103]. Also, it was observed that Ag$_2$S showed a lack of strong absorption, characteristic of an indirect band gap semiconductor [103].

4.5. Bacterial Biofilms

Bacterial biofilms exist naturally as distinct communities of bacteria located near the vicinity of mineral deposits. The formation of biofilms proceed through several stages: attachment of individual bacterial cells to (abiotic or biotic) surfaces, colonization of bacteria, quorum sensing, and growth of a mature biofilm [104]. Quorum sensing allows bacterial cells to participate in cell–cell communication, which synchronizes the activities of the organized biofilm community [104]. The classification of biofilms and their relationship to metals are sparsely reported in the literature. An excellent example of a biofilm mediated mineralization process was demonstrated in the prefossilization of *Platanus* and *Taxodium* leaves by ferrihydrite [105]. It was discovered that terrestrial leaf fossils originate from leaves coated with an iron oxide surface; however, the leaves are covered by a hydrophobic waxy cuticle, which is impervious to metal binding [105]. In aquatic environments, leaves are quickly colonized by iron oxidizing bacteria (*Pseudomonas* sp. and other gram negative rods) that form biofilms featuring an anionic surface amenable to metal binding [105]. It was claimed that as much as 10^7 colony forming units per square centimeter of leaf can inhabit a single leaf [105]. Upon exposure of the biofilm coated leaf to FeCl$_3$, within a period of 10–15 minutes the leaf became encrusted with Fe$_2$O$_3$ [105]. This encrustation by iron oxide accelerated the conversion from mineralized leaves to completely fossilized fauna buried in the sediment over time [105].

Another type of bacterial biofilm mass was identified near acid mine drainage sites at Iron Mountain in northern California [106]. The biofilm was classified as a new species of Archaea, representing a prokaryote population of *Ferroplasma acidarmanus* anchored within pyritic sediments forming dense slime streamers [106]. Uniquely, this Archaeon was observed to grow under harsh conditions of pH 0.5 and 40 °C as a result of the composition and structural construction of the cytoplasmic membrane [106]. The extremely low pH, although not particularly suited for microbial growth, supported high metal concentrations in solution (iron has been measured as high as 111 g/L) [106]. The nucleation and characterization of mineral deposits originating from the archaeon biofilm were not reported.

Natural biofilms are also associated with the sulfate-reducing bacteria family of *Desulfobacteriaceae* [107]. Labrenz et al. [105] have shown that these biofilms can preferentially mineralize ZnS spherical particles of 2–5 nm with micrometer sized aggregates (SEM) based on a sphalerite lattice structure in more ambient conditions (pH 7.2–8.6). The mineralization of ZnS occurs under moderately reducing conditions accompanied by the accumulation of sulfide generated by the biofilm mass. Additionally, it was apparent that the biofilms concentrated zinc by 10^6 times that of groundwater [107].

4.6. Summary

This collection of organisms best exemplifies the biomineralization of zero-valent metal, metal oxides, and metal sulfide nanoclusters. These bioproduced nanocrystals exhibit superior quality (i.e., 24 carat gold), morphology, crystallinity, and monodispersity to synthetic laboratory-grown clusters as a result of highly orchestrated detoxification mechanisms. The uses of such organisms to biomimetically control the nucleation of nanoclusters under laboratory conditions was successful with a number of biological systems. For instance, the fungus *Fusarium oxysporum* generated Au^0 and CdS nanocrystals extracellularly in good yields. Inspired by these systems, a variety of innovations and approaches toward nanocluster synthesis has evolved, such as the implementation of different nucleating domains ranging in complexity from peptides to proteins to polymers. These biomolecules have added a degree of control to the subsequent nanocluster growth along with providing a stabilization component to the nanocluster surface. For example, CdS crystallites were synthesized with the capping ligands of cysteine, glutathione, and phytochelatin peptides. Additionally, such biomolecules will play an important role in alternative fabrication methods involving the surface derivatization of nanoclusters with antibodies, antigens, or viruses.

GLOSSARY

Bacterioform gold   Gold particles originating via microbial processes.

Diatoms   Unicellular marine plant life able to biomineralize a rigid silica frustule.

Ethmoid region   Area of the salmon brain responsible for magnetic field sensing.

Magnetotaxis   Movement of organisms based upon responses to earth's geomagnetic field.

Oxic anoxic transition zone (OATZ)   Sediment level of fresh water sources in which the transition from the aerobic region to anaerobic region occurs.

Phytochelatins   Class of small metal-binding peptides $(\gamma EC)_n G$ found in yeast, fungi, and all plants.

Silver resistant plasmids   Small circular DNA molecules that possess genes encoding resistance to silver.

CONTENTS

1. INTRODUCTION

1.1. Nanotechnology, Biotechnology and Nanobiological Devices

Nanotechnology aims to satisfy desired objectives using materials and devices whose valuable properties owe to some specific nanometer-scale element of their structures. This definition puts no restrictions on the overall dimensionality of nanotechnologically derived constructs, but merely requires involvement of some precise-structure nanoscale feature in function. Thus, devices and structures of even macroscale dimensionality assembled from, or containing, functional nanoscale components can be legitimately gathered under the nanotechnology umbrella. As a second corollary to the definition, biotechnology must be considered a subdiscipline of nanotechnology. The function of biological macromolecules (proteins, nucleic acids) depends on their precise nanoscale structures, so inclusion of aspects of biotechnology relating to macromolecule engineering under the nanotechnology rubric is legitimate. Individual biological macromolecules (proteins, nucleic acid molecules, supramolecular complexes, etc.) often exhibit the coordinated, modular multifunctionality that is characteristic of purpose-built devices.

The topic of this article is nanodevices containing functional biological molecules, rather than nanomaterials *per se*, and device design and operational properties will be discussed in preference to discussion of novel physical, chemical, or electrical properties of nanomaterials and structures.

For instance, both nanomaterials used as drug formulation excipients (pharmacologically inert materials included in formulations that modulate pharmacophore uptake, biodistribution, pharmacokinetic, handling, storage, or other properties) and single molecule nanomaterials with therapeutic activity (as are most protein drugs), while important in their own contexts, will rightly be excluded from discussion of nanodevices here. The logic of this auctorial choice is clear, but is supported by another less obvious consideration that is gradually gaining broad acceptance. Unlike nanotechnology practice in most nonmedical contexts, access to novel physical properties associated with the nanosize regime (for instance, quantum effects) is not primary, or even significant, motivation for most nanotherapeutic design. The impetus to ultra-small and nanotherapeutics lies in the related desires for minimally invasive therapies and therapeutics which provide high densities of multi-faceted functionality in very small packages. In addition, nanotherapeutics generally must interface with biological nanocomponents of the patient (protein, nucleic acids, etc.), a goal frequently best satisfied by functional biological components (protein, nucleic acids, etc.) of nanodevices. Clearly, quantum and other physical effects, typically associated with other aspects of nanotechnology are not the primary drivers of the function of most biological macromolecules. This logic suggests that for the near future, and perhaps indefinitely, many nanotherapeutic devices will contain (or be primarily composed of) biological macromolecules. The argument is most persuasive in the cases of nanodevices used *in vivo*.

Devices are integrated functional structures which exhibit desirable emergent properties that are inherent in (and are the object of) their design. These properties emerge as the result of a spatial/temporal organization of components, as well as a coordination action of individual components. The organization of components in devices is the critical factor that allows them to perform cogent work processes and differentiates devices from admixtures of their constituent components. In the early 21st century, availability of synthetic functional nanocomponents is problematic. While some nanoscale catalysts, electrical components, and functional structures are available, current technology

does not allow the combination of precise nanoscale control of structure and chemistry coupled with high manufacturing throughput necessary to satisfy plenipotent nanodevice technology. Again, logic and circumstance dictate a critical role for biological macromolecules in nanotechnology.

In as much as biotechnology can be considered a subdiscipline of nanotechnology, it is fitting that biotechnology should provide a critical source of functional components for nanodevices. The diversity of chemical activity of proteins and nucleic acids in the biological world is vast and well beyond the capability of the most advanced current materials science to duplicate with synthetic materials. Furthermore, production and engineering of biological macromolecules is facile (see [1] for a review of protein engineering approaches for nanotechnological device construction) and relatively inexpensive. In the absence of a capacity to produce corresponding nanocomponents by synthetic means, incorporation of engineered or native biomolecules as functional components is a logical approach to functional nanodevices in which one or more protein species (or nucleic acid species) is organized around or within a synthetic nanostructure that causes the aggregate manifestation of the activities of the biomolecules to add to a useful outcome. As we will see, this can occur as the result of the coordination of disparate biological activities to nanoscale proximity, or by organization of functional components such that they interact in a controlled manner, leading to a desired result.

This said, biotechnology historically has focused on production of individual soluble protein and nucleic acid molecules for pharmaceutical use, paying only limited attention to functional supramolecular structures [1–6]. The bias towards free molecules on the part of the biotechnology industry has been driven by the marketplace. Single protein drugs are among the easiest biotechnological therapeutics to realize from both technical and regulatory perspectives. However, this commercially driven bias flies in the face of the importance of supramolecular structures in the biological world. Within even the least complex biological entities, biological macromolecules are aggregated into supramolecular assemblages performing concerted functions that cannot be achieved without such organization. Virtually all organismal activities and functions ultimately emerge from the activities and interactions of such supramolecular complexes, which themselves function as the result of the combined activities of individual nanoscale macromolecules. Viewed from this perspective, the biological world is populated with naturally occurring nanodevices, a fact that provides additional motivation for the incorporation of biomolecules in nanodevices used in therapeutic contexts. Hybrid nanodevices can interact with patients on multiple levels, ranging from organismal to molecular, but it is reasonable to expect that most nanotherapeutics will interface with patients at the nanoscale at least to some extent [1–4, 7–12]. This translates to interaction between therapeutic devices and patient biological macromolecules, supramolecular structures, and organelles. As previously discussed, this consideration often dictates the incorporation of biological macromolecules and other biostructures into nanodevices [2, 3, 11–13].

Until recently, incorporation of biomolecules into functional supramolecular structures (devices) has been technically difficult, and used only in special cases. However, synthetic materials derived using micro/nanotechnology techniques afford the opportunity to complement and transcend the (self-imposed) limits of biotechnology to the production of individual soluble macromolecules. These materials can provide scaffolds that support higher-level organization of multiple biomolecules into devices. The organization of functional components provided by nanoscale scaffolds allows nanodevices to perform work activities that mixtures of their protein components as soluble molecules cannot. Such supramolecular structures have been variously called nanobiotechnological devices [14], nanobiological devices [1–6, 15], or hybrid or semi-biological nanodevices.

1.2. Design of Nanobiological Devices

Construction of hybrid nanodevices involve incorporation of prefabricated biological components, an activity which presents distinctive challenges that are seldom encountered in other aspects of engineering. For instance, since native biological macromolecules are not made to human design, their properties are often much less well understood than are those of purpose-built synthetic structures. Additionally, the activities of biological molecules are often multifaceted (so-called pleiotropic activities), though this may not be immediately apparent to an engineer wishing to use a particular protein or nucleic acid sequence as a device component. These and other factors make design and prototyping of biological nanodevices highly iterative and empirical processes [1, 3, 4, 12].

First, the biological components of nanobiological devices must retain their function in new (*i.e.*, device) contexts. The specific bounds of a biological component in a semi-biological device are defined by the requirements of the component for function, and therefore identification of the minimal unit requires at least rudimentary knowledge of the biochemistry of the protein or nucleic acid involved. In some cases, incorporation of intact biological macromolecules is not necessary to satisfy device functions (see Figs. 1 and 2). For instance, specific molecular recognition functions can be useful for either nanodevice assembly or tissue targeting. Such recognition functions can be conveniently derived from antibodies, though it is not usually necessary to incorporate entire 150,000 atomic mass unit (AMU) antibody molecules into devices. Specific antigen recognition is conferred by a 20,000 AMU antibody fragment [16–18] and this antibody fragment is sufficient to confer specific recognition properties to nanoparticles or devices (Fig. 1B).

In other cases, desired functionalities are not inherent in a single molecule and multimolecular complexes must be incorporated into devices. Most biological molecular motor systems function as multiprotein complexes, and multiprotein complexes sometimes must be incorporated into functional nanostructures to impart motility upon them (Fig. 2). Rotary motors, such as the F-ATPase [19, 20] and the bacterial flagellar cap [21–25] are obligately multiprotein complexes to accommodate their rotary action.
Figure 1. Many biological macromolecules are multifunctional and essentially modular: distinct molecular functions are performed by discrete regions of the molecules. Here individual polypeptide chains of an immunoglobulin G molecule (IgG) (Fig. 1A) and an engineered derivative of an IgG (Fig. 1B) are represented as lines with amino- and carboxy-ends of the polypeptide chains are indicated by N and C, respectively. IgGs are monospecific, bivalent molecules composed of two low molecular weight light chains (L_c), two higher molecular weight heavy chains (Hc), covalently linked by intrachain disulfide linkages (crosshatches). IgGs perform a number of activities, some of which are antigen-specific (antigen recognition), and some of which are not (nonspecific effector functions including complement fixation, recognition of macrophage surface receptors, etc.). Individual activities are delimited to specific regions (domains) of the protein. For instance, specific antigen binding is mediated by a domain containing elements of the light chain and the heavy chain which are proximal in the three dimensional structure of IgG (boxed, bold lines). Amino acid sequence in this domain, variously called the variable region (Fv) or complementarity determining region (CDR), varies from one IgG molecule to the next, conferring on each individual IgG its exquisitely specific antigen recognition properties. Nonspecific effector functions are common to all IgGs, and are also mediated by domains that are proximal to each other in space and whose amino acid sequences are highly conserved in all IgG molecules. Nonspecific effector regions are clustered in the so-called constant region or Fc of IgG. Engineered immunoglobulins (in this case, a single-chain Fv or ScFv) illustrate how the modularity of proteins can be exploited by technologists (Fig. 1B). Each CDR accounts for less than one-seventh of IgG molecular weight, but confers all of the antigen-specific recognition properties of the antibody. Since the CDR consists of both a Hc and Lc component, ScFvs are conveniently synthesized as a single molecule by incorporation of a short flexible peptide region between the Hc and Lc versions of the CDR, using standard protein engineering methods. ScFvs confer the exquisitely specific antigen recognition properties of their parent IgGs to any molecule or nanostructure to which they are appended.
Figure 2. Some biological functions are performed by concerted action of oligomeric macromolecular complexes, rather than single macromolecules. Unlike the polypeptide chains of immunoglobulins, the individual polypeptides of such complexes are typically not covalently bound to one another. Here an oligomeric protein complex, F-ATPase (Fig. 2A), and an engineered derivative of it (Fig. 2B), provide examples of complexes of multiple proteins that act in concert to perform a single function. In this representation, individual polypeptides are presented as ovals, representing their globular natures and to more accurately represent the organization of the complex. F-ATPase also illustrates how nanotechnologists can isolate functionalities of interest from larger biological structures, provided they have sufficient biochemical and ultrastructural information. F-ATPase is an integral membrane mechanoenzyme complex that harvests energy from transmembrane proton gradients to synthesize ATP. Adenosine triphosphate synthesis involves the rotation of part of the complex (indicated by the clockwise arrow), driven by energy harvested from the proton gradient. The holoenzyme complex contains eight distinct protein species, and about 20 individual protein molecules, but only the α, β, and γ subunits are required for rotary motion. The potential for the relevant portions of F-ATPase (α, β, and γ subunits) to act as molecular motors has been recognized by both cell biologists and nanotechnologists, and the α, β, and γ subunits of the mechanoenzyme complex have been isolated and assembled with a propeller (either an actin filament or a micromachined structure) linked to the γ subunit (2b). If the α and β subunits are attached to a substrate, ATP hydrolosis by the structure results in rotation of the γ subunit and the propeller attached to it. The α, β, and γ subunits-propeller assembly can provide motive force to nanomaterials to which it is attached (see [19, 86–89]).

As previously described, device function emerges from the summed activities of device components. Coordination of component activities into a cogent work process occurs as the result of the organization of the components relative to each other that is imposed in device design. As Figure 2 shows, motor complexes require precise spatial positioning of individual protein subunits to allow them to interact productively, and impart motion to the nanodevice. Similarly, the spatial relationships between protein that do not interact with each other but interact with other nanoscale molecules and structures (such as auxiliary proteins or receptor beds present in various cell types or tissue spaces) can be critical to device function and properties. This has also been observed in cases in which growth factors and cytokines have been deployed on solid surfaces and the resulting structures have been used to trigger cell proliferation [26–29]. The magnitude of proliferation and other parameters of biological responses are intensely sensitive to the specific geometries of protein presentation on the proliferative surface, as will be discussed subsequently.

The bacmid (or Bac-to-Bac™) molecular cloning system exemplifies how specific arrangements of functional

biological components support device function, as will be discussed later. However, bacmid exhibits another critical property of nanobiological devices: the potential for such devices to perform functions without precedent in the natural world. Other nanobiological devices, for example, systems incorporating motor proteins, particularly those derived from F1 ATPase and similar supramolecular structures, also illustrate the potential to cause biological structures to perform functions that are other than those they perform in their native settings as the result of careful design and assembly of nanobiological devices. Nanobiological device designers are thus not limited to merely recapitulating naturally occurring supramolecular systems, as is described later in a discussion of specific supramolecular devices.

Some design guidelines for hybrid biosynthetic nanodevices, particularly for therapeutic applications, have been formulated [1, 3, 4, 10–13, 30–32]. One vision of nanoscale therapeutic platforms arose from collaboration between the National Cancer Institute (NCI) and the National Aeronautics and Space Agency (NASA) [3, 11, 13, 30]. National Space and Aeronautics Agency is concerned with minimal mass therapeutics, driving their interest in compact, multifunctional therapeutics. National Cancer Institute is interested in early detection of disease and non-invasive therapy to improve prognosis. Since this requires screening of a population of predominantly healthy patients, the screening mode must be minimally invasive. The interests of the two agencies are complementary and can be met both with ultra-small (micro- or nanoscale), multifunctional hybrid biosynthetic devices. Additionally, the proposed therapeutic entities are not only expected to remediate undesired physiological conditions, but also to recognize (sense) and report them. Extensive capability for molecular recognition and communication with external clinicians/operators is integral to the NASA/NCI vision and is eminently feasible using hybrid nanodevices. These capacities would allow controlled provision of therapeutic intervention, maximizing benefits and minimizing side effects, thereby yielding "smart" therapeutics (see the discussion of targeting and triggering). The authors have named these supramolecular entities therapeutic platforms, denoting their multifunctionality and differentiating them from conventional small molecule and protein drugs.

While substantial progress has been made in device design and realization, no multipotent nanoscale hybrid therapeutic platform has yet been commercialized. However, segregation of individual therapeutic functions into individual modules allowed in the therapeutic platform paradigm is potentially very powerful. Classes of broadly similar devices could be tailored by interchanging modules (targeting modules, sensing modules, drug dispensing modules, etc.) of the hybrid device as appropriate to particular disease states or therapeutic courses. Standardization and interchangeability of functional modules may eventually allow tuning of nanotherapeutics to needs of individual patients or conditions. Standardization of modules could potentially mitigate regulatory burdens for variants of individual therapeutic platforms.

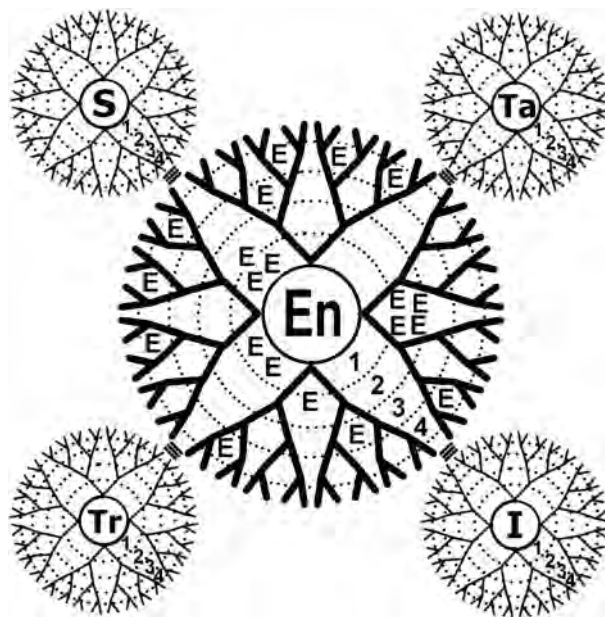
A dendritic polymer-based therapeutic platform design incorporating independent, fungible component modules, is illustrated in Figure 3. This structure represents a class of devices that have been termed "cluster agents" by their inventors. The device is a supramolecular complex built by exploitation of dendrimer self-assembly properties [33, 34]. This particular cluster agent is intended for cancer chemotherapy, and exhibits many of the canonical features postulated in the NCI/NASA vision [11, 13]. Individual functions (sensing, triggering targeting, drug delivery, etc.) are delimited to individual device subunits (i.e., individual dendrimers) that can be interchanged as needed to address therapeutic exigencies. For instance, many tumor types overexpress folate receptor on their surfaces, and so targeting/tethering to such tumors can be accomplished via a folic acid residue covalently linked to the targeting module. For other tumor types, folate might not be the appropriate molecular targeting moiety, and a different module would be used (for instance, one decorated with glycoproteins or cytokine molecules preferentially recognized by the target tumor type). Similar tuning could be applied to the specific drug and therapeutic delivery module, to best accommodate the drug sensitivities of individual tumors. As genomics and proteomics are applied increasingly to individual patients, the modularity of cluster agents and similar nanobiological devices may allow very nimble, personalized


Figure 3. Synthetic materials can be used to organize functional biological molecules into modules that can be assembled into therapeutic devices and modules can be interchanged to tune activity of the devices. Shown is a schematic of a modular "cluster agent" for cancer therapy [13, 33, 34, 163] consisting of multiple derivatized PAMAM dendrimers. PAMAM dendrimers are fractal nanoscale polymers grown in discrete steps called generations (indicated by numbers) from a central initiator core. Activities/subroutines of this cluster agent include tissue targeting (Ta), sensing of the local environment (S), encapsulation of therapeutic payload (En, encapsulated drug indicated as E), and triggering of therapeutic action (Tr). These activities, and the biomolecules responsible for them, are localized to the surfaces or internal spaces of the indicated dendrimer subunits. The modularity of the design allows the cluster agents to be configured as is appropriate for a number of related but distinct clinical circumstances.

therapeutic responses to disease leading to potentially vast improvements in individual therapeutic outcome.

2. NUCLEIC ACIDS IN NANOBIOLOGICAL DEVICES

2.1. Nucleic Acid Hybridization: Structure and Assembly

The base pair hybridization, specific sequence recognition, and replication properties of nucleic acids (Fig. 4A and 4B) and associated enzymes are potentially attractive properties for incorporation in semi-synthetic nanodevices and are often exploited by nanodevice designers [35–38]. For instance, reversible self-assembly by DNA hybridization is used to control the assembly and relative positions of nano-materials conjugated to nucleic acids in many nanodevices. Seeman et al. [35] and Shchepinov, Niemeyer, and Seeman et al. [39–43] have demonstrated that careful control of DNA sequence and hybridization conditions can generate nanoscale nucleic acid structures with extremely complex topographies (Fig. 4C). Because double-stranded DNA segments greater than 100 base pairs (a few nanometers) in length are quite flexible, these exquisitely defined topographies do not produce comparably well-defined geometries.

The inability to control the geometry of nucleic acid constructs can limit their utility for organizing pendent nanoscale components in three-dimensional patterns. However, nucleic hybridization can be used to bring individual nanocomponents into proximity, allowing them to interact efficiently (Fig. 5A). This principal is exploited in hybridization-driven photonic devices [44–46]. Fluorescence transfer (FT) between a photonically excited donor molecule and an acceptor can only occur when they are in very close (less than five nanometers) proximity. Donor and acceptor can be brought into the requisite proximity if each is pendent to oligonucleotides that hybridize to adjacent regions of a complementary, single-stranded nucleic acid target. Fluorescence transfer devices can be used in biosensors to detect target DNA segments, for instance the DNA of a pathogen. In the absence of pathogen (target) DNA, the donor and acceptor oligonucleotides cannot assemble, FT does not occur, and light emitted from the device is at the characteristic emission wavelength of the donor molecule D. If pathogen (target) DNA is present, the target DNA supports assembly of donor and acceptor oligonucleotides, bringing D and A into proximity, allowing FT to occur, and light is emitted at the emission wavelength determined by A. The shift in emission wavelength is easily detected and quantitated.

A highly analogous prodrug strategy has been developed [37, 47]. Prodrugs are pharmaceuticals that are administered in a form that has little or no pharmacologic effect until the prodrug is activated as the result of intrinsic conditions at the site of action or in response to a stimulus provided by an external operator. This delimits the action of the therapeutic in time, space, or both, and is useful for potentially toxic therapeutics. In this particular prodrug system, hybridization to a target single-stranded nucleic acid strand brings a hydrolytic catalyst linked to one oligonucleotide in sufficiently close proximity with a prodrug linked to another
Figure 4. DNA self-assembly is driven by noncovalent interactions between the nitrogenous bases of DNA strands. DNA is a linear polymer that arrays nucleotide bases, (purines: adenine (A), guanine (G), and pyrimidines: thymine (T), cytosine (C)) in specific order along a phosphodiester polymer backbone (Fig. 4A). Bases have specific hydrogen-bonding preferences (G for C, A for T) which allow base-pairing between bases of different DNA strands, and in aggregate, allow DNA strands with complementary nucleotide sequences to hybridize into a double-stranded (ds) complex. Note that DNA strands are vectorial in that they are synthesized from the 5′ end of the strand to the 3′ end of the strand only (5′ and 3′ referring to the specific phosphoester linkages of the phosphodiester backbone). Specific nucleotide sequences were chosen arbitrarily for illustration purposes. 5′ and 3′ at strand ends are as indicated, so that hybridizing DNA strands are arranged in an anti-parallel fashion. DNA strands wrap around each other to form an anti-parallel double helix (Fig. 4B) with a periodicity of 10 base pairs/turn (about 3.4 nm) and a width slightly larger than 1 nm. Lines between DNA strands indicate base pairs. Judicious choice of DNA sequence can allow the construction of nanostructures with highly defined, complex topographies by hybridization-driven self-assembly [41]. A schematic of a cubic topography achieved by hybridization of six designed DNA oligonucleotides is shown in Figure 4C. While the structure exhibits the connectivity of a cube, it is not rigid and can adopt multiple three-dimensional conformations. The base-paired double-helical regions that drive assembly of the controlled topography are as indicated.
Figure 5. DNA hybridization can be exploited to construct self-assembled functional nanostructures. Shown in Figures 5A and 5B are two nanodevices that depend on DNA hybridization to bring components into sufficient proximity to allow them to interact and provide device function. When shown, specific DNA sequences were chosen arbitrarily for purposes of illustration. In Figure 5A is a fluorescence transfer (FT) device consisting of a target DNA segment and two oligonucleotides complementary to it (donor and acceptor), but not to each other [35–38]. The donor oligonucleotide is conjugated to a small molecule (D) that can absorb a chosen (excitation) wavelength of light and the acceptor oligonucleotide is conjugated to second distinct small molecule (A) that can accept energy from the donor molecule in a quantum process and emit that energy at still another (emission) wavelength. FT between D and A molecules requires they be in close proximity and that condition is satisfied when the donor and acceptor oligonucleotides hybridize to the target oligonucleotide. Configured as illustrated, the distance between D and A is about a nanometer. Figure 5B shows an analogous therapeutic nanodevice that depends on hybridization to trigger controlled release of bioactive drug [37, 47]. In this case, one oligonucleotide is conjugated to a catalyst C (the catalytic oligonucleotide) and a second oligonucleotide is conjugated to a drug molecule (D_p) that is inactive in the conjugate state (the prodrug oligonucleotide). C catalyzes the breakage of the linkage between D_p and the prodrug oligonucleotide, liberating active drug (D_a, indicated with a star). The nucleic acid hybridization of devices of Figures 5A and 5B is intensely sensitive to environmental conditions (pH, salt concentration, temperature, etc.) at the site of hybridization. Figure 5C illustrates a strategy by which a local condition critical for hybridization (temperature) might be manipulated by a remote or external operator. In this system, a nanogold particle (Au) is conjugated to one of two complimentary oligonucleotides. The two oligonucleotides hybridize when the initial temperature (T_0) is below the melting temperature (T_m) for the hybridized species. Application of an alternating magnetic field by a remote operator produces eddy currents in the nanogold particle that produce Joule heating. When heating raises the local temperature to a T_1 that is above T_m, the double-stranded sequence melts and the two oligonucleotides dissociate. The process is potentially reversible, and might be applied controlling the assembly and activity of nucleic acid nanodevices [48].

oligonucleotide also hybridizing to the same target strand to cause the efficient release of active drug (Fig. 5B). Assembly of catalytic oligonucleotide and prodrug oligonucleotide on target nucleic acid brings catalyst in close proximity with its substrate, efficiently hydrolyzing the linkage between drug and prodrug oligonucleotide. Locally high concentration of catalysts results in the release of active drug (D_a) preferentially at sites where the target nucleic acid is present in relative abundance. Theoretically, such a system could allow preferential release of a cytotoxin or other drugs at tissues or sites expressing specific RNA (for instance, tumors) or containing specific DNA sequences (for instance, virally infected cells).

DNA hybridization is a reversible process that can be controlled by manipulation of the immediate chemical and physical environments of hybrids. Environmental salt and/or chaotrope concentrations and temperature, as well as the $G + C$ content, length, extent, and position of base pair mismatches in hybridizing strands can all be controlled to manipulate the association of hybridizing nucleic acid strands. Control of hybridization for nanobiological device assembly by sequence parameters as previously described occurs at the level of device design, and may not be easily amenable to manipulation of nanodevice component assembly over time by a remote device operator. Similarly, change of the chemical composition of the device operating environment may not be a practical means to control the association state of nanobiological devices assembled by nucleic acid hybridization. However, in *in-vivo* applications, environmental temperature may be the variable most amenable to manipulation by an outside clinician/operator. For instance, externally applied magnetic fields can be used to control the association of hybridized nucleic acid structures that are conjugated to nanometallic particles (Fig. 5C). Eddy currents induced by alternating magnetic fields can heat the particles and their immediate vicinity [48]. Colloidal gold particles are covalently conjugated to biomolecules (nucleic acids or proteins) and alternating magnetic fields are used to induce heating sufficient to cause dissociation of hybridized nucleic acid structures or denaturation of three-dimensional protein structures. Nucleic acid duplex hybridization and melting are fully reversible processes, and protein denaturation is reversible to some degree in some cases. This and other methods to control temperature in the nanobiological device operating environment [49–52] may allow remote, reversible activation/inactivation of nanobiological therapeutic devices.

2.2. Biologically Functional Nucleic Acid Nanodevices

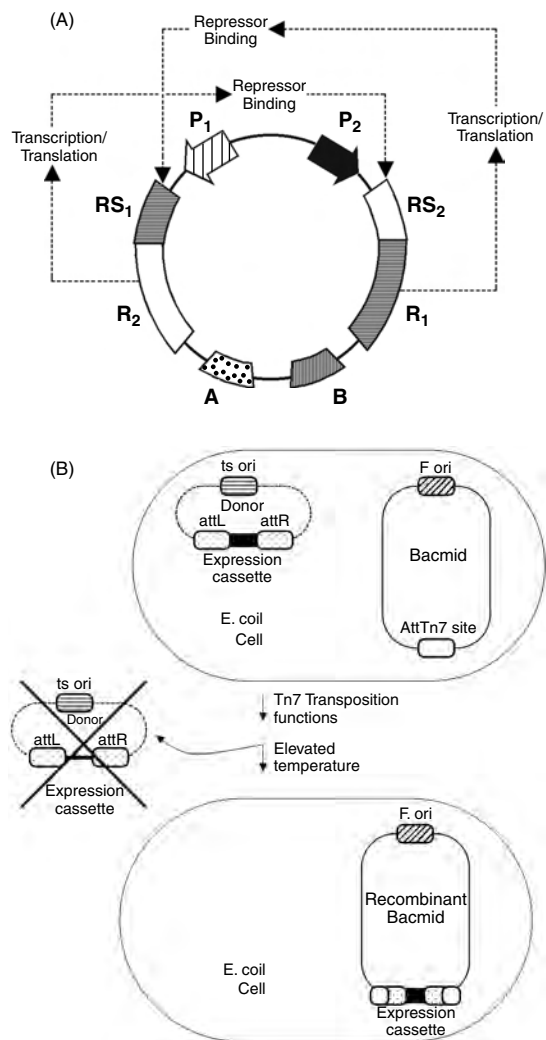
As the foregoing shows, the physical-chemical properties of oligonucleotides can be exploited to assemble and control the activity of nanodevices in biologic or nonbiologic contexts. These applications primarily exploit nucleic acid hybridization properties without reference to the genetic functions inherent in some nucleic acid sequences. Both the genetic toggle switch (Fig. 6A) and the bacmid (or Bac-to-Bac™ molecular cloning system) (Fig. 6B) previously mentioned, provide examples of nanodevices that exploit the


Figure 6. Biological components can be isolated from their native contexts, organized by a designer into a nanodevice whose function is unprecedented in nature, illustrated here by nucleic acid nanodevices that perform preselected tasks in biological environments. A prototypical toggle switch plasmid is shown in Figure 6A [53]. For simplicity sake, only those genetic elements directly involved in regulated switching behavior are shown. This device contains two distinct, divergently transcribed promoters (diagonally striped or black arrowheads: P_1, P_2). Overlapping each promoter is a distinct repressor binding site (RS_1: cross-hatched box; RS_2: open box). When the cognate repressor (encoded by the R_1 gene: horizontally cross-hatched box or encoded by R_2 gene: open box) binds its repressor binding site (R_1 repressor to RS_1 or R_2 repressor to RS_2, indicated by arrows), expression from P_1 or P_2, respectively, are repressed. Expression of functional repressor from one promoter decreases expression from the other promoter, so the system exists in one of two highly stable states where expression from P_2 or P_1 dominates. Control input for switching is provided by modulating the concentration of active R_1 or R_2 repressor. This can be done by induction of one of the promoters with a chemical substance that increases the efficiency of expression from one of the two promoters specifically. Alternatively, if R_1 or R_2 are temperature sensitive (that is, not functional at elevated or reduced temperature), temperature shift can be used as the control input. One utility of this bistable switching system could be to provide the ability to remotely control which of two (or more) genetic programs is followed by a target microorganism. Here two different genes, or blocks of genes, A (polka doted box)

biological functionalities of their constituent nucleic acid components in a biological context [53–55].

Prokaryotic plasmids (circular, autonomously replicating DNA segments) with the ability to switch between two alternative stable states in response to a control input have been used to control the physiological properties (protein expression) of bacteria [53, 54]. These systems configure genetic elements (promoters, repressor binding sites, positive control elements, transposition sites, etc.) to manipulate the physiology of host microbes. A bistable "toggle switch" plasmid is shown in Figure 6A. The toggle plasmid operates in an *Escherichia coli* cell and contains two distinct promoters (DNA sequences that direct the transcription of mRNA from the genes downstream of them on DNA segments), each promoter directing the synthesis of a distinct repressor (a protein that blocks transcription from its cognate promoter by binding to or near the promoter). Each promoter has a repressor-binding site positioned such that repressor binding represses transcription from the cognate promoter. Promoters and repressor binding sites are configured so that the repressor synthesized under the control of one promoter represses the promoter directing the synthesis of the second repressor.

The system exists in one of two states, corresponding to repression of one of the two promoters, and relatively unimpeded transcription of the other. In the absence of control input, these states are highly stable and persist through tens

and B (vertically crosshatched box), each representing a discrete genetic program, is expressed or not depending on whether P_2 or P_1, respectively, are repressed. Multiplexing of these and other control architectures may eventually lead to remote control of their biosynthetic and biodegradative activities, potentially expanding the utility of microorganisms in industrial, manufacturing, and bioremediation applications. The bacmid molecular cloning system (Fig. 6B) is a multi-component molecular device that allows efficient production of recombinant insect viruses (baculovirus) in *E. coli* cells [55, 164, 165]. Baculovirus (solid line) is replicated in *E. coli* by the F plasmid origin of replication (F ori: cross-hatched box), and is called a bacmid. The bacmid also includes an engineered transposable DNA element 7 (Tn7) attachment site isolated from the chromosome of an enteric bacteria (AttTn7: open box). AttTn7 can recombine with Tn7 elements transposed from other cellular locations. A donor plasmid (donor: dashed line) is replicated by a temperature-sensitive plasmid pSC101 origin of replication (ts ori: box with lines). The donor also incorporates a protein expression cassette containing both the gene encoding a protein of interest for ultimate expression in insect cells and a selectable genetic marker operable in *E. coli* (black box). The expression cassette is flanked by DNA sequences (attL and attR) that are derived from Tn7 and are recognized by the Tn7 transposition machinery. Tn7 transposition machinery resides elsewhere in the same *E. coli* cell (not shown). When donor plasmid is introduced into *E. coli* containing bacmid, Tn7 transposition machinery causes the physical relocation of the expression cassette from donor plasmid to bacmid. Unreacted donor plasmid is conveniently eliminated by elevating the incubation temperature, causing the ts pSC101 replicon to cease to function, with the result that the donor plasmid is lost. If selection for the genetic markers within the expression cassette is applied at this point, the only *E. coli* that survive are those containing recombinant bacmid (that is, those that have received the gene for insect cell expression by transposition from the donor). Recombinant bacmid are conveniently isolated from *E. coli* and introduced into insect cell culture, where expression of the gene of interest occurs (not shown).

of *E. coli* generations. In the configuration of Figure 6A, control input for switching is provided by inactivation of one of the repressors or exogenous induction of one of the promoters (wherein the level of induction is sufficient to overcome ground state repression of the corresponding promoter). Currently, these systems can mimic the behavior of simple physical-chemical switches and oscillators, but programming more complex activities will doubtless be possible in the future. Ultimately, these sorts of control strategies may allow programming of microorganisms to manufacture specific structures, compounds, or macroscale architectures.

The toggle switch is an example of a device in which the engineered, functional genetic components are linked into a single DNA molecule. Other devices incorporate multiple DNA molecules that interact to produce a desired work product. The work product of bacmid is recombinant baculovirus to be used for expression of foreign proteins in insect cells. The system allows construction of recombinant baculoviruses for insect cell expression in about a week (four- to six-fold faster than other available methods) using *E. coli* molecular genetic methods.

The bacmid molecular cloning system replicates an engineered insect cell (baculo-) virus in a nonnative environment (the *E. coli* cytosol) by linkage of the *E. coli* F plasmid (self-replicating DNA sequence) and origin of replication (ori). This construct is referred to as a "bacmid," and will replicate stably and indefinitely in *E. coli*. The bacmid itself contains additionally a DNA sequence, the *att*Tn7 site, which can accept the insertion of transposable elements related to bacterial transposon Tn7. The insect cell expression cassette to be inserted into the *att* site of bacmid is carried on a second plasmid (the donor plasmid) in the same *E. coli* cell. The expression cassette is flanked by DNA sequences *att*L and *att*R, which together with the *att*Tn7 site of bacmid, are recognized by Tn7 transposition enzymes. These are provided *in trans*, and mediate the physical relocation (transposition) of the expression cassette from the donor plasmid to bacmid, generating recombinant bacmid. Recombinant bacmid is harvested directly from *E. coli*, introduced into insect cells, and used to generate recombinant protein.

The bacmid system illustrates many of the canonical properties of nanobiological devices previously described. Specifically, the constituent nucleic acid segments of the bacmid system are harvested as intact functional modules from multiple biological sources (the *E. coli* genome, bacterial plasmids and transposons, and insect viruses). The specific arrangement of the elements (linkages between baculovirus and the F ori and the *att*Tn7 site, the flanking of the expression cassette by attL and attR, the provision of Tn7 transposition machinery *in trans*, etc.) is imposed in device design and drives device function. Critical changes in these structural relationships result in loss of device activity. For example, failure to link the mini-F origin of replication to the baculovirus would preclude its maintenance in *E. coli*, and failure to incorporate an attTn7 site in bacmid would preclude bacmid as a possible destination for the transposed expression cassette. Bacmid also hints at the vast potential of nanobiological devices to provide novel activities. Bacmid has spawned a series of highly similar nanobiological systems for generating recombinant eukaryotic viruses in bacteria

[56–60]. As discussed previously, no naturally occurring system creates eukaryotic viruses in prokaryotes, so bacmid and derivative systems demonstrate that nanobiological devices are not limited to recapitulation of natural systems, but can represent novel devices whose functions are truly new under the sun.

3. PROTEINS IN NANODEVICES

This discussion has emphasized the importance of the structure of nanobiological devices from the standpoint of the impact of the specific arrangement of functional biological components on device function. When considering nucleic acids in nanodevices, the relationships of interest can usually be satisfied in the order of genetic elements along a linear nucleic acid strand (but not always; consider the three-dimensional DNA topographies previously discussed). Protein-containing nanobiological devices are at least as sensitive to the configuration of their functional components as are nucleic acid-containing devices; but in this case, three-dimensional arrays of protein components, as opposed to simple linear arrays of genetic elements, are often required to support function.

Biological macromolecules undergo self-assembly at multiple levels, and like all such processes, biological self-assembly is driven by thermodynamic forces. Some biomolecules undergo intramolecular self-assembly (*e.g.*, protein folding from linear peptide sequences). Also, higher order structures are constructed by the intermolecular self-assembly of smaller self-assembled subunits (for instance, structures assembled by hybridization of multiple oligonucleotides, enzyme complexes, etc.).

Proteins are copolymers of 20 chemically distinct amino acid (aa) subunits [61]. Linear polypeptide chains form specific secondary structures via interactions between aa side chains. These secondary structures themselves associate to form tertiary (and quaternary) structures that constitute final folded protein structure(s). This self-assembly process generates consistent nanostructures that derive their biological properties from their strict control of the deployment of chemical specificities (the aa side chains) in three-dimensional space.

The biological diversity of proteins isolatable from nature is immense, and is augmented by the capacity to engineer proteins to suit in many applications (see [4] for discussion of protein engineering methods for nanobiological device applications). In fact, the number of potential nanobiological device functions that can be accommodated with engineered or native proteins is vastly beyond the capacity of any single treatise to fully enumerate. However, there are some particular applications of nanobiological devices that are widely used, even at this very early point in the development of the technology.

3.1. Polypeptide Affinity Reagents: Targeting, Triggering, and Assembly

Much like nucleic acid molecules, proteins can be used as affinity reagents to drive assembly of nanostructures, either as free molecules or when conjugated to heterologous nanomaterials. As discussed in the context of antibodies, the

domains of proteins responsible for specific molecular recognition of cognates are often sufficiently small, contiguous, and discrete to be abstracted from their native context as modules. Thus, binding domains of proteins (such as the variable regions of antibodies) can be appended to nanomaterials to drive specific nanostructure assembly. This can be applied to the delivery/tethering of nanostructures to sites containing the cognates of specific binding proteins in any number of contexts, including therapeutic settings.

In the simplest case, proteinaceous affinity reagents can be made as translational fusions with, or bioconjugates to, protein or small molecule drugs (Fig. 7). Immunotoxins are primarily anti-tumor therapeutics which append all or part of an antibody to a cytotoxic therapeutic to maximize toxicity to the tumor while minimizing systemic toxicity, based on the specific recognition of a tumor-associated antigen by the antibody portion of the conjugate [62–66]. This same strategy can be used to tether nanomaterials such as polymer therapeutics to disease sites [9, 10, 31, 32, 67–77]. Linear polymers or supramolecular polymer structures such as micelles can be tethered to desired sites using affinity reagents (Fig. 7).

The purpose of all therapeutic targeting is to delimit therapeutic action in space to minimize undesired side effects. The specificity of action of targeted therapeutics can be further enhanced if their actions are triggered, either by intrinsic conditions at the site of action (much as in the nucleic acid prodrug system discussed above), or by a stimulus provided by a clinician/device operator. Much as the three-dimensional conformation of, and therefore the function of,

proteins (as well as nucleic acid hybrids) can be controlled by external triggering strategies [48], proteins can be engineered to make their conformations sensitive to intrinsic conditions at their desired sites of activity. For instance, diphtheria toxin (DT) has been engineered to require a passage at low pH to achieve its toxic configuration. When the variant DT is associated with a receptor ligand, it can only be taken up and transported into low-pH lysozomal vesicles by cells with the appropriate counter-receptor on their surfaces [78]. Thus, toxicity of the variant DT is triggered only in cells expressing the appropriate receptor. Enzyme-activated delivery (EAD) is another triggering approach in which the properties of a nanoscale drug delivery vehicle are altered at the site of action by an endogenous enzymatic activity [72]. Enzyme-activated delivery involves a liposomal or micellar nanostructure from which synthetic pendant groups can be cleaved by metabolic enzymes (alkaline phosphatase, phospholipases, proteases, glycosidic enzymes, etc.) that are known to be highly expressed at the site of therapy. Nanostructures are designed so that cleavage of the pendent group causes a conformational or electrostatic change in the polymeric components of the delivery device, rendering the micellar structure fusogenic, leaky, or causing partial or complete dissociation of the structure to release its therapeutic payload at preselected sites [10]. Therapeutic administration by EAD approaches can be employed with or without a concomitant tissue-specific affinity targeting.

Obviously, affinity-mediated, tissue-specific delivery requires the presence of tissue-specific surface features (usually proteins or glycoproteins called tissue-specific antigens). Principal challenges in the search for tissue-specific antigens for drug targeting are specificity (few antigens are uniquely present in any single tissue) and availability (some tissues may not have their own unique antigenic signature or markers, or they may not be accessible from the vasculature). The recent discovery of a vascular address system [79–81] is exciting.

The vascular address system was identified by intravenous administration of a peptide phage display library (see [82] for a discussion of display technology) to animals, resecting individual organs from the animals and extracting phage from the vasculature of the isolated organs (Figs. 8A and 8B) [79–81]. The vasculature of individual organs was found to present unique constellations of receptors that could be recognized by short (10 amino acids or less) peptide sequences from the phage display library. Furthermore, the affinity-selected peptides can tether nano- to micro-scale particles to their cognate vasculature tissue-specific antigens, as illustrated in Figure 8C by the binding phage particles presenting the peptides to specific vascular locations. The vascular address system has been used to target a specific organ (the prostate) for destruction *in vivo* [83], establishing the utility of the address system in drug delivery [83, 84]. Mapping of the vascular address system is underway [81] and it remains to be seen whether each organ (or disease site) has a single molecular marker constituting its address which will be amenable to delivery of drugs tethered to the cognate peptide(s). Vascular addresses deliver materials to the organ vasculature—extravasation and access of organ tissue spaces by nanotherapeutics remains a separate issue.

Figure 7. Biological affinity reagents are commonly used to tether other materials to their cognate antigens. This strategy is typically, but not solely, used to target therapeutics or imaging reagents to sites of interest *in vivo*. Figure 7A shows a bioconjugate composed of an IgG molecule, as in Figure 1, and a covalently linked small-molecule drug (D_{sm}). Bioconjugates, as in Figure 7A, are not synthesized in a single step, but rather the individual constituents (in this case, the antibody and the small molecule) are made separately and covalently linked to one another in a subsequent conjugation reaction. A wide variety of molecules and nanostructures can be conjugated to antibodies to confer the specific binding/assembly properties of the antibody to the construct. Figure 7B shows a fusion protein consisting of a ScFv (as in Fig. 1) fused to a second protein, which might be a protein therapeutic of some description (a cytotoxin, cytokine, etc.). Such fusion protein constructs exhibit the specific antigen recognition properties of their parent antibodies. Unlike the bioconjugate of Figure 7A, this molecule is made as a single molecule because the construct is synthesized from a single gene, engineered by standard molecular biology means.

Figure 8. Biological affinity reagents can be derived *de novo* for a broad variety of molecules and nanomaterials using display technology. Figure 8A presents a schematic of an individual filamentous phage particle from a phage display library. Each particle contains a variant gene of interest (Vgoi) as a part of the replicable phage DNA (circle, replicable in *E. coli*) and presents on its surface the corresponding variant protein of interest (Vpoi). The linkage between protein and the gene encoding it afforded by phage display methods allows simultaneous sorting of proteins of interest and the replicable genetic elements encoding them. Sorting is based on the relative affinities of the variant proteins presented for a target counter-receptor. Figure 8B shows an overview of a procedure by which reagents that recognize tissue-specific vascular "addresses" can be identified using phage display libraries. Phage are depicted as in Figure 8A, and the diverse Vpoi (peptides presented on surfaces of phage of a library are represented by various shaded shapes presented by the phage). A phage library presenting a vast number (up to 10^{12} different species) of variant peptides is injected intravenously into an animal, whereupon individual phage bind the vasculature of different tissues by virtue of the affinity of the peptide they present for tissue-specific vascular receptors (addresses). The animals are sacrificed and organs of interest (represented by the irregular shape) are harvested. Phage particles bound to receptors of vasculature of individual organs are perfused with an eluent buffer, releasing phage from the vasculature, *E. coli* is infected with the eluted phage particles and clonally propagated (symbolized by a schematic of bacterial colonies growing on a culture plate), ultimately allowing the identification of specific peptide sequences that recognize specific receptors on the vasculature of the organ or tissue involved. Usually one or more consensus peptide groups, rather than a single peptide species, are isolated after such an experiment. Members of consensus groups vary in amino acid sequence, but have some common sequence properties. Particularly, they exhibit one or more conserved or chemically similar amino acids at specific positions in the peptide sequence, defining the consensus. Display methods have been used to identify peptides which recognize many nanostructures and materials of both biological and synthetic origin. Typically, peptidic binding determinants selected, using phage display, are modular, and when isolated away from the parent phage, retain the specific recognition properties of the parent phage. Figure 8C shows therapeutic payloads (drugs or therapeutic nanodevices: payload) delivered to tissue-specific receptors by virtue of the affinity of peptidic reagents selected from a display library as in Figure 8B. Specific targeting peptides (square and triangle) tether a drug or other therapeutic nanodevice to their cognate receptors on vascular surfaces. Schematized here is a micelle containing a drug for targeted delivery to Tissue A or Tissue B, depending on which affinity reagent (square or triangle) is appended to the surface of the nanostructure [79–81].

3.2. Mechanoenzymes in Nanobiological Devices

Motor proteins (mechanoenzymes) excite significant attention from the engineering perspective, in part because of their striking resemblance to macroscale engineered structures. Furthermore, the value of imparting motility to device components is well understood in the context of macroscale devices, also contributing to the interest in the potential use of motor proteins in nanobiological devices. Consideration of motor proteins in nanodevices can be initiated most productively with consideration of the classes and distinct properties of available mechanoenzymes. Motor proteins may be divided into four major classes based on their mechanisms of action: rotary motors, linear (track) motors, polymerization/depolymerization motors, and lastly, a loose group of several mechanoenzymes with diverse structures, mechanisms, and functions that do not fit into the other groups. Both rotary and track motors have been used in nanobiotechnology to date.

3.2.1. Biological Rotary Motors

The chemiosmotic theory [85] maintains that bacterial cells utilize the electrochemical potential generated by cellular transmembrane proton gradients to produce adenosine triphosphate (ATP) (ATP is the major energy storage molecule found in living things). The bacterial protein complex responsible for interconversion of electrochemical potentials to chemical energy is the F-ATPase (Fig. 2A) [19, 20]. To generate ATP, protons passing through this pump induce conformational changes in the enzyme's α and β subunits. These conformational changes result in the rotation of these subunits around a spindle (the gamma subunit), concomitant with ATP biosynthesis. Fortuitously, this process is fully reversible in the case of the F-ATPase, allowing the motor to hydrolyze ATP to ADP and inorganic phosphate to drive subunit rotation and proton transport. Because it possesses this property of reversibility, the F-ATPase offers an ATP-driven rotary motor for convenient use in nanobiological devices. Based on the "toroid and spindle" morphology of its assembled α, β, and γ subunits, the rotary mechanism of the F-ATPase had long been suspected. This mechanism was confirmed using a nanobiological device similar to the one shown in Figure 2B [86–88].

The device consists of a complex of the F-ATPase subunit α with modified versions of the β and γ subunits oriented on a metallic (nickel) stage which, in the presence of ATP, drives the rotation of an actin filament appended to the γ subunit. The α and modified β and γ subunits spontaneously self-assemble into the required toroid and spindle structure. This structure is oriented on the nickel surface by interaction between the metal and polyhistidine domains (polyhistidine sequences are known to bind metals), engineered as translational fusions to the β subunit. A biotin (a small organic molecule) is appended to the γ subunit, and a second biotin is appended to an actin filament using standard bioconjugation methods. The γ protein and the actin filament are linked by a streptavidin complex (streptavidin is a tetrameric protein complex that binds biotins with high affinities in interactions that are nearly as stable as covalent bonds). In

the presence of ATP, rotation of the actin filament "propeller" is detected by microscopic methods. A modification of this device has also been presented [19, 20]. There, the polyhistidine-beta subunit translational fusion protein orients the α-β-γ complex on a micro-machined, nickel-topped post. The actin filament is replaced with a biotinylated, micro-machined rod of approximately one micrometer. This version of the device may be marginally closer to the configuration we might expect for the use of the F-ATPase rotary motor in more complex nanobiological devices, but in its essential aspects, it is identical to the device of Noji et al. [86–90].

The devices of Noji and Soong [20, 87, 89] exhibit design features common to other nanobiological devices in that the relative positions and stoichiometries of assembled components are absolutely critical to device function. Furthermore, the toroid and spindle assembly sufficient for use as a nanoscale motor consists of only a small portion of the F-ATPase holoenzyme complex. The intact complex contains over 20 individual protein molecules, and eight distinct protein species [91, 92]. Additionally, the motor activity of the F-ATPase devices is incidental to the primary function of the enzyme complex, which is ATP biosynthesis. Thus, the designers of the devices of Figure 2B have caused modified biological components to perform a function (providing motive force) entirely dissimilar to their functions in their native biological contexts, by virtue of the designer's control of the constituents and assembly of the devices, and providing yet another example of a nanobiological device design which extracts an unprecedented functionality from prefabricated biological components.

Other reasonably well-characterized, biological rotary motors include the V-ATPases and the bacterial flagellar motor. The V-type ATPases are ion transporters and are structurally similar to and operate by similar mechanisms as the F-ATPase [93, 94]. V-type ATPases occur throughout the biological world, from Archaebacteria to higher eukaryotes. The F-ATPase and V-ATPases are attractive for use in nanotechnology by virtue of their compact sizes and high efficiencies. The efficiency of conversion of chemical energy into mechanical energy by these mechanoenzymes has been estimated to be between 60–100%, almost an order of magnitude greater than the efficiencies of myosin, dynein, and kinesin motor systems [90].

Bacterial flagellar motors utilize transmembrane proton gradients to power flagellar rotation, but they are structurally and genetically distinct from the F-ATPase and its relatives [95]. Though their prokaryotic origin should make flagellar motors convenient to genetically engineer and produce in quantity, their use in nanobiotechnological applications lags behind that of the F-ATPase for multiple reasons. For one thing, flagellar motors contain more distinct protein subunits and are more structurally complex than either F- or V-ATPases-derived rotary motors. Unlike the rotary motor structures of the V and F-type ATPases, parts of the flagellar motors transit the cell membrane, the peptidoglycan cell wall, and for Gram-negative bacteria, the outer membrane. The hydrophobicity of the domains involved in crossing hydrophobic structures (the cell and outer membranes) may

present challenges in incorporating the motor into semi-synthetic structures. Additionally, the specific structure and organization of flagellar motors also vary in different bacterial species. The diversity of flagellar motors may ultimately offer the nanotechnologist a selection of similar, yet distinct, rotary motors from which the best-suited motor could be chosen for any given application. However, with the possible exception of the flagellar motor of the Enterobacteriaceae (*E. coli* and related organisms), most flagellar motors have not yet been studied in sufficient detail to allow reasoned selection.

3.2.2. Biological Linear (Track) Motors

Linear motors such as myosin [96–99], dynein [100–116], and kinesin [117–138] are multi-protein complexes that migrate along a track of cytoskeletal protein. Myosin migrates along actin filaments, whereas both dynein and kinesin move along microtubules. Nucleotide hydrolysis (generally ATP) is the chemical energy source for all of these motor systems, so the motor proteins themselves are technically all ATPases, though they exhibit varying degrees of structural and functional analogy to one another. To date, only the kinesin/microtubule system has been put to extensive use in nanobiological devices.

All the linear motors discussed here migrate along a preformed polypeptide track. In nanotechnological applications, this allows the path, the motor unit, and any attached cargo will take to be determined by the specific deployment of the track protein. Actin filaments are double-stranded homopolymers of monomeric actin configured as a left-handed double helix [139, 140]. The diameter of a double-stranded actin filament is only very slightly in excess of 5.5 nanometers, which is the diameter of an actin monomer. The actin monomer is asymmetrical, and the filaments are polar, with so-called plus and minus ends. Most myosins migrate towards the plus end of filaments. Kinesin (Fig. 9A) and dynein migrate along microtubules, which are themselves supramolecular nanostructures of significant complexity [139, 141]. Individual microtubules are rigid, hollow tubes of 24 nanometers in diameter composed of left-handed double helices, one helix composed of α-tubulin and the other of β-tubulin (Fig. 9B). One end of the microtubule, the plus (+) end, terminates with β-tubulin while the minus (−) end terminates with α-tubulin. As was the case with myosin migration on actin filaments, individual kinesin species migrate towards either the plus or minus end of the microtubule. To date, only dynein species that migrate from plus to minus on microtubules have been described [139].

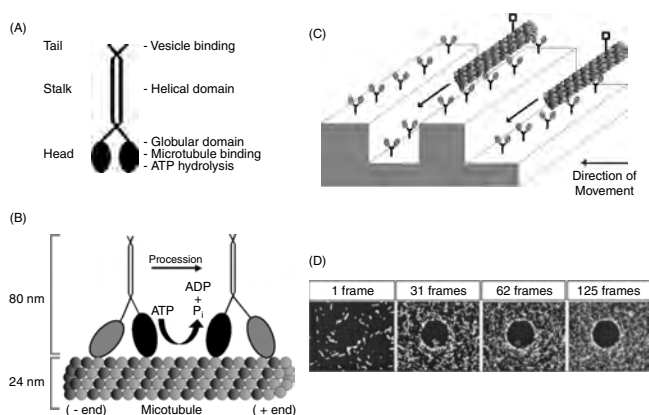
Movement of a mechanoenzyme along a biological linear polymer (such as the protein tracks previously described, but also nucleic acid strands, in the case of enzymes involved in DNA and RNA metabolism) in stable association with the linear polymer (*i.e.*, without falling off the polymer track) is called procession. Various linear molecular motors vary in their extents of processivity. All currently known kinesins and dyneins are highly processive, whereas many myosins require ultrastructural features in addition to the actin filament in order to exhibit appreciable processivity. In applications in which a nanodevice is intended to deliver a cargo to a preselected site, the processivity of the mechanoenzyme


Figure 9. Linear "track" mechanoenzymes responsible for moving organelles to specific locations in the cell can be exploited by nanotechnologists. The kinesin linear motor protein contains an extended helical domain and tail domains that can bind specific intracellular vesicles (Fig. 9A). At the opposite end of the helical domains are globular locomotor domains that bind microtubules and hydrolize ATP to move along them. The structure of myosin is analogous, though the primary nucleotide sequences of myosin is quite different from that of tubulin. Figure 9B shows − to + procession of kinesin along a microtubule. Microtubules are vectorial left-handed helicies of α and β tubulin monomers (black and white dots). Kinesins have been described which migrate from the plus to minus and the minus to plus end of microtubules, but all native kinesins described to date can move in only one direction along the microtubule. Locomotion of kinesin resembles nothing so much as bipedal walking of kinesin along the microtubule and is powered by ATP hydrolosis. Myosin locomotion along actin filaments proceeds by a similar mechanism. Figure 9C illustrates incorporation of kinesin and microtubules into a device [119, 120, 147, 148]. In this configuration, the motor protein is deposited on a micromachined (grooved) surface that acts as a guiding channel (either in the grooves or on the ridges between them) for a microtubule shuttle. Shuttles can be derivatized with payloads (box appended to shuttles) that will process along paths determined by the deployment of kinesin and surface topography. Figure 9D shows an application of this configuration [118]. A substrate with microfeatures (polyurethane posts) was imaged. Kinesin was deployed on the substrate, and 1.5 micrometer fluorescently-tagged microtubulin shuttles were deposited on the substrate, and ATP was provided. The shuttles move along areas of the substrate containing kinesin, but cannot access the tops of the polyurethane posts due to microtubule rigidity. Movement of the shuttles is confined to the regions of the substrate other than the polyurethane posts. Superposition of multiple photomicrographs of shuttle fluorescence resulted in the image of the polyurethane posts shown in Figure 9D. This imaging method may be applied to other microstructures. Reprinted with permission from [149], H. Hess et al., *Nano Letters* 2, 113 (2002). © 2002, American Chemical Society.

is clearly critical. Mechanoenzymes with insufficient processivity with respect to the biological polymer could simply dissociate from the track prior to delivering their payloads to their targets, defeating the purpose of the device. Alternatively, the requirement for ultrastructures in addition to the track might be exploited by device designers to build delivery systems that are functional in some environments (chosen or selected by the designer), but not in others.

Kinesins are a superfamily of highly related eukaryotic motor proteins. They were originally identified as a motor protein that moved vesicles in extracts along microtubules directionally from slow-growing to fast-growing ends, though

kinesin species that locomote in the opposite direction along the tubules have also been discovered [121–125, 127, 131–134]. The kinesin holoenzyme is a heterotetramer consisting of two heavy chains and two light chains (Fig. 9A) [126]. The motor domain is located in the so-called head of kinesin, and consists of a 320-amino-acid catalytic core with both a microtubule and nucleotide triphosphate (ATP) binding site. Appended to each head is a flexible neck domain that connects the head to the stalk and tail. Cargos carried along the microtubule are bound to the kinesin tail. Kinesin head and tail morphology is similar to that of myosin and, in fact, both myosin and kinesin exhibit similar modularity. The motor domains of both kinesins and myosins are highly conserved (though the kinesin and myosin motor domains are dissimilar to one another), and the specific tail-domain, amino acid sequence dedicates the kinesin or myosin to particular transport functions. The identity of the tail module determines the cargo the motor can carry and which diverse cellular process the kinesin (or actin) contributes to. In the case of kinesin, the protein participates in diverse cell processes such as vesicular transport [135], and associates with the scaffolding proteins of signal transduction pathways [136] and kinetochores [137, 138].

Kinesins function by binding to a specific site on microtubules and undergoing an ATP-dependent conformational change that is linked to release from the tubule. Since kinesin is a dimer, at least one kinesin monomer contacts the microtubule at all times. Adenosine triphosphate hydrolysis causes one of the kinesin heads to release the microtubule and swivel to recontact the microtubule downstream of its original position. The power stroke cycle completes with rebinding to the microtubule by the head. The second head of the complex then completes an identical power stroke (Fig. 9B) and the kinesin dimer literally walks along the microtubule in the presence of ATP. The overall mechanism is highly similar to that of myosin locomotion on actin filaments [142].

Locomotion of native kinesins is unidirectional, so ATP hydrolysis causes kinesin to rachet vectorially along the length of microtubules. Minus to plus (− to +) kinesin and plus to minus (+ to −) kinesin share essentially identical structures, but their polarity of motion on microtubules can be attributed to small structural differences in the neck domain [128, 129]. Indeed, a single point mutation in the neck region of kinesin renders the protein capable of movement in both directions on microtubules [130].

About 40 distinct myosin genes are recognized in humans [96], so like kinesins, myosins are a large superfamily of ATP-hydrolyzing mechanoenzymes. Unlike kinesin, myosins migrate along actin microfilaments [96–99]. Despite the fact that the two superfamilies are genetically quite distinct, myosin and kinesin share similar morphologies and mechanisms of action [142], as well as similar modularity if their tail domains that dedicate specific motor proteins to specific tasks. Myosin and actin are involved in various important physiological processes including organelle trafficking, muscle contraction, and cell division [143].

Dyneins are a third superfamily group of eukaryotic, linear mechanoenzymes associated with eukaryotic cilia and flagella [100, 101], and are also expressed in the cytoplasm where they are involved in vesicle and organelle transport

and reorganizations of the nuclear spindle during cytokinesis [100, 101]. Dynein is the largest of the linear cytoskeletal motor proteins, consisting of 4600 amino acids making it twice the size of myosin and four times the size of kinesin. Fully 3000 amino acids of this protein comprise the enormous motor domain, containing six tandemly iterated ATPase domains [107–109]. Like kinesin, dynein moves along microtubules, but the mechanism of dynein movement is thought to differ from those of myosin and kinesin [108, 115, 116]. The large size and relatively poor biochemical definition of dynein mechanism and activity may make it less attractive in nanobiological application in the near future.

Other biological linear track motors include all of the template-dependent oligonucleotide polymerases involved in replication, transcription, reverse transcription, and repair [144, 145]. In the course of oligonucleotide polymerization, these enzymes migrate along an oligonucleotide substrate (the template) synthesizing a second strand that is the reverse complement of the template. The energy for the motive-force generation ultimately comes from hydrolysis of nucleotide triphosphates, which are incorporated into the nascent oligonucleotide strand. This class of mechanoenzymes has yet to see extensive application in nanobiological devices, though they have potentially interesting features and properties. In particular, short nucleic acid segment are quite flexible, as discussed above. This flexibility allows oligonucleotides to be deployed to conform to nanoscale features considerably smaller than those to which rigid microtubules can.

The capacity of linear track motors to move along predetermined pathways is potentially attractive for use in nanobiological devices to shuttle carried materials or to actuate devices. The carried materials can be quite large relative to the linear motor proteins. For instance, microscale myosin-coated beads move on isolated actin filaments in an ATP-dependent manner [146].

Of the three major linear motors discussed, only the kinesin-microtubule system has enjoyed the extensive use in nanobiological devices. The system can be deployed with the track (microtubulin) adherent to a substrate, and the motor protein moving along the track. Alternatively, active motor proteins can be coupled to a substrate, and a segment of the track can be used as the shuttle [147, 148]. This expedient helps mitigate limitations imposed by the rigidity of microtubules. Microtubules can only be used to guide motors around features of five millimeters and greater, corresponding to the persistence length of the microtubules [118, 120]. However, deployed motor proteins are not similarly restricted, and when used with a textured surface featuring a guiding channel with the kinesin deployed in them, microtubule shuttles can describe complex paths with micrometer, and potentially greater, resolution in an ATP-dependent fashion (Fig. 9C).

Fluorescently labeled microtubule shuttles have put to novel use to image an elevated and recessed pattern on a surface decorated one micrometer polyurethane posts (Fig. 9D) [149] in a method that takes advantage of the high rigidity of microtubules. Kinesin was deployed densely and evenly across an 85×68 micrometer-patterned surface and approximately 600 fluorescently labeled 1.5 micrometer microtubule shuttles were deposited at random on the surface. In the presence of 1mM ATP, the shuttles commenced random motion on the surface. Owing to their rigidity, the microtubulin fragments could not traverse the raised posts from the recessed surface, despite the presence of active kinesin on those posts. Consequently, superposition of fluorescence photomicrographs revealed the fluorescence of the recessed surface while the raised posts appeared as dark regions. In this experiment, the image was collected in about five seconds. Effectively, the fluorescent microtubulin shuttles act as autonomous probes of the surface ("self-propelled robot probes"), and the investigators suggest their use as a highly fault-tolerant alternative to force microscopy imaging approaches.

3.3. Immobilized Growth Factors: Ex-vivo Cell Expansion

Cytokines and similar growth-promoting proteins are typically soluble proteins secreted by one cell to trigger the proliferation and/or the metabolic activity of itself (autocrine stimulation) or another cell (endocrine, paracrine, or juxtacrine stimulation) [28, 150]. In applications involving *ex-vivo* cell expansion (for instance, for hematopoietic reconstruction or other tissue engineering applications) it can be useful to immobilize such factors on solid surfaces to direct cellular colonization of a synthetic structure or to modulate the expansion of a cell product. Ultimately, these approaches may allow cultivation of cells in a media containing no proteins in solution [151–154]. Particularly in cases in which the expanded cell product is to be readministered to patients, these approaches can minimize the coadministration potentially inflammatory, immunogenic, or toxic-dissolved proteins along with the therapeutic cell product.

Insulin is a familiar example of a protein with both mitogenic and physiological regulatory properties: it not only stimulates conversion of glucose to glycogen to maintain normoglycemia, but it also only triggers proliferation of many cell types. Insulin, as well as other polypeptide growth factors like interleukin-2 (IL-2) and epidermal growth factor (EGF), can retain its biological activity when coupled to solid surfaces [26, 29, 151–156]. Not surprisingly, coimmobilizing accessory proteins (such as cell adhesion molecules) stabilize cell binding to the growth-promoting surfaces and enhance proliferative responses [26, 27, 157]. More remarkably, as shown in Figure 10A, the mitogenic specific activity of these proteins (their cell expansion activity expressed as a function of the concentration or absolute amount of the mitogen: a measure of potency) of these factors is increased by as much as one to two orders of magnitude in certain bioconjugates [26, 157, 158].

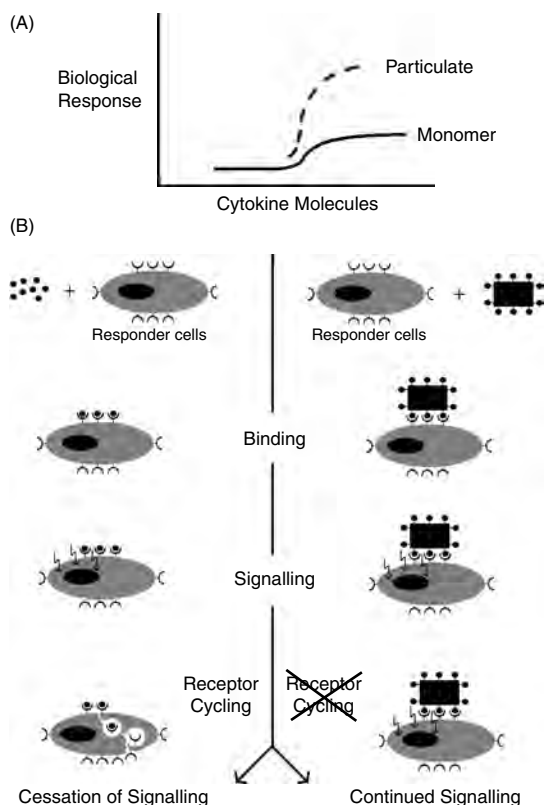
Though the bioconjugates in question are polyvalent (that is, present multiple individual growth factor molecules), and polyvalency might play some role in their enhanced activity, the primary mechanism of enhancement of proliferative activity is apparently related to the size of the bioconjugates (Fig. 10B). Bioconjugates large enough to prevent the cellular uptake associated with growth factor receptor cycling and ligand degradation seem to trigger prolonged cytokine signal transduction, resulting in enhanced proliferation [26, 157, 158]. This phenomenon may figure into the potent juxtacrine stimulation effects observed *in vivo* and *ex vivo* with


Figure 10. Deployment of biological signaling molecules on synthetic micro and nanosurfaces can enhance their activities. Figure 10A shows how the activity of cytokines and other signaling proteins (typically cell proliferative activity, but also other physiological activities may be similarly effected), normalized to their concentration, can increase when signaling proteins are provided to responder cells as a bioconjugate to nano- and microscale materials. Responses to appropriately sized bioconjugates can be supramaximal relative to responses to free monomeric protein (that is, giving responses higher than can be attained with any concentration of free protein). This suggests that signal transduction or response mechanisms associated with such bioconjugates somehow differ from those associated with free-signaling proteins, and a potential mechanism is shown in Figure 10B. Protein-signaling molecules, such as insulin and interleukins, (circles) bind receptors on the surface of responder cells (Y-shaped structures on cell surfaces), resulting in a signal (to proliferate, to differentiate, lightening bolt) being sent to the cell nucleus. To allow the cells to respond to subsequent waves of signaling molecules, receptors with bound signaling molecules are endocytosed (internalized) in vesicles, wherein the signaling molecules are degraded, and the receptors are subsequently returned to the surface. This process is referred to as receptor cycling, and individual signaling molecules cease to provide signals to responder cells when they undergo receptor cycling. It is hypothesized that bioconjugates to particles that are too large to be endocytosed (the box decorated with circles) are unable to participate in receptor cycling, and therefore provide a signal to responder cells for a much longer duration than do individual signaling protein molecules. This is thought to result in a higher magnitude proliferative and physiological response. The size range necessary to trigger the enhanced responses is currently poorly defined, and may vary with the signaling molecules, the responder cell, and particle topography and chemistry [26, 157, 158].

cell membrane-bound forms of protein growth factors [150]. The size limit that precludes uptake and leads to enhanced mitogenesis is not well defined, but sizes approximating the size of the cell taking the material up would seem to be logical. This would place the critical dimensionality for juxtacrine effects somewhere in the micrometer range. In the case of EGF, the density of the growth factors on the surface clearly impact proliferative activity [26]. Studies of a micropatterned surface with EGF deployed in stripes at various distances from one another revealed that optimal proliferation is supported when stripes of growth factors are considerably closer to each other than the medium length of individual cells. Taken together, these data show that it is possible to build nano- to micro-scale devices to support more efficient cell proliferation than can soluble growth factors. Such proliferative devices will feature growth factors and accessory proteins deployed on microscale surfaces at micrometer or submicrometer distances from one another.

4. CONCLUSIONS

The initial formulation of the nanobiological approach to device construction was driven by expediency. No technology was then available to make a selection of synthetic nanocomponents with ranges of activities as broad as those represented by biological macromolecules. In the years since this notion was first promulgated, there have been incremental improvements in nanocomponent construction, but incorporation of functional biomolecules often remains the only feasible approach to build many specific functional nanostructures of interest. Fortunately, the diversity of proteins available in the biological world and achievable by genetic engineering methods is practically inexhaustible.

Successful nanobiological devices exhibit some common features. Knowledge of the biology, chemistry, and mechanism of action of biomolecular components is critical for their incorporation into a functional nanostructure. Such knowledge allows designers to deal with biocomponents as modules, and to incorporate all biological features needed for the function in question, while minimizing the incorporation of extraneous features (Figs. 1, 2, 6–8). This assures that device components can perform the subroutines for which they were selected and mitigates the possibility that undesired activities and functions might be introduced into devices. Incorporating the minimal biological unit needed for function may also increase device stability, since minimizing the size of the components, also minimizes the number of possible enzymatic cleavage sites for proteases and nucleases that might contribute to component (and device) degradation.

Components are often abstracted from multiple, potentially phylogenetically distant biological sources, as the bacmid system illustrates in its incorporation of both prokaryotic and eukaryotic genetic elements in a single device. In most contexts, incorporation of components from disparate sources presents no barrier to device function, though device function requires the concerted or sequential action of multiple device components and emerges from this summed activity of components. The activities of components are able to sum to a desired result as the result of physical/temporal organization imposed by device design

rather than by component phylogenetic relationships. The necessity of coordinated action of multiple molecular components to nanobiological device function and the role of designed, specific structure to support function is apparent in virtually every nanodevice discussed herein. An important differentiation between fully synthetic and semi-biological hybrid devices is that the full range of properties of biological components are often more complex and less well understood than are those of purpose-designed synthetic components. Operationally, this means that nanobiological device design and synthesis is often a highly iterative business involving rapid prototyping and assay, followed by redesign, resynthesis, and reassay until a version of the device with the desired properties is achieved. The iterative nature of nanobiological device design makes facile synthesis and sensitive assay of device function and properties immensely valuable.

Finally, nanobiological devices are not limited to biomimetic structures. The range of possible functions that nanobiotechnology can realize are less dependent on precedents from the biological world than on the ingenuity of device designers. At one level or another, virtually every structure described here presses one or more biological component into a service that is distinct from the actions those biomolecules perform in their native contexts. Specific device functionalities are implicit in the organization provided in design, and not inherent in the biological components themselves.

Nanodevices are potentially highly congruent with applications in drug delivery, *in vivo* sensing, and diagnostics [1, 3, 4, 11, 12, 30]: disease states involving aberrant behavior of nanoscale components (proteins, nucleic acids, other biological macromolecules, and supramolecular structures) must often be addressed with dimensionally appropriate (nanoscale) therapeutics. The drive to medical device miniaturization is also supported by the desire for minimally invasive therapeutic interventions (or in NASAs case, the desire for low-mass therapeutics). At some point, the distinction between materials science and pharmacology begins to blur, but the nanoscale therapeutic devices are differentiated from more conventional drugs by their multifaceted activities and by the potentially complex physiological services such devices might someday deliver. Though nanobiological approaches were initially devised as a stopgap, therapeutic nanodevices may represent a special case that will always be best served by incorporation of biomolecules, regardless of advances in materials science, microfabrication, and polymer chemistry which might support fully synthetic nanotherapeutics. Biomolecules can potentially provide a compositionally and dimensionally appropriate interface between nanodevices and biological systems (patients).

Realization of the potential of nanobiological devices for human therapy will require meeting numerous technological challenges, some of which attach to nanobiological devices in any context, and some of which apply primarily to nanobiological devices in therapeutic use. In the former category, the means to deal with the lability of the biological components of nanobiological devices are required. The lability of biomolecules delimits those environments and conditions under which nanobiological devices can function. Biomolecule lability also delimits the processing and

assembly conditions available for nanobiological device realization. Not only must processing methods preserve the structural and functional integrity of biological components, but those methods must be massively parallel and require limited direct operator intervention. Annual demand for individual therapeutic devices could be in excess of tens of moles of devices in some cases, so manufacture must be highly reproducible, cheap, and facile.

With specific regard to therapeutic nanobiological devices *in vivo*, the biocompatibility and immunogenicity of the devices are critical concerns. Currently, there is no reliable means to eliminate opsonization, inflammatory, foreign body and wound-healing responses to nano-microscale implants. Ultimately, these responses compromise the efficacy of many macroscopic therapeutic implants, and are likely to similarly impact the function of nanobiological therapeutics [159]. Furthermore, it is becoming clear that many synthetic nanomaterials can sometimes trigger specific immune responses. For instance, carbon nanotubes and PAMAM dendrimers trigger specific antibody responses under some circumstances [6, 160–162]. Antibody responses can neutralize the therapeutic properties of protein and small molecule drugs, and have the potential to produce similarly negative impacts on the action of nanobiological therapeutic devices [6, 160–162].

This does not represent an exhaustive list of the challenges lying between current technology and robust nanobiotechnology, but rather represents a sampling of some of the most pressing issues. Doubtless, as yet unimagined challenges will manifest themselves as the technology matures. Still, nanobiotechnology offers vast technological power and opportunity. The extent of possibility can best be glimpsed from a survey of the diversity of function, the economy of action, and the shear magnitude of the synthetic capability manifest in the biological world. This constitutes a motivation sufficient to justify the expenditure of resources that will be necessary to fully realize nanobiotechnology and associated nanobiological devices.

GLOSSARY

Antibody A soluble immune effector protein induced in response to and capable of recognizing a specific epitope. There are multiple types of antibodies, with IgG, occurring in serum, being the most commonly encountered. IgG molecules are bivalent but monospecific antibodies.

Bacmid A baculovirus containing a bacterial plasmid origin of replication, capable of replicating in bacteria and insect cells.

Baculovirus One of a family of viruses (nuclear polyhedrosis viruses) that infect insects, and which are used as cloning vectors for heterologous protein production in insect cell culture.

Cytokine One of a class of typically soluble protein growth factors involved in the growth, differentiation and activation of hematopoietic cells.

Dendrimer cluster agents A class of therapeutic platform consisting of multiple dendritic polymers, each individual dendritic polymer derivatized to perform a specific device function *in vivo*. Cluster agents are constructed using dendritic polymer self-assembly properties.

Diptheria toxin (DT) Toxin of the bacterial pathogen *Corynybacterium diptheriae*.

Enzyme activated delivery (EAD) A prodrug strategy typically involving drugs carried in nonfusogenic liposomes in which the liposomes are rendered fusigenic with cell membranes (and therefore delivering their pharmacological payloads) by the action of cell-membrane enzymes at their desired sites of action.

Epitope A molecular feature recognized by a specific immune effector, such as an antibody.

Ex vivo **cell expansion** Directed proliferation of cells (often hematopoietic precursors) isolated from a living thing, typically done with the intent to readminister the expanded cells.

Growth factors Specific substances that direct growth and differentiation of specific cell populations.

Hematopoiesis The process of generating cellular components of blood.

Mechanoenzymes Enzymes that transduce energy (from ATP or transmembrane ion gradients) into mechanical energy.

Mitogen A substance that causes the proliferation of cells.

Nanobiological device A nanodevice containing both synthetic and biological components in which the components are organized to perform a desired work process.

Nanodevice A structure whose function is mediated by some precise nanoscale feature or component.

Nucleic acid hybridization The propensity of complementary nucleic acid sequences to associate with each other noncovalently via inter-strand hydrogen bonding interactions.

Plasmid An autonomously replicating, nonchromosomal DNA sequence of prokaryotes or eukaryotes, typically a double-stranded, circular nucleic acid molecule.

Prodrug A drug moiety with no or minimal pharmacological activity upon administration, but which is processed to an active form *in vivo*.

Therapeutic platform A multifunctional therapeutic nano- to microscale device or diagnostic, typically for *in vivo* use, that incorporates the capacity to be modified to address specific disease states or patients.

Transposon A genetic element capable of moving from one specific DNA site to another.

CONTENTS

1. BIONANOTECHNOLOGY

Nanotechnology is the technology embedded and determined by the world of atoms, molecules, and clusters at the nanometer scale. Whereas machining and handling accuracy at the nanometer level is already state of the art for the advanced semiconductor industry, a number of new phenomena become important in this ultrasmall world. Bionanotechnology aims at developing the techniques of characterizing, processing, and organizing ordered molecular structures via biomolecules and biomolecular recognition principles, which can be used in fabricating molecular functional elements and molecular circuits.

The main research activities are the molecular manipulation and organization made by the self-assembly of molecules, bioinduced alignment techniques, LB films, the development of biomolecule-nanoparticle structures with unique opto- and electronic activities, ordered assembly techniques for nanoparticles, nanowaveguides, techniques of nanoscale fabrication by, for example, electron beam or scanning probe microscope, novel bioanalytic techniques, fundamental studies on biooptoelectronic processes on the molecular level, selection and characterization of functional molecules, and, last but not least, modeling and prediction of bionanoscale structures. These goals are summarized by the following list:

- **Bio-system.** Characterization of biological recognition, biomolecular assembly, and molecular motors.
- **Production of nanomaterials.** Quantity, quality, properties, and production.
- **Production of assembled nanomaterials.** Autoassembly via (bio)interactions.

- **Characterization at both atomic and bulk scales.** Fundamental mechanical, electrical, magnetic, and optical properties.
- **Modeling and simulation.** Prediction of properties and behavior from macroscale to nanoscale.
- **Applications development.** Tools and techniques for applications of nanotechnology. Verification of predicted behavior/performance in actual environments. Systems analysis to guide technology development

Critical Bionanotechnology Areas:

- Materials with programmable optical/thermal/mechanical/other properties.
- 3D-biomolecular self-assembly and processing.
- Bio-inspired adaptable, self-healing systems.
- Low-power, integrable nanodevices.
- Quantumdevices and systems for ultrasensitive detection.
- Materials with embedded sensing.
- Lab-on-a-chip for *in-situ* life science.
- *In vivo* analysis or analyses in small volume or small entity (e.g., subcellular).
- Noninvasive diagnostic tools.
- Molecular signature for early detection.

1.1. Bionanomachines

Eukaryotic and prokaryotic cells are nanoscale machines. Organisms work via protein nanostructures to shuffle material within the cell, to slide over surfaces, to drive themselves, and sometimes even to move biomolecules distances of inches to meters (e.g., within the axons of nerve cells). Muscles make use of the molecular motor myosin (only 10 nm in size) to move along the filaments made of a protein called actin. Microtubules, a cylinder of only 25 nm, moves DNA to the two daughter cells during cell division.

In developing nanodevices it will be critical to take stock of the nanomachines already existing in nature. Thus, nature is an essential component of bionanotechnology that enables us to learn how to build nanosystems.

Bionanotechnology offers novel ways to fabricate artificial biological structures, artificial cells, and even artificial tissues, as well as new ways to enhance the performance and functionality of existing devices. Whereas simple planar structures are produced via enhanced lithography, complex artificial tissues (such as the sophisticated structures of organs) are fabricated by biological self-organization, which is effective for three-dimensional networks.

E-beam and laser-based direct writing as well as techniques that use beams for moving and positioning microscale and nanoscale biological particles (e.g., living cells, bacteria, bioactive nanoclusters) are explored and are fundamental elements of such applications.

Cell-based nanodevices offer new chances. Encapsulation of, for example, pancreatic cells in microcapsules with nanopores will permit the treatment of diabetes in a curative approach. Nanopore materials are vital for preventing the body's immune cells from rejecting implanted cells or biocatalysts.

Assembly, nanolithography, and template-based building and etching techniques are of fundamental importance in creating these nanofilters. The combination of nanofabrication techniques and nanofilters will be essential for such implantable microdevices.

Biomedical nanosensors will play an important role in the future of medicine. The ability to detect biological molecules via small and fully automated devices is central to many advanced diagnostic techniques. *In-situ* detection of cancer is only possible by tracing cells and metabolites within the living organism. Novel detection principles based on the interaction of nanomarkers and nanoreceptors are essential to these novel devices (e.g., multicantilever biochips for sensitive force, magnetic field, or friction measurement represent a promising approach). Increased resolution via carbon nanotube tips allows identification of single bimolecular particles because of their shape. Novel tips with selective transducers recognize molecules based on their mechanical, magnetic, or electrical characteristics.

The gain in functionality of current analytical devices by nanotechniques is ideal for modifying the surface of implantable devices that rely on many surface interactions with the biological host tissue and the host immune system. Tuned surfaces at the nanoscale level allow high performance in biocompatibility and biocorrosion resistance.

Synergy between chip technology and biosciences allows micro- and nanobiodevice fabrication. While static biodevices, such as biosensors, DNA, and protein arrays, are already established in the field, much has to be done to develop dynamic nanobiodevices. Of these biodevices, microfluidic devices, for example, are already available but still are large and not real nanodevice but more or less microdevices. On the other hand, all other dynamic bionanodevices are in the state of infancy because of the novel surface effects that must be understood and mastered at the nanometer scale.

Molecular motors based on proteins (rotary and linear) are ideal tools for the fabrication of bionanomachines. For successful application much must be done to understand their operation and their behavior in artificial environments. Direct methods have been developed, such as laser trapping and atomic force microscopy, and successfully applied to actin-myosin and kinesin-tubulin motors. Know-how gained from these experiments supplies engineering information that is necessary for the fabrication of future nanodevices based on these motors.

Nanofabricated devices are expensive in the first run but ultimately are more affordable. Whereas laser trapping offers zero-D confinement probing, nanofabricated structures offer the possibility to confine biological motors at the 1D, 2D, and 3D levels, and thus, at flat surfaces, in channels, on ridges, in wells, or on pillars. In the most advanced form, arrow-shaped microchannels have been used for example, to statistically enforce the directionality of the movement of tubulin filaments (Fig. 1). Whereas flat-surface 1D structures are easiest to fabricate, a 3D confinement in nanowells gives the highest level of information and control—for example, converting a molecular motor into a directional pump, or coupling two enzymes into a synthesizing cascade.

1.2. Nanoparticles

Nanoparticles or nanocluster research makes use of the strong size dependence of the physical and chemical properties of nanometer-sized particles. Clusters are well-defined building blocks for the construction of materials and devices with novel mechanical, electrical, and optical properties.

We define clusters as a number of atoms bound or arranged together, without specifying the size, shape, or property of this assembly. Within the state of matter described by cluster-type behavior we define a nanocluster, nano-island, precipitate, colloid particle, or whatever name is used for these assemblies as a nanoparticle composed of between 2 and 10^8 atoms (Fig. 2).

A cluster can be formed from a wide variety of materials. Even biomolecules such as DNA oligomers and proteins are essentially nanoparticles in the nanometer size range. These bionanoparticles are either biosynthesized or made by, for example, electrospraying technique, followed by electrostatic classification or manipulation.

To achieve efficient collective behavior and thus resonance of the electrons, these particles are preferably composed of a conducting metal such as gold, silver, indium, or tin or semiconductors such as cadmium sulfide or cadmium selenide. Clusters made of a few atoms still exhibit more molecular than cluster-type behavior. Large particles composed of more then 10^8 atoms exhibit macroscopic behavior, such as metallic luster or conductivity for micrometer-sized metallic particles. Thus, clusters cover an extremely wide range between a few and up to nearly a billion atoms [1–4] (Figs. 3–5).
Figure 1. Nanomotor based on tubulin filaments.
Figure 2. EM of metal nanoparticles (∼10–20 nm).

Figure 4. Cluster and light.

A field of increasing interest is the use of nanoclusters for novel (bio)electronic and (bio)optical devices. Attempts to reduce the size of electronic devices with current technologies will encounter insurmountable barriers within one or two decades. The use of nanoparticles as building blocks for new devices is a new route for overcoming these barriers and building highly integrated, three-dimensional electronic circuits. Manufacturing these devices will require the development of completely new approaches to the manipulation and localization of nanoparticles on substrates.

To describe fundamental properties we will be dealing with isolated clusters first and later on will upgrade to more complex cluster–cluster, cluster-molecule, and cluster-resonator systems. Systems made up of a plurality of clusters are often referred to as cluster matter, nanocrystalline materials, or mesoscopic systems.

The history of clusters dates back hundreds of years and includes such scientific highlights as the work of Faraday, Ostwald, Mayer, Mie, Seitz, Svedberg, and Zsigmondy. Within the last decade the cluster as a base for nanotechnology, nanoengineering, and nanodevices has assumed a central role in the upswing caused by STM and AFM techniques followed by the nano-boom. Clusters are not a fifth state of matter but combine rather specific properties of metals, semiconductors, and surface and particle plasmons, to name just a few.

Quite often effects are divided into intrinsic and extrinsic behaviors. The first is, for example, chemical reactivity, ionization potential, or crystallographic structure, the second is collective electron gas and lattice resonance, often cited as Mie resonance. The scheme of electronenergy levels and its relation to cluster size and cluster shape are often cited as quantum or quantum-size effects. A fundamental change in behavior is the transition from macroscopic metals to semiconductor-type clusters and, farther on, to isolating atoms or atom assemblies. This transition to the isolating state for most metals, such as Au or Hg, is observed between 10^1 and 10^2 atoms. Some unique states are obtained if the magic number is reached and defect-free nanocrystals are obtained. Gold in a perfect nanocrystal is stable against any oxidation, even more stable than any macroscopic gold metal sheet.
Surface effects such as SERS (surface-enhanced Raman spectroscopy), SEA (surface-enhanced absorption), SEF (surface-enhanced fluorescence), or catalytic effects are novel phenomena of nanoscopic systems. The high surface-to-volume ratio of nanoparticulate matters offers the opportunity to use otherwise inefficient surface-confined energy transduction pathways.

Last but not least, a great number of clusters are found in everyday life, such as silver centers in photographic films, red-colored glass, aerosols, exhausts, precipitates, or just dust and dirt.

For small clusters the boundary region penetrates to whole grains, thus influencing the state of every atom in a more or less distinct way. Even clusters containing 1000 or more atoms still contain up to 25% surface-modified material. At more than 100,000 atoms the behavior can be described by the bulk property because less than 1% of the atoms are at or near the surface.

Clusters have been synthesized by various means as particles that are free, surface-bound, embedded in a material, or in the form of a nanopowder. Electrical and optical properties are modified by shape, by surface-bound molecules, as well as by the surrounding medium. Although clusters can be made by size reduction of macroscopic matter (e.g., grinding

Figure 3. Spectral signal of the Mie resonance of a silver nanocluster.
Figure 5. Resonance of the cluster driven by a laser pulse at resonant frequency.

or milling), most techniques use the synthetic approach to build clusters from the bottom up.

Ultrasmall clusters built from a few atoms can be modeled with quantum-based ab initio methods. In contrast to this, large clusters can be described using solid-state physics.

Ultrasmall clusters (a few to 10^3 atoms) are often examined with high-vacuum beam techniques because of their chemical reactivity, based on their high surface-to-volume ratio. Within this size regime order structures with "magic numbers" are targets of major interest. Quite often mass spectrometry is used to obtain insight into the size and setup of these small particles. A variety of techniques can be applied to study fundamental properties, including photoionization, magnetic moment, polarizability, or optical spectra.

Surface-supported systems or clusters obtained via chemical reduction of metals are usually "big" clusters with more than 10^4 atoms. To study these clusters, electron microscopy, surface tunneling microscopy, atomic force microscopy, or optical near-field techniques offer the chance to directly access size, shape, and electrooptical properties of individual clusters.

To describe the electrodynamics of clusters the standard approach may be used for "big" clusters, whereas for small particles the optical functions become size dependent. Simplified models can be set up for ideal clusters from sodium, for example; nevertheless, these calculations are of reduced practical value because none of these clusters can be used in any technical setup under ambient temperatures, in air or in a humid atmosphere.

1.3. Nanocluster Devices

Clusters as optical signal transducers of molecular binding are chosen because of their significantly higher extinction coefficients compared with any organic or inorganic chromophores. These nanoparticles are more intensely colored than the most intensive phthalocyanine dyes used for staining. With the use of cluster-based assays it is possible to visualize the binding of biomolecules at a given surface by a bound layer of modified metal clusters. A similar direct approach of detection with chromophores turns out to be very insensitive without the use of an additional amplification by an enzyme (ELISA).

Since the introduction of gold and silver colloid staining methods, signal transduction by metal nanoclusters has undergone an enormous evolution. A wide variety of techniques have been developed to synthesize clusters by physical and chemical means.

The narrow size distribution and surface ligand modification permit the application of nanoparticles as transducers of biorecognitive binding and molecular structure.

The success of these methods has been and is based on preparation as monodisperse particles by chemical synthesis, efficient stabilization and coating with various biomolecules, and electron-dense matrix, highly resonant plasmons, direct visualization, enhancement by deposition of other metals (e.g., silver), and signal stability (contrary to chromophores and fluorophores). In recent years the nanocluster has become the basis of new devices employing cluster resonance, cluster field enhancement, and cluster–cluster interactions:

Nanospecific property:	Used for:
Formation of ultrafine pores	Molecular filters
Large surface area	Heat-exchange materials
Lower sintering temperature	Fabrication via sintering
Single magnetic domain	Magnetic recording, data encryption
Small mean free path of electrons	Designing conductors
High and selective optical absorption	Biochips, colors, filters, solar absorbers, photovoltaics
Mixture of clusters	New materials
Grain size too small for dislocation	High strength and hardness
Large specific surface area	Catalysis, sensors
Plastic behavior of ceramics	Ductile ceramics
Cluster coating and metallization	Special sensors
Multishell particles	Optical devices, catalysts

Not only spherical clusters but rod-shaped metal particles or tubes are the tools for bionanodevices. A research group explored the transport properties of membranes that contain a parallel collection of gold nanotubules that span the complete thickness of the membrane.

These nanotube doped membranes are prepared via a template method using deposition of Au within the pores of a polycarbonate template membrane. It was proved that the inside diameters of Au nanotubules can be adjusted down to molecular dimensions by controlling the metal deposition time. Because nanotubules have inside diameters of molecular dimensions, these membranes can be used to cleanly separate small molecules on the basis of molecular size, in contrast to standard biomembranes, which suffer from biological limitations.

For the construction of a nanoanalytical device, nanotube membranes are placed in a salt solution, and a constant potential is applied across the membrane. The transmembrane current is based on the migration of ions through the nanotubes. When an analyte molecule of dimensions comparable to the inside diameter of the nanotubes (e.g., a DNA molecule or a protein) is added these molecules enter the nanotubes and occlude the pathway for ion conduction across the membrane and the transmembrane current drops. To achieve the desired selectivity a biochemical molecular recognition agent is bound to the channel. In essence this approach is an artificial cell membrane gate similar to an ligand-gated ion channel. AC impedance and a potential-step method have been used to investigate the change in conductivity of gold nanochannels.

1.4. Nanobiotechnology

With respect to biotechnology, artificial nanostructured material is either a template for assembling biological materials, or the other way around. The biochemistry

included in this field is broad, ranging from fundamental bioorganic processes, to DNA and other biopolymers, and farther on to living cells

The use of nucleic acids as a matrix and means of self-assembly of nanoparticles (Fig. 6)(clusters, tubes (Fig. 7), molecules) into programmable arrangements provides the basis for manufacturing nanobiodevices. Contrary to top-down lithography, in which features are written onto a structure by a lithographic process, the bottom-up approach makes use of the base pairing in DNA molecules for assembly. The ability to set up three-dimensional structures enables DNA (RNA or PNA) nanotechnology to construct nanoscale assemblies far exceeding those created with lithographic techniques and is able to provide building blocks for applications in nanoelectronics, nanorobotics, and nanomaterials (Fig. 8).

Artificial nanostructured materials are a novel support for natural materials, such as living tissue. These structures mimic the natural properties of natural objects. One core element of nature is nanofibers—thus nanofibrils of bioorganic substances are a useful construction element for building soft biomaterials such as polymeric nanogels with molecular recognition capabilities (e.g., for rapid sensing) or ultrastrong but reactive nanolinkers.

While inorganic matrices such as silica surfaces or rare elements are generally not considered to interact specifically with biological systems, novel biological molecules built via phage display or ribosome selection techniques are a novel means of biomechanical interfacing. Dow-Corning announced a joint venture with Genencor International, putting $35 million into silicon biotechnology nanofabrication.

1.5. Bionanoelectronic Devices

With the ever driving need for greater capacity in information storage and ultra-high-speed information processing, the usability of conventional lithographic technologies is approaching its limit. Novel techniques for decreasing structure width in pattern formation down to the nanometer scale are directly correlated with an increase in storage capacity. Nevertheless, advancement in data processing and data storage will require not only a better performance in lithography, but new design concepts as well.

Research is focused on the possible use of nanoclusters as a basic element of novel electronic and optical devices. A nanocluster can serve, for example, as the gate in a nanoscale field effect transistor (Fig. 9), as an optical switch in a nanooptical waveguide (Fig. 10), or as the storage point in a high-speed memory. The use of clusters for waveguides and storage dots addresses scaling issues of conventional

Figure 7. Carbon nanotube.

devices. Electron and surface plasmon tunneling effects at nanodistances offer novel gateways for processing information, using principles based on nonlinear systems fundamentally different from conventional computer systems, and are more related to the neural networks within living organisms.

As a well-established tool in nanoscience carbon nanotubes (around 2 nm in diameter) or metal-(or metal cluster)-coated DNA or protein filaments exhibit semiconducting and metallic properties. These basic elements can be engineered via biological recognition systems to serve as nanoscale tunneling junctions, nanoscale field-effect transistors, and other electronic devices. Although this research is still poorly developed, these construction elements have a bright future. Small but highly promising industrial research activities have already been begun in these areas by Lucent Technologies and Motorola.

Areas of interest are improving direct electron transfer to and between molecules, nanoclusters, and metallic

Figure 6. Array of nanoclusters arranged via bio-self-assembly.

Figure 8. Coupling and assembly of DNA-functionalized clusters.
Figure 9. Cluster-based nanocluster device for electronic readout.

electrodes; the characterization of transport properties in nanostructured and clustered molecular systems; and the development of nanoclusters and quantum dots with useful electrical characteristics (magnetic nano storage dots, cluster laser, etc.).

Application in the coming years will be found in forms of information storage technologies, including hard drives, tapes, and optical media, where the critical parameter, bit density, will be optimized via biologically arranged magnetic and opto-switching nanoparticles.

1.6. Molecular Positioning and Dispensing

A major area of research is controlling the position and motion of macromolecules, DNA/RNA, proteins, and nanoparticles to enable functional processes such as molecular recognition, biochemical reactions, and, later, the self-assembly of nanoscale devices. A number of techniques have been developed

One way to handling sensitive biological species makes use of fluid streams on a chip. A key goal is the creation of nanofluidic technologies to handle nanoscale particles and molecules in microscale reactors. A fundamental understanding of the interactions between individual
molecules and a single molecule with the quite large surface of the device is vital. Tunable forces provide a path for developing efficient nanofluidic technologies. Ultimately, nanofluidics forms the backbone for a wide spectrum of bionano-applications. Fluidic processes include delivery of minute amounts of fluid, mixing/separation, and surface property control through functional molecules.

A way to deliver subpicoliter fluid droplets uses an e-jet (similar to MS injection techniques, but at ambient pressure) or microthermal actuation in a cavity. Single liquid droplets with volumes of less than a picoliter can be ejected through a metal fiber or nozzle (Fig. 11). In thermal actuation devices the actuator controls the pressure gradient and solves the satellite droplets problem, which has troubled industry for the last two decades. In e-jet devices a potential around 1–1.5 kV drives picodroplets along the field lines (in a 200-μm gap) to the chip surface.

The ability to move molecules and to guide them on a chip surface plays a vital role in the efficiency of micron-size biochemical reactors. Among the techniques of interest, electrokinetic, hydrodynamic, or magnetic forces can overcome surface forces and drive the fluid to chaotic mixing (significantly shortening the reaction time). An electrokinetic force-based focusing device that focuses negatively charged DNA into a region the size of tens of nanometers is now established and commercially available from Nanogen or November AG, for example. The surface-to-volume ratio increases dramatically in nanodevices. Thus, a large portion of molecules will interact with the surface in these devices. Well-designed molecules placed on the surface of a nanofluidic circuit can either recognize certain molecules or suppress nonspecific adsorption. In this way either the analyte of interest is lost or more positively selective filters are available.

In recent years the group around Chad Mirkin [5] has developed a nanopen. It writes on a flat gold surface, using a standard atomic force microscope (AFM) tip as the nib of the pen. The ink is loaded onto the nib by dipping into a evaporating sulfur-containing compound. Although the principle had been discussed years ago, the breakthrough relies on the formation of a meniscus of water between the tip and the gold surface, drawing the ink off the nib onto the surface. The relative humidity allows control of the flow of ink off the tip. Lines are well controlled down to a width of a few molecules. The use of 1-octadecanethiol or 16-mercaptohexadecanoic acid allows patterning or overwriting of lines. Biomolecules are easily attached to the patterned surface with the appropriately functionalized thiols.

Figure 10. Cluster-based biotransistor.
Figure 11. E-spray device with pl-precision.

Another nanotool within the necessary kit developed at Harvard University [6] is the "nanotweezer." Nanotweezers consist of carbon nanotubes attached to electrodes made, for example, on glass micropipettes. When a voltage is applied to the electrodes the tubes bend, and thus the ends of the nanotubes open or close. With the tweezer it is possible to pick up nanoobjects or move tiny structures. First experiments proved that the nanotubes are suited for gripping a cluster of nanospheres from a support. At 0 V, the tweezers are fully open. Applying a voltage closes the tweezers. At around 10 V, they are closed. Nanotweezers introduce the possibility of manipulating delicate objects, such as individual biological cells or subcellular elements. Improvements to the nanotweezers may lead to the ability to move single atoms.

Several groups have investigated the effect of dc and ac electric fields on fiber-type biological molecules such as DNA in aqueous solution. The electric fields are generated between parallel electrodes lithographically patterned on the chip. For easy manipulation, the gap between the electrodes is chosen to be less than 10 μm. The ac electric field applied is up to 1,000,000 V/m, with frequencies around 100 kHz. The field polarizes the DNA molecules and leads to an orientation of the DNA parallel to the electric field lines. If an electric field gradient is present, the polarized molecules are attracted to regions of higher field strength. DNA aggregates in the gap between the electrodes. If the ac electric field is switched off after a few seconds, the molecules diffuse out into the solution. If the field is left on for a few minutes, the DNA molecules adhere to the contacts with their ends and keep spanning the contacts when the ac electric field is switched off. It turns out, however, that the high voltages applied during the orientation procedure lead to an electrolysis of the water and a redeposition of metal between the contacts. Thus, the above orientation procedure is feasible only for small voltages but high electric fields, requiring an electrode spacing of less than 100 nm.

1.7. Single (Bio)molecule Conductivity

Ultimately electronics will consist of networks of individual molecules carrying electrical currents of a few electrons. Single-molecule conductivity measurement was first achieved with the use of a scanning tunneling microscope (STM) tip positioned above a molecule adsorbed to a metallic or semiconducting surface [7]. These experiments proved the viability of the concept of molecular electronics by measuring the conductivity of individual molecules. However, this method is limited by its lack of mechanical stability. Furthermore, it is impossible to determine whether a substrate-molecule-tip contact really occurs, and it is difficult to maintain a long molecule perpendicular to the surface. Nevertheless, the experiments marked a step toward single-molecule electronics.

In recent years a number of research groups have passed electricity through single molecules ranging from DNA to organic molecules often less than 1 nm long. Measurements of DNA conductivity were recently obtained by several groups [8, 9]. Currently most groups use a technique based on breaking a gold bridge around 50 nm wide and 50 nm thick. The first real metal-molecule-metal junctions

were the mechanically controllable break (MCB) junctions, created by Reed and used then in France by Bourgoin and Magoga [10, 11]. They used molecules with a sulfur atom at either end. The sulfur atoms at the ends of a molecule precisely bonded to the two gold electrodes to form the electrical contacts. Nevertheless, it should be noted that the sulfur atoms introduce additional electron barriers.

Varying the voltage across the gap made it possible to characterize the behavior of the single molecule trapped within. When researchers varied the voltage across asymmetric molecules, the current changes turned out to be asymmetric. At least part of that asymmetry arose from changes in the asymmetric distribution of molecular orbitals across the molecule.

A number of groups focus on the development of nanojunctions separated by a sub-50-nm gap for the electrical characterization of biomolecules. The gap is filled by a few (one to five) deposited biomolecules. The objective is either single-molecule science or the study of interactions between a greater number of molecules (e.g., a nanocluster) and a single molecule. These experiments are essential for refining the models and an understanding of charge transfer phenomena at the molecular scale in biomolecules. Nanoelectrodes must be ultrasharp. Moreover, it must be possible to verify *in-situ* the quality of the gap and of the metal-molecules-metal junction with an atomic force microscope (AFM).

Recently, electric conduction in double-stranded lambda-DNA has been studied at room temperature with the use of low energy electron point source (LEEPS) imaging. For this purpose, the DNA molecule was strained over a perforated conducting membrane. The measurements indicated a surprisingly large electrical conductivity. This result suggests that DNA-based biomolecules can be applied to electric circuits, for example, as electric sensors with recognition capabilities.

Microtubules are essential in cell architecture and cellular transport. Single-molecule experiments were carried out with the use of microstructured electrode surfaces and microtubules between the electrodes. Arrays of electrode pairs are built from a ∼100-nm gold layer (primed with a titanium layer)on a thermally oxidized silicon wafer according to standard photolithographic techniques. Microtubules are purified from brain by three cycles of temperature-dependent disassembly/reassembly and stabilized with 20 mM taxol. For adsorption experiments, the assemblies are applied to a substrate of microstructured gold lines on oxidized silicon.

A new approach to the wiring of nanostructures is linking metallized DNA or microtubules to prestructured microelectrodes. Briefly, the protein structures are activated by the adsorption of Pt-catalyst particles with the use of K_2PtCl_4 solution, followed by a metallization with Ni acetate [12]. Similar metallization techniques are well established for gold or silver coating. Electron beam-induced deposition (EBD) was used for the structuring of connecting gold lines as nanoelectrodes, which wire a single microtubule to microelectrodes created by photolithography. A metalized microtubule yielded a resistance below 50 Ohm over the length of 1 μm.

EBD line writing is an add-on to simplify the electrical connection of single molecules (Fig. 12). Repeated line scan induces the polymerization of amorphous carbonaceous material along the path of the electron beam on the substrate, which appears as a black line in the SEM contrast. A prerequisite for successful EBD lines is a minimal drift of the SEM; otherwise a broadening of the lines occurs. The conductivity of the substrate enhances the growth. This phenomenon is explained by charging effects suppressing the EBD effect. Localization, EBD line writing, and a first characterization of the created line structures can be obtained by SEM in about an hour.

1.8. Scanning Probe Microscopes

Imaging and manipulation of nanometer-sized objects, single molecules, or individual atoms are the playground for bionanoscience and nanobiotechnology. Whereas classical macroscopic techniques rely on molecular ensembles, averaging over all possible molecular conformations, singlemolecule techniques make it possible to address and observe molecular individuals in their individual shapes and activities.

The field of novel scanning probe techniques is enormous and cannot be covered—even to a minor extent—in this bionanotechnique summary (Fig. 13). The applicability of, for example, atomic force microscopy for imaging biological molecules in their native environment was demonstrated shortly after the invention of this technique. Through time AFM has become a successful tool that complements other structural techniques such as NMR, X-ray crystallography, and electron microscopy. AFM is applicable not only for the visualization of biomolecules and surfaces, but also for the manipulation of nanostructures such as proteins, DNA, or nanoclusters. To make use of the AFM to monitor biological molecules, a number of techniques have been developed. The three main modes of operation are contact mode (CM),
Figure 12. E-beam line writing to contact nanotubes or metal-coated DNA strands.
Figure 13. A few novel techniques of the large family of surface scanning microscopes.

noncontact mode (C), and tapping or intermittent contact mode (IC). The principles by which the AFM works are very simple. An atomically sharp tip is scanned over a surface with feedback mechanisms that enable the piezoelectric scanners to maintain the tip at a constant force (to obtain height information) or height (to obtain force information) above the sample surface. Other "scanning probe" techniques use a wide variety of parameters to obtain this feedback (e.g., scattering of light, fluorescence, magnetic field, thermo current, etc.).

Just to illustrate the use of AFM: it permitted the detailed study of the intra- and intermolecular forces of the DNA double helix, which are central to understanding its structure and rich functional behavior. DNA exhibits very interesting biophysical and physicochemical properties that are essential for a proper functioning of the biomolecular processes involved. Interaction forces between single strands of DNA are conveniently determined via atomic force microscopy. The ability to measure the force between the tip and the sample is an additional important feature of the atomic force microscope. The cantilever on which the tip is mounted is moved toward the sample, and, after touching it, the tip is pulled back from the surface of the sample. The attractive force of the sample, which holds the cantilever back by pulling it away from it, is displayed as a diagram (Fig. 14).

Already around 1994 DNA oligonucleotides were covalently attached to the probe and surface. Adhesive forces had been measured between complementary oligonucleotides (~20 bases). Data exhibit several distinct force distributions, which are associated with the rupture of the interchain interaction between a single pair of molecules, which involves breaking of short fragments. When a third long DNA molecule was coupled between complementary surfaces, both intra- and interchain forces were observed. The intrachain interaction resulting from the molecule's elasticity manifested itself as a long-range cohesive force. Fundamental phenomena like molecular elasticity, binding to proteins, supercoiling, and electronic conductivity also depend on the
Figure 14. Force curve obtained by unwinding a DNA double strand from an AFM tip.

numerous possible DNA conformations and can currently be investigated on the single-molecule level.

Similar experiments had been done with proteins as, for example, antigen-antibody complexes. The antigen is immobilized covalently via, for example, a long hydrophilic spacer of polyethylene glycol to the silicon nitride PM tip. Closely related antibody molecules differing in only one amino acid at their binding site can be distinguished via the measurement of binding forces.

Experiments with single molecules were reported with scanning tunneling microscopy [13], fluorescence microscopy [14], fluorescence correlation spectroscopy [15], optical tweezers [16, 17], bead techniques in magnetic fields [18, 19], optical microfibers [20], low-energy electron point sources (electron holography) [21], and atomic force microscopy (AFM) [22].

Whereas standard scanning microscopes are tabletop instruments, novel devices shrink the scanner equipment down to the millimeter scale, thereby increasing the resonance frequency of the scanner. Cantilever sensors rely on well-known and simple transduction principles and have attracted interest (Fig. 15). This is due, at least in part, to the combination of silicon fabrication techniques and surface modification biochemistry with the development of multi-cantilever sensing methods. Interest in microfabricated cantilevers has grown since the development of the AFM in 1986. Cantilever sensor techniques allow direct measurement of specific interactions between surfaces at the molecular scale. A micro-AFM measures the tiny forces acting on a sharp tip of a multicantilever chip. By shrinking the cantilever structure to a microscopic size one obtains a low spring constant (high sensitivity), a high resonant frequency, fast response times, and high immunity to external mechanical noise. Miniaturization and mass production are achieved by taking advantage of silicon micromachining techniques developed for IC process technology.
Figure 15. Sketch of a cantilever sensor.

With a microcantilever operated in the oscillating mode, it is possible to count the number of bacteria adsorbed to an antibody-coated cantilever. The specific binding of a herbicide to an antibody-coated cantilever causes a significant shift in resonance frequency. It was proved that this chip differentiates between the adsorption of low-density lipoproteins and oxidized lipoproteins bound to a heparin surface. Coating the cantilever surface with specific receptors and labeling the analyte with the beads will yield an extremely sensitive single-molecule sensor. Cantilever sensors also show great potential in genomics. One hot topic is the detection of single nucleotide polymorphisms (SNPs), the origin of biological diversity and diseases.

A common modification of the AFM is the scanning electrochemical microscope (SECM) (Fig. 16). The microscope requires an almost completely insulated AFM tip, leaving the minimum area possible (conducingly)exposed at the end. This metal or carbon tip forms the working electrode in an electrochemical cell. This nanomicroelectrode is scanned across a surface, and the current is measured as a function of position to acquire an electrochemically topographic map of the chip. The ultimate detection limit of the single molecule has already been achieved.

The scanning near-field optical microscope (SNOM) is realized by scanning a small spot of "light" over the specimen and detecting the reflected, scattered, or transmitted light. The SNOM principle relies on optical tunneling, which is a quantum phenomenon resulting from photon delocalization that allows light to cross propagation barriers. The resolution of the SNOM image is defined by the size of
Figure 16. Electrochemical scanning microscope (the redox signal is obtained by cycling a redox-active molecule in the nanometric electrode gap).

the aperture. SNOM utilizes nanoapertures with a diameter in the range of ~50 nm. Typically such apertures are prepared in the metal coating of pulled fibers. The optical near-field decays exponentially with distance. Scanning the aperture at a typical distance of ~10 nm from the sample produces a high-resolution optical image. A detection limit of a single molecule is achievable. The single molecules most often detected and characterized in the literature are dye molecules on DNA fragments.

A new member of the scanning probe microscope family and one of the most prominent of the emerging nano-electromechanical systems technologies is magnetic resonance force microscopy (Fig. 17). The energy separation of useful magnetic sublevels within a molecule ranges from μeV to meV and is detectable by either nuclear or electron spin resonance.

2. NANOCLUSTER-BASED TECHNOLOGY

As could be deduced from the summary of technologies, the use of nanoparticles is one of the most promising areas of bionanoscale research. Unique behavior in the interaction with electromagnetic fields and radiation is among the most exciting properties (Fig. 18). This article will focus on nanoclusters, start with their intrinsic properties, and later on focus on potential bioapplications in the field.

2.1. Properties

In an extended metal unconfined electron movement is possible, resulting in strong, unspecific reflectivity, well known as metallic luster. In contrast, for clusters of any size or geometry the optical spectra are primarily determined by the strongest oscillation process. Resonance of metal clusters is dominated by collective oscillation of the electron gas within the cluster, forming either plasmons or plasmon-polaritons. We will mainly focus on electronic excitation from visible light to IR and add some basic phenomena of vibration and Raman spectroscopy.

Optical spectroscopy of metal clusters is best described by electrodynamics. It is appropriate to apply a quasi-static regime only for a cluster smaller than 10–20 nm for visible light. Within a static regime phase shifts in the particle are small enough and thus might be neglected. This simplifies the excitation of the cluster to an oscillating dipole.

For real clusters the resonance is smeared out because of clustersize and shape distribution. Furthermore, the influence of matrix boundaries, as well as a finite penetration of the electromagnetic wave, has to be considered.
Figure 17. Nano-NMR scanning microscope.
Figure 18. Preferred plasmon propagation within nanoscale structures.

The electron mean free path plays a key role in modifying the optical properties of metal clusters. Whereas for small clusters the field attenuation is small, in larger clusters (>30 nm) only surface regions are excited by the field. The skin depth (at 2 eV) is 24 nm for Ag, 13 nm for Al, 31 nm for Au, 30 nm for Cu, and 38 nm for Na.

To apply electromagnetic theory, the negative charges are allowed to move when they are excited by an external field. In contrast, the positive charges are more or less immobile. Metals that exhibit strong optical effects are free-electron metals, based on the fact that most of the electronic properties are caused by conduction electrons. These metals have completely filled valence bands and partially filled conduction bands. For free electron metals the optical response is based on the conduction electron band, whereas other metals exhibit various interband transitions.

Noble or seminoble metals such as silver, gold, or copper exhibit both free electron and interband transition behavior, depending on the frequency range. For basic studies alkali metals proved to be very useful. Because of their instability in an ambient environment, noble metals are the only clusters studied in aqueous solvents.

The response of a metal cluster to an exciting electromagnetic field is based on the dielectric function $\varepsilon(\omega)$ of Drude-Lorentz-Sommerfeld. The internal field of a metal cluster is calculated by adding the boundaries of the sphere surface. Thus the static electric polarizability of a spherical cluster of radius r is given by $\alpha_{cl} = 4\pi\varepsilon_0 r^3 \cdot (\varepsilon - \varepsilon_m)/(\varepsilon + 2\varepsilon_m)$. This formula is suited for small metal clusters. It is not applicable for large nanoparticles.

Thus for a small ε_2 a resonance is given at $\varepsilon_1 = -2\varepsilon_m$ with a resonance frequency (at $\varepsilon_m = 1$) of $\omega = \sqrt{(e^2/(m_e 4\pi\varepsilon_0 R^3))}$. Often ω is interpreted as the plasmon frequency; nevertheless, it is a resonance (and polarization) of a particle. To sum up, the conduction electrons in clusters act as an oscillator system, whereas those in a bulk metal act as a relaxator system with no excitation at the eigenfrequency ω.

Realistic coupling of the electron gas with the ion core can be described by refinement procedures (e.g., by introducing an effective optical mass instead of the electron mass) and was first introduced by Mie-Gans-Happel based on a solution of Maxwell's equations with appropriate boundary conditions. Mie divided the problem into two parts: the electromagnetic one and the one based on material properties he excluded by using a dielectric function $\varepsilon(\omega, R)$.

The dielectric function is an average of all electronic and atomic behavior of the cluster as dipolar, multipolar, or magnetic modes of absorption and scattering. The success of this theory is based on extracting data from experiments.

Basic data are gained by correlating ε_1 with $\Delta\lambda_{max}$, the peak height with ε_2, and the bandwidth with n. Thus, a steep $\varepsilon_1(\omega)$ results in a narrow resonance peak, whereas a flat $\varepsilon_1(\omega)$ results in a broad band.

2.2. Cluster and Quantum Dots

In the visible spectral region the dipolar surface plasmon is dominating for alkali metals since damping is small. In contrast, noble metals (mainly Ag, Au, and Cu) show significant deviation from free electron behavior due to interband transitions. These transitions influence the spectra in the visible region. The plasmon energy limit shifts from the free electron value of 9 eV to less than 4 eV! The threshold in eV is 3.9 for Ag, 1.5 for Al, 2.4 for Au, 1.3 for Ba, 2.1 for Cu, 0.9 for Cs, 1.3 for K, >6 for Mg, and ~2 for Na.

Thus, this resonance cannot be regarded as a free electron resonance but is a cooperative effect based on conduction and d electrons. Whereas silver is even the less pronounced member of the group of noble metals cited above, in copper the plasmon energy limit shifts from more than 9 eV to around 2 eV.

Only Ag has a well-developed resonance near 400 nm. Gold has a peak around 520 with a shoulder to higher energy. Copper exhibits no resonance in embedding media with ε_m around one, but a sharp resonance peak can be found in media of higher refractive index.

Resonance of Pt clusters is damped away in the visible region of the spectrum but is useful in the near-IR. Metals like Ti and Ta exhibit plasmons combined with various elementary excitations of the metal.

Advances in nanotechnology have led to the development of highly sensitive cluster-nanoprobes, which have had a large impact on fundamental biology research and medical diagnostics. These semiconductor clusters, quantum dots, exhibit visible room-temperature photoluminescence that is shifted to higher energies compared with bulk materials because of quantum confinement. Even indirect bandgap materials such as silicon, molybdenum sulfide, and pyrite, which show no significant PL at room temperature, can have intense room-temperature luminescence in nanocluster form.

Quantum dots are nanometer-size colloidal particles with dimensions smaller than the exciton Bohr radius. In comparison with traditional organic probes, semiconductor quantum dots are 20 times brighter and 100 times more stable against photobleaching.

At present, the use of quantum dots for multicolor staining, homogeneous assays, and imaging for tissues is already established. Bioassays are accomplished by modifying the surface of quantum dots with hydrophilic molecules and conjugating selectively interacting biomolecules onto the surface.

Colloidal gold is orange, red, or red-violet, depending on the preparation method. Colloidal gold is prepared by catalytic deposition of metallic gold produced by the reduction of gold salts with numerous reagents. The most common are phosphorus, tannic acid, ascorbic acid, and sodium citrate. Depending on the method used, colloidal gold preparations vary in particle size and size variability expressed as the coefficient of variation of the gold particle diameter in a sol. Such a sol is called monodisperse when the coefficient of variation is smaller than 15%.

A new route to the synthesis of colloidal Au clusters with diameters between 30 and 100 nm is described by Brown and Natan [23]. On the basis of surface-catalyzed reduction of Au^{3+} by NH_2OH, the approach is used to grow existing nanoparticles into larger particles of a size determined solely by the initial particle diameter and the amount of Au^{3+} added. The resulting clusters exhibit improved monodispersity relative to those prepared in one step by the reduction of Au^{3+} by citrate. Surface-bound Au clusters can also be enlarged with this method. Thus, this technique provides an attractive route to colloidal Au monolayers with variable interparticle spacing.

The colloid preparation is one of the major methods employed for the purposes of cytochemistry, especially staining of electron microscopic samples [24, 25].

2.2.1. Techniques for Preparing Nanoclusters

- One of the most well-known methods (due to Frens) provides monodisperse colloidal gold. In short: a solution of gold chloride is diluted in double-distilled water, the solution is heated to boiling, trisodium citrate is added quickly, and the solution is boiled gently until an orange red color develops. The size of the clusters between 6 and 60 nm can be adjusted by adding varying amounts of reducing agent.
- Another well-known method provides monodisperse colloidal silver. In short: $AgNO_3$ solution is diluted double-distilled water, tannic acid solution is added, the mixture is heated to 80 °C, sodiumcitrate is added under rapid stirring, and the solution is kept at 80 °C until the colloidal color becomes yellow. Colloid formation can be followed via an absorption peak at around 400 nm. The colloids prepared in this way are polydisperse, with an average particle diameter of 30 nm.
- Graphite-encapsulated metal nanoclusters are synthesized with high-temperature electric arc techniques. Carbon and the metal of interest are coevaporated by producing an electric arc between a tungsten cathode and a graphite/metal composite anode. The encapsulation occurred *in-situ*.
- CdS and PbS colloids of nanometer dimension are synthesized by controlled precipitation of the metal sulfide in water and acetonitrile solution. These colloids exhibit quantum size effects but have a broad size distribution.

- CdS nanocluster can be synthesized within the pore structure of zeolite. The coordination of Cd atoms with the framework of the zeolite leads to the formation of stable nanoclusters with a structural geometry superimposed by the host matrix.
- Metal nanoclusters are prepared by solution-phase thermolysis of molecular precursor compounds.
- Nanoclusters of CdSe have been synthesized with the use of organometallic reagents in an inverse micellar solution. Precipitation in reverse micelles gives a semiconductor lattice and *in-situ* molecular modification of the cluster surface.
- Gold nanoclusters might be fabricated with metal vapor deposition techniques. In this method, gold is codeposited with, for example, liquid styrene or methylmethacrylate.
- Block copolymers are used to fabricate metal nanoclusters with the deposition of metal on the surface of a microphase separated PS-PMMA diblock copolymer. After deposition, the film is annealed. The shape and size of the nanoclusters are determined by the microphases of the polymer mixture.
- Researchers at MIT synthesized metal nanoclusters inside the microphases of diblock copolymers. Nanoclusters within these copolymer show 3D ordering, and the density of nanoclusters is high enough for commercial applications.

In the absence of stabilizing agents, aqueous dispersions are inherently unstable. All will form aggregates. The strong tendency is caused by attractive van der Waals forces, which basically always act at short distances. For submicrometer clusters, the primary van der Waals minimum is much deeper than the thermal energy, and therefore two particles that collide by Brownian motion will stick to each other.

The rate of cluster formation was calculated by von Smoluchowski a century ago. A more detailed description is based on the hydrodynamic resistance and the finite range of the van der Waals attraction. Nevertheless, dispersed colloidal particles will inevitably aggregate within seconds unless some stabilizing mechanism is available. The most basic process in colloidal stability is the dimer formation in an initially stable dispersion. Aggregation may be triggered by an increase in the ionic strength, changes in the solution pH, or by the addition of flocculants like polymers or surfactants.

A dispersion of charged nanoclusters is usually stable at low salt concentrations. It can be destabilized by mixing with a salt solution of higher concentration. At a high concentration of salt ions, the particle charge is screened, and the repulsive electrostatic force is overcome by the attractive van der Waals force and the particles precipitate.

2.3. Nonspherical, Core-Shell, and Phase-Boundary Clusters

Based on the theory of Mie, several modified concepts deal with nonspherical cluster shape and core shell particles. Based on the quasi-static approach, various geometric forms have been treated (e.g., oblates, ellipsoids, cubes, and cylinders).

The axial ratio a/b as a main parameter is suitable for calculation extending the polarization to L_i, where $i = a, b, c$ and $\Sigma L_i = 1$ (for spheroids $L_a = L_b = L_c$). To treat samples with arbitrarily oriented ellipsoids the signal has to be averaged over all orientations. Clusters of a single size and eccentricity exhibit a splitting of the peak to three more or less distinct peaks. Clusters of a continuous distribution correspond to a flat and broad peak (Fig. 19) [26].

Clusters set up from more than one metal can often be treated by combining the functions of pure metals. Often one observes broad-band and multipeak spectra. For very thick layers spectra converge to the spectra of the top-layer metal (Fig. 20). Especially amorphous metal can significantly modify long-wave absorption of metal-cluster films.

Already monomolecular surface layers exhibit pronounced effects. In the visible region even small ad-layers of sulfides, iodides, oxides, or borates lead to a significant deformation of the spectra [27] (Fig. 21).

Ordered arrays of metal columns deposited on or etched out of a substrate surface exhibit similar or even enhanced effects. High local fields permit efficient signal generation with SERS.

Of particular interest is chemically confined growth or catalytic growth, in which the catalyst is used to direct highly anisotropic growth. Methods using a catalyst cluster with a diameter in the 10-nm size range permit the growth of nanocolumns and wires. Nanowire growth is initiated after generated clusters become supersaturated.

Bimetallic nanostructures act as unidirectional light pipes. The effect is attributed to plasmon propagation. This optical analog to the diode may be used to directly construct optically addressable memory elements, logic devices, and sensors at the nanoscale.

As a straightforward approach silver-gold core-shell clusters are synthesized via gold nucleated silver-deposition. In short: Au colloids are diluted in water, the solution is heated, $AgNO_3$ and trisodium citrate are added, in intervals, additional aliquots of $AgNO_3$ are added, and finally trisodium citrate is also added to complete the reduction. The resulting solution has an absorbance maximum around 329 nm (typical for Ag). The two types of particles can readily be separated by centrifugation.

Whereas a simple discussion of $\varepsilon(\omega)$ depicts the setup of single spherical clusters in an isotropic material, it has to be extended for anisotropic phase boundary systems. Clusters on surfaces are influenced by the adjacent medium. In a

Figure 22. Spectral change induced by cluster aggregation.

very simple case ε_m can be replaced by an averaged dielectric ε of the surrounding media, giving reasonable results (Fig. 22). In a more complex description an oblate cluster shape induces a well-defined splitting of the polarization. Thus, by. choosing the appropriate polarization of the exciting beam, selective excitation of modes can be accomplished. Moreover, the cluster plasmon peak will split up into at least two defined peaks, one shifting slightly to shorter wavelengths, the other quickly moving to red and infrared.

2.4. Magnetic Clusters and Magnetodendrimers

Magnetic nanoclusters are monodomains. Thus, one expects that in magnetic nanophase materials the grains also correspond to domains. Very small clusters have special atomic structures with discrete electronic states, which give rise to special properties in addition to superparamagnetism.

Studies of magnetism in small nickel clusters have found them to be highly magnetic. The moments per atom exceed the bulk value per atom. These observations support theoretical predictions of enhanced magnetization in systems with reduced dimensionality.

This effect extends throughout the transition metals. Cobalt and iron clusters are also more magnetic than the bulk, and clusters of rhodium (nonmagnetic transition metal) exhibit strong magnetic moments.

While the surfaces of clusters show enhanced magnetizations, such surface effects are difficult to observe. A large surface-to-volume ratio and an absence of nearest neighbors

Figure 21. Coating of a silver cluster with a monolayer of iodine and a strong damping of the plasmon peak.

induce rapid rotation of the magnetic field. As a result, the clusters appear to be macroscopically nonmagnetic, and only at a very low temperature is the rotation frozen.

In bulk materials, surface magnetism is hard to separate from bulk magnetism. Since small clusters are more or less entirely on the surface, they are ideal to study surface magnetism. The very smallest clusters, which have no internal atoms at all, are thus extremely magnetic, in agreement with theoretical predictions.

Thus, most nanoclusters are considered to be isolated single-domain ferromagnetic materials. Magnetic resonance (MR) and magnetic scanning microscope (MSM) imaging offers both high resolution and large area imaging capability. To be visualized, structures must be labeled with a nanoscale marker that can be detected by MR imaging. Superparamagnetic iron oxide nanoparticles currently provide the highest sensitivity when used as a MR contrast agent.

A new type of iron oxide nanoparticle, magnetodendrimers, have excellent magnetic and NMR relaxation-enhancing properties, and, because of their coating with a dendrimer as a transfection agent and their nanosize, they are efficiently taken up by a number of mammalian cells. The magnetodendrimers exhibit a high saturation magnetization of ~100 emu g/Fe, no magnetic hysteresis at 300 K, and T2 relaxivities of 200 mM^{-1}s^{-1} (at 37 °C), with a rapid approach to saturation at magnetic field strengths well below 1.5 Tesla. Magnetically tagged cells show a high degree of cellular uptake and thus intracellular labeling, with the cytoplasm containing large numbers of iron-containing vesicles and endosomes. Magnetodendrimers represent a new class of cellular nano-contrast agents that can be used efficiently for magnetic cellular labeling and *in vivo* tracking of cells down to the molecular scale.

2.5. Cluster–Cluster Interaction

Standard electromagnetic theory can only be applied as long as no significant coagulation of the clusters takes place. The origin of the two peaks observed on aggregate formation can be deduced from experiments clearly showing that the low-frequency peak is reduced with increasing p-polarization, in contrast to high-energy peaks, which are nearly insensitive to a change in polarization of light. Thus, the low-frequency peak is caused by longitudinal mode excitation, whereas the high-frequency peaks correspond to the transverse mode of the system.

The stability of a cluster system against coagulation and, furthermore, on coalescence is due to electrostatic repulsion of the clusters (see above). Repulsion, sometimes combined with added steric inhibitors such as polymers, blocks cluster–cluster contact. This prevents a metal-to-metal contact induced by thermal motion.

A color change results from the formation of aggregates of the nanoclusters, or the precipitation of the aggregated nanoclusters (from red to violet and, farther on, blue for Au-colloids). This color change may be observed with the naked eye or spectroscopically (Fig. 22).

Aggregation of nanoclusters can be quantified by EM or light scattering. A color change can be more readily observed against a background of a contrasting color. The observation of a color change is facilitated by spotting a sample on a solid white surface of an RP-18 TLC plate. Upon drying at room temperature, a blue spot develops if the nanoparticle conjugates are linked by biochemical interactions; otherwise the spot appears red-pink. The results can be stored in this format.

Conventional silver enhancement kits greatly increase the sensitivity of the reaction.

2.6. Coating Clusters with Biomolecules

Gold clusters are unstable as sols in the presence of electrolytes. It is believed that the gold nanocluster has a gold-0 core and a gold-1 shell, because of incomplete reduction at the outer surface. The coreagent used in synthesis coats the surface with citrate or chloride ions, for example. When salts are added to a cluster sol the color turns to blue, and the clusters precipitate. However, if proteins are added under proper conditions, these bind spontaneously to the gold cluster surface. Surfaces are modified and the sols remain stable in the presence of added electrolytes.

The binding of proteins to metal clusters is more or less irreversible. Most of the proteins retain their biological activities, at least in part. This property makes nanoclusters highly useful as transducers.

Because of their high reproducibility and robustness, cluster-based assays are useful tools in protein assays and high-throughput profiling of the proteome. The degree to which biological activity is lost depends upon the structural integrity of the protein. The degree to which conformational changes are vital for the proper function of the protein depends on how tightly the protein is bound to the surface. Furthermore, the pH during immobilization versus isoelectric point of the protein is important.

No general rule can easily be obtained for the degree to which biological function is retained, but mostly it is better than or at least comparable to other covalent immobilization techniques.

On the average one 14-nm colloid is covered with 25–100 proteins 3 nm in diameter. Therefore even poor immobilization results in sufficient biological activity of the cluster reagent.

Binding of protein to the gold clusters is pH-dependent. Stable complexes are achieved at a pH 0.5–1 units higher than the isoelectric point of the protein to be immobilized.

The pH of the colloidal clusters can be adjusted by the addition of 0.1 M NaOH or by the addition of 0.1 N HCl.

The pH is measured with pH paper or with gel-filled electrodes. Glass electrodes are coated by colloids and thus might be modified in their response.

In the case where very tiny amounts of protein are available for coating the gold sol it is important to estimate the minimum amount of protein needed to stabilize the sol. To provide optimal conditions for protein binding, the ionic strength should be low, since salt induces cluster aggregation (a red gold sol turns blue).

Particle sizes	Unconjugated colloidal gold sols, 2–50 (250) nm
Aggregation	80–90% singles with no clusters greater than triplets
Stability	Gold conjugates with 20% glycerol are stable if stored at ≤ -25 °C.
Storage buffer	20 mM Tris-base, 20 mM NaN_3, 200 mM NaCl, pH 8, +1% BSA, 20% glycerol
Assay buffer	20 mM Tris buffer, 200 mM NaCl, pH 8.2

Gold conjugates with protein ∼100 kDa

Size (nm)	OD (520 nm)	Protein concentration (μg/ml)	Proteins/cluster
1	—	50	1
5	3	36	3
10	3	30	∼10
15	4	30	∼30
20	4	30	∼50
30	5	15	∼100

Gold colloids are coated with protein in a 2–3-fold excess for several hours. Excess protein has to be removed by washing. Coating can take place with reduced amounts of the desired or any other protein if, in addition to the functional protein, in a second step an unreactive protein is applied for the stabilization of colloids. In a similar way other proteins can be attached to the colloid surface, considering their isoelectric points.

Monolayers of the polypeptide poly-L-lysine are useful for controlling the specific adsorption of proteins onto gold cluster surfaces. A poly-L-lysine monolayer modified with biotin is electrostatically adsorbed onto a gold cluster coated with a self-assembled monolayer of a carboxylated thiol (e.g., 11-mercaptoundecanoic acid). The immobilized biotin groups act as specific biorecognition sites for avidin. By varying the percentage biotinylation of poly-L-lysine, it is possible to control the surface coverage of avidin to create either full or partial monolayers (4.1 nm). The poly-L-lysine monolayer and any adsorbed avidin can be rinsed from the surface with a low- or high-pH solution to allow quantitation of the adsorbed molecules.

2.7. AFM Imaging

For HT-biomolecular screening, novel comparative techniques permit rapid identification of modified genomic DNA molecules. Specific DNA sequences are labeled with

conductive reagents such as colloidal gold particles, and the position of conductive reagents along DNA contours is detected via nanofabricated electromechanical devices.

Individual DNA molecules are labeled with colloidal gold particles by hybridization of synthetic nucleotides conjugated with biotin into human genomic DNA fragments and subsequent coupling with colloidal gold particles coated with avidin. DNA, labeled with colloidal gold particles, is straightened and immobilized on the silicon surface. Electromagnetic force, surface tension, or hydrodynamic force is used to uncoil and stretch DNA molecules. The positions of colloidal gold particles are detected by AFM or other scanning probe microscopy techniques along the straightened DNA molecule.

Direct imaging can be done in ultralarge biomolecular assemblies, such as the extremely large ribonucleoproteins (RNPs), the molecular mass of which may be several million Daltons. For such polymorphic assemblies, visualization by electron microscopy provides structural information at a resolution that is difficult to obtain in any other way. Yet, localization and tracing of RNA within RNP complexes are not straightforward. A novel way to accomplish these is through the synthesis of RNA molecules that are covalently derivatized with gold nanoclusters, which thereby can be visualized by EM or by atomic force microscopy.

2.8. Immunocluster Techniques

Conjugates, prepared by coupling of antibodies on colloidal gold particles, were used in a homogeneous sol particle immunoassay for various proteins. Most assays are based on cluster coagulation, resulting in color reduction. The best results were obtained with big particles of 50 nm or more near the stability limit. The addition of polymers sometimes increased the agglutination rate considerably. The influence of temperature on the agglutination is small. Higher concentrations resulted in steeper calibration curves. The dose–response curves in buffer or urine are almost identical, and the reproducibility in biological fluids is fine. Homogeneous aggregation assays have a high practicability and are easy to automate. A disadvantage might be the method's moderate sensitivity.

Based on well-known colloid labeling, various semiquantitative flow-immunoassay methods for the detection of antibodies or antigens have been developed. The label is a colored colloidal particle such as gold (red), carbon (black), silica (several colors), or latex (several colors) for direct visualization of the immune reaction. In practice, colloidal gold particles or gold nanoclusters with a diameter of 25–40 nm are the most commonly applied labels in strip tests. The colloidal particles are coated with an organic reagent, which, in turn, is attached to the antibody by covalent bonds. Appropriate antibodies or antigens for a sandwich-type immune assay are immobilized on the cluster surface and on chromatography paper or in a nanochannel in the most advanced devices.

Thus, a typical strip test device consists of a test strip that is mounted in a plastic cassette (housing). The test strip is made up of a number of components, including a sample pad, a conjugate pad, an absorbent pad, and a membrane that contains the capture reagents. The paper strips

are developed with an appropriate immuno-gold reagent in a plastic tube in the presence of urine (e.g., pregnancy) or serum [28, 29]. The mixture migrates up the strips toward the test band. A purple band develops, which indicates the presence of the corresponding antigen or antibody. About 50 mIU of hCG in urine can be detected in 5 min or less.

These test kits are simple and rapid and require no complicated or costly instruments. A disadvantage may by the limited sensitivity of the assay and lack of multidimensional multianalyte capabilities. This immunoassay format is also known as the strip test, one-step strip test, immunochromatographic test, rapid flow diagnostic, rapid immunoassay, lateral flow immunoassay (LFI), on-site test or assay, or near-patient test.

To prepare large gold nanoclusters (40 nm) for immune-strip tests, heat 100 ml of 0.01% (w/v) tetrachloroauric[III]acid trihydrate ($HAuCl_4 \cdot 3H_2O$) to boiling under reflux conditions, and add 1 ml of 1% (w/v) trisodium citrate dihydrate under constant stirring. In about 25 the slightly yellow solution will turn faintly blue and nuclei are formed. After approximately 1 min the blue color changes to dark red, indicating the formation of sperical clusters. The solution is boiled for another 5 min. The optical density, measured at 540 nm, will be about 1. Add 0.05% (w/v) sodium azide for storage.

A standard immuno protocol might be done as follows: Blocking for 30 min at room temperature; primary antibody for 30–60 min at room temperature or 37 °C; rinse 1 with buffer; gold conjugate incubation for 30–45 min at room temperature or 37 °C; rinse 2 with buffer +2 M NaCl; rinse 3 with buffer; rinse 4 with distilled water. The binding is monitored in real time by observation of a developing absorption peak in a setup with a 125-μm aqueous top layer. Because any compound penetrating the polymer film will potentially react with the metal mirror layer (e.g., Ag mirror and chloride ions) and alter its optical and adhesive properties, care has to be taken to obtain distance layers without pinholes or cracks.

2.9. Assembly of Functionalized Nanoclusters and Nano-Objects

Any standard hybridization test can be done with metal cluster aggregation. It should be noted that the formation of particle arrays gives a very sharp signal due to the large number of interactions between different particles. However, this cooperative effect limits the dynamic range of the reaction. Because nanoclusters assemble only in the presence of a complementary DNA strand, the change in material properties induced by assembly can be used as an indicator of whether a particular sequence is present in a sample or not. Such signatures include the changing optical, mechanical, and electrical properties.

Based on the appearance of the second peak on cluster aggregation, a new analytical device was developed by Mirkin et al. [30–34]. The method is based on colorimetric detection of DNA and RNA based on mercapto-alkyl-coated oligonucleotide-modified gold nanoclusters. Introduction of a hybridizing oligonucleotide into a solution containing the modified particles results in the formation of a polymeric network of clusters. This aggregation of clusters

can be directly monitored as a red-to-purple-violet shift of the solution. Transfer of the aggregated cluster net to a silica matrix results in a shift of the signal to a clearly visible blue spot. The assay can detect femtomoles of oligonucleotides.

First assays (e.g., targeting anthrax bacteria) are extending now to clinical DNA detection. DNA arrays with DNA-functionalized gold nanoparticles assemble metal cluster arrays onto a sensor surface induced by the complementary target. The procedure even permits the detection of single base-pair mismatches. Gold nanoclusters are chosen as the major building block because of the ease of synthesis from tetrachloroaurate and citrate.

In a novel process, even small DNA-modified optoelectronic components are transported to the surface of a microelectrode by electrophoresis, whereupon sequence-specific oligonucleotide interactions direct component localization and binding. This biologically inspired method of component localization is a new approach to circuit fabrication. It provides self-assembly-based manufacturing methods as a substitute for pick-and-place technology.

The attachment of short synthetic oligonucleotides to gold nanoparticles in particular follows rules slightly different from those of the attachment of proteins or larger polyelectrolytes, which is due to the linear nature of the species. A preparation as cited above (Au colloids, 12 nm in diameter, 17 nM in particle concentration) is reacted with a 200-fold excess of a thio-functionalized oligonucletoide (3.5 μM) in water. The reaction is allowed to stand for 24 h at room temperature to allow reorientation at the surface and provide optimal space filling. About 80 molecules are assumed to immobilize to the surface of a 12-nm particle. The excess of oligonucleotides is removed by centrifugation. The particles show very good stabilities at high salt concentrations. However, to provide temperature stability at 70 °C and higher the linking group has to be modified. Either a multivalent thiol linker is applied or the particles are derivated with an alkylsiloxane. The oligonucleotides can then be bound covalently to functional groups in the surface of the coated particle. The test itself leads to the aggregation of nanocluster arrays. Two types of particles are coated with two sequences specific for the same target molecule. Upon addition of the target the particles bind to the target. Since any particle bears a large number of identical sequences, aggregation of particles will occur. The formation of these 3D arrays gives a detectable change that occurs upon hybridization of the oligonucleotides on the nanoparticles to the nucleic acid; this is a color change from red to blue.

To set up ordered nanostructures at chip interfaces, nanoarrays based on cluster monolayers became a growing area of experimental and theoretical research. Metal colloids and nanoparticles such as biopolymers, bioparticles, or even small polymer spheres in the size range from a few nanometers up to 5 μm have been used to form lithographic masks on surfaces. The masks consist of (often hexagonally) arranged monolayers of these particles.

When a droplet of the colloidal suspension is placed on a substrate, the masks form independently via a self-organized process. The deformation of the liquid film causes an attractive force between the nanoparticles: the lateral capillary force. Protruding nanoparticle caps deform the surface of the fluid and induce an attractive force between the

nanoparticles, which exceeds the thermal energy, kT. Often a nonmiscible solvent is used and the nanostructure forms upon solvent evaporation at the interface. With a floating technique, for example, the masks can be transferred to almost any arbitrary substrate. These nanoarrays have been utilized, for example, as masks for vacuum deposition of metal cluster arrays, plasma etching, or masters for nanoprinting.

Current research focuses on catalytic and chemical properties of nanodot arrays and the potential application of cluster monolayer lithography for the production of optical and electronic switches, guides, and memories.

2.10. Nanocluster Arrays by Biotemplating

Aggregated nanoclusters are excellent tools. A variety of analytical techniques use them to detect fluorescence, Raman scattering, atomic and magnetic force, and electrical conductivity. Hybridization of DNA is an excellent tool for directly and precisely assembling nanometer-sized structures. This methodology allows for the fabrication of materials with defined nanodevices to be used, for example, biomolecule sensing and separation technologies. The strategy is applicable to the synthesis of new nanostructured materials made from metals, semiconductors, and inorganic and polymer insulators. Nanosized assemblies are designed by changing the DNA linker and the particle composition and controlled construction and deconstruction of the materials by hybridization and dehybridization.

Nanotechnology is severely needed for lithographic methods applicable to pattern inorganic material at the nanometer-length scale. The nanoapproach for the fabrication of molecularly engineered nanostructures is the method of biotemplating [35–37]. This technique makes use of the well-defined structural, physical, and chemical properties of self-assembled biological macromolecular complexes.

Well-defined biolayers are used as templates for the buildup of organic and inorganic nanoassemblies. Thus, the bottom-up approach allows the setup of nanometer fabrication facilities via molecular engineering.

Biomolecular templating focuses on two different aspects:

- The geometrical shape of the template is employed for the fabrication of artificial nanostructures such as metallic nanowires, for example, by coating the specimens with thin metal.
- Large macromolecular assemblies built from identical subunits possess a regular structure.

The periodicity arises from the self-organization of biomolecules into ordered molecular arrays [38]. These layers are a precise spatial modulation of chemical surface that can be used to accomplish site-specific chemistry. In contrast to standard lithography, such as electron beam lithography, templating techniques provide the advantage of parallel fabrication. A well-defined deposition of metal and semiconductor clusters onto a 2D protein template was demonstrated by several groups. In a further processing step the metal is used for example, to set up a regular array of holes. The topology of the pattern is determined by the geometry of the template used. Thus, the deposited layer represents the intrinsic spatial structure of the underlying

protein monolayer. The protein template that is most often used is a bacterial surface layer (S-layer). These layers are regular protein crystals that form the outermost cell envelope component of many prokaryotes exhibiting different kinds of lattice symmetry (p1, p2, p3, p4, and p6). S-layers are 5 to 15 nm thick. The spacing between structural units varies from 3 to 30 nm. Isolated S-layers are suspended in a buffer solution (e.g., 50 mM sodium phosphate, pH 7.5, 1 mM $MgCl_2$, and 0. 02% sodium azide) at a concentration of ~2 mg/ml and stored at 4 °C. The possibility of coating two-dimensional arrays with perfect uniformity on solid surfaces or at liquid–air interfaces makes them an ideal biological template. A variety of clusters have been deposited on these films, including gold, silver, platinum, or cadmium sulfide. Well-defined sites are decorated with metal particles deposited from the aqueous or gas phase.

In the presence of protein, cluster formation is strongly accelerated compared with the reaction in pure solution. For *in-situ* generation of clusters on S-layer surfaces the protein is often activated by molecular deposition of metal catalyser, such as Au, Pd, or Pt from a metal salt solution. After activation the S-layer suspension turned from colorless to light yellow, becoming darker with increasing reaction time and thereby indicating metal deposition on the protein template. The activation kinetics were studied by recording the optical absorption of the solution. The chemical deposition of metal on the S-layer leads to the formation of highly ordered arrays of metal clusters. Well-separated, clusters are aligned along the crystalline structure of the protein template, reproducing the symmetry of the S-layer.

The usability of biological templates for such purposes has been proved not only for nucleic acids and S-layers, but even for microtubules and viruses.

Microtubules are highly ordered protein polymers consisting of regularly arranged α-β-tubulin dimers, which have a length of about 8 nm and a diameter of ~5 nm. Microtubules are useful templates for assembling small metal clusters. The surface of the tubulin molecules exposes a defined pattern of amino acid residues that provides a wide variety of active sites for nucleation, organization, and binding of metal clusters. Clusters formed organized arrays, ordered chains, and defined patterns, reflecting the regular arrangement of the tubulin subunits within the microtubule. Taxol-stabilized Zn induced two-dimensional tubulin sheets. It was shown that histidines are centrally located on α-tubulin. These histidines are easily accessible and correspond to the pattern of the metal clusters. Thus, it is assumed that these histidines are candidates for chelating noble metal clusters.

2.11. *In-Situ* Assembly of Clusters on Electrodes

Biosensors can be set up by *in-situ* assembly of colloidal particles on micropatterned electrodes. Microspheres or nanospheres from suspension are collected via electrophoresis or dielectrophoresis in the micrometer-sized gaps between planar electrodes. The assembled particulate patches are fixed by changing the colloidal interactions to induce coagulation, for example. Biorecognitive molecules on the nanoparticle surface bind the analyte molecules. A direct electric conductivity readout is made after labeling

with colloidal gold particles and, if necessary, by further enhancement with silver nucleation. The method is a basis for setting up disposable on-chip arrays for specific proteins, DNA, or other biomolecules [39].

Chip substrates are set up, bearing photolithographically fabricated metal electrodes with micrometer gaps between them. Nanospheres are suspended in a low-electrolyte aqueous medium and are collected in the gaps between the electrodes. A nonuniform alternating electric field is used to drive the particles via dielectrophoresis. Aggregated microspheres, however, do not exhibit enough signal and disassemble when the field is turned off. The critical step for binding the nanoparticles is to decrease the repulsive interactions and to coagulate the particles. Particles that are stabilized by electrostatic repulsion can be coagulated on an oppositely charged surface; particles stabilized by polymers or surfactants are deposited by washing away the protective layer. The detection is carried out by immunological tagging of colloidal gold clusters to the nanosphere layer. Before the test results are read, the gold particles might be enlarged and fused together via catalyzed deposition of a silver enhancement.

The readout is carried out by measuring the resistance between the electrodes. In the case of a positive immunological reaction, the electrodes become connected via thin metal bridges.

2.12. SPR Transduction

Surface plasmon excitation is obtained when photons are coupled into a metal/dielectric interface. These plasmons are resonant charge density oscillations at that surface of the metal. The wave is a perturbation of the electron plasma or, more precisely, a surface plasmon-polariton extending several tens of nanometers into the metal and up to 500 nm into the adjacent medium. The plasmon exhibits an exponential electromagnetic decay of the field perpendicular to the interface.

For SPR coupling the light must be at a well-defined angle to the interface. Any coating of the surface of the metal with an overlayer of varying ε will change the coupling angle of the resonant system. This change induces a shift in resonant angle up to a few degrees. Based on this principle and related techniques, various devices are commercially available directly (mostly without any label) that can transduce biochemical binding into a variation of resonant angle [40–42].

Although a direct transduction is very useful for basic interaction studies, its overall sensitivity is low. Thus based on the large difference in ε_{H20} and ε_{metal}, a significant increase in assay sensitivity was obtained by adding a metal nanocluster label to the assay.

The significant increase in sensitivity by nanoclusters has to be evaluated against the disadvantage of labeling the analyte.

2.13. Clusters as Nanoswitches

In recent years a first step has been taken toward synthesizing reversible molecular switches and integrating these switches into electronic circuits. Any digital microelectronic

device is based on switches known as transistors and diodes. Complex elements, such as flip-flops, are created from a combination of these simple elements. Two transistors are combined, for example, to set up a Schmitt trigger. A Schmitt trigger defines a bit of binary information as either zero or one.

In a recent development novel nanocluster-based devices turned the conductivity on and off by changing the oxidation state of a single molecule. Some organic molecules contain a redox-active center where reduction or oxidation can be achieved more or less reversibly. If they are sandwiched as molecules between electrical contacts they support quite large currents. The phenomenon is based on resonant tunneling, when the electron energy bands of the molecule overlap with those of the metal.

The effect has previously been shown with layers of an organic molecule containing the bipyridinium group (bipy). In a nano-approach, a molecule sandwiched between a gold electrode and a gold nanocluster serves as the molecular switch. A convenient setup can be obtained by attaching thiols to each end of the redox switch (one thiol at the gold electrode, the other at the gold nanocluster). To obtain a simple readout the tip of a scanning tunneling microscope might be used to record the current through the nanocluster.

New results show that changing the redox state of the bipy molecule can control electron transport between the gold electrode and the nanocluster. A switch based on these clusters might work with fewer than 30 electrons. When the molecule is in the reduced state, large currents flow through the device; when a certain threshold voltage is applied, the tunneling current decreases markedly. The threshold voltage corresponds to the redox state of the molecule used as a switch. A molecular trigger would operate too slowly and have insufficient gain to be applied as an electronic circuit.

Nevertheless, biointeractions coupled to a nanoparticle allow a novel type of biosensor to be set up. Such a device can detect single molecules or single chemical reactions. The system reported by Schiffrin adds a novel switch to a rapidly expanding list of switchable nanoelectronic devices.

In a related setup it had been shown that individual gold nanoclusters can be controlled by adding protons to molecules bound at the cluster surface. Future bioelectronic devices may thus be related to flip-flops well established in the microelectronic field.

2.14. Resonant Cavities

When a point defect is created in a regular cluster array, it is possible for that defect to pull a light mode into the band gap. Because such a state is forbidden from propagating in the bulk layer, it is trapped. The mode decays exponentially into the bulk.

Such a point defect, or resonant cavity, can be utilized to analyze biorecognitive interactions by opening or closing these defined spots via biorecognitive interactions. For example, such an array can be coupled with a pair of waveguides to produce a very sharp filter through resonant tunneling. Through a change in the size or the shape of the defect, its frequency can easily be tuned to any value within the band gap. Moreover, the symmetry of the defect can also be tuned. Point defects are already the heart of many other

non-biodevices, such as channel drop filters or resonant cavities, and enhance the efficiency of lasers.

2.15. Electroluminescence

To produce ultrasmall clusters, a thin film of silver oxide is treated with an electrical current of about 1 A. This creates a thin line of silver clusters of two to eight atoms. Under the influence of an alternating current these clusters exhibit electroluminescence, emitting light at a frequency that depends on their size. Experiments have shown that a high-frequency (>100 MHz) alternating current produces an electroluminescence response that is 10,000 times as great as that produced by a direct current. Whereas bulk materials cannot respond quickly enough to an alternating current, the alternating current creates rapid electron-hole recombination within single molecules in nanoclusters in a very narrow section of the sample. Similar fluorescence emission phenomena have been observed with nanoclusters of copper atoms.

3. NANOCLUSTER AND FIELD EFFECTS

3.1. Surface-Enhanced Optical Absorption

The optical properties of metal island films are used in surface-enhanced optical absorption (SEA), the so-called anomalous absorption. An absorbing cluster layer positioned at a defined distance from a metal mirror represents a special kind of reflection interference system. At a certain distance of the cluster from the mirror the electromagnetic field reflected by the mirror has the same phase at the position of the absorbing layer as the incident fields, and thus by this feedback mechanism the effective absorption coefficient of the absorbing layer is strongly enhanced. Since for a given interlayer distance the optimum phase is only given for a defined wavelength, the system is characterized by a spectrally narrow reflection minimum. The spectral position shifts sensitively with the cluster-mirror distance [43, 44] (Fig. 23).

The optical characteristics of the sensor can be modeled by either the stratified medium theory or the CPS theory developed by Chance, Prock, and Silbey. These theories focus either on optical thin films or on a cluster in proximity to a metal surface.

The stratified medium theory (SMT) can be applied for the calculation of any cluster films, whereas the CPS model
Figure 23. Field within SEA chip.

is best suited for single clusters. Application of the SMT is based on the complex optical constants in all three layers. Whereas optical constants of mirror metals (Ag, Au, Al) can be found in the literature, the optical constants of island films are strongly dependent on preparation parameters. Mostly they must be found experimentally. Standard methods for the determination of optical constants are based on independent measurements of the cluster film reflection and transmission. A (relative!) maximum of the signal can be obtained if the mean mass thickness of gold or silver clusters is around 5 nm. Depending on the number of bound clusters, the reflection varies by several orders of magnitude. With the use of optimized equipment, even single clusters close to the surface are visible as color dots.

Similar to interference-based systems, there are several regimes of reflectivity change. According to the selected cluster-mirror distance, the desired dynamic range of the system, the optimum wavelength, and the layer thickness can be tuned (Figs. 24 and 25). The spectral reflectivity minimum strongly depends on the cluster distance, and thus a thickness change of any interlayer will be visually observable upon white-light illumination by the altered color impression of the reflected light.

Resonance-enhanced absorption of nanoclusters is a novel means by which nucleic acids, enzymes, or binding proteins can be detected in a simple and reproducible way. The analytes induce binding or dissociation of metal clusters, which have been or will be bound at a defined distance from a reflecting, preferentially electron-conducting substrate surface. The binding or dissociation is transduced into a clearly detectable optical signal through resonant enhancement of clusters interacting with their mirror dipoles. Metal clusters or colloids are chosen with a diameter smaller than 100 nm, preferentially around 40–50 nm to suppress multiple peaks in the spectrum, to enhance diffusion and to avoid precipitation and coagulation during storage.

The setup is more cost effective than standard ELISA tests and reduces handling time through a novel one-step test procedure. Rapid and sensitive one-step test kits for clinical and lab use can be set up based on this technology. Possible fields of application include the diagnosis of urinary tract infections; screening of allergens; detection

Figure 25. Capture assay and cluster approaching the surface.

and quantification of pathogenic bacteria, glucose, and C-reactive protein; food identification, etc.

If the analyte interacts with the chip, it

- induces changes in the packing density of the cluster layer or
- induces changes in the spatial arrangement of bound clusters,

both leading to characteristic changes of the optical appearance of the sensor surface. The color of the surface is altered because of binding, catalytic activity, or a structural rearrangement of the analyte or a biorecognitive active component added to the mixture.

Given an optimized setup, the spectral position is highly dependent on the spatial arrangement, especially

- the distance of the cluster layer from an electron-conducting surface and
- the local variation in ε_m.

Moreover, the sensor setup can transduce changes in the extent of surface coverage with bound clusters into a clearly visible optical signal, by

- a strong change in absorption at a defined wavelength or
- a spectral shift of an absorption maximum.

To estimate the ultimate sensitivity of the chip, clusters with a diameter of 40 nm were arranged in a two-dimensional lattice of 150 nm, at an optical resolution of 1/200 mm, inducing a change of 10% of the signal, equal to 400 molecules. This sensitivity has been proved with an antigen–antibody setup that detects proteins. Decreasing the

Figure 24. Chip surface versus coating time of the interlayer (glass-type SnN$_x$).

optical field to around 1 μm permits monitoring of the resonance of single metal clusters bound to the chip surface.

The application of catalytically active analytes or labels such as urease is another way to increase the sensitivity significantly and allows single molecule detection.

Clusters (preferentially silver or gold cluster) can be bound by means of a variety of biochemical linkers at a defined distance from a mirror. A detectable signal will result if these linkers are either formed or cut by biochemical recognition or by catalysis, or if their spatial arrangement is altered. According to the setup, oligonucleotides, for example, are applied as linkers, which can then be cut by specific restriction enzymes from microorganisms. Many pathogenic microorganisms express specific restriction endonucleases and can therefore be detected by means of the new sensor without expensive instrumentation.

Because of their particle structure cluster films do not form a barrier of diffusion to gases or fluids. The analyte concentration can be measured with high sensitivity via visual inspection of the sensor surface. The intensity of the absorption band is directly proportional to the number of interacting clusters. Any reduction of the number of clusters results in a lowering of the absorption of the system at a high surface coverage in a spectral shift due to a change in cluster–cluster interactions.

Reduction of nonspecific background absorption of the sample measurement can be carried out at two angles of observation. Whereas absorption of chromophores is independent of the angle of observation, the specific signal shifts strongly, depending on the angle. Thus by simple subtraction of both signals the background resulting from matrix effects can be eliminated.

In addition to the cluster-based color, a thin film color might show up, based on the extent of phase difference of the multilayer system. This color depends on the thickness and refractive index of the interlayer film, the angle at which the light strikes the film surface, and the color of the light. If for a particular color the two reflected rays are in phase with each other when they rejoin, then they will combine to produce a constructive interference. If they are out of phase, they will eliminate each other and a strong color will appear.

3.1.1. SEA Biochips

Surface-enhanced absorption is an increased optical absorption of clusters in nanometric proximity to a wave-reflecting surface. Total enhancement in absorption of spherical metal colloids is at least 8-fold, and relative adsorption enhancement is more than 100-fold and independent of the method of application of sputtered clusters but depends on the attachment of clusters under given conditions [45–50].

A SEA biochip consists of a mirror layer on a substrate surface (mostly metal), an inert distance layer, deposited by spin coating or chemical vapor deposition, on top of which individual biorecognitive molecules are arrayed.

After incubation with the analyte, clusters are bound with protein or DNA-coated colloidal particles. This binding step can be monitored in real time if required. Such direct and sensitive kinetic monitoring makes it possible to transduce a number of molecular binding events into an macroscopic optical signal visible to the eye.

To relate the number of individual clusters to the optical signal obtained, scanning techniques based on STM and AFM are employed. An interlayer deposited via spin coating of polymers and activation of the sensor surface by plasma chemistry permits cost-efficient, small-series production. For large numbers and high quality, interlayers deposited by sputter or CVD techniques are an excellent choice.

Any conventional ELISA can be adapted to the new detection protocol transducing various antigen-antibody interactions (Figs. 24 and 25). To test for *Escherichia coli* proteins as impurities in commercial drug produced via genetic engineering in *E. coli*, anti-*E. coli* (IgG) was coated on gold colloids. *E. coli* proteins are microdotted onto the chip SEA surface. Upon incubation of *E. coli*-covered sensor surfaces, the anti-*E. coli*-coated colloids bound to the sensor surface and the proteins developed a color visible to the eye. The detection limit of *E. coli* protein was in range of fmol/mm^2. For the study of multistep interactions, antibody detection with recombinant protein G-coated clusters proved to give excellent sensitivity.

A significant advantage of surface-enhanced optical sensors is the ultrahigh density that can be achieved with printing techniques on surfaces similar to a CD-ROM or DVD (digital versatile disk). Areas of 1×1 μm can easily be read out with rather cheap and simple devices based on a commercial CCD camera chip at prices as low as 1–2 Euro.

Because of the ultraflat, high-quality surface, array-based sensor chips are easily set up by photolithography, microdotting, or inkjet printing. With these techniques thousands of molecules, such as ligands, proteins, or oligonucleotides, are immobilized in a well-defined array on a SEA chip fully compatible with glass-slide-based systems (Fig. 25).

It should be noted that up to a wavelength of 600 nm the optical properties of SEA sensor chips covered with chemically synthesized clusters are equivalent to chips covered with sputtered metal clusters. At any wavelength substantially above 600 nm sputtered cluster layers show optical properties dramatically different from those of crystalline colloids attached to the polymer surface via affinity interactions. This results from the difference in shape as well as from varying degrees of crystalline nanostructure.

During a gold colloid synthesis based on the procedure of Frens, significant changes in the color of the reaction mixture occur. Upon the addition of the reducing agent to a boiling yellow gold solution, the color changes within minutes from black to dark blue to violet and finally shifts suddenly to red. By comparing the absorption spectra of the reaction mixture as a function of time during the synthesis, one finds that the characteristic sharp absorption peak of nanocrystalline colloidal gold develops only slowly. Earlier stages of the synthesis absorb light also substantially above 600 nm, which can be isolated by a rapid cool-down or the addition of metal ions blocking crystallization of the gold cluster.

If such glass-type noncrystalline colloids are applied, in a surface-enhanced absorption setup resonance enhancement at $\lambda > 600$ nm is significant. This makes it possible to shift the desired absorption peak all over the visible spectrum to IR and therefore to wavelengths favorable for technical reasons of measurement, such as matrix absorption or light source.

Summing up, a direct, even kinetic monitoring of biomolecular interactions is achieved by transforming a molecular binding event into an optical signal visible to the eye. The optical sensor permits the setup of one-step assays because detection does not necessitate any extra incubation steps. Surface-enhanced absorption transduces changes in surface coverage of submonomolecular cluster layers.

As substrates glass slides (e.g., Corning or Menzel), aluminum foils and polycarbonate or polyethyleneterephthalate sheets (Goodfellow-UK) hydrophilized by oxygen-plasma etching proved to be suitable.

On a polymer chip the deposition of a mirror layer is necessary. Silver, aluminum, gold, or gold-palladium is deposited by DC or RF sputter-coating. Under conditions of glow discharge, ion bombardment of the cathode will occur; this results in the erosion of the cathode material and the subsequent omnidirectional deposition of the sputtered atoms, forming coatings of the cathode material. The most common arrangement for sputter coating is to make the negative cathode the target material to be sputtered and the location of the chip the anode so that the chip is effectively at "ground" potential; for high-throughput coating a low-frequency AC double-electrode source should be used. The pressure is obtained by a rotary pump (if necessary combined with a turbomolecular pump). For metal coating argon is bled into the chamber. Sputtering has to be optimized for the optical quality of the metal film (highest possible reflection) as well as adhesion of the metal film on the support and applicability of the metal film for spinning of varying polymer dilutions. Attachment of silver, gold, or gold-palladium on glass is rather poor; thus, adhesion layers of tungsten, chromium, or titanium are required. At lab scale sputtering is carried out in a sputter coater, for 60–120 s, at 0.1 mbar argon and a power of up to 500 W.

As prefabricated mirror substrates, aluminated or titanium coated polyethyleneterephthalate can be applied instead of the above substrates. Moreover, highly polished metal foils or sheets can be used provided that their surfaces are sufficiently reflective. The chemical stability of the mirror is excellent for gold, whereas Ag darkens quickly and Al is often etched in an aqueous environment if the solvent can penetrate the protecting distance layer. Please note that chloride-based buffers easily dissolve standard adhesion layers used for gold or silver mirrors such as chromium or tungsten.

To obtain the desired resonance an interlayer tuned to the appropriate optical thickness is coated on the mirror. One way to achieve this is by spin-coating of polymer layers. Adhesion of the polymer film on the metal or mirror surface is critical for chip stability. A nanoscale film of hexylpolymethacrylate (with an average molecular weight of 400,000) (Aldrich) is applied by spin-coating at 4000 rpm with varying dilutions of the polymer in AZ 1500 Photothinner (Hoechst) and n-decane (Sigma). The appropriate solvent for the polymer should be chosen depending on the molecular coating of the metal film. The thickness of the interlayer is best studied with atomic force microscopy.

For further chemical derivation the etching of polymer layers by oxygen plasma is vital. The polymer surface is etched, for example, with oxygen plasma for 10 s at 45 mA at an oxygen pressure of 0.1 mbar. Strong hydrophilicity is observed by exposure to oxygen plasma.

Another method of chemical activation of the polymer and attachment of biomolecules is the chemical breakdown of the polymer surface. A way to create functional -COOH groups at the surface of an ester polymer is to hydrolyze the bonds of the polymer. Hydrolysis is achieved by incubation with 2–4 N KOH. To limit polymer damage by total ester hydrolysis, reaction time should be less than 10 min. No substantial deterioration of film stability is observed; however, a slight film hydrophilization is observed. For application the protein is coupled covalently to carbodiimide-activated surfaces or is bound via noncovalent absorption to a plasma-etched polymer. For most applications simple adsorption is sufficient to bind the ligand layer to the polymer surface, adapting know-how from ELISA technology.

Most polymer-based chips need an oxygen plasma treatment to achieve sufficient adhesion of metal or polymer layers to the chip. The surfaces of the chips are functionalized by oxidation in plasma. The latter step greatly increases the hydrophilicity of the surface and allows better handling in combination with any standard assay format. The chip is inserted into the substrate holder inside the vacuum chamber of the sputter coater. The chamber is evacuated, and after the chamber is washed with oxygen (or air) at a pressure of 1 mbar, the pressure is adjusted to 0,1 mbar. Next, around 8 kV (AC, 20 kHz) is applied, which results in the ignition of a plasma. A plasma is formed between an aluminum target and the metal wall of the sputter coater ($P = 35$ W). The activated oxygen atoms bombard the chip surface and perform an oxidation reaction there. Thereby surfaces can be cleaned from organic substances and polymers can be rendered hydrophilic. In the case of polymers the oxidation reaction results in a wide variety of oxidized forms of carbon: hydroxyl, carbonyl, and carboxyl groups. Carboxyl groups are generated only at a minor percentage of the whole number of reactive groups formed at the surface of such plasma-activated polymers.

To functionalize the interlayer so that DNA, proteins, or thin films can be covalently attached, silane derivatives can be bound and cross-linked to form a stable monolayer or thin film by backing the chips at 105 °C. A silane layer serves as an adhesion layer for a variety of polymer, ceramics, glasses, and even nanocluster films. For vapor phase-coating techniques the silanes need a considerable vapor pressure to guarantee a sufficient adsorption rate. Two techniques might be employed to coat the chip with a stable silane layer.

Vapor coating is done to achieve a very homogeneous coverage. The chip surfaces are cleaned by subsequent washing with isopropanol, ethanol, and water or under reactive oxygen plasma. Both the chips and the silane or silane solution are placed in a vacuum chamber, to which a vacuum is applied with a membrane pump for several minutes. After the pump is turned off, silane fills the evacuated chamber and attaches to all of the surfaces therein. The adsorption process takes about 4 to 6 h but is usually done overnight. Subsequently, the chips are heated for 1 h to 60 °C or 10 min at 105 °C. Heating is necessary to cross-link silane molecules with each other and the surface by condensation.

To obtain a thick and cross-linked silane layer the coating is done from solution. The surfaces to be coated are cleaned

by washing with isopropanol, ethanol, and water. The silanes are diluted in ethanol at concentrations from 0.01% to 5%, and an equivalent amount of distilled water is added to the solution. Depending on how fast the reaction should occur (maximum of a few minutes in 5% solution) and how much a monolayer is desired (a few hours in 0.01% solution), the concentrations and periods of immersion in the silane solutions are chosen. Thereafter, the chips can be dried directly, strongly increasing the tendency to form multilayers, or the chips are washed with isopropanol to remove access silane. Then the chips are heat-treated as given above.

The gold clusters are labeled with proteins by first dissolving the protein in 200 μl of water at 1 mg/ml. Serial dilutions (1:5 to 1:10) of the protein in distilled water are prepared with 100 μl of each. Five hundred microliters of the pH-adjusted gold sol is added to each tube, and after 10 min 100 μl of 10% NaCl in distilled water is added. Tubes that contain enough protein to stabilize the gold sol maintain a red color even in the presence of electrolytes. Flocculation takes place immediately if the gold sol is unstable, and the red color turns to violet and blue. The amount of protein considered sufficient corresponds to the second tube containing more protein than the one whose color changes to blue. The success of conjugation can of course be followed spectrophotometrically. The maximum absorption of the colloidal solution is at $\lambda = 520$ nm. Once the optimal pH and amount for adsorption has been determined, large-scale protein-gold complex preparation (500 ml to $\times$ l) is carried out. The optimally stabilizing amount of protein plus about 10% is dissolved in distilled water and filtered through a 0.2–0.45-μm filter. The pH of colloidal gold is adjusted, and then the sol is added to the protein solution. The mixture is incubated overnight. The cluster is washed by centrifugation the next day, and thereby the excess of protein is removed. After cluster particles are pelleted, they can be resuspended in a small volume for the preparation of more concentrated solutions.

Most protein-gold conjugates retain their biological activity for months in the refrigerator at 4 °C with 0.02% sodium axide added to the buffer solution. Good bioactivity preservation for a longer period is also obtained upon storage at −20 °C in the presence of 45% glycerol.

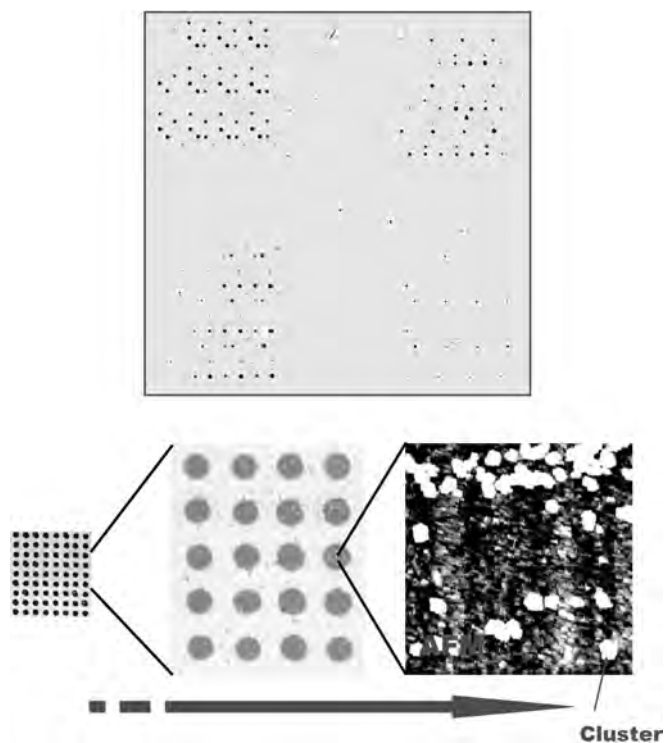
To set up a polymer-interlayer SEA biochip, the following protocol might be employed. Onto mirror-coated glass chips or metallized plastic a 6% solution of polyhexyl metacrylate is applied by spin coating (5000 rpm). The surface of the thin film is functionalized under oxygen plasma. Capture proteins are bound via adsorption or EDC coupling (2 h, RT). After several washing cycles the chip is incubated with the analyte for 1 min (analyte at mmol/liter) to several hours (analyte at nmol–pmol/liter). Gold colloids 14–40 nm in diameter, coated with the secondary capture protein, are added and bind to the analyte at the surface. Aggregation of clusters or nonspecific binding is prevented by the addition of 0.1% Tween 20. The reaction is followed visually or via a CCD camera (Fig. 26). The chip is scanned in direct reflection mode (no standard scanner applicable!).


Figure 26. Optical and AFM scan of a cluster biochip.

3.1.2. Nanodistance Transduction via SEA Biochips

The "metal island coated on reactive interlayer system" (MICORIS) is an optical thin-layer system consisting of a mirror, a transparent interlayer (in this case represented by the active analyte-induced swelling or shrinking macromolecule), and a metal cluster (island) film as the topmost layer.

Because of the special optical behavior of the cluster film and the special layer design, this system shows a characteristic spectral reflection behavior cited above. Thus the setup is strongly dependent on the thickness of the transparent interlayer (Fig. 27).

The visual impression obtained by observation of the reflected light upon diffuse white light illumination of MICORIS in the interlayer optical thickness ranges up to
Figure 27. Shift in optical response induced by a change in the reactive interlayer.

1 μm of optical thickness (thickness × refractive index). There is sufficient color contrast for visually distinguishing thickness changes of a few nanometers, and with elaborate equipment even sub-nanometer changes are easily detected. Swelling or shrinking of the interlayer molecule is equivalent to changing the cluster-mirror distance.

The response of a MICORIS sensor induced by different analytes is fully reversible if the interlayer can perform a reversible conformational change. Thus, for example, the spectra obtained upon variation of ions in a number of polymer layers can be compared with calculated spectra and calibrated in effective thickness. The increase in absorbance (which corresponds to a decrease in reflectance) at a certain wavelength is an appropriate measure for the interlayer thickness change. For small changes a linear relation between absorbance and thickness change can be assumed.

As a typical polymer, polyvinylpyrrolidone cross-linked with sulfonated bisazidostilbenes exhibits ion-dependent shrinking and swelling, which can be observed by using this polymer as an interlayer polymer in a MICORIS device. The response of the sensor depends on the type, the charge, and the concentration of the ion. It is fully reversible and, because of the direct exposure of the very thin swelling polymer layer to the analyte, a fast volume change. As a chemical sensor the MICORIS system was used to monitor different ions, pH, organic solvents, and polyphenols [51–56].

Moreover, with this device, it could be proved that polyvinylpyrrolidone is an excellent model for protein behavior. Because of its related polyamide structure the effects of chaotropic agents on polyvinylpyrrolidone polymers and on proteins are very similar. Chaotropic agents not only interact with the surface of a polymer, but increase the free volume of polymer chains. A comparative study of the ion effect with a cross-linked polyvinylpyrrolidone polymer demonstrated a fundamental correlation of the polymer swelling properties with the "Hofmeister series" of chaotropic agents. The ion effects are in good accordance with the molecular theory of chaotropic agents. The experiments showed, moreover, that the device can directly and dynamically monitor volume changes in polymer layers with a thickness of only one or several molecules.

A wide variety of polymers or biopolymers cross-linked for gel formation are suitable sensory materials. Cross-linking has to be adapted to the chemical properties of the polymer. In most cases a distinct reversible color change is observed when the concentration of an ion in a buffered solution is changed.

For medical applications ion variations are established with a buffer system similar to that of human blood. Variations of chloride induced within the pathological concentration range are transduced by cross-linked polyvinylpyrrolidone after the exclusion of large proteins from the polymer. No or only minor pH-induced changes were observed at blood pH. Thus between pH 5 and pH 8 ion effects can be well separated from pH effects. The volume response of the sensor induced by different ions is fully reversible over more than 500 cycles.

Regarding a wide concentration range, a sigmoid logarithmic calibration curve of polymer-based sensor is obtained with monovalent cations and anions. Bivalent cations induce a more complex behavior of the polymer gel. The calibration curve for Ca^{2+} is an overlay of the sigmoid logarithmic shrinking curve with a swelling effect at high ionic concentrations. Because of the direct exposure of the active swelling polymer layer to the analyte, an immediate response (within seconds) to changes in ionic environment can be observed.

Similar to a polymer, any protein is a suitable sensor layer [57, 58]. However, since most proteins do have a globular shape it is necessary to cross-link protein to form a thin-film gel pad without destruction of the three-dimensional structure. Thus the proteins should undergo volume changes but never dissolve. To build a sensor array various proteins representing a spectrum of properties can be chosen and applied to the chip. To coat the total chip surface with a homogeneous protein gel layer, a spin coating of proteins is superior.

Covalent layer-by-layer immobilization has distinct disadvantages in reproducibility and in the degree of cross-linking. An ordered protein film with a high degree of cross-linking turned out to have less flexibility of chain folding and thus less response.

To obtain a protein conformation array, protein gel pads have to be deposited via a microarrayer. Similar to spin coating, a cross-linking procedure within the deposited protein dot leads to the formation of a small (0–250 μm) gel pad. In contrast to microdotting for binding assays, the concentration of the protein solution microdotted as 1-nl microdots is reasonably high, with up to about 5%. Cross-linking is achieved similar to spin-coated layers.

In addition to the direct techniques described above, surface-enhanced optical sensors can also transduce the action of an enzymatic label, for example, by application of a pH- or ion-sensitive distance layer performing reversible volume changes upon, for example, a pH shift.

A setup can be as follows. Proteins to be assayed for their binding of pharmaceuticals are immobilized to the sensor. Urease is coupled to an anti-protein antibody as a label. Binding to receptors on the sensor surface occurs in a narrow compartment. Upon incubation with urea the enzyme will produce ammonium and carbonate, which will lead to local pH and ion changes that are reversibly transduced into a macroscopic optical signal. This setup offers the highest spatial resolution and the direct use of ELISA protocols.

In the following some experimental protocols should ease the application of this promising technology:

Coating of a polymer interlayer: Any solid surface with sufficient optical flatness can be used as a support. The supports are carefully cleaned by sonication in a detergent and washing in ultrapure water for 24 h. Immediately before the first deposition step the supports are treated in a plasma cleaner (nitrogen or oxygen plasma) to remove any organic contaminations. Deposition of the mirror layer is performed by evaporation or sputtering of about 200 nm of a gold/chromium or silver/tungsten sandwich. The swelling polymer has to be deposited with sufficient thickness precision and uniformity. This is best done by spinning (3000–5000 rpm). If a dip coating method is used, the formation of crystals from the cross-linker must be avoided by lowering the crosslinker concentration. A universal swelling polymer is synthesized according to the following procedure: stock solutions containing 2.5%

(w/v) PVP (polyvinylpyrrolidone, MW = 360,000) or 5% (w/v) MA-PVP (polyvinylpyrrolidone-dimethylaminoethyl methacrylate quarternized) in distilled water and 0.75% (w/v) DIAS (4,4′-diazidostilbene-2,2 disulfonic acid disodium salt tetrahydrate) in distilled water are mixed (3:2 v/v). The sensor support is coated and dried. Cross-linking is done by exposing the chip to the light of a UV 50-W Hg medium-pressure lamp for 5 s. Over-cross-linking will induce cracks in the layer; insufficient cross-linking will result in dissolution of the film. Finally, a metal cluster film is deposited, for example, by evaporation of gold onto the polymer surface. The mechanism of island growing strongly depends on the mobility of single metal atoms on the support surface. For PVP this criterion is widely fulfilled. If necessary the metal cluster film can be replaced by covalent or adsorptive coupling of colloids to the polymer surface.

Spin-coating and microdotting of proteins: To set up an appropriate resonance interlayer it is vital to deposit a polymer film by spin-coating or microdotting. For low-resolution-low-prize applications, highly polished aluminum chips (diameter: 12 mm; thickness: 0.5 mm) served both as support and mirror layer in a polymer-based chip design; for high-performance applications sputter-coated chips are used. Typically, a nanoscale film of protein is coated onto the surface by spin-coating of a solution of the protein (5%) at 4000 rpm for 30 s. For microdotting the solution given below is dotted onto the chip with the use of, for example, a pin and ring arrayer. Care is necessary to avoid excessive illumination during microdotting; otherwise the protein is already cross-linked in solution and thus precipitates.

Cross-linking of reactive proteins: Some proteins are applied with a 5% (w/v) solution of the protein in deionized H_2O. Cross-linking is done by exposing the chip to the UV light of a Stratagene DNA cross-linker at 25 mJ for 5 min. At the wavelength employed (about 300 nm) aromatic amino acids (Tyr, Trp, Phe) and thiols on the outside of the protein are activated and thus couple to other proteins as well as to the surface of the support. Finally, either a gold cluster film (mass thickness ∼5 nm) is deposited by sputter coating (0.1 mbar Ar) onto the protein surface with the use of a sputter coater, or clusters are coated from aqueous solution via chemisorption.

Cross-linking of standard proteins: Most proteins, such as glucose oxidase (GOD) and urease, require reactive photo-cross-linking. Stock solutions containing 5% (w/v) protein and a solution of 3% (w/v) 4,4′-diazidostilbene-2,2′ disulfonic acid disodium salt tetrahydrate (DIAS) solutions in distilled water are mixed in a 10:1 ratio (v/v). The solution containing protein and cross-linker are spin-coated on the chip and activated with a monolayer of an adhesion promoter as 1-(3-aminopropyl)-methyl-diethoxysilane. Silanization of aluminum-coated chips is done via gas-phase silanization with amino-silane in a vacuum desiccator overnight. The chips are baked at 100 °C for 30 min to cross-link the amino-silane. To remove unbound amino-silane the chips are washed with methanol and dried. Cross-linking of the spin-coated film is done by irradiation of the chips with UV light for 30 s (350 nm, 60 W). It is not recommended to use a DNA cross-linker because its emission near 300 nm causes DIAS decomposition. The gold cluster film is deposited by covalent coupling or adsorptive binding of

colloids synthesized in solution via citric acid according to the method described by Frens. Chemically synthesized clusters of 9–40 nm are concentrated (20-fold) via centrifugation and resuspension in H_2O and deposited by adsorption to the protein surface (1–3 min). Sensors are rinsed with H_2O.

Spin-coating of DNA: A 5% solution of herring sperm DNA is dissolved under vigorous stirring in deionized water. one hundred microliters of this solution is mixed with 40 μl of 3% 4,4′-diazidostilbene-2,2′-disulfonic acid disodium salt tetrahydrate (DIAS), spin-coated directly onto the chip surface at 4000 rpm for 30 s, and dried. The chip surface must be hydrophilized with oxygen plasma to increase the surface density of hydroxyl groups. The chips are activated with 1-(3-aminopropyl)-methyl-diethoxysilane. Silanization of aluminum-coated chips can be done via gas-phase silanization in a vacuum desiccator overnight. The chips are baked at 100 °C for 30 min to cross-link the amino-silane. To remove unbound amino-silane the chips are washed with methanol and dried. Cross-linking of the spin-coated film is done by irradiation of the chips with UV light for 60 s (350 nm, 60 W). A metal cluster film is deposited by sputter coating under high vacuum onto the chip surface with a turbo molecular pump (Varian, 10 s, mass thickness 3–5 nm). To increase stability, the chips are incubated with saturated NaCl for 30 min. This step is necessary to reach a more stable conformation of the polymer. In the last step the chips are washed with deionized water.

3.2. Resonance-Enhanced Fluorescence

Nanoresonant multilayer films have the potential to amplify the local field and thus to enhance the fluorescence signal of labeled biomolecules on biochip surfaces. Fluorophores are bound at a well-defined distance within the field of the resonant structure, resulting in enhanced absorption and emission of the fluorophore driven by the resonant field.

This amplification of fluorescence makes the system highly useful to the study of any type of interaction, including those of RNA, DNA, proteins, peptides, or any pharmaligand. Often biochips suffer from insufficient absolute signal or a low signal-to-noise ratio. Thus chips are limited to molecules of medium to high abundance, or long incubation times are needed to bind molecules from a large volume. Novel approaches are needed for the identification of regulatory proteins or low-copy RNA.

Enhanced fluorescence is a new technique that is useful for a variety of biorecognitive interaction systems strongly enhancing any fluorescence signals at a biochip surface. Compared with standard fluorescence assays, both the signal-to-noise ratio and the fluorescent intensity are considerably higher in this field boosting technology [45–67]. The novel approach of signal amplification is based on surface enhancement of the field and a direct influence on the excitation-deexcitation pathways (Fig. 28).

There are several setups, including nanoparticle layers, rough surfaces, surface plasmons in thin metal films, or multilayer waveguides—some with a microstructured surface—providing increased local field, resulting in a fluorescence amplification from 2 to 200 times.

Novel biochips based on nanoresonant layers of metal particles are among the best in enhancing fluorescence by
Figure 28. Decay of a fluorophore near a metal surface.

coupled resonant field effects. They are set up by a cluster layer deposited at the surface of the chip. By coating a second transparent nonmetal layer on top of the cluster film, the fluorophores are easily positioned at a certain defined distance from the resonant structure. A resonant interlayer is used to couple the energy from the metal film into the fluorophore. Two to three enhancement zones are found at well-defined distances from the resonant cluster film located at multiples of the wavelength of the desired fluorophore (Fig. 29).

To set up a REF chip, the substrate surface has first to be covered by metal clusters, which can be done by sputter or evaporation coating or by adsorption of metal colloids from an aqueous solution.

A cluster enhanced resonant chip is set up by

1. A layer consisting of a plurality of nanometric clusters, islands, or colloids of electrically conductive material (silver or gold for best plasmons!), which is applied to the surface of a substrate,
2. An inert interlayer tuned to the optical thickness which allows a resonance at the desired wavelength (thickness and refractive index are important!),
3. A biorecognitive layer at the surface, and
4. Biorecognitive molecules that are labeled with fluorophores.
Figure 29. Electromagnetic field in a multilayer system and fluorescence amplification in a Ag-cluster layer–SnN$_x$-interlayer system (0–700 nm).

A method for measuring the concentration of an analyte in a sample comprises the following steps:

a. Contacting the sample with a biorecognitive sensor layer.
b. Contacting the sample with an analyte-specific fluorescent compound.
c. Binding the analyte-specific fluorescent compound to the analyte, which in turn is bound by the biorecognitive layer.
d. Radiating excitation radiation which is suitable for excitation of the analyte-specific fluorescent compound (the quantum yield per molecule and per time of the analyte-specific fluorescent compound increase strongly in the vicinity of the cluster layer).
e. Determining the fluorescence radiation emitted by the bound analyte-specific fluorescent compound as a measure of the analyte concentration.

Fluorophores at the resonant distance (see above) show a significant gain in fluorescence compared with fluorophores in the bulk solution. Therefore discrimination between surface-bound and free fluorophores is possible.

Fluorescence is a two-step process: with absorption of light at wavelength A and emission of light at wavelength B. Steps a and b are driven upon interaction between the resonant film and the fluorophore. In absorption fluorophores and metal plasmons are oscillators driven by irradiated light. In emission, the fluorophore is the origin of radiation. The molecule is an oscillator with a resonant structure in its vicinity.

Multilayer resonant films exhibit a much stronger interaction with light than the fluorophore. Thus, the fluorophore is no longer directly driven by the irradiated light, while the excitation field distribution is strongly modified.

In surface plasmon resonance devices (SPRs) thin metal films are used as sensor elements. The field strength of the incoming light is enhanced by a factor of about 8-fold because of the resonant excitation of surface plasmon (not Mie) modes at the interface with the analyte solution. Irradiation of a cluster layer drives surface plasmons and Mie plasmons at their oscillation resonance wavelength. The intensity of this resonance strongly exceeds the intensity of the original light field without the cluster layer. Most energy is coupled into the Mie plasmon, whereas only about 1/10 is driving the surface plasmon of the film. The resonant interlayer is now driven by the plasmons. In a second step the fluorophore feels the enhanced light field of the interlayer and has consequently an enhanced absorption probability.

In photon emission, the fluorophore is a radiating dipole. The oscillator is influenced by the resonant layer nearby. Thus, an additional charge is induced and the emission process is enhanced. The influence of the layer can be considered as the buildup of a more efficient fluorophore antenna, leading to better radiation efficiency.

Fluorophores feel more laser light than standard glass slide-based chips and emit more photons per unit time. Given a good fluorophore, such as Cy3, Cy5, or fluorescein, the signal amplification will reach up to 8 on smooth films. In contrast to these smooth metal films, significantly larger enhancement factors of around 200 times have been observed for cluster structures. In these clustered films more

energy can be coupled because of Mie and surface plasmons. For a layer of silver a surface plasmon propagation length of more than a millimeter is found; nevertheless, this value is significantly reduced in stripe-like structures.

Annealing of metal films deposited on a glass substrate leads to self-organized metal cluster films (Fig. 30). As proved by Aussenegg, Schalkhammer, and recently Strekal et al., these films work for REF as well as SERS. Surprisingly, annealing at higher temperatures (300–400 °C) seems to drive SERS, whereas annealing at 200 to 300 °C drives REF.

To attach biomolecules to the chip (interlayer) surface all standard processes of immobilization can be used. Layers of various molecules such as polylysine or SAM of pentanethiol are beneficial for binding molecules at the ideal distance for REF well out of the quenching field of the metal surface.

In a special setup excitation of the cluster layer can be done with an incidental beam in attenuated total reflection (ATR) geometry. ATR geometry results in high background suppression of signals generated by molecules in the bulk solution, since a zone of just about 100 nm adjacent to the surface is irradiated. The enhancement effect of the metal particles contributes to this bulk suppression and further increases the signal-versus-background ratio of the method.

A modified protocol for REF in microtiter plates has been developed. This microtiter-plate-based REF setup performs kinetic single-step biorecognition assays with fluorophore-labeled compounds, using the fluorescence enhancement properties of well-bound silver clusters. Silver clusters are bound to standard microplates, mostly via silanization of the plastic surface. The use of standard microplates makes this method fully compatible with conventional microplate processing and reading devices. Neither excitation with coherent laser light nor ATR geometry is required; the measurement is performed in a standard fluorescence microplate reader.

Methods are adapted to coat clusters into microplates and set up the interlayer for fluorescence enhancement. In a standard protein bioassay the detection limit is in the picomolar range. The ease of colloid-surface preparation and the high sensitivity make fluorescence enhancement at colloid-coated microplates a valuable tool for studying reaction kinetics and performing rapid single-step immunoassays.
Figure 30. AFM scan of a silver cluster layer prepared via thermal curing at 225 °C.

According to the optical spectra, the absorption maxima of the different silver colloid preparations shift to higher wavelengths with increasing silver concentration used for synthesis of the colloids. This shift of the absorption maximum of Ag clusters from 400 nm to 470 nm reflects the increase in particle size and the multipolar modes of silver-cluster film prepared at higher silver concentration. Concurrent with the shift of the absorption maximum, broadening of the spectra is observed. This indicates multipolar modes and a loss of spherical shape at higher silver concentrations (around 6 mM silver; see protocols below).

The coating of clusters to amino microplates is followed by reading the absorption around 400 nm. The amount of colloid bound to the microtiter plate surface strictly increases with time. On incubation with 2–4 mM colloid solutions, saturation of the surface is achieved after 1 h. Colloidal clusters prepared from 6 mM silver solution need more time for adsorption and showed an almost linear increase for at least 2 h. The colloid adsorbed at the surface with respect to a given incubation time should not be linearly correlated between preparations of different sizes because of diffusion speed and agglomeration degree. To study the quality of the structure and the relative silver amount at the surface of the colloid films, scanning electron microscopy or atomic force microscopy is necessary. A homogeneous surface coating with silver clusters and a few larger crystallites should be obtained.

With a sputter coater a number of metals can be deposited as cluster layers, including silver, gold, palladium, copper, tin, and indium. These metals have rather low evaporation temperatures and can therefore be sputtered even at low energies. Metal is deposited as atoms, and if the surface temperature is high enough they migrate and finally assemble into clusters on the surface. These clusters usually are small, often flat, and asymmetrical. At higher coating thickness most clusters are interconnected after sputtering. Upon heating to 100–350 °C (Au up to 600 °C) the clusters melt and thus form round, noninterconnected nanoclusters. The sputter process itself is carried out in an inert or semi-inert plasma with an argon or nitrogen plasma. Standard targets are used, the chamber is evacuated to a vacuum of less than 10^{-2} mbar, and after the chamber is purged extensively with argon, the pressure is adjusted to 10^{-2} to 10^{-1} mbar. Please note that these pressure data vary depending on machine, metal, and size of chamber. Next a pulsed DC field is applied to ignite the plasma. The metal is deposited on the substrate. The thickness of the metal layer is adjusted by sputter time, pressure, and current.

Three modes are found:

- *Layer-by-layer growth mode.* The interaction between substrate and layer atoms is stronger than that between adjacent layer atoms;
- *Island growth.* The interaction between neighboring film atoms exceeds the overlayer substrate interaction, leading to an island growth; and
- *Layer-plus-island growth.* An intermediate case.

After formation of a layer, island formation occurs and islands grow on top of the first layer.

Thus, formation of islands or layers is dependent on both the metal and the surface. Furthermore, the nanostructure is

influenced by temperature and sputter gas. For example, silver on glass will preferably form islands, whereas chromium will form an adherent film.

To set up a cluster-layer-enhanced fluorescence chip, use standard microscope slides. The slides are coated with silver or gold clusters by absorption (see part on adsorption) or with a silver or gold cluster layer deposited by a sputter process. Nitrogen (Ag) or argon (Au) is used as the sputter gas. To "cluster" the film, curing at a temperature of 200 to 600 °C is required. (silver near 200–300 °C, gold around 400–600 °C). For increased adhesion of silver or gold to glass, a sublayer of an adhesion promoter is often required. Chromium, tungsten, titanium, or palladium (or a bilayer) is coated beyond the resonant cluster layer. By sputter-coating, an inert and hard distance layer is applied to the metal cluster film. Among other things silicon dioxide or tin nitride might be used. For tin nitride use tin as a target material and nitrogen as a sputter gas. Aging in air for several days is necessary to produce an adsorptive surface for tin nitride interlayers. Apply atomic force microscopy to study the surface of the film. For chip enhancement calibration, bovine serum albumin (BSA) (Sigma) is used to coat the entire surface at a concentration of 1 mg/ml in phosphate-buffered saline (PBS) (pH 7.4). Alternatively, 0.1% of polylysine can be used. After 20 min of incubation, the chip is washed with MQ water, and the surface is dried with air. Ten mg/ml N-(3-dimethylaminopropyl)-N-ethylcarbodiimide hydrochloride (EDC $\cdot$ HCl) is used to cross-link and activate the BSA surface (20 min, fresh!). Single-stranded DNA, amino-modified at its 3′ end, is diluted to 5 pmol/μl in PBS (pH 5.4) and microdotted at the chip (on EDC-activated surface within a few minutes after activation!). Polylysine is able to bind DNA without EDC activation via a strong ionic interaction. After microdotting, the chips are kept wet in a humidity chamber for at least 20 min (best inverted over a bath of warm water, small droplets should form were the microdots are!). The chip is washed with MQ water and dried. Adsorbed DNA is further stabilized by cross-linking with UV light. The analyte DNA is hybridized in SSC or Dig Easy hybridization buffer (1–16 h). Complementary DNA, Cy3, Cy5, or rhodamine labeled, is diluted in Dig Easy hybridization or SSC buffer to 2 pmol/μl and incubated for 15 min to 3 h. The chip surface is washed with 10 mM $MgCl_2$, 5% glycerol. The chips are dried and used for scanning.

For aminosilanization of polystyrene chips the chip is covered with ∼300 μl 10% (v/v) aqueous solution of 3-aminopropyltriethoxysilane. The substrate is protected via a lid and incubated for 60 min at 50 °C in a convection oven. The aminosilane solution is poured off and the chip is dried for 60 min at 50 °C without a lid. Excess aminosilane is removed by three subsequent washing steps with deionized water. Chips are dried in a dry air stream.

To prepare silver clusters for aminated surface coating (see procedures above), silver nitrate is dissolved in boiling double-distilled water, and sodium citrate in double-distilled water is added. The solution is kept boiling for 5 min.

A novel technique for coating with silver clusters might be employed [68]. In short: the reduction of Ag^+ ions by N,N-dimethylformamide (DMF), both in the presence and in the absence of a stabilizing agent, results in the formation of small cluster-type nanoparticles. The reduction can lead to the formation of either thin films of silver nanoparticles electrostatically attached to surfaces, or stable dispersions of silver nanoparticles if the silane (e.g., 3-aminopropyltrimethoxysilane) is present. Various parameters affect the reduction process and the reducing ability of DMF.

3.3. Surface-Enhanced Infrared Spectroscopy

Surface-enhanced infrared absorption (SEIRA) is a process that is highly dependent on the nanostructure of the matrix. The electromagnetic field effects as well as chemical effects contribute to the total enhancement process. The bands due to different vibration modes give rise to distinct enhancement processes, suggesting a "chemical" origin of this process.

In 1980 the first enhancement of chemisorbing molecules on Ag and Au surfaces was described. This phenomenon was later denoted as surface-enhanced infrared absorption. Of all the papers published on this topic, nearly half of them were printed within the last 3 years. SEIRA has several advantages over standard infrared spectroscopy and. SERS, such as nondestructivity and a remarkable signal-to-noise ratio. A full understanding of SEIRA is nevertheless required before it can be widely applied [69–71].

Samples used for SEIRA are prepared by methods similar to those used for SERS. A thin film of metal clusters is deposited on the chip. The effect is highly dependent on the appropriate nanostructure of the cluster film. In contrast to UV-vis techniques, silicon or germanium is the preferred substrate. The organic material to be analyzed is dispersed on the chip. Most studies point out that the effect is very short-range and applicable only to the first monolayer adsorbed to the surface. Some of the molecular vibrations are dramatically enhanced, whereas others remain unamplified. The models indicate that the molecule must be bound chemically with an appropriate orientation to the metal surface.

First applications of this concept were set up to detect *Salmonella* species. Antibodies to the organism are bound to the chip surface. The spectrum is recorded and the chip is placed in a solution with *Salmonellae* for a few minutes. A further spectrum is obtained and compared with the former. A band is observed at 1085 and 990 cm^{-1}, which after interaction with the analyte is shifted to 1045 cm^{-1}. The experimenters assigned this vibration to a phospholipid in the cell wall of the captured cell. Furthermore, the contour of the spectrum changes significantly.

3.4. Scattered Evanescent Waves

The setup first described and patented by Schutt et al. relies upon the detection of back-scattered light from an evanescent wave disturbed by the presence of a colloidal gold label brought to the interface by an immunological reaction [72]. The evanescent wave at the interface is the result of a totally internally reflected incident light wave. Placement of the

detector at a back angle above the critical angle ensures a superior signal-to-noise ratio.

The SEW assay relies upon the identification of the critical angle associated with total internal reflectance. The angle is largely a function of the refractive index of the material through which an incident light wave is directed (e.g., plastic) and the relatively lower refractive index of the material in which the immunoassay is being conducted (e.g., an aqueous solution). It is measured from a line perpendicular to the interface between the two materials (90° = plane of the interface).

Light directed through the chip toward the interface formed by the aqueous sample and chip surface layer at the critical angle will result in total internal reflectance of the light within the layer. Note that materials in the real world are perfect, and, accordingly, it is preferred that the incident light be directed toward the interface at an angle several degrees greater than the critical angle. At such an angle, the incident light, preferably from a laser, is totally internally reflected within the chip layer. Unlike conventional fluorescent techniques, this assay is flexible with respect to light wavelength, since particle size may be readily adjusted to match the available light source.

A light source such as a He-Ne laser is used, and still other sources suggest themselves, including light-emitting diodes and other non-laser-light sources.

The system is based on conventional immunoassay techniques. The system employs a cluster label (with a refractive index higher than that of the solution, and most preferably higher than that of the first light transmissive material, e.g., plastic). Such clusters (most preferably, colloidal gold) are used as a label for the solution-phase immunologically active component. Because of the interaction of the colloidal gold particles with the evanescent wave, light is decoupled from the evanescent field. Particles with an increasingly higher index of refraction than that of the underlying solid generally increasingly scatter light.

The detector is placed at an angle greater than the critical angle and in a location whereby only light scattered backward toward the light source is detected. This location thereby avoids the detection of scattered light within the bulk liquid medium.

3.5. Surface-Enhanced Raman Scattering

The extremely small cross sections of Raman scattering would preclude its use at the single-molecule level. However, this situation is dramatically altered for surface-enhanced Raman scattering. Molecules in close proximity to metal-cluster-coated surfaces exhibit large (typically 10^6-fold) enhancements in vibration spectral intensities. Even larger enhancement factors on the order of 10^{14} corresponding to effective Raman cross sections of $\sim 10^{-16}$ cm^2/molecule have been reported. These Raman cross sections are comparable to or even higher than fluorescence cross sections.

When a laser used to excite SERS is in resonance with an electronic transition of the substances (surface-enhanced resonance Raman scattering or "resonant SERS"), an additional 10^3-fold enhancement is obtained. SERS has been utilized in a wide variety of applications, including detection of molecules, elaboration of structure and function of large biomolecules, and elucidation of chemical processes at interfaces.

This assay format is particularly suitable for sandwich-type immunoassays and hybridization assays. The readout can only be done with standard instrumentation.

A wide variety of approaches were published for the setup, fabrication, and assembly of structures with the required nanostructure. These include evaporated metal films, cured metal films, aggregated colloidal metal sols, and electrochemically roughened electrodes. In all of these approaches, the substance studied by SERS is placed in direct contact with or close proximity to the surface.

At metal SERS substrates most biomolecules adsorb and denature. In contrast, biomolecules conjugated to colloidal gold often retain their biological activity.

The SERS intensities for standard colloids are often quite weak. To observe SERS signals from chromophores within proteins, it is necessary to drive them via the electromagnetic field of the SERS active surface. Thus, for proteins an additional step is required.

Placing a strong chromophore near the surface of a metal cluster generates a more suitable SERS active particle. The metal clusters are adsorbed to a metal chip surface, preferably in a sandwich-type assay. Thus, it is important to bind the protein to the surface of a colloidal particle and to bind the particle to the SERS active surface. Ideally the analyte is sandwiched between two SERS active clusters.

From theoretical modeling of SERS processes it clearly turned out that the enhancement process has to be divided into two categories:

- The short-range or molecular or chemical enhancement seems to rely on adsorption-induced changes in Raman susceptibility.
- The long-range electromagnetic enhancement is a manifestation of the strongly enhanced fields present at clusters and rough metal surfaces.

At present, the electromagnetic part seems to dominate the overall effect in most situations. Optical detection of single molecules on single clusters has been done with rhodamine 6G, and an overall amplification of the Raman signal of 10^{14} to 10^{15} has been obtained. This enormous enhancement leads to vibration signals that are more pronounced and stable than single-molecule fluorescence. SERS enhancement is at least a factor of 10 higher with gold-coated silver particles.

Proteins are perfectly suited for adsorption to particles with gold at their outside surfaces. The SERS active surface is coated with the first antibody. The SERS active particle is created by coating gold colloids first with the second antibody and, if necessary, with a Hem protein. The analyte is sandwiched between the cluster and the surface. Devices providing two-dimensional resolution of the signal-generating surface can be used to apply the principle to array-type assays.

Standard performance of a SERS metal surface is highly dependent on the nanostructure. Whereas smooth metal films give only very small enhancement, the nanostructure of the surface has to be very defined to obtain reproducible results. Variation in the coating process may change the effect by orders of magnitude. In particular the particle size

and shape and, moreover, the grain boundaries within the particles contribute to the effect. Grain boundaries are sufficiently different from the bulk material to support local plasmons. Most pronounced effects are found at larger grain sizes of 30–200 nm. This might be explained by an increase in volume plasmon damping of around 10 times observed in Al if the grain size is small.

Recently it has been shown that the tip of an atomic force microscope can be used to selectively excite surface-enhanced Raman scattering. A conventional AFM tip can provide spatially selective enhancement of a Raman signal by SERS. The AFM tip is acting as a locally introduced nanometer-sized cluster from which enhancement mechanisms operate.

3.6. Cluster-Quenched Fluorescence

A molecular assembly setup of a small gold nanocluster, a fluorescent dye, and a ssDNA molecule is called a molecular beacon. The beacon is a nucleic acid probe with a hairpin-shaped structure in which the ends are self-complementary, bringing a fluorophore and a quencher into close nanometric proximity. The metal particle quenches the fluorescence of the organic molecule because of near-field deexcitation. The fluorescence is restored when the probe binds to a complementary nucleic acid and refolds.

Beacons or molecular beacons exhibit one main advantage: easy direct detection of unlabeled oligonucleotides. Nevertheless, a limiting factor is the fluorescence quenching efficiency due to the background generated by nonquenched fluorescence. An organic quencher such as 4-((4′(dimethylamino)phenyl)azo) benzoic acid quenches down to 1% or residual fluorescence of the dye placed in its proximity. The quenching efficiency decreases for dyes emitting at longer wavelengths. A better quencher would greatly increase the dynamic range and, moreover, the sensitivity of molecular beacons. Small metal nanoclusters can replace organic molecules as a quencher of fluorescence. Because of strong near-field effects they quench fluorescence as much as 100 times better. The extremely high quenching efficiency opens new perspectives for beacon probes in fluorescence-based assays [73] (dynamic range (DABCYL/gold cluster): fluorescein (71/172), rhodamine 6G (43/1000), Cy5 (27/68), Texas red (27/64).

Covalent linkage of a gold cluster and a fluorophore to ssDNA is done using a 25–30-base synthetic oligonucleotide modified with a primary amine at its 3′ end and a sulfide at its 5′ end. The oligonucleotide sequence is chosen to create a hairpin-loop structure because the five nucleotides at its extremities are complementary. The design of the sequence provides a hairpin structure at room temperature. Often a poly-TTTTTTT tail is used in the middle of the sequence to allow the proper back-folding of the DNA molecule.

Such a beacon opens easily on hybridization of the loop to the analyte DNA. A fluorophore (e.g., rhodamine 6G or cyanine dye) is attached with an amine-reactive dye to the 3′ end of the oligo. The protection group from the 5′ end is removed, and the free sulfhydryl is covalently attached to small 1–3-nm gold clusters. Either direct interaction with metal gold or N-propylmaleimide-coated cluster ("Nanogold") is used. An excess of gold clusters is necessary

to avoid multiple attachment. A high concentration of salt ensures that the ssDNA forms a hairpin.

The beacon is tested in a standard microcuvette. As the target hybridizes to the hairpin-DNA loop, the fluorescence rises considerably. The ratio of the fluorescence intensity is measured in the cuvette before and after the addition of the analyte DNA. Rhodamine 6G is the best quenched dye, with an average quenching efficiency of ∼99.5%. Some probes exhibit quenching efficiencies of >99.9%. High quenching efficiencies extend the dynamic range of molecular beacons from 50 to around 1000.

DNA hybridization technology is applied at a temperature at which the hybridization can discriminate between a perfectly matched probe and a mismatched one. The standard temperature is around 55 °C. This is not optimal for the quenching of the dye, because its average distance from the quencher increases with temperature because gold nanoparticles are unstable above 50 °C.

To overcome this problem and to be able to work at room temperature, buffers with low salt concentrations are used. A buffer containing 90 mM KCl and 10 mM Tris (pH 8.0) gives the best sensitivity.

Quenching of fluorescence by metal clusters results primarily from nonradiative energy transfer from the molecule to the metal. The surface provides an alternative nonradiative relaxation mechanism, resulting in the production of electron-hole pairs or surface plasmons. These mechanisms increase the nonradiative decay rate of the fluorophore. The nonradiative deexcitation involves dipole-dipole interactions, which are described by a Foerster-phenomenon. Thus, the nonradiative relaxation depends on the distance of the fluorophore from the surface of the cluster and on the overlap of the energy profile of the fluorophore and the cluster. The cluster relaxes radiatively or nonradiatively. Resistive heating as a result of fluctuating electric fields within the metal cluster is significant. With undecagold no quenching is observed. Small 1–2-nm-diameter gold particles show no sign of surface plasmon resonance, in contrast to larger particles, which exhibit a strong plasmon resonance at 520 nm. If necessary, the surface plasmon resonance of a metal cluster might be tuned precisely by changing the shape, the size, or the composition of the cluster.

In short: The amino-reactive dye is bound to the terminal 3′ amino group, the product is purified with a Sephadex column and fractionated on a C18 reverse-phase HPLC, fluorescent DNA fractions are collected and dried in a SpeedVac, the powder is resuspended to a final oligonucleotide concentration of 15 μM, the disulfide bond is cleaved, the oligonucleotide solution is purified by reverse-phase chromatography, and the elution product is suspended in water and immediately reacted with monomaleimido-gold clusters. The cluster-modified DNA is analyzed by gel electrophoresis.

3.7. Cluster Emission Devices

For detection of biorecognitive interactions, usually fluorophores are bound to the target molecule. However, fluorophores have a limited lifetime of $<10^7$ absorption-emission processes, resulting in a declining signal for consecutive measurements. A cluster emission device (CED)

provides a novel method for detecting biomolecules with far-field optics at single-molecule resolution [74].

Figure 30 shows a crosssection of a microchannel in which a protein (ligand) is labeled with a nanoparticle (cluster, nanofiber, etc.). Figure 31 shows a 30-nm gold cluster that has been bound at a microdotted receptor molecule on a biochip. When after evacuation a high voltage is applied to the bottom chromium electrode, the cluster will emit electrons toward the extractor (a 20-nm aluminum thin film on glass), making use of electric breakdown in the protein complex (Fig. 32). The thin film thus locally heats up and evaporates within milliseconds, clearing an area of about 1 μm^2. A microscope monitors the process by shining light from below through the thin (~20 nm) chromium electrode, displaying each cluster as a bright spot. The voltage should be pulsed to allow the device to cool down between evaporation cycles, and the polymer distance layer should have a high breakdown strength (>1 kV/mm).

The field-dependent transmission coefficient was calculated for the vacuum potential barrier in the right figure with the Wentzel-Kramers-Brillouin approximation. Integrating over all energies in a nearly free electron gas at room temperature resulted in an exponentially increasing I–V curve that reaches 1 nA at 0.7 kV. As proteins are insulators (band gap of >2 eV), electric breakdown is proposed as a conduction mechanism. As no reliable data are available on the intrinsic breakdown strength of single surface-bound proteins, an average of ~0.5 kV/μm for insulating polymers seems reasonable. Taking into account the enhanced electric field line density under the cluster at zero current, breakdown occurs at a voltage of about 200 V. Use of nanofibers further decreases the potential necessary for tip emission to less than 100 V. As an alternative to ablation, thermal oxidation in air may be used to create transparent areas within seconds; the required extraction potential may then be lowered because of plasma formation.
Figure 31. Cluster emission device. Proteins are insulators: band gap of ~2 eV, electric breakdown at ~500 V/μm, nanocluster-enhanced breakdown at about 3–200 V.
Figure 32. Cluster emission.

GLOSSARY

Cantilever sensor   A multi-micro-AFM measures the tiny forces acting on the sharp tips of a cantilever chip. By shrinking the cantilever structure to a microscopic size one obtains a low spring constant (high sensitivity), a high resonant frequency, fast response, and high immunity to external mechanical noise.

Electron beam-induced deposition (EBD)   Repeated line scan induces the polymerization of amorphous carbonaceous material along the path of the electron beam on the substrate, which appears as a black line in the SEM contrast. The lines are used for nanobonding of molecular devices.

Gold conjugates   Gold (sometimes silver or platinum) colloids are coated with protein or DNA in a 2–3-fold excess (for several hours). Excess of the ligand is removed by washing. Bioreactive clusters are used, for example, as detection agents or as nano-building blocks.

MCB junction   A mechanically controllable break device set up by breaking a small metal strip deposited on a chip via bending of the substrate and then attaching a single molecule to the nanotips formed.

Molecular beacon   The beacon is a nucleic acid probe with a hairpin-shaped structure in which the ends are self-complementary, bringing a fluorophore and a quencher into close nanometric proximity. The metal particle quenches the fluorescence of the organic molecule because of near-field deexitation. The fluorescence is restored when the probe binds to a complementary nucleic acid and refolds.

Molecular motors   Nanoscale motor based on proteins (rotary and linear) as ideal tools for nanoactuation and fabrication.

Nanocluster (nano-island, precipitate, colloid particle)   A number of atoms bound or arranged together, forming an assembly of nanoscale size. Metal nanoclusters exhibit tunable resonant behavior; semiconductor clusters show quantum-dot behavior.

Nanotweezer   Nanoactuators to pick nano-objects or move tiny structures. Tweezers consist, for example, of two carbon nanotubes. With the application of a potential, these tubes bend and thus the ends of the nanotubes open or close (compare optical tweezer using a laser beam).

Resonance-enhanced fluorescence (REF) Nanoresonant multilayer films have the potential to amplify the local field and thus to enhance the fluorecence signal of labeled (bio)molecules on biochip surfaces. Fluorophores are bound at a well-defined distance within the field of the resonant structure, resulting in enhanced absorption and emission of the fluorophore driven by the resonant field.

Resonant cavities Nanostructures with a high degree of symmetry are resonant in a way similar to that of, for example, micrometer-sized glass structures for light waves. Optimized design allows wavelength tuning via defined band-gap materials.

S-layer These layers are regular protein crystals that form the outermost cell envelope component of many prokaryotes exhibiting different kinds of lattice symmetry. S-layers are used for nanocluster arrays and biotemplating.

Scattered evanescent waves (SEWs) The setup relies upon the detection of back-scattered light from an evanescent wave disturbed by the presence of gold colloids brought to the interface by an immunological reaction. The evanescent wave at the interface is the result of a totally internally reflected incident light wave. Placement of the detector at a back angle above the critical angle ensures a superior signal-to-noise ratio.

Surface-enhanced infrared spectroscopy (SEIRA) Surface-enhanced infrared absorption is a process highly dependent on the nanostructure of the matrix. The electromagnetic field effects as well as chemical effects contribute to the total enhancement process. The bands due to different vibration modes give rise to distinct enhancement processes, suggesting a "chemical" origin of this process.

Surface-enhanced optical absorption (SEA) An absorbing cluster positioned at a defined distance from a metal mirror represents a special kind of reflection interference system. At a certain distance of the cluster from the mirror the electromagnetic field reflected by the mirror has the same phase at the position of the absorbing layer as the incident fields, and thus by this feedback mechanism the effective absorption coefficient of the absorbing layer is strongly enhanced.

Surface-enhanced Raman scattering (SERS) The extremely small cross sections of Raman scattering would preclude its use at the single-molecule level. However, this situation is altered for surface-enhanced Raman scattering. Molecules in close proximity to metal-cluster-coated surfaces exhibit large (typically 10^6-fold) enhancements in vibration spectral intensities. Even larger enhancement factors on the order of 10^{14} have been reported. These Raman cross sections are comparable to or even higher than fluorescence cross sections.

Purdue University, West Lafayette, Indiana, USA

CONTENTS

1. INTRODUCTION

The ability to perform active movement is one of the most prominent features that distinguish living organisms from inanimate matter. Nanobiomotors are nanoscale machines formed by macromolecular complexes that convert a primary energy source to mechanical motion between moving and framework components. They are responsible for most forms of active biological motion, including internal material transport. Motor complexes are vital to the sustenance of biological systems, and they support efficient, directional motility of cellular components within cells, adenosine thiphosphate (ATP) synthesis, the packaging of viral DNA, rotation of bacterial filaments, and muscle contraction [1–3]. Thanks to progress in structural biology, single molecule methods [4], and molecular biology approaches, our understanding of the molecular basis of biological movement has improved to the point where we can start thinking about possible applications of biomolecular motors in nanotechnology [5].

On a macroscopic scale, we are all very familiar with motors, because we are surrounded by both combustion engines and electric motors. So the question arises: can we downscale the way we think of motors to the molecular range? The possible applications of molecular motors in nanotechnology will certainly be very different from the way we use traditional macromotors. However, when we look at

the basic mechanisms of these motors, there are many striking parallels: just like macroscopic motors, biological nanomotors are assembled from static components that form a framework for moving components, even though the moving parts are not always restricted to rotary motion but can instead, in some motors, perform linear motion. Also, both macroscopic and molecular motors work by repeating the same cycle of steps over and over.

Another parallel is that biomolecular motors also need a primary energy source from which to derive mechanical energy. There is even a strong equivalence with the two types of energy sources, fossil fuels and electrical energy, that we most often use in conventional motors; some biomolecular motors are powered by breaking down an energy-rich bond of nucleotide triphosphates, typically ATP, just as our combustion engines break down the molecules of oil products. Yet other molecular motors are driven by the flow of protons along a proton gradient (i.e., an electrochemical potential across a membrane) just as electric motors are powered by the flow of electrons along an applied voltage. In fact, these two types of energy supply can be readily interconverted in biology: by sharing a rotating axle between two biomolecular motors, F_1F_0-ATP synthase [6–8] can convert the energy stored in the proton gradient to rotation and then to energy stored in ATP. The process is reversible and exhibits nearly 100% efficiency [1]. If we look at our macroscopic equivalent, an electric generator driven by a combustion engine, we must deal with efficiencies below 50% and an irreversible reaction: we cannot produce fossil fuel from electrical energy. These unique attributes of biomolecular nanomotors should be our focus as we contemplate possible applications. These features involve instances where molecular motors outperform conventional motors, or where molecular motors perform motions and tasks that have no conceptual equivalent in our macroscopic world. Such examples include the continuous specific translocation of single DNA molecules by the DNA packaging motor of bacteriophage phi29 [3, 9–12], the linear "walking" mechanism of the cytoskeletal motor protein kinesin [13–16], and the ability of the flagellar motor to switch between clockwise and counterclockwise motion [2, 17] (Table 1). There are many proteins and biomolecular machines (Table 2) that

Table 1. Well-characterized bionanomotors.

Name	Energy source	Functions
Linear motors		
kinesin	ATP	organelle transport, mitosis, microtubule dynamics
myosin	ATP	muscle contraction, organelle transport, cytokinesis
dynein	ATP	organelle transport, mitosis, cilia beating
Rotary motors		
F_1F_0 complex	H^+/ATP	ATP synthesis
bacterial flagellar	H^+/Na^+	bacterial movement, rapidly reversible motor
Nucleic acid translocating motor		
helicases	ATP	DNA strand separating activity
RNA polymerase	ATP	RNA transcription
viral DNA packaging	ATP	packaging of viral DNA

perform functions similar to those of the biological nano-motors covered in this chapter: G-proteins undergo ATP-driven conformational changes as part of their function [18–21], and the 19S subunit of the proteasome moves and unfolds proteins actively [22]. These examples of active work performed by biomolecules are enabled by the P-loop structure [23], a protein fold that is also present in the ATP-driven motors described here. Ion pumps [24] and active transporters [25] are also capable of converting a primary energy source into active work. However, for this chapter, we have restricted the term "bionanomotor" to those biological complexes that (i) have active mechani-

cal work as their main function, (ii) derive their activity through utilization of a primary energy source, (iii) function via the relative motion between active and framework components, and (iv) perform tasks through repetition of the same cycle of steps. We analyze the most thoroughly characterized biomolecular motors: F_1F_0-ATP synthase, the bacterial flagellar motor, myosin, kinesin, the viral DNA-packaging motor, helicases, and RNA polymerase (Table 1).

2. GENERAL CLASSIFICATION OF MOTORS-LINEAR, ROTARY, AND NUCLEIC ACID TRANSLOCATING OR SLIDING MOTORS

Molecular motors can be divided into linear, rotary, and nucleic acid translocating/sliding motors (Table 1) [26–32]:

2.1. Linear Motors

The motor proteins kinesin and dynein are the most commonly cited and studied examples of this class. They move along microtubules to induce directional motility of membranous vesicles, organelles, chromosomes, proteins, and RNA [32–38]. Another important member of the class of linear motors is myosin. It is involved in cellular motility, cytokinesis, endocytosis, and vesicle transport. In muscle fibers, bundles of myosin act on actin filaments, thereby driving muscular contraction [39].

2.2. Rotary Motors

The F_1 ATPase and bacterial flagellar motors are common representatives of this class of motors. F_1F_0-ATP synthase is a double-rotary motor located in the mitochondrial, bacterial, and chloroplast membranes. This motor is responsible for ATP generation and is powered by a proton gradient [1]. Bacterial rotary motors drive the spinning of flagella and therefore make active swimming of bacteria possible [2].

2.3. Nucleic Acid Translocating or Sliding Motors

There is a group of nucleic acid-processing complexes that plays a similar role in DNA or RNA translocating, tracking, or sliding related to DNA replication, translocation, recombination, and RNA transcription [36, 40–42]. It can be categorized into two subsets, components that bind nucleic acid and components that act on nucleic acid. The common feature of these two subsets is that they interact with RNA or DNA in a polymer conformation with a ring-shaped morphology. Most members of this group are hexamers. This subset includes helicase [43, 44], viral DNA-packaging motors [45–48], DNA polymerase [49], RNA polymerase [50], the *E. coli* transcription termination protein Rho [51, 52], the yeast DNA polymerase processivity factor [53],

bovine papillomavirus E1 replication initiator [54], and the *E. coli* DNA polymerase III holoenzyme [55, 56], which exist as hexamers [43, 57–60]. Though the mechanisms of this kind of DNA–protein interaction remain to be elucidated, the finding of the common feature in the formation of hexameric ring indicates it might have something in common. The process of both viral DNA packaging, DNA replication, RNA transcription, or DNA/RNA riding involves the relative motion of two components, one of which is nucleic acid. In bacterial virus phi29, the motor involves a novel RNA that forms a ring with six subunits [42, 61, 62]. It would be intriguing to show how phi29 hexameric pRNA may play a role similar to that which protein enzymes, such as DNA-helicases or the termination factor Rho, play.

Some members of the subset that acts on nucleic acid require ATP to provide energy and play an active role in motion. These members will be placed in the category of nucleic acid translocating or sliding motors. Most motors contain members of the other subset, proteins that bind nucleic acid. This chapter will only cover the well-studied motors, such as DNA helicase, RNA polymerase, and the viral DNA-packaging motors. Some, if not all, of the motors in this group might rotate. Since the action of these motors has yet to be further characterized, they are tentatively classified into this special category.

3. COMPONENTS OF MOLECULAR MOTORS-MECHANICAL FRAME AND ENERGY SUPPLY

Molecular motors exhibit wide variability in structure. Most are quite complex, but in general the structures consist of the same essential components: a mechanical frame that consists of both moving and static parts, along with an energy supply. The mechanical frame is formed by proteins in most molecular motors. However, the DNA-packaging motor of bacteriophage phi29 also includes a hexamer of RNA molecules as an essential component [63], F_1F_0 complex is located in a lipid membrane, and the flagellar motor is anchored to the cell envelope. The energy supply can be from energy-rich nucleotide triphosphates, typically ATP, or from a proton gradient. The linear-acting motor proteins need extended cytoskeletal macromolecules for their action. Even though we describe these features as static components when considered in terms of motor mechanism, they are not static at all within the cell: actin filaments, the substrate of myosin, continuously assemble and disassemble in the cell in a highly dynamic, ATP-driven manner. The continuous assembly and disassembly of microtubules, the substrate of kinesin and dynein, from protein monomers is also controlled by ATP [64, 65]. Furthermore, actin filaments and microtubules are being actively moved through the action of myosin and dynein, respectively.

The DNA helicases and RNA polymerase are track-laying motors. DNA and RNA can be considered components of these motors since they are required for the unwinding or polymerization process [43, 66–69].

4. ENERGY SOURCE-ATP HYDROLYSIS AND PROTON FLOW

Molecular motors, just like any other sort of motor, need energy in order to function. Most molecular motors use chemical energy derived from the hydrolysis of adenosine triphosphate. The active sites on motor proteins bind ATP and catalyze the decomposition to adenosine diphosphate (ADP) and inorganic phosphate (Pi), thereby releasing a significant quantity of energy, which in turn leads to conformational change in the motor protein and ultimately results in motor movement. This catalytic process then repeats with another ATP molecule, and the motor protein can continue further movement.

For instance, kinesin "walks" using 8 nm steps along the microtubule protofilament axis, and each of these steps expends one ATP molecule [15, 16, 70–73]. In the case of cytoskeletal motors such as myosin and kinesin, ATP circulation causes a motor to cycle between weak and strong binding states with their tracks. ATP binding and turnover deliver the energy to detach the motor from its track and indirectly give the opportunity to reattach to a new site in the step-forward direction. Both the pRNA and gp16 of phi29 bind ATP [73a, 239]. ATP hydrolysis also provides the driving force for viral DNA-packaging motors. Current estimates indicate that one ATP molecule is required for every two DNA base pairs that are packaged [45, 48].

The F_1F_0 complex is composed of two motors [1] which are connected by a common rotor axle and can exchange the energy of proton translocation and ATP synthesis/hydrolysis through mechanical rotation. The F_0 motor generates torque connected with proton flow across a membrane and the F_1 subcomplex rotates with discrete 120° steps, each driven by the hydrolysis of one ATP molecule. In the typical situation in a chloroplast, mitochondrion, or bacterial cell, a steep proton gradient is maintained by photosynthesis or substrate oxidation, and this allows for proton flow through the F_0 motor of F_1F_0 complex, thereby driving the synthesis of ATP. However, if the ATP concentration is high and the electrochemical potential is low, the F_1 motor is stronger and reverses the F_0 motor, creating a proton pump [74, 75].

The bacterial flagellar motor is another example of the use of proton flow (protonomotive force) as an energy source. This motor is powered by the flux of hydrogen (H^+) or sodium (Na^+) ions (depending on the organism) across the membrane [2]. The protonomotive force is supported by metabolic processes that pump protons out of the cell and drive the flagellar motor through reverse flow. Each proton that flows back into the cell can supply up to 2.4×10^{-20} J of free energy to drive the motor, and a flow of approximately 10^3 protons is associated with each rotation of the motor [2].

5. SPECIFIC BIONANOMOTORS

5.1. Linear Motion Motors

5.1.1. Kinesin

Kinesin is a filament-dependent motor protein and is part of the cytoskeletal motor family [65]. Kinesin was first discovered in neuronal tissue, and it has been found to move

microtubules in an ATP-dependent mode; that is, the movement of this motor along the surface of the microtubule is supported by chemical energy released from the hydrolysis of ATP. Kinesin is processive [76] and moves forward in discrete steps of 8 nm [4, 77, 78], which corresponds to the distance between tubulin dimers along the microtubule [79]. Like many polynucleotide motors (polymerases, helicases, nucleases, etc.), kinesin can translocate through many enzymatic cycles before dissociating from the substrate [66, 68, 79]. Individual molecules typically move about 800 nm before disengaging at a speed of 800 nm/s (100 steps/s) *in vitro*, and they are capable of continuing movement against loads of up to −6 pN. A number of significant characteristics of kinesin movement, including the unidirectionality of the motion, the force–velocity relationship, the time dependence of the movement, and the displacement variance have been demonstrated *in vitro* [15, 16, 70–73, 80, 81].

Native kinesin is a dimeric molecule with two well-separated globular ($\sim 9 \times 3 \times 3$ nm) heads (Fig. 1) that are rotated by about 120° and displaced from each other by 8 nm. Each of these heads is formed from a single polypeptide that is 345 amino acids long and is responsible for both enzymatic and motor activity. Kinesin also contains two identical "heavy" and two identical "light" chains that can be divided into four domains: the catalytic core, the neck, the stalk, and the tail [82–84]. It has been found that single-headed kinesin constructs do not support processive movement [85, 86]; instead, the two heads of kinesin have been found to work in a coordinated mode, such that the binding and hydrolysis of ATP by one head stimulates ADP release by the other head [68].

Also, it has been shown [87] that in the presence of ADP, the motor domain of kinesin, while still bound to the microtubule, adopts a highly mobile state. All of these support the conception that dimeric kinesin moves "hand-over-hand," moving its heads forward alternately. In this way, at least one head stays bound to the substrate at any given time (Fig. 1).

Two basic classes of possible models for the stepping of kinesin have been proposed [88]. One is the "long-stride" model, in which during the stepping process the back head passes the bound front head and advances 16 nm. At this point, the heads change their roles and a new step may take place [89]. Another model has been examined which suggest a "two-step" process [90, 91]. These models provide an explanation for the experimentally measured low dislocation variance, suggesting two consistent subprocesses: for the duration of one cycle one of the two heads takes an 8 nm step first, and then the other head takes an 8 nm step in order to maintain the 8 nm distance.

5.1.2. Myosin

Myosin is not one particular protein motor but rather a large family of proteins that can be divided into at least 15 different classes by amino acid sequence similarity. These proteins are responsible for many of the tasks involved in cell motility, including muscle contraction, chemotaxis, cytokinesis, pinocytosis, and targeted vesicle transport [92].

In general, myosins consist of three functional subdomains: the motor (or catalytic) domain, the neck domain,
Figure 1. The schematic illustration of a kinesin movement along the microtubule. Dimeric kinesin moves "hand-over-hand," moving its heads forward alternately. At least one head stays bound to the substrate at any given time. D and T—bound nucleotides ADP and ATP respectively. X—nucleotide free. Reprinted with permission from [247], F. J. Kull, *Essays in Biochem.* 35, 61 (2000). © 2000, Portland Press.

and the tail domain [92]. The most common example is muscle myosin, which was discovered over 60 years ago in the muscles and cytoplasm of animal cells; it is an asymmetric 470 kDa protein containing two 90 kDa globular *N*-terminal heads, subfragment-1, and an α-helical coiled-coil tail [27]. A catalytic domain is located in the globular head and contains the ATP and actin-binding sites. A neck region connects the catalytic domain to the tail and its cargo.

Class I of the myosin family is involved in both endocytic and exocytic membrane traffic. Myosin II is a component of the contractile ring in dividing cells and the sarcomere in muscle cells. Myosin III assists in signal transduction in retinal photoreceptor cells [93]. Class V myosins play an important role in organelle transport. It has been shown [94–96] that myosin V is a highly efficient, processive motor

like kinesin (Fig. 2). Myosin V and XI function as organelle motors in animal and plant cells, respectively. Myosin VI is a reverse motor that can move toward the "minus" end of actin filaments [64, 97, 98].

In order to help explain myosin's role in the mechanism of muscle contraction, several models have been proposed. In the "swinging cross-bridge" model, myosin pulls an actin filament by swinging its head [99, 100]. However, direct evidence for the swinging cross-bridge model has not been obtained to this point. According to the "lever-arm" model, structural change in the catalytic domain of the myosin head is amplified by the pivoting of the light-chain binding domain, which acts as a lever arm [4, 101, 102].

Unlike kinesin and the polynucleotide motors, not all myosins are processive; classes I and II are prominent examples. Instead of the "Inchworm" model, the "hand-over-hand" model was confirmed by single fluorophore imaging [103].

5.2. Rotary Motors

5.2.1. $F_1 F_0$ ATPase

ATP synthesis is the basic method of cell energy production and one of the most frequently occurring enzymatic reactions in biology. This synthesis takes place on the F_1F_0-ATP synthase enzyme.

F_1F_0-ATP synthase consists of two motors, F_1 and F_0, and is found in the inner membranes of mitochondria, the thylakoid membranes of chloroplasts, and the plasma membranes of bacteria [1]. These two motors are connected by a common rotor shaft (Fig. 3a). Such a connection allows for proton translocation energy to be converted and utilized in ATP synthesis through mechanical rotation [1].

The motors of ATP synthase have different functions and characteristics. F_1 subcomplex can be dissociated from F_0. The resultant enzyme is termed F_1-ATPase, and its catalyzed

reaction is the hydrolyzation of ATP. The energy of ATP hydrolysis is transferred to mechanical rotation (Fig. 3b). This complex consists of $\alpha_3\beta_3\gamma_1\delta_1\varepsilon_1$ subunits and as has been shown [104] requires at least a $\alpha_3\beta_3\gamma$ to maintain ATPase-activity. Three α and three β subunits arranged into a hexameric ring with a central cavity [105] and half of the γ subunit is inserted in this cavity. F_1 subcomplex catalytic sites are located on the β subunit and $\gamma\varepsilon$ subunits attached to the c subunits of F_0 subcomplex and form a rotor shaft [106, 107]. The rotation of γ is the result of the cooperative changing of nucleotide binding states of the three catalytic sites on the β subunits. These catalytic sites can adopt different binding states. The first binds with Mg-AMP-PNP [adenosine 5'-(β, γ-imino)-triphosphate], the second binds with Mg-ADP, and the third is empty [1].

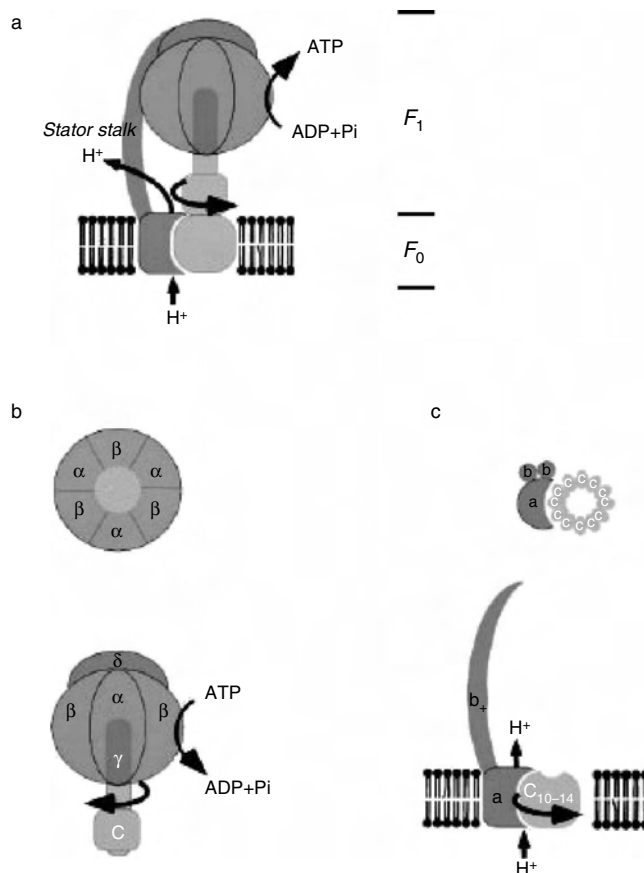
Direct observation of F_1 motor rotation [6] has been accomplished with an optical microscope (Fig. 4). As has been shown, the motor rotates in discrete 120° steps [4], and each step requires the hydrolysis of one ATP molecule. An intermediate state [108] after ATP binding and before ADP


Figure 3. Schematic diagram of ATP synthase (a) F_1F_0-ATP synthase consists of two motors, F_1 and F_0, which are connected by a common rotor shaft. The energy of ATP hydrolysis is transferred to mechanical rotation of the F_1 subcomplex (b) Structure of F_1 subcomplex. The $\gamma\varepsilon$ subunits attached to the c subunits of F_0 subcomplex and form rotor shaft (c) Structure of F_0 subcomplex. This subcomplex generates torque associated with the movement of proton flow. Reprinted with permission from [1], H. Noji and M. Yoshida, *J. Biol. Chem.* 276, 1665 (2001). © 2001, American Society for Biochemistry and Molecular Biology.

Figure 2. Myosin walks hand-over-hand using three steps. Model for movement of two myosins heads along actin filament. The "power stroke" of the leading head causes a transition from state 1 to state 2 with ATP hydrolysis and production of ADP and inorganic phosphate; trailing head becomes leading head. The leading head falls to state 2 as a result of biased diffusion, which induces extra movement and aids in the completion of the third step. Reprinted with permission from [310], J. Molloy and C. Veigel, *Science* 300, 2061 (2003). © 2003, American Association for the Advancement of Science.

(and Pi) release at 90° degree of the γ subunit was shown. So each 120° step can be dissolved into 90° and 30° substeps driven by ATP binding and ADP (and Pi) release respectively. A new crystal structure of an intermediate state was shown [109].

The F_0 complex does not use energy from ATP hydrolysis. The rotation of this motor is associated with the flow of protons (Fig. 2c). When protons flow through F_0, the F_1 complex synthesizes ATP. This synthesis is reversible and when F_1 hydrolyzes ATP, the F_0 motor can pump reverse flow of protons through the membrane [1].

5.2.2. Bacterial Flagella

The bacterial flagellar motor is one of the most intriguing biological nanomotors. Many well-known bacterial species can swim using flagellar filaments [2, 110]. These filaments have a stiff, helical structure, are approximately 10 μm in length, and have a period of about 2 μm.

The flagellar motors of enteric bacteria *E. coli* and *S. typhimurium* have been the most often analyzed examples. All rotary motors can be divided into two parts: the rotor and the stator (the stationary section of the motor). Four rings (C, MS, L, and P) and the rod together form the rotor of the flagellar motor (Fig. 5). About 12–14 particles together form the stator. They are organized around the MS and C rings in the cytoplasmic membrane and are attached to the cell wall. The L and P rings (FlgI and FlgH) are located in the outer membrane and peptidoglycan, respectively. The MS (FliF) ring ($\sim$25 nm disk) crosses the cell inner membrane. The C ring (FliM and FliN) is attached to the MS ring and extends into the cytoplasm. The filament (FliC) is connected to the motor by a flexible hook (FlgE) and to the hook by hook-associated proteins (FlgK, FlgL, and FliD). Such a connection provides the filament
Figure 5. (a) A schematic diagram of the flagellar motor. (b) Reconstruction of electron microscope images of hook-basal bodies [309]. Reprinted with permission from [306], N. R. Francis et al., *J. Mol. Biol.* 235, 1261 (1994). © 1994, Elsevier Science.

and motor the freedom to rotate around different axes. FliG is bound to the inner face of the MS ring. MotA and MotB cross the inner membrane and are organized in a circular group around the MS and C rings [111]. These two Mot proteins bind to each other [112]. One possible method of torque generation is the alternating protonation and deprotonation of Asp32 of MotB, which modulates the interaction of a specific charged region in the cytoplasmic domain of MotA with a complementary charged region in the C-terminal domain of FliG.

The flagellar motor is powered by an ion flow trough channels located in the plasma membrane. Ions utilizing this trough include hydrogen (H^+) and sodium (Na^+). Chemical energy derived from metabolic processes helps to support the ion flow. Such energy is required in order to pump ions out of the cell; reverse ion flow in cells drives various systems, including the flagellar motor [110, 113]. Flagellar motors can rotate both clockwise and counterclockwise and this rotation changing is regulated in such a manner as to allow the bacteria to perform chemotaxis.

A number of models have been proposed to explain the mechanism of flagellar motor function [114–123]. In the model proposed in [118] the rotation mechanism is based on the symmetry mismatch between the C and M rings. Other models (Fig. 6) are based on the geometric relation between the position of the rotor and the paths of ions flowing through the flagellar motor. The "electrostatic" model [120, 121, 123] is based on electrostatic interaction between proton flow and negatively charged areas of the rotor. Such interaction forces the rotor to rotate in order to keep negatively charged areas close to positively charged protons. Another model is based on the geometrical mismatch of in- and out-proton channels in the rotor [114, 115]. As a result, protons flowing through the outer channel can pass into the cell only through other channels in the stator, and they must be transferred to these channels by the rotation of the rotor.

5.3. Nucleic Acid Translocating or Sliding Motors

5.3.1. Viral DNA-Packaging Motor

One striking feature in the assembly of many linear double-stranded DNA (dsDNA) viruses, including adenovirus [124–128], herpesvirus [129–131], poxvirus [132–134], and bacteriophages T1 [135], T3 [136], T4 [137], T5 [138], T7 [139, 140], P1 [141], P2 [142, 143], P22 [144–146], Mu [147], ∅21 [148], ∅29 [11, 149–151], SP01 [152, 153], SPP1 [154, 155], λ [156–159], and their relatives, is that the viral genome is inserted into a preformed shell called a procapsid during maturation [160–163]. This energetically unfavorable DNA-packaging reaction is accomplished by a viral nanomotor using ATP as energy.

One of the essential components of the motor is a connector complex that is a dodecameric structure with a central channel (30–60 Å) through which viral DNA is packaged into the capsid and exits during infection [143, 164–169]. Though the portal proteins from different viruses have little sequence homology and large variation in molecular weight, portal complexes show significant morphological similarity [160]. In the case of phi29, a bacterial virus that infects *Bacillus subtilis*, the structure of one phage portal protein has been determined at atomic resolution [164, 165]. The connector ring consists of a 12 α-helical subunit, with three long helices of each subunit forming the central channel. The ring is 138 Å across at its wide end and 66 Å at the narrow end. The internal channel is 60 Å at the top and 36 Å at the bottom. The wider end of the connector is located in the prohead and its narrow end partially protrudes out of the capsid. The connector is located at the fivefold vertex of the viral capsid, which leads to a symmetry mismatch between capsid and portal [160, 170]. As has been assumed, such a mismatch is required for the smooth rotation of the portal protein during DNA packaging [3, 170].

An examination of extensively studied dsDNA viruses, such as T3 [136], T4 [171, 172], P22 [146, 173, 174], P1 [175], psiM2 [176], Sfi21 [177], lambda [156, 178, 179], T7 [180, 181], phi29 [45, 61, 63, 182], and herpesvirus [167, 183], reveals that all DNA packaging motors involve two nonstructural components typical of ATPase. Further examina-

tion has found that these two proteins can be classified into two categories according to their major role in DNA packaging [45]. One category is for procapsid binding, such as gpA of λ [156, 159], gp12 of phi21 [184], gp17 of T4 [185], gp19 of T3/T7 [48, 140, 186], and gp16 of phi29 [63, 187]. The second category is for interaction with DNA, such as gpNu1 of λ, gp1 of phi21, gp16 of T4; gp3 of phi29 and gp18 of T3/T7 [45]. Emerging information reveals that the mechanism of herpes virus DNA packaging is very similar to that of phages [167, 183, 188–191]. The DNA-packaging reaction is energy dependent and involves ATP hydrolysis. Estimates indicate that one ATP molecule is required for every two base pairs that are packaged [45]. Emerging information reveals that the mechanism of herpes virus DNA packaging is very similar to that of phages [167, 183, 188–191].

The translocation of double-stranded DNA into the phi29 procapsid requires a virus-encoded packaging RNA (pRNA) [36, 63, 187] (Fig. 7a). Mg^{2+} induces appropriate folding of pRNA for dimerization [192, 193]. pRNA dimers bind to the portal vertex (connector) and serve as the building blocks for hexamer assembly [192, 194] (Fig. 7b). The pRNA molecules interact intermolecularly via hand-in-hand interaction to form a hexameric complex that is a crucial part of the viral DNA translocation motor [36, 42, 62, 193, 195, 196]. pRNA appears to be directly involved in the DNA translocation process, and it leaves the procapsid when DNA packaging is completed [193, 197, 198].

pRNA contains two functional domains: the procapsid binding domain, located at the central region [194, 199–201] and comprising bases 23–97, and the DNA translocation domain, which is found at the $5'/3'$ paired ends [202]. This conclusion has resulted from several diagnostic studies, including (a) base deletion and mutation [202–205], (b) ribonuclease probing [193, 200, 203, 206], (c) oligo targeting [207, 208], (d) competition assays to inhibit phage assembly [195, 208, 209], (e) UV-cross-linking to portal protein [199], (f) psoralen cross-linking, and (g) primer extension [210].

In vitro virus assembly involves two steps: DNA packaging with the aid of the viral motor and virion maturation [161–163, 211, 212]. The defined *in vitro* DNA-packaging systems have been constructed for phi29 [61], T3 [213], T4 [214], and λ [215]. Infectious virions have been assembled *in vitro* by extract complementation [216–234], or by the use of synthetic nucleic acid and purified recombinant protein components [149, 235]. With the purified procapsid, gp16, pRNA, and ATP, upto 90% of the added DNA-gp3 can be packaged into the procapsid via the motor constructed with recombinant gene products. After DNA packaging, the *in vitro* assembly system can convert a DNA-filled capsid into infectious phi29 virions with the addition of the purified proteins gp9, gp11, gp12, and gp13 [149, 235]. With this system, up to 5×10^9 infectious virions per ml can be obtained in the presence of all the required components, yet not a single infectious virion is detected in the absence of even one essential component. This system, with a sensitivity of eight orders of magnitude, is used for the assay of the function of the DNA-packaging motor [12, 36, 198].

Several models for DNA translocation into the phi29 procapsid have been proposed [3, 154, 165, 196, 236]. It is generally believed that DNA is translocated through the axial

Figure 8. DNA-packaging model of bacterial virus phi29. (A) 3D model of the motor showing connector and pRNA hexamer. (B) Depicts the sequential action of pRNAs in the phi29 DNA-packaging motor. The left panel shows the 3D structure of the motor complex, including the connector and pRNA hexamer. A-G show the six steps of rotation; the hexagon represents the phi29 connector, and the surrounding pentagon represents the capsid. The six protrusions represent six pRNAs with variable pRNA patterns portraying the pRNA in serial energetic states. For example, pRNA 4 and 1, in panel A, represent contracted and relaxed conformations, respectively. Arrows marks the different transition states of pRNA 1. Each step, e.g., A to B, rotates 12°, since a five to six-fold symmetry mismatch generates 30 equivalent positions, and 360°/30 = 12°. The portal vertex turns 72° after six steps of rotation. For example, pRNA 1 moves from vertex a in A to vertex b in G, and rotates 72°. Each step consumes one ATP to induce one conformational change in pRNA, and six ATPs are used for the transition from one vertex to another. The drawing is the view from inside the procapsid. hole of the portal vertex, much like a threaded rod moving along a nut. Another model hypothesizes that supercoiled DNA wraps around the portal vertex and that rotation of the portal vertex allows DNA to pass into the procapsid via the outside of the portal vertex [236]. In the model that was proposed in 1997 [3] (Fig. 8B), sequential action of multiple pRNAs, in conjunction with other components, is vital to DNA packaging. Six copies of pRNA form a hexamer that interacts with the capsid pentamer and moves in discrete 12° steps. Thirty ATPs are needed for each completed cycle of motor rotation. This model shows good agreement with three-dimensional (3D) structural data (Figs. 8A and 7C, D) that were obtained recently by crystallography [165], complementary modification, photoaffinity cross-linking, chemical modification, chemical modification interference, nuclease probing, AFM, and computer modeling [237] methods.

In the model proposed in [165], DNA located in the central channel interacts with one subunit of the portal. A 12°

rotation of the narrow end of the connector leads to lengthwise expansion of the connector via a slight change in the angle of the long helices, and the wide end of the connector follows the narrow end. Such a "following" allows the structure to relax and contract while translating two base pairs of DNA into the capsid [165]. Also, the "motor-ratchet" hypothesis model of DNA packaging has been proposed and reviewed recently [211]. In this model, the connector rectifies DNA motion via either thermal, biased thermal, or oscillating processes. The motor-ratchet hypothesis has also been used to explain data in biochemistry, genetics, energetic, structure, and dynamics in packaging.

In recent times, the forces involved in phi29 DNA packaging were measured directly [238], using a defined *in vitro* DNA-packaging system [61]. In these experiments, a polystyrene bead was attached to biotinylated DNA of partially prepackaged complexes and captured in an optical trap. The capsid was fixed by binding with another bead coated with anticapsid antibodies. During the addition of ATP, the distance between the two beads decreased due to the packaging process. It was shown that the motor can drive DNA into the head with approximately 30% efficiency until the internal force builds to ∼50 pico-Newtons. This indicates that the phi29 motor is one of the strongest known molecular motors, with a strength about two times that of RNA polymerase and eight times that of kinesin. All of this suggests that the viral DNA-packaging motor represents a powerful new class of motor worthy of further investigation.

One of the recent advances in the study of the phi29 nanomotor is the finding that its pRNA binds ATP [239]. This is the first demonstration of a natural RNA molecule that binds ATP, and the first case to report the presence of a

SELEX-derived RNA aptamer in living organisms. RNA is much easier to manipulate than proteins. Inclusion of RNA as essential components makes the phi29 motor a fascinating potential part for nanodevices.

5.3.2. Helicase

Helicases are motors that move along nucleic acid polymers by using energy derived from nucleoside triphosphate hydrolysis to facilitate both translocation and double–strand nucleic acid polymer unwinding [240–243]. Many cellular processes, such as nucleotide excision repair, homologous recombination, transcription, conjugation, and replication, require helicases [240, 244–246].

Because helicases are involved in important bimolecular processes such as recombination, replication, and DNA repair, helicase dysfunction can lead to a number of human pathologies, including cancer, premature aging, and immunodeficiency [247–253].

Helicases can be classified according to any of several characteristics: direction of movement ($5' \rightarrow 3'$ or $3' \rightarrow 5'$ polarity) [242], nucleic acid substrate type (DNA or RNA helicases) [240, 241], their primary sequences, and by their quaternary or oligomeric structures. For instance, helicases can be separated by structure into two different structural classes: hexameric helicases (assembled into ring-shaped hexamers) and nonhexameric helicases.

The presence of Mg^{2+} ions and binding with nucleotides are necessary for the formation of a hexameric structure. Also binding with NTP and the formation of hexameric structures are necessary for binding with DNA or RNA. Binding with DNA or RNA stabilizes hexamer structure and stimulates NTPase activity [254–257].

Helicase movement and DNA unwinding activity require energy derived from the hydrolysis of NTP. The NTP hydrolysis activity of helicases is from 10 to 100 times lower in the absence of DNA when compared with the presence of DNA [254, 258–260]. Though hexamer helicases can hydrolyze different ribonucleoside and deoxyribonucleoside triphosphates, not all nucleotides support DNA unwinding, and ATP is the preferred nucleotide for most hexameric helicases.

As has been shown, one strand of duplex DNA is bound in the central channel of the hexameric ring [69, 254, 261–264]. This binding is sequence-independent, and not all of the six DNA binding sites are involved in interaction simultaneously [257, 265–267]. Because helicases must not only bind DNA but also need to translocate along it, they may change between several DNA binding states (tight, weak, and no affinity) during translocation.

Several translocation models have been proposed [263, 266, 268, 269]. According to the three-site sequential translocation model, the three catalytic sites all participate in the NTPase reaction. They can adopt different conformational states such as: tight interaction with DNA, bound to NTP; weak interaction with DNA, bound to NDP; and empty state, not bound to DNA. These states undergo simultaneous change for each site in the order NTP-bound, NDP-bound, empty. Binding with NTP leads to conformational change and results in movement; the NDP-bound site loses its DNA connection and the empty site binds DNA in a different location. The cycle then repeats. Such a repetition

of cycles allows helicase to achieve processive and unidirectional movement. In the two-site model, the catalytic sites can adopt only two states: NTP-bound and NDP-bound. The NDP-bound subunit does not change to the empty state but starts to rebind DNA at a different location after release. The translocation model is based upon the notion of a fluctuating electrostatic field [67]. According to this model, the binding of NTP to a hydrolysis site induces conformational change that exposes one pair of negatively and positively charged regions per nucleotide hydrolysis site near the inner surface of the channel. These charged regions are not of equal size, are oriented at an angle to the circumferential meridian, and are not constant, appearing and disappearing with the binding and hydrolysis of NTP respectively. The field of these charged regions can sequentially interact with the closest negatively charged DNA phosphate that gives an "electrostatic push" in the direction of the charge pair axis. The combined effect of the charged pairs produces a sustained torsional and axial thrust.

The action of helicases includes not only unidirectional translocation along DNA but also base pair separation, and this process requires the disruption of the intermolecular forces that stabilize the duplex DNA. Several models have been proposed to help describe this unwinding mechanism. In the "wedge" model, only one of the separated DNA strands is tightly bound in the central channel; the other strand does not have tight interactions with the helicase. NTPase activity supports unidirectional movement of the helicases along the strand bound in the central channel and provides enough force for the destabilization of DNA base pairs by helicases through functioning like a wedge. Unlike in the "wedge" model, in the torsional model both separated DNA strands interact with helicase—the one bound in the central channel and the other with outside parts. Such interaction allows helicase to generate torque and rotate strands, leading to unwinding of the dsDNA. According to the helix-destabilization model, helicase interacts with both strands of DNA. But unlike the torsional model, in this model the outer part interacts with dsDNA. Such interactions and conformational changes caused by NTPase activity allow helicase to separate DNA and translocate along the separated strand [269, 270].

Not all helicases adopt a hexameric configuration; some of them can act as dimers or monomers [271–280]. Well-known representatives of such helicases include PcrA helicase [274, 275], RecBC helicase [242], *E. coli* DNA helicase II (UvrD) [271], and Rep helicase [277].

For describing translocation and the unwinding mechanism of RecBC helicase, the "inchworm" model has been proposed [242]. According to this model, the translocation and unwinding of DNA are two separate, consecutive events. First, translocation occurs in a 23-bp "step" and, second, unwinding occurs in several smaller events of 2–5 bp for each ATP molecule hydrolyzed. It was proposed that the RecBC enzyme possesses two nonequivalent DNA-binding sites: the first DNA-binding site is the leading domain of the enzyme that binds to one strand of double-stranded DNA and functions to anchor the enzyme during DNA unwinding. The second DNA-binding site is the trailing domain that functions as the helicase domain of the enzyme and is responsible for separating the strands

of DNA. One complete cycle of translocation and DNA unwinding is achieved by the expansion and contraction of the enzyme that includes the hydrolysis of at least 5 to 12 ATP molecules [242]. It has been shown that helicases such as PcrA DNA helicase [274, 275], *E. coli* DNA helicase II [271], *E. coli* RecG helicase [273], and P143 DNA helicase [281] also most likely utilize an "inchworm" mechanism.

A different, "rolling" model for DNA unwinding has also been proposed for Rep helicase. In this model, ATP binding, hydrolysis, and release cause a series of conformational changes of the Rep dimer. Each conformational state differs from the others with regard to the relative affinity of the second subunit of the Rep dimer for single stranded (ss) versus double stranded (ds) DNA. The Rep dimer is moved along the DNA and is driven by a subunit switching mechanism, and duplex DNA is actively unwound when one subunit of the Rep dimer is bound to the duplex region ahead of the ss/ds DNA junction [282].

5.3.3. RNA Polymerase

RNA polymerase is a molecular motor that processes along a DNA strand and transcribes the information coded in the DNA's base pair sequence into RNA [43, 66–69, 283–287].

Like the other biological nanomotors, RNA polymerase converts chemical energy to mechanical movement. In the case of polymerase, such chemical energy takes the form of free energy supplied by nucleotide polymerization and RNA folding. In order for the polymerization process to be initiated, RNA polymerase must bind to a promoter. During this first step, RNA polymerase binds to DNA and then randomly slides along the duplex until it meets a promoter. Protein initiation factors are necessary elements for establishing sequence-specific binding with promoter. After initiation of the RNA chain, this binding with the promoter is terminated and initiation factors are released. The chain elongation process will take place until polymerase reaches the termination DNA sequence. During transcription, ~35 bp fit into the major DNA groove and the DNA is separated into a template strand and a nontemplate strand, forming a "transcription bubble" that is ~17 bp long (Fig. 9). This domain contains the catalytic (active) site. The catalytic site normally consists of two binding sites—a substrate binding site and a product site. In the substrate binding site, NTP can weakly bind to a template base, and if they are complementary, they form a hydrogen bond. This can lead to
hydrolysis of the pyrophosphate group and the formation of a phosphodiester link with the previous base [66].

To explain how RNA polymerase utilizes chemical energy for translocation, two main models, the "Brownian ratchet" model and the "power-stroke" model, were proposed [288, 66]. According to the "Brownian ratchet" model [288], the enzyme fluctuates between the two closest template positions under the influence of Brownian motion. When binding occurs, the polymerase in the next position undergoes a conformational change which prevents movement back to the previous position. The process then repeats [288, 289]. In the "power-stroke" model, movement of polymerase on 1 bp along DNA is powered by conformational change produced by the strong binding of an enzyme domain with the DNA template [66].

For obtaining information about the movement of RNA polymerase and for the determination of what mechanism is responsible for this process, single-molecule experimental techniques have been employed (Fig. 10). These techniques are all based upon isolating a single RNA polymerase molecule and immobilizing it on a surface. Such an approach allows for the observation of single DNA translocation by microscopy. Several different single-molecule methods, such as the tethered particle motion method, the laser tweezers method, and the surface force microscopy, method have been utilized in the study of RNA polymerase [287, 290–292]. These studies demonstrate both the high efficiency of chemical-to-mechanical energy conversion and the ability of RNA polymerase to translocate DNA against large opposing loads. It was also found that RNA polymerase rotates DNA by tracking its right-handed helix and that the polymerase does so over thousands of base pairs, thereby producing >5 pN nm of torque [293].

6. CONCLUSIONS

Nanobiomotors are tiny machines that help convert a primary energy source into mechanical motion. They are crucial to the sustenance of living systems, since they allow for most forms of biological motion, helping to direct cellular components to their proper destinations, package DNA, contract muscles, and perform a variety of other functions. Biomotors exhibit a diversity of complex structures. Most have the same basic components, including a mechanical frame (usually composed of proteins) with both moving and static parts that is powered by an energy supply. This energy is typically derived from the hydrolysis of ATP, which leads to conformational change in the motor protein and results in movement; some motors use energy produced from ion gradients. These motors are typically divided into categories based on the type of motion displayed: the most well-studied motors are categorized tentatively into linear motors, rotary motors, and nucleic acid translocating/sliding motors.

GLOSSARY

Nanobiomotors Nanoscale machines formed by macromolecular complexes that convert a primary energy source to mechanical motion between active and framework components.

Bismuth Nanostructured Materials

Joshua T. Moore, Charles M. Lukehart

Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

1. INTRODUCTION AND SCOPE

For many years, bismuth (Bi) has found applications in various materials ranging from pigments, pharmaceuticals, and cosmetics to alloys, catalysts, and electronics. Most recently, there has been increased interest in the preparation of nanostructured bismuth, bismuth alloys, and bismuth intermetallic substances because of useful properties exhibited by these materials. The unique electronic structure of bismuth, specifically a small electron effective mass and a long electron mean-free path, make quantum confinement effects much more pronounced in nanoscale bismuth materials. Of particular interest is the application of nanoscale bismuth structures as thermoelectric materials.

The efficiencies of thermoelectric materials are determined through measurement of the dimensionless thermoelectric figure of merit, denoted ZT. The equation for this figure of merit is given as

$$ZT = S^2 \sigma T / \kappa$$

where S represents the Seebeck coefficient, σ represents the electrical conductivity of the material, κ represents the thermal conductivity of the material, and T is the absolute temperature of the measurement. Most state-of-the-art thermoelectric materials used for solid-state refrigeration have a value of $ZT \leq 1$. Bismuth and bismuth alloys exhibit favorable thermoelectric properties, and, as a result, many state-of-the-art commercial thermoelectric devices contain elemental Bi, Bi_2Te_3, or other Bi alloys as the thermoelectrically active components. Theoretical calculations indicate that nanostructured Bi or Bi alloy materials might exhibit greatly enhanced ZT values due to quantum effects. There is much current interest research in the preparation of nanostructured Bi materials to investigate how such quantum confinement effects could enhance desired thermoelectric properties.

A comprehensive review of the preparation of zero-, one-, and two-dimensional nanostructures of elemental bismuth and bismuth intermetallic substances or alloys is provided. Nanostructured materials described in this review have at least one dimension in the range of 1–100 nm, where the dimensionality of a nanostructure denotes the number of dimensions in which electron motion is not confined to the nanoscale. Two-dimensional nanostructures exhibit quantum confinement in one dimension as represented by very thin films, quantum wells, or superlattice structures. One-dimensional nanostructures, such as quantum wires, nano-rods, or nanofibers, are spatially confined in two dimensions, and zero-dimensional nanostructures have shapes confined in all three dimensions, as found with nanoparticles, nanocrystals, or quantum dots.

Bi nanostructures (n-Bi) have been prepared using a variety of physical, chemical, or electrochemical synthesis strategies, as summarized in Table 1. More detailed discussion of these various preparation methods and the types of nanostructured materials formed is presented below.

2. ZERO-DIMENSIONAL BISMUTH NANOSTRUCTURED MATERIALS

2.1. Elemental Bismuth Nanoparticles

Bismuth nanoparticles have been prepared as nanocomposite materials in metal, ceramic, or organic polymer matrices, and as nascent particles having various degrees of surface passivation. In general, chemical synthesis strategies give better control of average particle size.

Bi/metal nanocomposites are known for aluminum or Al-Cu-Fe matrices. Goswami and Chattopadhyay [1] have reported the formation of a 10 wt% Bi material in an

Table 1. Listing of bismuth nanostructured materials, including method of preparation and particulate size range classified according to order of dimension (D).

	Nanomaterial	Method	Size (nm)	Ref.
0D	Bi/Al matrix	Induction melting	20–100	[1]
	Bi/Al-Cu-Fe matrix	Melt spinning	50	[2]
	Bi/SiO$_2$ matrix	H$_2$ reduction of Bi^{3+} dopants	100–250	[3]
	Bi/Mo-Ti oxide matrix	H$_2$ reduction of Bi^{3+} dopants	10	[4]
	Bi/SiO$_2$ (or TiO$_2$) matrix	Sol-gel/H$_2$ reduction of Bi^{3+} dopants	5.3–10	[5]
	Bi	Evaporation of Bi metal	4.5–9.5	[6]
		Chemical reduction of Bi^{3+} compounds	15	[7]
		Inverse micelles/chemical reduction	3.2–8.0	[9]
			20	[10]
	Bi/polymer matrix	Microemulsion/polymerization	13.2	[11]
	Bi$_2$S$_3$	Metathesis between Bi^{3+} and S^{2-}	5	[12]
	Bi$_2$Se$_3$	Dissolution in acetonitrile	N/A	[13]
	Bi$_2$Te$_3$	Inverse micelles	10	[14]
	Bi-E/SiO$_2$ matrix (E = Te, Sb, Sn, Sb/Sn)	Sol-gel/H$_2$ reduction of Bi^{3+} dopants	11–15	[15]
1D	Bi	Vacuum melting/pressure injection	4.3–56	[28, 29]
		Vacuum deposition	7–200	[19, 30]
		Electrodeposition	20–70	[31, 32]
			50	[33]
			3–100	[34]
			95–400	[35]
		Capillary filling of C nanotubes	Approx. 1	[36, 37]
		Electrolysis of Bi powder in molten LiCl	N/A	[38]
		Electron beam lithography	50	[39]
	Bi$_2$S$_3$	Solvothermal decomposition	130–200	[41]
	Bi$_2$E$_3$ (E=S, Se)	Solvothermal reaction	20	[42]
	Bi$_2$Te$_3$	Electrodeposition	40	[43]
			280	[44]
2D	Bi	MBE	5–80	[45]
			40–80	[46]
	Bi/Sb	MBE	N/A	[47]
			1–10	[48]
	Bi$_{0.88}$Sb$_{0.12}$	MBE	75	[49]
	Bi/Bi$_{0.89}$Sb$_{0.11}$		7.5/6.5	[50]
	Nanoporous Bi film	Spin coating/H$_2$ reduction	5–10 (channel width)	[51]
	Bi$_2$Te$_3$/Sb$_2$Te$_3$	CVD	1–10	[52, 53]

Note: MBE = molecular beam epitaxy, CVD = chemical vapor deposition.

aluminum matrix. The nanocomposite is prepared by induction melting of ultra high purity elemental Al (99.999%) and Bi in an Ar atmosphere. The as-cast alloy is rapidly cooled producing a large number of Bi nanoparticles in an Al matrix. Transmission electron microscopy (TEM) micrographs reveal Bi particles ranging in size from 20–100 nm. Similarly, Singh and Tsai [2] have reported the preparation and melting behavior of Bi nanoparticles embedded in an Al-Cu-Fe matrix. This nanocomposite is prepared by melting a mixture of highly pure metals under an Ar atmosphere in an electric arc furnace. Bi particles are embedded into the melt-by-melt spinning at a loading of 10 wt%. The Bi nanoparticles formed have an average size of 50 nm and display spheroidal morphology with little or no faceting of the particles.

Several n-Bi/ceramic nanocomposites are known. Czajka et al. [3] prepared n-Bi/silica composites by doping SiO$_2$ melts with Bi$_2$O$_3$. Reduction of Bi-doped silica glass by

hydrogen at temperatures ranging from 160–500 °C gives a uniform distribution of solid particles having diameters ranging from 100–250 nm within the glass matrix. The observation of a strong X-ray diffraction peak centered at 27.1°2θ is consistent with diffraction from the (012) lattice planes of Bi metal.

While investigating the redox chemistry of bismuth molybdate (Bi$_2$O$_3$ · 2MoO$_3$) catalysts embedded in TiO$_2$, Grunwaldt et al. [4] found that Bi^{3+} ions are easily reduced to Bi^0 at room temperature under a reducing atmosphere. Bi-Mo-Ti mixed-metal oxides are prepared using sol-gel processing by adding a Bi precursor, such as BiCl$_3$ or Bi(NO$_3$)$_3$, along with a Mo precursor compound to a solution of Ti[OCH(CH$_3$)$_2$]$_4$ in isopropanol. Aqueous HNO$_3$ is used to initiate Ti-alkoxide hydrolysis and condensation. Reduction of the obtained mixed-metal oxide gel intermediate gives a Bi/Mo-Ti oxide composite containing Bi nanoparticles of ca. 10 nm average diameter.

Using a similar strategy, Moore and Lukehart [5] prepared n-Bi/SiO$_2$ or TiO$_2$ xerogel nanocomposites by the sol-gel processing of solely metal alkoxide reagents. Co-hydrolysis and heterocondensation of the Bi alkoxide, Bi(OCH$_2$CH$_2$OCH$_3$)$_3$, with either Si(OCH$_3$)$_4$ or Ti[OCH(CH$_3$)$_2$]$_4$ results in formation of mixed-metal oxide gels. Calcination of the gel intermediates to remove excess organic functionalities followed by reduction in flowing hydrogen at 250 °C affords n-Bi/SiO$_2$ or n-Bi/TiO$_2$ xerogel composites containing Bi nanoparticles of 10 nm or 5.3 nm average diameter, respectively. Powder X-ray diffraction (XRD) scans typical of n-Bi/SiO$_2$ and n-Bi/TiO$_2$ xerogel nanocomposites are shown in Figure 1. The principal peaks expected of crystalline Bi are observed. Peak broadening is an independent measure of nanoparticle size. Energy dispersive spectra (EDS) of these two nanocomposite materials are shown in Figure 2. X-ray emission from Bi and the matrix metals, Ti or Si, are observed. The relative intensities of these emission peaks can be correlated to the relative atomic fraction of each metal present within the sample.

Nascent Bi nanoparticles have been formed and stabilized with various degrees of intentional surface passivation. Wurl et al. [6] prepared unsupported Bi nanoparticles by high-temperature evaporation of Bi metal. Aggregation of Bi atoms within a flow of inert gas leads to the growth of Bi nanoparticles. Depending on evaporation temperature and the rate of gaseous flow, Bi particles are formed having particle diameters in the range of 4.5–9.5 nm.

Fang et al. [7] prepared self-assembled Bi nanoparticles using a high-temperature decomposition process similar to arrested precipitation methods known to form CdSe nanoparticles. Reduction of bismuth(III) 2-ethylhexanoate in dioctyl ether by Li[B(CH$_2$CH$_3$)$_3$H] precipitates nanocrystalline Bi. The Bi nanoparticles have near spherical morphology with an average diameter of 15 nm. These nanoparticles self-assemble into a two-dimensional monolayer exhibiting local hexagonal ordering.

Yu et al. [8] produced nearly monodisperse nanoparticles of Bi, as well as Sn and In, using a heterogeneous seeded-growth process. Bi nanoparticles form when Bi([N(Si(CH$_3$)$_3$)]$_2$)$_3$ is thermally decomposed in a solution containing 1.5 nm Au seed crystals. The polymer, poly(styrene$_{0.86}$-co-vinyl-pyrrolidinone$_{0.14}$), is present to stabilize the Bi nanoparticles during particle formation. The
Figure 2. Energy dispersive/(EDS) spectra of a typical Bi/titania xerogel nanocomposite (top) and Bi/silica xerogel nanocomposite (bottom); Cu emission from the sample holder is also evident.

resulting Bi nanoparticles are then precipitated from solution as a black powder. Bi average particle sizes ranges from 8.6–12.4 nm depending on reaction conditions.

Nearly monodisperse Bi nanoparticles are obtained using inverse micelle, or microemulsion, synthesis methods. Foos et al. [9] prepared Bi nanoparticles having average diameters of 3.2–8.0 nm by adding an inverse-micelle solution containing aqueous BiOClO$_4$ to a second inverse-micelle solution containing aqueous NaBH$_4$ as a reducing agent. The as-prepared, surfactant-capped Bi nanoparticles are precipitated from solution and washed with methanol to remove excess surfactant molecules leaving an insoluble black powder of Bi nanoparticles. Similarly, Fang et al. [10] found that reaction of inverse micelles containing bismuth(III) citrate with inverse micelles containing NaBH$_4$ also affords Bi nanoparticles. When mixed surfactant systems are used, Bi particles having an average particle diameter of approximately 20 nm are formed.

Using a variation of the inverse micelle method, Fang et al. [7] obtain polymer-encapsulated Bi nanoparticles using an *in-situ* polymerization-microemulsion process. Addition of a microemulsion solution containing slightly acidic aqueous Bi(NO$_3$)$_3$ to a second microemulsion containing aqueous NaBH$_4$ results in the formation of surfactant-capped Bi nanoparticles. Dissolution of methyl methacrylate and hydroxyethyl methacrylate as comonomers in the oil phase along with ethylene glycol dimethacrylate as a cross-linking agent and 2,2-dimethixyl-2-phenylacetophenone as a (UV) polymerization initiator results in the formation of a polymeric network surrounding the nano-sized water pockets present in the microemulsions. Bi nanoparticles of average diameter 13.2 nm are formed in the initial emulsion. Annealing the polymer-stabilized nanocomposite in Ar at 160 °C, 200 °C, and 240 °C gives n-Bi/polymer composites containing Bi particles having average diameters of 15.3 nm, 22.6 nm, and 23.9 nm, respectively.

2.2. Bismuth Alloy and Intermetallic Nanoparticles

Bismuth alloy and intermetallic nanoparticles have been obtained as either unsupported or matrix-stabilized nanoclusters. Chalcogenide elements serve as the most common intermetallic component.

Suarez et al. [12] prepared nanocrystalline Bi$_2$S$_3$ colloids using two different methods. In the first method, acetonitrile solutions of BiI$_3$ are reacted with H$_2$S gas to precipitate colloidal Bi$_2$S$_3$. In the second method, addition of a solution of Na$_2$S to a solution of Bi$_2$I$_3$ in acetonitrile solvent initiates formation of a Bi$_2$S$_3$ colloid. A light brown solution quickly

Figure 1. XRD scans (Cu Kα radiation) of a typical Bi/silica xerogel nanocomposite (top) and Bi/titania xerogel nanocomposite (bottom) along with the standard line pattern for Bi metal. The top scan shows a diffraction peak near 29° in 2Θ corresponding to a small amount of unreduced Bi$_2$O$_3$ impurity.

forms during both procedures, thus indicating the formation of Bi_2S_3 colloidal material. Upon standing for approximately 15 min and then degassing the respective reaction suspensions, a brown colloidal suspension of Bi_2S_3 is obtained. In both cases, Bi_2S_3 is formed with an average particle size of ≤ 5 nm.

Comor et al. [13] have obtained Bi_2Se_3 quantum dots by slow precipitation of Bi_2Se_3 from acetonitrile solvent. A colloidal dispersion 6×10^{-6} M in Bi_2Se_3 is formed while heating a solution of high purity Bi_2Se_3 in acetonitrile at 60 °C over a period of four days. Although the Bi_2Se_3 particle size was not determined, analysis of absorption spectral data is consistent with the formation of particles containing 150 Bi_2Se_3 formula units.

Foos et al. [14] formed nanoparticulate Bi_2Te_3 using an inverse micelle strategy. Reaction of an aqueous solution of $BiOClO_4$ as an inverse micelle dissolved in hexane with a hexane solution of $[(CH_3)_3Si]_2Te$ yields a black suspension of Bi_2Te_3. Removal of surfactant molecules present in the inverse micelle formulation by successive washing followed by drying in vacuo affords a dry black powder identified as Bi_2Te_3 by both elemental microanalysis and powder X-ray diffraction. The product contains Bi_2Te_3 nanoparticles having an average diameter below 10 nm.

Moore and Lukehart [15] prepared nanocrystals of Bi-Te, Bi-Sb, Bi-Sn, or Bi-Sb/Sn alloys widely dispersed throughout a SiO_2 xerogel matrix using elemental alkoxide reagents and a sol-gel processing synthesis strategy. Co-hydrolysis and heterocondensation of solutions of $Bi(OCH_2CH_2OCH_3)_3$ containing various amounts of $Te(OCH_2CH_3)_4$, $Sb(OCH_2CH_3)_3$, or $(C_4H_9)_2Sn(OCH_3)_2$ as a dopant reagent with $Si(OCH_3)_4$ results in the formation of mixed-metal oxide gels. Calcination of the mixed-metal gel to remove excess organic functionalities followed by reduction in hydrogen at 250 °C affords Bi alloy nanoparticles having average diameters of 11 nm, 15 nm, 12 nm, and 14.5 nm for the Bi-Te, Bi-Sb, Bi-Sn, and Bi-Sb-Sn alloys, respectively. TEM micrographs reveal predominantly spheroidal particles for the Bi-Sb, Bi-Sn, and Bi-Sb-Sn alloy particles, while the Bi-Te particles exhibit nearly regular hexagonal particle morphology (see Fig. 3). Powder XRD
Figure 3. Transmission electron micrograph of a Bi-Te/silica xerogel nanocomposite showing Bi-Te alloy nanoparticles having nearly hexagonal shape (bar = 30 nm).
Figure 4. XRD scans (Cu Kα radiation) of typical Bi-E/silica xerogel nanocomposites for alloying elements, E = Te, Sb, Sn, Sb/Sn (top to bottom) along with the standard line pattern for Bi metal.

scans typical of these n-Bi-E alloy/SiO_2 xerogel nanocomposites are shown in Figure 4. The principal peaks of crystalline Bi are observed with only slight displacement in the expected two-theta values due to the presence of the alloying metal, E. Peak broadening provides an independent measure of nanoparticle size. Energy dispersive spectra of these same four nanocomposite materials are shown in Figure 5. X-ray emission from Bi, the alloying element E, and the matrix metal, Si, are all observed. The relative intensities of these emission peaks can be correlated to the relative atomic fraction of each metal present within the sample.

3. ONE-DIMENSIONAL BISMUTH NANOSTRUCTURED MATERIALS

One-dimensional Bi nanostructured materials have been an area of intense research interest during the past 5 years due to the enhanced thermoelectric figure of merit expected of elemental Bi or its alloys as nanowire structures. As noted by several researchers, the very low electron effective mass and the semimetallic nature of Bi make it an ideal candidate for the study of quantum confinement effects in nanostructured "1D" structures. Although the physics and theory leading to these predictions is beyond the scope of this review, the findings relevant to the synthesis of 1D Bi materials will be summarized here.

Sun et al. [16] developed a theoretical model of the electronic band structure of Bi showing relationships between the band structure and the thermoelectric properties expected of Bi nanowires. Calculations reveal that Bi quantum wires
Figure 5. Energy dispersive/(EDS) spectra of typical Bi-E/silica xerogel nanocomposites for alloying elements, E = Te, Sb, Sn, Sb/Sn (top to bottom); Cu emission from the sample holder is also evident.

grown along the trigonal axis of the rhombohedral unit cell of Bi would have a greatly enhanced thermoelectric figure of merit. Since that time, a significant amount of theoretical work has led to better predictions of the optimum nanowire diameter and appropriate doping conditions necessary to achieve enhancement of the thermoelectric figure of merit of 1D Bi structures.

Semimetallic Bi possesses an equal number of electrons and holes with electrons localized at the L points of the Brillouin zone and holes localized at a T point. Lin et al. [17] report that a semimetal to semiconductor transition should occur at a critical nanowire diameter between 39–55 nm. The one-dimensional thermoelectric figure of merit ($Z_{1D}T$) is predicted to be substantially increased for nanowires having diameters less that 10 nm when the Bi is properly doped. Suppression or removal of T points in Bi nanowires, such as by doping with antimony, can further enhance $Z_{1D}T$. Discussions of the thermoelectric figure of merit [18, 19], thermoelectric and electronic transport properties [20–24], conductance [25], and magnetoresistance [26, 27] of Bi or Bi alloy nanowire arrays are available.

3.1. Elemental Bismuth Nanowires

The most prevalent method for the production of Bi nanowires and arrays of nanowires is based on template-assisted or template-directed nanowire growth processes. Anodized alumina discs have been used extensively for this purpose. Alumina anodiscs contain a hexagonal array of open, parallel nanochannels with pore diameters ranging from 9–30 nm. Zhang et al. [28, 29] prepared Bi quantum-wire arrays using a vacuum-melting and pressure-injection process. Molten Bi is injected at high pressures (40 GPa of Ar gas) into evacuated porous alumina anodiscs forming an array of Bi nanowires of diameters ranging from 4.3–56 nm. Control of the Bi nanowire diameter is achieved by variation of the pore size of the open channels present within the alumina anodisc. Using the same template, Heremans and Thrush [19] prepared Bi nanowire arrays by vacuum deposition of Bi vapor into the pores of alumina anodiscs. Bi nanowire arrays having wire diameters ranging from 7–200 nm can be prepared using this technique. This method has also been extended to the preparation of Sb nanowire arrays [30].

Electrodeposition of Bi in the channels of either anodized alumina discs or polycarbonate membrane templates can produce Bi nanowire arrays. Using alumina anodiscs having highly ordered open channels as a template matrix, Wang et al. [31, 32] electrodeposited Bi in these open channels as single-crystalline nanowires having diameters of 20 nm, 50 nm, or 70 nm and high aspect ratios when using $Bi(NO_3)_3 \cdot 7H_2O$ as the source of Bi. Similarly, Yin et al. [33] prepared highly oriented hexagonal arrays of Bi nanowires of 50 nm diameter with lengths of up to 50 μm by electrodeposition of Bi in the open channels of alumina anodiscs using $BiCl_3$ dissolved in DMSO as an electrolyte solution.

Peng et al. [34] isolated unsupported Bi nanowires by first electrodepositing Bi in the pores of anodized alumina discs using an electrolyte solution containing $BiCl_3$. Subsequent dissolution of the alumina matrix using 0.1 M $NaOH_{(aq)}$ gives matrix-free Bi nanowires having diameters

ranging from 3–100 nm. Using a similar strategy, Piraux et al. [35] prepared arrays of Bi nanowires by electrodeposition of Bi from a Bi^{3+} electrolyte solution in the pores of a polycarbonate membrane containing parallel open channels formed by nuclear-track etching. Dissolution of the polycarbonate membrane by an organic solvent yields matrix-free Bi nanowires having diameters ranging from 95–400 nm.

Bi nanowires have also been obtained by capillary filling of single-walled carbon nanotubes in a template-directed synthesis. Kiang et al. [36, 37] first reported the preparation of single-walled carbon nanotubes synthesized from a graphite rod containing 2% cobalt catalyst and 5% bismuth as a cocatalyst. Approximately 1% of the large-diameter carbon nanotubes produced are filled with Bi metal. Heating a mixture of large-diameter single-walled carbon nanotubes with Bi nanoparticles to 400 °C for 30 min leads to capillary filling of the carbon nanotubes and increases the fraction of Bi-filled carbon nanotubes to approximately 10%. The Bi nanowires produced by this procedure have diameters of approximately 1 nm with lengths on the order of tens of nanometers. Demetallated single-walled carbon nanotube soot absorbs acidified 1 M $Bi(NO_3)_3$ solution, and reduction of these solution-filled carbon nanotubes under H_2 gas at 350 °C for 3 h gives carbon nanotubes filled with Bi. About 30% of the nanotubes contain Bi nanowires having lengths ranging from a few nanometers to a few hundred nanometers.

Hsu et al. [38] observed formation of Bi nanowires inside carbon nanotubes during the electrolysis of molten LiCl using graphite electrodes. Addition of small amounts (<1% by mass) of Bi powder to the molten LiCl electrolyte results in Bi incorporation inside the nanotubes.

Choi et al. [39] used low-energy electron beam lithography with silver nanocrystal shadowmasks for the preparation of Bi nanowires. A 40-nm thick Bi single-crystal film grown on a CdTe (111) substrate is generated by molecular beam epitaxy. The Bi/CdTe composite is then coated with 1% PMMA (polymethylmethacrylate). Silver nanowires of high aspect ratio are transferred as a Langmuir–Schaeffer film onto the Bi/CdTe substrate. This decorated substrate is exposed to a 50 μC/cm^2 dose of electrons and is subsequently developed with a 1:3 mixture of methyl isobutyl ketone and isopropanol. Following development, reactive chlorine etching produces Bi nanowire structures on the surface of the substrate that are 50 nm wide and have a height of 40 nm.

Li et al. [40] prepared Bi nanotubes using a low-temperature, controlled hydrothermal reduction method. Bismuth(III) nitrate reacts with aqueous hydrazine solution in distilled water to give a black precipitate. Following adjustment of the pH to ~12 and heating the reaction mixture to 120 °C for 12 h in an autoclave, Bi nanotubes are isolated. The Bi nanotubes are composed of α-Bi sheets and have uniform diameters of approximately 5 nm and lengths of 0.5–5.0 μm.

3.2. Bismuth Alloy and Intermetallic Nanowires

Yu et al. [41] obtained Bi_2S_3 nanowires using a solvothermal decomposition process. Ethanol solutions of $BiCl_3$ and thiourea (H_2NCSNH_2) react in an autoclave at 140 °C for

12 h to precipitate dark brown Bi_2S_3 nanowires. These nanowires have average diameters of 130–200 nm and lengths of 3.5 μm. Using a similar method, Su et al. [42] prepared Bi_2E_3 (E = Se, S) nanowires by solvothermal reaction of $BiCl_3$, Se powder, and triphenyl phosphine sulfide in ethylenediamine. Heating this reaction solution at 120 °C for 20 h results in the formation of Bi intermetallic nanowires having diameters of 20 nm and lengths of 1.5 μm.

Nanowires of Bi_2Te_3 have also been obtained by electrodeposition within the pores of anodized alumina discs. Prieto et al. [43] formed high-density nanowire arrays of Bi_2Te_3 by electrodeposition of Bi_2Te_3 within the channels of alumina anodiscs using an electrolyte solution prepared by dissolving Bi^0 and Te^0 in 1 M HNO_3. Etching away the alumina matrix using a solution of H_3PO_4 and CrO_3 affords matrix-free Bi_2Te_3 nanowires having average diameters of 40 nm. Sapp et al. [44] electrodeposited Bi_2Te_3 nanowires in the pores of anodized alumina from an electrolyte solution prepared by dissolving $Bi(NO_3)_3 \cdot 5H_2O$ and Te powder in 1 M HNO_3. Bi_2Te_3 nanowires having an average diameter of 280 nm are obtained.

4. TWO-DIMENSIONAL BISMUTH NANOSTRUCTURES

4.1. Nanostructures Formed by Molecular Beam Epitaxy

Epitaxial growth of Bi and Bi alloy or intermetallic films is typically carried out using semi-insulating CdTe wafers as the substrate material. DiVenere et al. [45] first reported successful epitaxial growth of Bi layers on a CdTe substrate. The Bi layer thickness could be varied from 5–80 nm. Subsequent work demonstrated that epitaxial Bi films of 100 nm thickness show thermoelectric properties in good agreement with those of the bulk crystal [46]. However, when the thickness of Bi films is reduced to 40–80 nm, the thermoelectric properties are enhanced over those of bulk Bi.

Superlattice structures with alternating Bi and Sb layers grown by MBE have been reported by Takahashi and Miyagawa [47]. Epitaxial growth of a Bi/Sb superlattice containing a total of 60 layers has been achieved. Cho et al. [48] produced epitaxial Bi/Sb superlattices having individual layer thicknesses ranging from 1–10 nm with a periodicity ranging from 30–300.

Solid-solution Bi alloy superlattice structures have also been prepared by MBE. Takahashi et al. [49] produced a $Bi_{0.88}Sb_{.012}$ thin film having a thickness of 75 nm. Yi et al. [50] prepared a bilayer structure comprised of a 7.5 nm layer of $Bi_{0.89}Sb_{0.11}$ and a 6.5 nm layer of Bi that was repeated 20 times to form a superlattice.

4.2. Nanostructures Formed by Chemical Methods and Chemical Vapor Deposition

Shen et al. [51] prepared nanoporous Bi thin films using a wet chemical deposition method. Solutions of either bismuth 2-ethylhexanoate or bismuth acetate in 2-methylpropanol containing 5% glycerol are spin-coated onto Si(100) wafers.

Subsequent reduction at 250–270 °C for 3–6 h under hydrogen gives a nanoporous Bi thin film containing porous channels 5–10 nm in width.

Chemical vapor deposition (CVD) and metal-organic chemical vapor deposition (MOCVD) have been used to prepare thin films containing Bi. Venkatasubramanian et al. [52, 53] used MOCVD methods to obtain Bi_2Te_3 and Sb_2Te_3 thin films and superlattice structures. Trimethyl bismuth, $[(CH_3)_3Bi]$, diisopropyl telluride, $[((CH_3)_2CH)_2Te]$, and tris dimethylamino antimony, $[((CH_3)_2N)_3Sb]$, are used as metal-organic precursor molecules. Deposition of Bi_2Te_3 thin films of 1–10 nm thickness on basal plane sapphire or GaAs (100) substrates occurs at 350 °C and 350 torr.

5. SUMMARY

A variety of chemical and physical synthesis methodologies have been used for the chemical preparation of Bi nanostructures. Inverse micelles, sol-gel processing, and controlled precipitation have been used to prepare Bi and Bi alloy nanoparticles or nanowires with dimensions as small as 1–2 nm or as large as 200 nm. Formation of the nano-Bi phase is typically carried out by the reduction of a Bi^{3+} source using solution or gas-phase chemical methods or electrochemical reduction. CVD, MOCVD, MBE, and high-pressure injection are useful techniques for preparing Bi and Bi alloy or intermetallic nanowires, thin films, or superlattices.

GLOSSARY

Energy dispersive spectroscopy (EDS) The spectrum of x-radiation emitted by a sample under high-energy bombardment by electrons.

Nanocomposite A solid mixture or two or more substances in which at least one component exists in a morphology having at least one dimension less than 100 nm in scale.

One-dimensional (1D) nanostructures Particle morphologies in which two dimensions are less than 100 nm in scale, such as rod-like nanoparticles.

Two-dimensional (2D) nanostructures Particle morphologies in which only one dimension is less than 100 nm in scale, such as nano-scale thin films.

Zero-dimensional (0D) nanostructures Particle morphologies in which all three dimensions are less than 100 nm in scale, such as nearly spherical nanoparticles.

Boron-Carbon Nitride Nanohybrids

Yoke Khin Yap

Michigan Technological University, Houghton, Michigan, USA

CONTENTS

1. INTRODUCTION

Tremendous research interest on nanotubular structures was stimulated after the evidence of carbon nanotubes (CNTs) was found in 1991 [1–6]. Structural similarity between pure carbon and boron nitride (BN) solids has motivated the investigations on the boron nitride nanotubes (BNNTs) [7–9], and the hybrid of CNTs and BNNTs: boron-carbon nitride ($B_xC_yN_z$) nanotubes [10–12]. CNTs are either semi-conductor or metallic, while BNNTs are predicted to have wide energy bandgap of 5.5 eV [8]. The $B_xC_yN_z$ nano-tubes/nanohybrids are expected to have physical properties between those of CNTs and BNNTs. Thus, $B_xC_yN_z$ nanohy-brids are prospective semiconducting nanomaterials [10].

In fact, research interest on $B_xC_yN_z$ hybrids was initiated more than three decades ago. The first claim of hybridized $B_xC_yN_z$ compound was a solid solution of graphite and hexagonal phase BN (h-BN) [13]. The possible atomic arrangement for hexagonal phase hybrid (h-BC_2N) was then reported [14]. This hybrid is expected to be a new semi-conductor. Another motivation on $B_xC_yN_z$ materials is to combine properties of diamond and cubic phase BN (c-BN) [15–20]. Such a cubic phase hybrid (c-BC_2N) is expected to be harder than c-BN and chemically more stable than dia-mond. Many experiments have been conducted on preparing these $B_xC_yN_z$ compounds. However, a common difficulty in the synthesis of BCN hybrids is phase separation [21, 22]. Atoms inside the $B_xC_yN_z$ compounds have the tendency to segregate as pure carbon and BN materials. That is, car-bon atoms tend to bond among each other, while B and N atoms prefer to form pure BN grains. Competition between phases like pure carbon, BN, boron carbides, and carbon

nitrides is possible during the formation of $B_xC_yN_z$ hybrids and nanotubes.

Recent results indicate that $B_xC_yN_z$ hybrids can be grown as fibrous nanostructures [23, 24]. The increase of film thick-ness or physical dimensions of these nanostructures leads to phase separation. In fact, the first report on hybridized $B_xC_yN_z$ compound had grain dimension below 20 nm [13]. These results suggest that h-BC_2N and c-BC_2N should be considered as nanostructures or nanocrystals instead of macroscopic single crystals. The research interest on BCN hybrids appears to move towards $B_xC_yN_z$ nanohybrids including the $B_xC_yN_z$ nanotubes/nanofibers, h-$B_xC_yN_z$, and cubic (c-$B_xC_yN_z$) nanocrystals. All these aspects will be reviewed in this chapter.

2. PRECURSORS OF $B_xC_yN_z$ HYBRIDS

The research on $B_xC_yN_z$ hybrids was initiated for combining structural and physical properties of pure carbon and BN materials. Thus the properties of $B_xC_yN_z$ hybrids are related with the bonding configurations of their precursors. In order to understand $B_xC_yN_z$ hybrids, it is important to review the bonding configurations of phases in pure carbon and BN materials. The bond lengths of various carbon and BN bonds are summarized in Tables 1 and 2.

2.1. Phases of Pure Carbon Solids

Carbon is the sixth atom in the periodic table and has six electrons, which occupy $1s^2$, $2s^2$, and $2p^2$ atomic orbitals. The valence electrons in $2s$, $2p_x$, $2p_y$, and $2p_z$ orbitals are involved in various bonding configurations in carbon solids. Since the energy differences between these orbitals are small compared to the binding energy, the electronic wave func-tions for these four electrons can readily mix with each other to maximize the binding energy of C atom with its neigh-boring atoms. The mixing of a single $2s$ electron with one to three $2p$ electrons is called sp^n hybridization ($n = 1, 2, 3$). Thus carbon can be bonded in sp, sp^2, and sp^3 hybridiza-tions. That is, each C can be bonded to one to four carbon atoms in various carbon polymorphs [4, 5].

In diamond, each carbon is sp^3-hybridized to form four covalent sigma (σ) bonds in a tetrahedral structure using all

Table 1. Bond lengths for various carbon and BN bonds [4, 5, 27, 35–39].

Bonds	Bond lengths/nm		
	sp^3	sp^2	π bond between two hexagonal planes
C-to-C	0.142	0.154	0.355
B-to-N	0.145	0.157	0.334

the $2s$, $2p_x$, $2p_y$, and $2p_z$ orbitals. These sp^3 bonds can be arranged in either cubic or hexagonal (würtzite) polymorphs [25, 26]. The cubic diamond is stable in ambient conditions and will be referred hereafter. The bond length for sp^3 C—C bonds in diamond is 0.154 nm [27]. Likewise, all carbon atoms in graphite are sp^2-hybridized for three covalent σ bonds ($2s$, $2p_x$, and $2p_y$) in a planar trigonal structure and thus form a hexagonal network with sp^2 C=C bond length of 0.142 nm. The $2p_z$ orbital of each of the carbon atoms will form the π–bonding between hexagonal networks/sheets that are stacked in an ABAB ... sequence, with a separation of 0.355 nm between sheets. The sp-bonded carbon was know as "carbyne" for many years and remained a subject of research [28–31]. Little is known about the properties of carbines [4]. Likewise, graphite is soft, semi-metallic, and has a zero energy bandgap while diamond is superhard with a bandgap of 5.4 eV. Beside these carbon materials, fullerenes [32–34] and CNTs [1–6] are both sp^2-hybridized carbon solids realized in the past two decades. These two materials have different bond angles and molecular packing as compared to graphite and thus have very distinguishable physical properties. Articles for further reading on diamond [35, 36] and graphite [4, 37] are available.

2.2. Phases of Pure BN Solids

BN solids are structurally similar to those in the pure carbon system. We have h-BN, c-BN, and BNNTs polymorphs, which are analogous to the graphite, diamond, and CNTs, respectively. Despite the structural similarity, these carbon and BN materials have very different physical properties. For instance, h-BN has a layered structure that is similar to graphite with the exception that hexagonal rings of the basal planes in h-BN are positioned directly above each other and rotated by 180° between alternative layers [38–40]. The h-BN sheets are stacked in an eclipsed ABAB... sequence with B eclipsed by N and vice versa. As a result, graphite is a semimetal with a slight energy overlap (0.04 eV) [41, 42] of the valence and conduction band, while h-BN is an insulator with a bandgap >3.8 eV [43]. Experimental result indicates that h-BN thin films and single crystals could have a bandgap of 5.8 eV [44] and 5.6 eV [45], respectively. The

Table 2. Bond lengths of various types of bonds in h-BC$_2$N hybrids [10, 14, 57].[a]

Bonds	Bond lengths/nm
C-to-C	0.142
B-to-C	0.155
B-to-N	0.145
C-to-N	0.132

[a]These are also applicable for BC$_2$N nanotubes.

sp^2 B=N bond length is 0.145 nm, while the distance between hexagonal BN planes is 0.334 nm [40].

Like the sp^3 bonded carbon solids, there are cubic and würtzite BN phases that have tetrahedral bond configuration [40, 46]. Again, the cubic phase (c-BN) is stable in ambient condition and will be considered hereafter. The sp^3 B-N bond length is 0.157 nm, slightly longer than that of diamond [17], and the density of c-BN is thus 3.48 g/cm^3, lower than that of diamond (3.52 g/cm^3). This cubic phase has a Vickers hardness of about 4500 kg/mm^2, second in hardness only to diamond (9000 kg/mm^2) [17, 47, 48]. The fact that c-BN does not react with ferrous metals [47] (as does diamond [49]) makes c-BN a better material for hard coatings. Recent reviews on c-BN thin films are available in various articles [46, 50–52].

The BNNTs are sp^2-bonded like CNTs. BNNTs are expected to have a bandgap of 5.5 eV, lower than that of h-BN [8]. This bandgap is nearly independent of the tube diameter, number of walls, and chirality (the way the h-BN sheet rolls up as a seamless hollow cylinder). This means the electronic properties of BNNTs are stable and uniform. This is the advantage of BNNTs compared to CNTs. The bandgap of CNTs could exist only for single-wall nanotubes, which depend on the chirality and tube diameter. Further reading on BNNTs are available elsewhere [5, 6].

3. B$_x$C$_y$N$_z$ HYBRIDS

The attempts to synthesize B$_x$C$_y$N$_z$ hybrids are motivated by the possibility to merge the physical properties of their pure carbon and BN precursors. To date, there are three themes on preparing BCN hybrids: (1) hybrid of graphite and h-BN; (2) hybrid of diamond and c-BN; and (3) hybrid of CNTs and BNNTs. Hereafter, discussion will be separated into these subsections on their bond configuration, properties, and synthesis approaches.

3.1. Hexagonal Phase Hybrid: h-B$_x$C$_y$N$_z$

There seems to be little doubt that h-B$_x$C$_y$N$_z$ hybrid has been made by chemical vapor deposition (CVD) processes [13, 17, 53]. However, there is evidence that co-deposition of carbon and BN materials leads to a two-phase compound composed of pure BN and boron doped graphitic domains [21]. Such a condition is usually called phase separation. As quoted in [21], deposition of BCN compounds by CVD using the mixtures of BCl$_3$, NH$_3$, and C$_2$H$_2$ at 1700 °C also resulted in phase separation [54, 55].

Formation of crystalline h-B$_x$C$_y$N$_z$ hybrid seems to occur at a very narrow experimental window [13]. Polycrystalline h-B$_x$C$_y$N$_z$ films were deposited by CVD from mixtures of BCl$_3$, CCl$_4$, nitrogen, and hydrogen at 1900 °C. Below this temperature, crystalline B$_4$C films were formed, and above 1900 °C, the h-B$_x$C$_y$N$_z$ films were contaminated by Si from the quartz tube. The composition of the crystalline hybrid was (BN)$_x$C$_{1-x}$, $0 < x < 1$, and its lattice constant a changed from 0.246 nm at $x = 0$ (graphite) to 0.250 nm at $x = 1$ (BN). It is noteworthy that the grain dimension along the a-axis of the hybrid was 20 nm and that along the c-axis was 8 nm. This means that the crystalline h-B$_x$C$_y$N$_z$ hybrid was nanostructure: B$_x$C$_y$N$_z$ nanohybrids.

In fact, there is another evidence that crystalline h-$B_xC_yN_z$ hybrid has the tendency to form nanostructures [56]. In that report, $B_xC_yN_z$ compounds were prepared from the interaction of BCl_3, acetylene (carbon black), and ammonia at 400–700 °C. The compositions of the products ranged from $B_{0.485}C_{0.03}N_{0.485}$ to $B_{0.35}C_{0.3}N_{0.35}$ when prepared at 400 °C and 700 °C, respectively. The $B_{0.35}C_{0.3}N_{0.35}$ compounds were crystallized in the hexagonal phase with lattice constants $a = 0.249$ nm and $c = 0.335$ nm. According to high-resolution transmission electron micrographs, these h-$B_xC_yN_z$ hybrids had grain diameter of 10 nm. These hybrids had a room temperature conductivity = $6(1) \times 10^{-4}$ S cm^{-1} and showed a linear relation to the inverse of the absolute temperature. These results implied that h-$B_xC_yN_z$ hybrids are semiconducting with a thermal bandgap of 0.2 eV [56].

Although many experimental results on the h-$B_xC_yN_z$ hybrids have been reported, the actual atomic configuration is not easy to determine. In general, a truly hybridized BC_2N compound must consist of all the C—C, C—N, B—C, and B—N bonds. Theoretically, three types of atomic configuration of h-BC_2N hybrid were calculated [14]. Two of these configurations were found to have the lowest total energy and the highest chemical bond energy. These configurations are shown in Figure 1a and b and are predicted to be metallic and semiconducting, respectively [10]. In the first configuration (type-I sheet), each C atom has a C, B, and N nearest neighbor, while each B (N) has two C's and one N (B) as the nearest neighbors. This arrangement is likely to have zero structural stress and a chemical bond energy of 23.7 eV/molecule. In the second configuration (type-II sheet), each C atom is bonded to two other C's and either one B or one N. Every B (N) atom has two N (B) and one C nearest neighbors. This atomic arrangement has some structural stress but has a higher chemical bond energy (24.7 eV/molecule) than the type-I sheet. Thus the type-II configuration is expected to have higher stability [10]. The local-density-approximation (LDA) gap of the type-II configuration is approximately 1.6 eV, and was quoted as an *indirect* bandgap [14]. However, the type-II sheet was stated as a direct bandgap of 1.76 eV in a later literature [10]. The bond lengths chosen for these calculations are: $d_{C-C} = 0.142$ nm, $d_{B-C} = 0.155$ nm, $d_{B-N} = 0.145$ nm, and $d_{C-N} = 0.132$ nm [10, 14, 57]. All bond angles are 120°, and 120° ± 2° for the arrangements in Figure 1a and b, respectively. Several theoretical investigations of h-BC_2N hybrid were reported on the equivalent structure [58] and the vibrational properties [59, 60].

Many experimental works have been devoted to preparing $B_xC_yN_z$ thin films [21, 61–76]. There are uncertainties regarding the homogeneity of some of these compounds and the actual atomic configurations. Some of these works claimed that BC_2N films are semiconducting with an indirect bandgap of ∼1.8 eV [77]. These BCN films were prepared by CVD method using BCl_3 and acetonitride (CH_3CN) at 850 °C [61, 74–76]. These BC_2N films were previously reported to emit photoluminescence (PL) with a peak at 2.1 eV (∼590 nm), and a bandgap of ∼1.4 eV as estimated by scanning tunneling microscopy (STM) [78]. Previous results indicate that these films were p-type semiconductor [75, 76].

3.2. Cubic Phase Hybrid: c-$B_xC_yN_z$

One of the motivations for preparing a cubic phase $B_xC_yN_z$ hybrid (c-$B_xC_yN_{1-x-y}$) is to realize superhard materials that are harder than c-BN. The hardness of c-BN is just half of that of diamond. However, c-BN is chemically inert to ferrous metals and more stable than diamond at high temperatures in the presence of oxygen. It is believed that c-BC_2N hybrid could be harder than c-BN and chemically stable like c-BN. The possible atomic configuration of c-BC_2N is shown in Figure 2b, as compared to those of diamond (Fig. 2a) and c-BN (Fig. 2c) [18]. The cubic phase hybrid is also expected to be a new wide bandgap semiconductor. Like c-BN and diamond, the c-$B_xC_yN_z$ hybrids are expected to be a high-pressure phase. Thus, experiments on preparing such a cubic phase hybrid were concentrated at high-pressure, high-temperature (HPHT) procedures [79–86]. Besides, reactive vapor phase deposition employed for preparing c-BN films [22], and ball milling [87, 88], were also attempted to prepare the c-$B_xC_yN_z$ hybrids. Unfortunately, results reported by different authors differ considerably. Some reported on achieving solid solution of c-$B_xC_yN_z$ hybrids, but other reports describe phase separation into other phases. A promising synthesis route for preparing such a cubic phase has not been identified.

Badzian showed that c-$B_xC_yN_z$ hybrids can be obtained by using HPHT technique at static pressure of 14 GPa and temperature of 3000 °C [79]. Polycrystals of h-$B_xC_yN_{1-x-y}$ produced by CVD were used as the starting materials [13], without using any catalyst as required to form diamond and c-BN. The composition of these starting materials was $(BN)_{0.26}C_{0.74}$. The c-$(BN)_{0.26}C_{0.74}$ hybrids had lattice constant of 0.3582 ± 0.0002 nm, in between that of diamond
Figure 2. Graphical representations of several cubic phase materials including (a) diamond, (b) c-BC_2N, and (c) c-BN structures with the black, white, and gray spheres as C, B, and N atoms, respectively. (0.3570 ± 0.0001 nm) and c-BN (0.3615 ± 0.0001 nm). Electron microscopes showed that these hybrids were polycrystals, with a dimension of several micrometers. However, according to the data of transmission electron microscopy (TEM), the grain size of c-$(BN)_{0.26}C_{0.74}$ crystals is on the order of nanometers. A similar experiment was also carried out using a laser-heated diamond cell [86]. Again, c-$B_xC_yN_z$ hybrids were obtained at static pressures >30 GPa and temperatures >1500 K. Starting materials were polycrystals of h-$B_{x0.35}C_{0.3}N_{0.35}$ and h-$B_{x0.2}C_{0.6}N_{0.2}$ [56]. The lattice constants for the c-$B_{x0.35}C_{0.3}N_{0.35}$ and c-$B_{x0.2}C_{0.6}N_{0.2}$ obtained were 0.3613 ± 0.0003 nm and 0.3596 ± 0.0003 nm, respectively, as estimated using the lattice constants of diamond (0.3567 ± 0.0001 nm) and c-BN (0.3617 ± 0.0001 nm). A reststrahlen band ranging from 1000 to 1120 cm^{-1} and a Raman longitudinal optic mode at 1323 (±2) cm^{-1} were detected from these samples. The bulk modulus of c-$B_{x0.33}C_{0.33}N_{0.33}$ was determined as 355 (±19) GPa, lower than those of diamond (442 GPa) and c-BN (369 GPa). Theoretical effort was attempted to simulate the bulk modulus of c-$B_xC_yN_z$ [89]. On the other hand, direct transformation of h-$B_xC_yN_z$ to c-$B_xC_yN_z$ was also demonstrated using a shock-wave compression technique at 30–40 GPa [80–82]. Possible physical properties of c-$B_xC_yN_z$ are summarized in Table 3.

Direct transformation of h-$B_xC_yN_z$ to c-$B_xC_yN_z$ hybrids at HPHT conditions appeared to be promising. However, these crystals are generally poor in crystallinity and their diffraction patterns are substantially difficult to identify a genuine BCN hybrid [83]. A catalytic HPHT technique was attempted at a pressure of 5.5 GPa and temperatures of 1400–1600 °C using Co metals as the catalyst [83]. Such an attempt failed to produce c-$B_xC_yN_z$ hybrids from h-$B_xC_yN_z$. A mixed crystal of diamond and c-BN was obtained with some graphite and h-BN. Such kind of phase separation was also observed in a later attempt using the direct transformation technique without catalyst at 7.7 GPa and 2000–2400 °C [84, 85]. Again, h-$B_xC_yN_z$ was used as the starting material and subjected to static pressure of 7.7 GPa for 15–60 minutes. The sp^2 to sp^3 transformation started at temperatures above 2150 °C and completed at 2400 °C. The products consisted of three components, c-BN, diamond with minor B and N, and c-$B_xC_yN_z$. With the increase of temperature, the B and N impurities inside the diamond were reduced, and the c-$B_xC_yN_z$ was decomposed into c-BN and pure diamond. These results suggest a phase separation of c-$B_xC_yN_z$ to c-BN and diamond. The cubic phase crystals (c-BN, diamond, and c-$B_xC_yN_z$) obtained at 2300 °C were 20–30 nm in diameter. Again, c-$B_xC_yN_z$ hybrids obtained so far were nanocrystals.

Table 3. Physical properties of c-$B_xC_yN_z$ hybrids [79, 86].

Properties	Cubic phase materials		
	Diamond	c-$B_xC_yN_z$ hybrids	c-BN
Lattice constant (nm)	~0.3570	0.3570–0.3615	~0.3615
IR absorption band (cm^{-1})	N/A	1000–1120	1367–1390
Raman vibrational mode (cm^{-1})	~1333	~1323	~1304
Bulk modulus (GPa)	~442	~355	~369

Attempts to prepare c-$B_xC_yN_z$ hybrids by using other techniques were reported. Annealing of amorphous BCN compounds was reported to form c-$B_xC_yN_z$ nanocrystals [87]. The starting materials were prepared by ball-milling of graphite and h-BN powders with a mole ratio of 1:1. The mixture-to-ball-weight ratio was 1:20. After a milling duration of 120 h, all h-BN and graphite crystals converted into an amorphous BC_2N compound. Subsequent annealing of this compound in atmosphere at temperatures of 800–900 K results in the formation of B_2O_3 and c-$B_xC_yN_z$ crystals. The hybrids were notated as c − $(BN)_{0.35}C_{0.65}$ with grain dimension of 10–50 nm. The lattice constant of this cubic phase was determined as 0.3587 nm, in between those of diamond and c-BN. However, these results could not be repeated in a later experiment [88]. In this case, ball-milling results in an amorphous BCN phase (a-BCN) in a nanometer scale. Such an a-BCN phase is a mechanical mixture rather than a chemical mixture. This a-BCN phase undergoes a phase separation after annealing at ambient pressure. Phase separation also occurred after annealing at 7.7 GPa and 2300 °C. The resultant phases are c-BN, amorphous carbon, and turbostratic graphite. In another report, annealing of similar a-BCN plate prepared by ball-milling was reported to produce a new structure comprising alternate arrangement of h-BN and hexagonal graphite layers [90]. However, similar result could not be repeated in a recent experiment [88].

Phase separation of BCN compounds was also detected in the attempts to prepare BCN compounds by using other techniques. By using reactive magnetron sputtering, BCN films were found to consist of c-BN, amorphous carbon, and amorphous boron grains [22]. In fact, recent calculation using *ab initio* linear-muffin-tin orbital (LMTO) in the atomic-sphere approximation (ASA) have shown that the cubic phase β-BC_2N structure energetically favors segregation into superlattices of alternate diamond and c-BN layers [91].

3.3. $B_xC_yN_z$ Nanotubes and Nanofibers

CNTs are promising building blocks for future nanoelectronic devices. Single-wall carbon nanotubes (SWNTs) can be metallic or semiconducting depending on the tube diameter and chirality (the way the graphene sheet rolls up as a seamless hollow cylinder) [92–94]. Semiconducting SWNTs have been used as the building blocks of advanced electronic devices for single electron transport [95, 96], spin transport [97], rectification [98, 99], and switching [100]. Recent research also points to the need for nanotube-based wide bandgap semiconductors. Boron nitride nanotubes (BNNTs) are predicted to have uniform bandgap of 5.5 eV, making them an intrinsic wide bandgap semiconductor for future nanoscale electronic devices [8].

Like the motivation of preparing cubic and hexagonal $B_xC_yN_z$ hybrids in the past three decades, there are interests to merge the properties of CNTs and BNNTs: $B_xC_yN_z$ nanotubes with tunable energy bandgap between those of SWNTs and BNNTs. According to theoretical calculation, hybridized BC_2N nanotubes have a direct bandgap of ~1.26 eV [10]. The corresponding atomic configurations of these BC_2N nanotubes were investigated based on those of h-BC_2N hybrid [14] as shown in Figure 1b, that is, type-II

h-BC$_2$N sheet. This bandgap is smaller than that of type-II h-BC$_2$N sheet. Thus, B$_x$C$_y$N$_z$ nanohybrids are expected to have a direct bandgap ranging from 1.26 eV (BC$_2$N nanotubes) to 5.5 eV (BN nanotubes), tunable by the atomic composition. Potentially, B$_x$C$_y$N$_z$ nanotubes are applicable for high-power electronic and photonic nanodevices which are not achievable by using CNTs. Potential applications of B$_x$C$_y$N$_z$ nanotubes include nanoscale laser and light emitting devices (LED) with tunable wavelengths that cover the whole visible range and extend to the ultraviolet.

The approach of growing B$_x$C$_y$N$_z$ nanotubes is similar to the techniques employed for growing CNTs: substitution of carbon in CNTs by boron and nitrogen species. The growth of CNTs requires specific metal nanoparticles. These nanoparticles are commonly called catalysts and their dimensions determine the diameter of nanotubes. The well-accepted mechanism involves the diffusion of growth species into the catalyst until saturation, and then segregation as nanotubes from the catalyst [6, 101, 102].

Like the growth of CNTs, B$_x$C$_y$N$_z$ nanotubes were grown by using arc discharge [103–106] and laser ablation [107]. These techniques involve physical evaporation of electrodes by either dc arc discharge or laser ablation. The actual temperatures involved are higher than 3000 °C within the arc and laser plasmas. In the first report, arc discharge is performed in nitrogen atmosphere between a pure graphite cathode and a graphite anode with a central hole filled with a mixture of boron and graphite powders [103]. The products are a mixture of thin graphite sheets, CNTs, boron doped CNTs, B$_x$C$_y$N$_z$ nanotubes, and other amorphous products. According to the data of electron energy-loss spectroscopy (EELS), the composition is not uniform along the length or cross section of the tubes. Concentration profiles of B and N in some tubes resemble outer carbonated BN coating shells for the inner BN-substituted carbon tubes. This result indicates the formation of BN-rich/C-rich/BN-rich sandwich-like structures, a tendency of phase separation toward a BN/C/BN structure. Concentration profiles of B and N acquired along a BCN sheet indicate the formation of pure BN and C islands within a same graphitic shell [103, 105]. Nanoscale domains of pure carbon and pure BN networks are formed within a same tubular shell. This result coincides with the total energy calculation that a two-dimensional BC$_2$N sheet tends to form islands of pure BN and C [58]. In a later experiment, a BC$_4$N electrode is used to replace the B/C composite electrode [105]. Boron doped CNTs are the dominant product instead of the B$_x$C$_y$N$_z$ nanotubes. The tendency of forming B$_x$C$_y$N$_z$ nanotubes with a higher concentration of B and N is small, as compared to the yield of boron doped CNTs. Again, the detected B$_x$C$_y$N$_z$ nanotubes are constructed of BN-rich/C-rich/BN-rich sandwich-like structures. Synthesis of B$_x$C$_y$N$_z$ nanotubes is also attempted by arc discharge in a helium environment between a graphite cathode and a graphite anode filled with a solid BN rod at the center [104]. The elemental concentration profiles of these nanotubes were not reported.

In another report, a graphite cathode is used to arc with an HfB$_2$ anode in a nitrogen atmosphere [106]. In this case, nanoparticles and nanotubes with well-separated layers of BN and C are detected. The dominant product is metallic hafnium boride nanoparticles (5 to 20 nm), encapsulated in polyhedral concentric graphitic shells with 10 to 50 layers. The outer shells of these particles are pure carbon layers and the inner shells are BN-rich or pure BN layers. Besides, pure BNNTs are detected. Two types of B$_x$C$_y$N$_z$ nanotubes are detected: one where the inner BN layers are coated by carbon layers, and another, which is dominant with a C-rich/BN-rich/C-rich sandwich-like structure. Again the tendency of phase separation is observed. In fact, phase separation was reported on so-called BN:C nanoboxes [108]. In this case, square-like nanotubes were grown on NaCl substrates by dc magnetron sputtering. These tubes appeared like nanoboxes when observed along the tubular axis under the transmission electron microscope. These tubes are in a sandwich-like pattern of C/BN/C shell structure. All these nanofibers are structurally different from the theoretically predicted BC$_2$N nanotubes [10].

The BN-rich/C-rich/BN-rich sandwich-like structures are also detected from B$_x$C$_y$N$_z$ nanotubes produced by laser ablation with a Nd:YAG laser in a nitrogen atmosphere [107]. The target is a pressed pellet made of mixed powder of BN, carbon, nickel, and cobalt with an atomic ratio of 100:100:0.6:0.6. The products from this attempt consist of micrometer-sized h-BN crystals in addition to the usual soot of laser ablation. Multiwall CNTs, nanoparticles, and amorphous B$_x$C$_y$N$_z$ phase are found in the soot with no evidence of SWNTs. The multiwall CNTs usually have an inner diameter of 2–3 nm and an outer diameter of 4–10 nm. The B$_x$C$_y$N$_z$ nanotubes, on the contrary, have a larger outer diameter. These B$_x$C$_y$N$_z$ nanotubes have uneven diameters from one end to another end of a tubular structure. They consist of segments with different number of tubular shells. The radial distributions of boron and carbon atoms of these nanotubes are investigated by EELS line scan technique. Figure 3 shows the concentration of boron and carbon scanned across a B$_x$C$_y$N$_z$ nanotube with 13 tubular shells. As shown, the peak positions of boron and carbon concentration profiles do not coincide. This nanotube is interpreted as constructed of six inner layers of pure carbon tubes and seven outer layers of BC$_7$N tubes. This is a carbon-rich/pure carbon/carbon-rich sandwich-like structure. Again, it is difficult to introduce higher B and N atoms into the CNT structure.
Figure 3. Elemental concentration profiles of B and C scanned across a B$_x$C$_y$N$_z$ nanotube. The as-shown concentration of B was multiplied by a factor of 5. Reprinted with permission from [107], Y. Zhang et al., *Chem. Phys. Lett.* 279, 264 (1997). © 1997, Elsevier Science.

The schematic growth models of such heterogeneous structures are shown in Figure 4. The first step of the growth involves the nucleation of multiwall CNTs, which determines the inner diameters of the nanotubes. The second step is the partial coating of $B_xC_yN_z$ layers, which may originate from a defect, or attached particles on the CNT surface. These heterogeneous nanotubes are structurally different from the theoretically predicted BC_2N nanotubes [10].

Besides the physical evaporation techniques discussed so far, $B_xC_yN_z$ nanofibers were also prepared by catalytic pyrolysis of CH_3CN and BCl_3 over Co powder at 900–1000 °C [109], as well as BH_3 and $N(CH_3)_3$ over Co powder at 1000 °C [110]. All these $B_xC_yN_z$ nanofibers have the bamboo-like structures with the internal graphitic walls of the fibers linked across the fiber axis. Similar structure is detected from $B_xC_yN_z$ nanofibers that were grown by hot-filament CVD on CNT templates [111]. In such a CVD approach, N_2, H_2, and CH_4 were first introduced for the growth of the multiwall CNTs on nickel wafers. Then, an addition of B_2H_4 gas was filled into the growth chamber for the formation of $B_xC_yN_z$ nanofibers on top of the multiwall CNTs. The growth temperatures for the whole process were maintained at 600–650 °C, significantly lower than other techniques discussed so far. The bamboo-like structures of these $B_xC_yN_z$ nanofibers are shown in Figure 5 [112]. In fact, this figure indicates the structural difference between multiwall CNTs and $B_xC_yN_z$ nanofibers. Figure 5a is the typical multiwall CNT. These CNTs are in the tubular structure with a hollow core along the tube axis. When $B_xC_yN_z$ nanofibers are grown on top of these CNTs, the bamboo-like structures of the nanofibers are formed as shown in Figure 5b and c, regardless of the composition. By comparing these two images, the number of cross-links and compartments are observed to increase with the increase of B and N compositions. A magnified structure of such $B_xC_yN_z$ nanofibers is shown in Figure 6 [113]. As shown, these $B_xC_yN_z$ nanofibers contain significant structural defects. In fact, similar defects are typically observed on $B_xC_yN_z$ nanofibers obtained so far by various pyrolysis processes [109–117]. The actual mechanism involved is still unknown. Again, these $B_xC_yN_z$ nanofibers are different from the theoretically predicted BC_2N nanotubes [10]. Some of the $B_xC_yN_z$ nanofibers were demonstrated to emit photoluminescence [113–116].

There have been attempts to grow $B_xC_yN_z$ nanotubes by substitution reaction of carbon nanotubes, which were carried out at 1600 °C [118, 119]. This technique was also used to prepare BN nanotubes ($y = 0$) [120, 121]. In this technique, CNTs were reacted with B_2O_3 powder in the presence of N_2 gas. It was shown that subsequent heating of these
Figure 5. Images of (a) multiwall CNTs, (b) $B_{0.08}C_{0.76}N_{0.16}$ nanofibers, and (c) $B_{0.45}C_{0.29}N_{0.26}$ nanofibers. Reprinted with permission from [112], J. D. Guo et al. *Appl. Phys. Lett.* 80, 124 (2002). © 2002, American Institute of Physics.

$B_xC_yN_z$ nanotubes in air at 700 °C converts the $B_xC_yN_z$ nanotubes into BN nanotubes with an efficiency of 60%. This result is explained by the oxidation of pure carbon shell of the C/BN/C sandwich-like $B_xC_yN_z$ nanotubes. Oxidation could remove the outer pure carbon shells and leave the pure BN shells remaining as BN nanotubes. This means 60% of these $B_xC_yN_z$ nanotubes are in C/BN/C sandwich-like structures. The remaining 40% could be in the BN/C/BN sandwich-like structure where the oxidation of pure carbon shells was prevented by the protection of pure BN shells. Again, $B_xC_yN_z$ nanotubes produced by the substitution reaction are phase separated into pure carbon and pure BN shells, different from that predicted theoretically [10].

Recently, careful elemental profile analysis was carried out on some of the $B_xC_yN_z$ nanofibers that were prepared by pyrolysis [122, 123]. Line scan across the tubular axis using high-resolution EELS indicates that these nanofibers are constructed of sandwich-like pattern of C/BN/C shell structures. As discussed earlier, similar structures were detected on $B_xC_yN_z$ nanofibers that were prepared by arc discharge [103, 105, 106], laser ablation [107], BN:C nanoboxes [108], and substitutional reaction of carbon nanotubes [119]. Such a phase separation in $B_xC_yN_z$ nanofibers seems to be a universal phenomenon regardless of the synthesis technique. The elemental concentration profiles of most $B_xC_yN_z$ nanotubes/nanofibers are still not clear [110–118, 124–126].

4. PROSPECT OF B$_x$C$_y$N$_z$ HYBRIDS

As a summary, the present research status of B$_x$C$_y$N$_z$ hybrids has been reviewed. There is strong evidence that both the h-B$_x$C$_y$N$_z$ and c-B$_x$C$_y$N$_z$ that have been synthesized so far are nanostructures. Together with recent interest on B$_x$C$_y$N$_z$ nanotubes, the research interest on B$_x$C$_y$N$_z$ hybrids is converting into the investigation of B$_x$C$_y$N$_z$ nanohybrids. This trend will be continued because of the motivation of nanoscale materials for novel devices in future nanotechnology and nanoscience.

However, a clear deviation between theoretical and experimental works is observed. Phase separation appeared to be the main obstacle to realize the theoretically predicted B$_x$C$_y$N$_z$ materials. It seems to be a thermodynamic tendency that pure carbon and pure BN will separate into nanoscale domains. Ability to control the bonding between B, C, and N atoms is still challenging—a true nanoscience that needs to be emphasized in the future. Recent attempt with extremely low deposition rate in a superlattice manner (BN/C/BN/C atomic layers) has indicated the possibility to hybridize B$_x$C$_y$N$_z$ materials on nickel substrates at high synthesis temperature [23, 24]. Such a manner could allow mutual bonding between B, C, and N atoms at suppressed tendency of phase separation. Novel fibrous nanostructures were revealed as shown in Figure 7a. It was shown that such hybridized nanostructures are stable only in nanoscale dimension. Phase separation occurred at thicker deposition and/or at higher carbon content. At thicker deposition, the morphology of the nanostructures changed toward continuous films as shown in Figure 7b. These results indicate that formation of macroscopic-scale B$_x$C$_y$N$_z$ materials is challenging. Alternatively, one should consider B$_x$C$_y$N$_z$ hybrids as nanostructures. Further, it is not easy to maintain the hybridized bonding at elemental composition approaching the theoretically predicted BC$_2$N configurations. According to a correlated characterization technique involving IR absorption, Raman spectroscopy, and X-ray photoelectron spectroscopy (XPS) [23, 24], the fibrous nanostructures are constructed of various bondings (BN, CN, BC, and CC bonds) required for the hybridized BCN ternary phase. In Figure 8a, the IR absorptions of h-BN are detected from phase-separated BCN films deposited on Si substrates. In Figure 8b, the IR absorption bands of BN, CN, and BC bonds from the hybridized B$_x$C$_y$N$_z$ nanostructures are indicated. The IR absorption spectra seem to be a convenient technique to identify hybridized B$_x$C$_y$N$_z$ materials.
Figure 8. IR spectra for B$_x$C$_y$N$_z$ films deposited on (a) Si substrates, and (b) Ni substrates. Reprinted with permission from [23], Y. K. Yap et al., *Diamond Relat. Mater.* 10, 1137 (2001). © 2001, Elsevier Science.

IR spectra were used to identify hybridized and/or crystalline B$_x$C$_y$N$_z$ materials [127–131]. Recently, crystalline or hybridized B$_x$C$_y$N$_z$ films were also synthesized by using nickel substrates [132], pulsed laser deposition [133], laser-assisted CVD [134], and other reactive deposition techniques [135, 136].

On the other hand, B$_x$C$_y$N$_z$ nanotubes were recently reported to display semiconducting behavior with an estimated bandgap of ~1 eV [137]. This result seems to have overcome the phase-separation issue of the tubular nanohybrids discussed so far. The nanotubes were prepared by a technique similar to the substitutional reaction [118–121] with the addition of metal oxide promoters [138, 139]. A graphite crucible with mounted layers of B$_2$O$_3$, Au$_2$O$_3$, and CVD-grown CNTs was heated in a furnace under a constant N$_2$ flow of 3.2 l/min. The heating proceeded gradually to 1950 K, held at 1950 K for 30 minutes, before cooling down to room temperature over 2 hours. The growth mechanism is not yet well understood, although B$_x$C$_y$N$_z$ nanotubes are frequently observed on the CNT templates. Energy-filtered transmission electron microscopy (TEM) was used to determine the elemental profile of B, C, and N. Figure 9 shows the zero-loss and energy-filtered TEM images of (a) a four-walled and (b) a double-walled B$_x$C$_y$N$_z$ nanotube. The mapping of B, C, and N atoms seems to match with the tubular structure of the four-walled nanotube. This is also indicated by the (c) intensity profiles of B and C atoms across the tube. As shown, the peak positions of B and C intensity profiles are spatially coincident. These results imply that the nanotube consists of homogeneous B, C, and N atoms. Mapping of nitrogen on the double-walled tube failed due to the low signal intensity and tube damage due to the electron beam irradiation. The B and C mapping contrast intensity profiles along the double-walled tube (from top to bottom) are shown in (d). The authors suggest that high-resolution EELS alone, routinely used in most previous work [103, 105–107, 122, 123], could not conclude that

Figure 7. Surface morphologies of (a) B$_x$C$_y$N$_z$ fibrous nanostructures deposited for 6 h, and (b) B$_x$C$_y$N$_z$ films deposited for 10 h under the same deposition condition. Figure 9. Zero-loss and energy-filtered TEM images of (a) a four-walled, and (b) a double-walled $B_xC_yN_z$ nanotube. Mappings of B, C, and N are recorded for the four-walled tube. Tube damage due to electron irradiation causes the N-mapping of the double-walled tube to be unattainable. The B- and C- elemental profiles scanned (c) across the four-walled, and (d) along the double-walled nanotubes are shown. Reprinted with permission from [137], D. Golberg et al., *Chem. Phys. Lett.* 359, 220 (2002). © 2002, Elsevier Science.

$B_xC_yN_z$ nanotubes are composed of phase-separated BN and C shells and/or domains.

Clearly, another challenge that needs more emphasis in the near future is techniques that enable reliable characterization of atomic bonds, and atomic configuration between the B, C, and N atoms. This is critical for the analysis of nanoscale materials. The issue of imaging and characterizing nanostructures has gained increasing attention [140, 141]. As discussed so far, high-resolution EELS and energy-filtered TEM have been used for atomic-scale characterization. Many other techniques have been examined for characterizing $B_xC_yN_z$ materials, including secondary ion mass spectroscopy (SIMS) [142], X-ray absorption near edge spectroscopy (XANES) [143–145], and X-ray emission spectra [146]. However, it is difficult to identify the actual atomic configuration of $B_xC_yN_z$ materials by a single characterization technique. Recently, interesting approaches have been demonstrated by using a combination of various techniques including IR absorption, X-ray photoelectron spectroscopy (XPS), Raman spectroscopy [23, 24, 147] or IR absorption, and XANES [145]. These approaches require careful comparison and correlation of different information acquired from various techniques. Most of these techniques involve macroscopic area analysis, which could not provide detailed structural information of $B_xC_yN_z$ nanohybrids. The addition of high-resolution EELS and/or energy-filtered TEM is required.

Various properties of $B_xC_yN_z$ materials have been examined despite the uncertainty of phase separation, and the lack of information on the actual atomic configuration of many $B_xC_yN_z$ materials. Field electron emission has been tested on some $B_xC_yN_z$ thin films [148–152] and $B_xC_yN_z$ nanofibers [113, 125, 153]. Mechanical properties like stress [154–157] and hardness [158–166] have attracted significant attention. Some of these films were found to have higher hardness and lower friction coefficient than the diamond-like carbon (DLC) films [163]. Besides, other physical properties of $B_xC_yN_z$ thin films like thermal diffusivity [167–169], magnetoresistance [170], refractive index [171], and low dielectric constant (as the insulator for ultra-large-scale integrated semiconductor devices) [172–175] have been reported. Efforts on exploring properties of $B_xC_yN_z$ materials are important. However, structural properties of the tested materials are not well established in some cases. The relation between the structural and physical properties of $B_xC_yN_z$ materials needs more emphasis in the future. In any case, physical properties are the driving force that promotes the research on $B_xC_yN_z$ materials. The efforts on growing $B_xC_yN_z$ materials have remained very active in the past few years. Various synthesis techniques have been attempted including CVD [176–184], physical vapor deposition [185–193], pyrolysis [194], and physical evaporation techniques like arc discharge [195]. This trend is expected to continue with the additional interest in $B_xC_yN_z$ nanohybrids like the nanotubes and nanofibers.

In fact, superhard c-BC$_2$N was recently synthesized at pressures up to 30 GPa and temperatures up to 3500 K by static and dynamic compression of graphite-like BN-C solid solution [196]. These materials are harder than c-BN single crystals and have grain sizes ranging from 10 to 30 nm

[196–198]. The detected lattice constant ($a = 0.3642$) is larger than those of both diamond and c-BN [198].

Theoretical calculation is very important to assist the experimental investigation on $B_xC_yN_z$ materials. Future calculations are required to predict novel structures, physical properties, and the growth dynamic of $B_xC_yN_z$ materials. For instance, calculations on the sandwich-like BN/C/BN or C/BN/C heterostructures should also be initiated for both the nanotubular and thin-film materials. Novel physical properties could be realized from such a configuration [199]. Theoretical prediction can always inspire new research on $B_xC_yN_z$ materials. However, the issue of deviation between theoretical prediction and experimental evidence should be emphasized in the near future. In fact, the ultimate goal for the research of $B_xC_yN_z$ materials is to prove that mankind can predict, design, and synthesize materials with desirable structural and physical properties.

GLOSSARY

$B_xC_yN_z$ Boron-carbon nitride ternary phase constructed of boron, carbon, and nitrogen. It is also represented by abbreviations like BCN, B-C-N, or B/C/N in literature.

$B_xC_yN_z$ nanotubes Boron-carbon nitride ternary phase in a tubular structure. Theoretically referred to as the h-$B_xC_yN_z$ network(s) that roll up to make seamless hollow cylinder(s) about a common axis.

c-$B_xC_yN_z$ Boron-carbon nitride ternary phase in a face-centered cubic crystal structure.

Fibrous nanostructures Nanomaterials in a fiberlike appearance.

h-$B_xC_yN_z$ Boron-carbon nitride ternary phase in a hexagonal crystal structure.

Nanofibers Nanomaterials in an elongated appearance.

Nanohybrids Nanomaterials that hybridize or combine from two or more types of substances.

Nanomaterials Materials with physical dimension below 100 nm.

Phase separation Inhomogeneous mixing of a compound with grains/sections of different phases/types of materials.

Wide bandgap semiconductors Semiconductor materials with bandgap larger than 2 eV. Bandgap is the difference in energy between the lowest point in the conduction band and the highest point of the valence band.

Boron Nitride Nanotubes

Dmitri Golberg, Yoshio Bando

National Institute for Materials Science, Tsukuba, Ibaraki, Japan

CONTENTS

1. INTRODUCTION

A boron nitride (BN) nanotube (NT) [1] is a carbon (C) nanotube [2] analog: alternating B and N atoms may partially or entirely substitute for C atoms in a graphitic sheet without significant changes in atom spacing. BNNTs were first foretold theoretically [3, 4] and then were successfully synthesized in 1995 [1]. Primarily, the interest to the BNNTs is due to the undisputed fact that in contrast to the metallic or semiconducting CNT [5] the BNNT is insulating with a ~5.5 eV bandgap independent of its chirality and morphology (i.e., diameter and number of layers) [4]. In addition, layered BN is known to be much more thermally and chemically stable than graphitic C [6]. Therefore, there have been intuitive expectations that the BNNTs should inherit these advantageous properties. Therefore the main interest in BNNTs is related to specific applications in nanotubular protective shields for various nanomaterials embedded within (i.e., nanowires, nanorods, and/or clusters). Surprisingly, the amount of successful research work performed to date on BNNTs has been negligibly low compared to that on CNTs [7–22].

It is worth noting that the lack of research performed on BNNTs is solely due to the significant difficulties involved in their preparation as compared to the relative ease in making conventional CNTs.

The present contribution, along with a comprehensive state-of-the-art review in the field, is additionally enhanced by the original authors' data on high-temperature chemical syntheses and structural analysis of BNNTs over last several years using thorough high-resolution transmission electron microscopy (HRTEM) paired with electron diffraction analysis and energy-filtered TEM, and pioneering thermal and electrical property measurements.

2. BORON NITRIDE (BN) NANOTUBE SYNTHESIS

Initially, we note that reliable and well-established techniques of NT growth developed for C systems, for example, arc discharge [2], laser ablation [23], and chemical vapor deposition (CVD) [24], do not effectively work for the BN system. Resultantly, a number of new techniques including continuous laser heating at superhigh [25–27] or ambient pressure [28, 29], oven heating of milled B powders [30] or B-containing reagent mixtures [31, 32], a plasma-jet method [33], direct recombination of spraying B and N atoms on a clean tungsten substrate in a ultrahigh vacuum [34], metal-boride-catalyzed CVD [35], La-catalyzed arc discharge [36], and high-temperature chemical syntheses [37–49] have been developed, although with limited success as described in the following sections.

2.1. Arc Discharge

First BNNTs were discovered in an arc-discharged material by Chopra et al. [1]. Many BN nanotubes were found to contain metallic nanoparticles attached to the tips. The particles presumably originated from a tungsten hollow electrode used for encapsulating a starting BN powder. Later on, arc-discharge syntheses of BNNTs were performed by Loiseau et al. [16] and Terrones et al. [50]. In [16] the electrodes made of graphite and HfB_2 were used as a cathode and an anode, respectively. An arc was created in a N_2 atmosphere. The setup presumes that a C source is separated from that

of B and N; this was thought to be the reason for BN-rich nanotube compositions. NTs with definite phase separation of BN and C layers were observed in a deposit on the anode. The purity of a BN nanomaterial was not high enough with respect to C contamination. In [50] a tantalum tube press-filled with a BN powder and a water-cooled Cu disk were used as electrodes. As the anode rod was consumed a product containing BN nanoparticles and NTs was collected. In both methods (i.e., [16, 50]) the yield of NTs, as compared to that of bulk BN particles, was not claimed to be high.

Saito and Maida [51] used ZrB_2 rods as electrodes and high purity nitrogen gas (99.999%) during their arc-discharge runs. BNNTs were found in the products crystallized on the anode, albeit at limited yields.

2.2. Laser Ablation

Pioneering experiments on laser ablation of a hexagonal or cubic BN target were carried out by Golberg et al. [25]. A continuous CO_2 laser was focused on a target placed into a diamond anvil cell filled with liquid nitrogen. After reducing a spacing between diamond anvils, superhigh nitrogen pressure was generated inside the chamber. A temperature of approximately 5000 K was estimated on the BN target surface, where dozens of short pure BNNTs were found to protrude from an amorphous-like melted BN residue. The drawback of the synthesis was a relatively small number of BNNTs as compared to standard amorphous-like, cubic, or hexagonal BN.

Later on, catalyst-assisted excimer laser ablation experiments at high temperature were carried out during which some BNNTs were also observed [28]. Lee et al. [52] reported on catalyst-free continuous CO_2 laser ablation of BN targets leading to BNNT formation. Most of nanotubes were reported to have only a single layer and form long bundles. Boron nanoparticles, frequently observed as a by-product, were frequently encapsulated into the tip-ends of NTs. They were thought to play a key role for the growth mechanism. By contrast, Laude et al. [29], though applying a similar setup and also continuous CO_2 laser vaporization, did not find single-layered BNNTs; rather the NTs, assembled in bundles, frequently had a few layers. The results bring a significant controversy to the reproducibility of single-layered BN nanotube synthesis.

2.3. Chemical Vapor Deposition

Lourie et al. [35] reported on first CVD synthesis of BNNTs on nickel boride catalyst particles at 1273–1373 K using the borazine as a precursor. A characteristic feature of the process was the fact that the precursor was generated *in-situ* from a molten salt which formed mixtures of $(NH_4)_2SO_4$, $NaBH_4$, and Co_3O_4 at 573–673 K. The BNNTs exhibited lengths of up to 5 micrometers and often possessed bulbous, flaglike and/or clublike tips.

In another CVD run, Ma et al. [53] used a $B_4N_3O_2H$ precursor during synthesis of BNNTs. It was suggested that the tips encapsulating boron oxynitride nanoclusters doped with silicon, aluminum, and calcium served as the effective promoters for BN tube CVD growth. Recently, somewhat controlled preparation of BNNTs and related nanostructures—BN nanobamboos and nanorods—has been achieved by the

same authors [54]. To date, the method has allowed to researchers prepare only milligram quantities of a product containing BNNTs.

2.4. Other Chemical Syntheses

Terauchi et al. [55] used simple oven heating at $\sim$1473 K of B and Li powders in a BN crucible in a N_2 atmosphere and observed a few short pure BNNTs of less than 30 nm in diameter in the resultant powders. Chen et al. [30] produced BNNTs by thermal annealing at 1273 K of elemental B powders which were previously ball-milled in ammonia gas for 150 h at room temperature. It was suggested that high-energy ball-milling induced nitriding reaction between the boron powder and the ammonia gas; thus a metastable material is formed consisting of disordered BN and nanocrystalline boron. BNNTs then grew out from this metastable and chemically activated structure during heat treatment in the presence of nitrogen gas. However, the yield and structural perfection of BNNTs were not high enough, as revealed by transmission electron microscopy observation.

An efficient route to synthesize tens of milligram quantities of BN and B–C–N NTs was invented by Han et al. [37]. During the synthesis pure CVD CNTs served as templates. They were chemically modifying by highly reactive boron oxide vapor and flowing nitrogen gas at 1300–1900 K. The diameters of the resultant tubes perfectly matched those of the starting templates; this lead the authors to suggest that C to BN substitution took place. The major drawback of the synthesis was a significant fraction of ternary B–C–N NTs with significant amounts of the remaining C at the expense of pure BN nanotubes. A dramatic increase in pure BNNT fraction was later achieved by Golberg et al. [40] using the same method through careful selection of synthesis promoters. Metal oxides (i.e., MoO_3, CuO, and/or PbO) were found to be most useful. The oxide vapors caused the CNT template to begin to open at the initial reaction stages at moderate temperatures (600–900 K) via intense oxidation. This promotes an effective substitution BN to C on both sides of the C templates and crystallization of BN domains from inside-out and outside-in of the tubes. In addition, the substitution reaction route was utilized by the same authors [38, 39] to produce B-doped, B–C–N, and BNNTs from the bundles of pure C single-walled nanotubes, albeit with limited success. Marginal B-doping of the C-based nanostructures was found to occur easily; by contrast, large-scale preparation of pure BN single-layered NTs was not successful; the latter were only rarely found.

2.5. Atom Deposition Technique

Bengu and Marks [34] first described *in-situ* synthesis of BN nanostructures using electron–cyclotron resonance nitrogen and electron beam boron source onto polycrystalline tungsten substrates. The nanostructures of 0.5–3.0 nm in diameter were prepared in an ultrahigh vacuum of 2×10^{-9} Pa. Characterization of the resultant structures was performed without their exposure to air; thus all possible artificial structures due to chemisorption were entirely excluded. The crystallinity of the BN nanostructures was not perfect; rather

they frequently revealed undulating, wavy BN layers. However, the method was claimed to be useful for production of different BN-based coatings with well-controlled structure.

2.6. Plasma-Jet Method

Shimizu et al. [33] reported on a flash evaporation method using a direct current plasma. Porous BC_4N sintered bodies were used as a raw material. The plasma was operated under conditions of 25 V and 300 A by using Ar and N_2–H_2 for plasma gas and sheath gas, respectively. The porous BC_4N was evaporated by irradiation of the plasma flame. Nanotubes were formed in a high temperature zone ($\sim$3000 K). Significant amounts of the remaining C were determined in the structures, decreasing its purity, whereas the product was clearly divided into three morphology types such as CNTs, BNNTs, and CNTs surrounded with BNNTs.

Based on Sections 2.1–2.6 it is obvious that the presently achievable yield of BNNTs still remains negligibly low compared to that of CNTs. Moreover, even if the BNNTs are successfully produced and ready to be analyzed, their structural identification and/or analysis are prone to many almost insurmountable difficulties arising from the electrically insulating nature of BN and consequent charging phenomena during electron microscopy, which, in turn, lead to image blurring. As a result, the number of research groups successfully overcoming all of the above-mentioned complications is very small, as described in the following sections.

3. STRUCTURE OF BN NANOTUBES

3.1. Morphology as Revealed by Transmission Electron Microscopy

Similarly to CNTs [2, 7], BNNTs crystallize in multiwalled (MWNT) and single-walled (SWNT) morphologies, albeit notable yields of SWNTs were observed only in a single recent work by Lee et al. [52] as was mentioned previously. All other research groups very accidentally found BN SWNTs [16, 34, 38, 39], a double-layered NT morphology being preferred [17, 29, 44]. In fact, in an early paper on BNNT synthesis by Chopra et al. [1] only BN MWNTs were observed. Later Loiseau et al. [16] presented a few HRTEM pictures of BNNTs with a varying number of layers (including SWNT). However, it was noted that BN SWNTs always had undulating, wavy, and poorly structured wall fringes. Theoreticians assigned this to the fact that in a BN hexagonal sheet the B and N atomic planes are slightly shifted in a direction perpendicular to the tube axis [56]. In addition, it is thought that the high ionicity of BNNTs (i.e., strong B–N bonds) may stabilize MWNT morphologies due to the strong so-called "lip–lip" interactions between adjacent layers [56]. In a homogeneous C graphene sheet, where chemical bonds of only one type are present (i.e. C–C), the interactions between layers are weaker and not important for NT growth. Thus, in contrast to C, where high yields of SWNTs are routinely obtained nowadays [57], the single-layer morphology is supposed not to be natural for the BN system by many researchers.

Figure 1a and b depicts representative HRTEM micrographs of a BN MWNT and SWNT [19, 38]. The BN tubular
Figure 1. (a) Representative HRTEM image of a BN MWNT. The typical intershell distance is 0.33–0.34 nm. (b) HRTEM image of an isolated BN SWNT exhibiting a nested four-shelled BN fullerene encapsulated within. The fullerene lattice image does not resemble a circle typical for a standard C_{60}-based molecule. By contrast, the image would be consistent with a nanocage of the octahedral symmetry. Note also a wavy, undulating contrast for the BN SWNT wall fringes in (b). Figure 1a reprinted with permission from [19], D. Golberg et al., *J. Appl. Phys.* 86, 2364 (1999). © 1999, American Institute of Physics. Figure 1b reprinted with permission from [38], D. Golberg et al., *Chem. Phys. Lett.* 308, 337 (1999). © 1999, Elsevier Science.

shells are imaged as dark contrast fringes separated by an average intershell distance of $\sim$0.33–0.34 nm (in the case of MWNTs), characteristic of the d_{0002} spacing in hexagonal BN [6]. Figure 1b particularly highlights that a nested BN fullerene is embedded in the channel of a SWNT. The unique feature of the fullerene is a nonspherical HRTEM image, contradicting the characteristic spherical shape of the well-known C_{60} molecule. Obviously, this is due to a striking difference in topological defects (leading to graphitic-like sheet curling) in the C and BN systems, as described below.

It is established that the energetically favorable defect in C is a five-membered ring defect (i.e., a pentagon), leading to a 60° inclination of a graphene sheet made of hexagons. By contrast, in BN, the presence of a five-membered ring defect requires the existence of B–B and/or N–N bonds, which are less energetically stable than the B–N bond [56]. Thus, in the BN system an even-membered ring defect (i.e., square and/or octagon) normally forms, leading to a nearly 90° inclination in a graphitic-like sheet [16, 58]. As a result a fully closed structure in BN (i.e., the fullerene-like molecule) accumulates only 6 squares instead of 12 pentagons (Euler rule), as in C. It, therefore, exhibits octahedral symmetry rather than icosahedral symmetry typical for all C sealed nanocages. In terms of crystallography, it turns out that a BN curled and closed nanocage should have very differing HRTEM projections in various crystallographic orientations: square-like [zone axis $\langle 100 \rangle$], rectangle-like [zone axis $\langle 211 \rangle$]; hexagon-like [zone axis $\langle 111 \rangle$], as in Figure 1b, and rhomb-like images
