[zone axis ⟨100⟩] are visible depending on the orientation of a nanocage with respect to an incident electron beam [58]. Therefore, a BNNT cap, which requires a semiclosed fullerene, might frequently exhibit flat motifs like the one shown in Figure 2a. The existence of the flat cap, absent in CNTs, was initially prescribed as a distinguishing feature of a BNNT [16], although later some conical caps were also observed [51, 59]. In addition, BN tube caps may be open (Fig. 2b). This type of capping was frequently observed in the case of high-temperature NT chemical syntheses [20, 40–45], when the nonhexagonal defects are effectively annealed out due to the high atom mobility and/or aging effect resulting from the presence of metallic catalysts [44].

In practice, the particular type of BNNT topological defect is determined by the interplay between structural and energetic factors. Clearly, a 90° inclination (an even-membered ring defect) requires larger internal stress introduced into a graphite-like sheet than that of a 60° inclination (an odd-membered defect). For instance, Bourgeois et al. [60] demonstrated that basically both types of defects exist in a BN nanocone apex, depending on the particular growth kinetics and stress distribution. This is also applicable to BNNTs: Saito and Maida [51] have considered square, pentagon, and heptagon rings in BNNTs, as revealed by experimentally observed tube cap TEM images.

Frequently, the BNNTs tend to assemble in bundles/ropes made of dozens of individual tubes, as shown in Figure 2b [17, 20, 29, 38–45]. These ropes were seen for both MWNTs [41] and SWNTs [38, 39]. It was proposed that the individual tubes within the ropes interact through weak Van der Walls interactions and are packed in a honeycomb-like array (in cross-section view). Splitting of the diffraction spots on the equatorial line in the electron diffraction patterns makes possible calculation of the intertube spacing, $d = 0.34$ nm, between individual tubes in a rope [41, 43], the characteristic value of the d_{0002} distance in many graphitic materials, including CNTs [57].

3.2. Atomic Order as Revealed by Electron Diffraction

The theory of nanotube electron diffraction was developed by Iijima [2] and later extended by Zhang et al. [11]. This theory is fully applicable to BNNTs. For instance, Figure 3a depicts a typical nanobeam diffraction pattern (NBD, electron probe size was 1.6 nm) taken from an individual BNNT [19]. The NBD displays a row of (000l) reflections originating from the NT walls oriented edge-on to an incident electron beam and a hexagon-like pattern originating from the front and back NT fragments oriented perpendicular to the beam. The pattern is a characteristic of the so-called "zigzag" nanotube (the [10–10] direction of the graphitic sheet is parallel to the tube axis) [5].

Figure 3b displays the NBD taken with a larger electron probe size (∼50 nm) from a whole rope composed of dozens of BN MWNTs [41]. An exciting feature of the pattern is fairly uniform shell chirality. Diffraction spots are clustering around those typical for the "zigzag" arrangement (compared with Fig. 3a). The marginal deviations from the ideal "zigzag" orientation are just within $\alpha = 10°$ (semiangle, α, between marked diffraction spots in the vicinity of the [01–10] reflection in Fig. 3b).

The preferential "zigzag" orientation was further verified through taking NBDs from a plenty of individual BN MWNTs, as shown on the histogram in Figure 4 [41]. Although "armchair" (tube axis is parallel to the [11–20] orientation of the graphitic-like sheet) and helical tubes with varying chiral angle were also observed, the majority of tubes, namely, ∼82%, displayed "zigzag" or near "zigzag" atomic arrangements, as revealed by a statistical analysis of NBDs from 45 individual tubes (Fig. 4).

Importantly, the preferential BNNT "zigzag" atomic configuration has been observed in various BN tubular products by many researchers. For instance, Golberg et al. [25–27] showed that such assembly is natural for BNNTs produced

Figure 2. (a) HRTEM image of a typical BNNT flat tip-end termination with a possible arrangement of three four-member ring defects in the cap [50], shown on the inset with arrows, explaining the experimentally observed flat tip. (b) HRTEM image of solely open BN MWNTs. Figure 2a reprinted with permission from [19], D. Golberg et al., *J. Appl. Phys.* 86, 2364 (1999). © 1999, American Institute of Physics. Figure 2b reprinted with permission from [44], D. Golberg and Y. Bando, *Appl. Phys. Lett.* 79, 415 (2001). © 2001, American Institute of Physics.

Figure 3. Representative diffraction patterns (DPs) taken from an individual five-layered BNNT (a) and from a BN MWNT rope containing dozens of nanotubes (b). Both DPs exhibit diffraction spots that are clustered around characteristic of the so-called "zigzag" atomic arrangement of a graphitic-like sheet. The deviations from the ideal "zigzag" orientation (the [10–10] direction is strictly parallel to the tube/rope axis) are represented by the semiangle $\alpha = 10°$ in (b) between a couple of the marked diffraction spots in the vicinity of the [10–10] reflection. Figure 3a reprinted with permission from [19], D. Golberg et al., *J. Appl. Phys.* 86, 2364 (1999). © 1999, American Institute of Physics. Figure 3b reprinted with permission from [41], D. Golberg et al., *Solid State Comm.* 116, 1 (2000). © 2000, Elsevier Science.
Figure 4. A histogram showing BNNT shell helicity distribution in MWNTs based on the statistical analysis of 45 individual BNNT DPs (taken with an electron probe of 1.6 nm in diameter). The corresponding three-dimensional structural models of the representative "armchair" {10,10}, "zigzag" {20,0}, and helical {14.5} tubes are shown for clarity above the histogram. by BN target laser heating under superhigh N_2 pressure and for those obtained via simple high-temperature chemical syntheses [19, 40–45]. A preferential "zigzag" arrangement of BNNTs was later observed by Bourgeois et al. [59] in BN tubular fibers synthesized through heating of BN powders. It is noted that these experimental results are opposed to the theoretical predictions based on the molecular dynamics calculations performed by Blase et al. [56]; those favor the growth of "armchair" BN tubes rather than "zigzag" ones. However, the significant difference between experimental synthesis temperatures, 5000 K [25–27] and 1773–1973 K [19, 40–45], and those used for calculations, 3000 K [56], may be of prime importance for this disagreement. By contrast, later Menon and Srivastava [61] calculated that for the most frequently observed flat BN tube caps [16, 19] the "zigzag" morphology is energetically preferable. This latter phenomenon is in line with the experimental HRTEM data by different research groups. It is worth noting that the "zigzag" atomic arrangement in B-doped CNTs was also found to be dominating [62]. Most recently, "zigzag" BNNTs were repeatedly observed by Terauchi et al. [55], Ma et al. [53, 63], Demczyk et al. [64], and Lee et al. [52] in BNNTs prepared via different synthetic routes.

It is noteworthy that conventional CNTs do not show any preferential helicity and display a wide variety of chiralities [2, 5, 65], which are statistically equally probable. Thus, preferential crystallization of the "zigzag" BN tubular shells is related to the definite kinetic characteristics of the BNNT growth yet to be clarified by energy calculations.

Existence of preferential helical angles in BNNT shells leads to a number of the unique features in BNNTs compared to CNTs, as far as the MWNT layer stacking is concerned. HRTEM images of two BN MWNTs are shown in Figure 5a and b [42]. Lattice fringes with an average distance of ~0.22 nm which correspond to the (10–10) lattice spacing

in BN are clearly resolved for wall fragments. The difference in HRTEM dotlike contrast in the tube walls is apparent between Figure 5a and b. Vertical atomic columns (hexagonal *h*BN-stacking) are visible for the wall fringes in Figure 5a, whereas those in Figure 5b have an angle of 12.5° with respect to the tube axis (rhombohedral *r*BN-stacking) [6], as highlighted in the enlarged atomically resolved wall segments (insets). Both tubes in Figure 5a and b have a similar BN hexagon arrangement along the tube axis; that is, the tube axes are parallel to the [10–10] graphene-like sheet orientation ("zigzag" type). The computer simulations of hexagonally and rhombohedrally packed tubular segments for the "zigzag" oriented BNNTs, revealing a perfect fit with the optical contrast on the HRTEM micrographs, are finally shown on the right-hand sides of the HRTEM images.

Existence of definite stacking in BNNT shells reflects the particular importance of the intershell interactions in BNNTs compared to the C system where turbostratic stacking between shells typically dominates. Thus it is suggested that the driving force behind the particular shell stacking in BNNTs is due to the alternating B and N sites in the neighboring shells in the direction normal to the tube axis in line with bulk BN ordering.

For many of BNNT HRTEM images experimentally observed so far, no visible changes between the fringe contrast intensity in NT wall and core regions, which are common characteristics of cylindrical tubes, were detected [42]. In the view of the authors this may imply that the cross-section of the BNNT is flattened (i.e., elliptical), with the longer ellipse axis in the image plane. In fact, in such
Figure 5. (a), (b) HRTEM images of "zigzag" BN MWNTs. Definite but different stacking order is apparent in marked areas in (a) and (b) as highlighted in the insets. Hexagonal type stacking in (a) and rhombohedral-type stacking in (b) are confirmed by corresponding computer-simulated HRTEM images (right-hand side images) for BN MWNTs having the axes parallel to the [10–10] orientation ("zigzag" NTs). Reprinted with permission from [42], D. Golberg et al., *Appl. Phys. Lett.* 77, 1979 (2000). © 2000, American Institute of Physics.

a case one should expect nearly similar atomic densities for the wall and core domains for the HRTEM micrographs. The flattened CNTs have been indeed reported [66]. Mazzoni and Chacham [67] have recently calculated that flattening causes a reduction of the bandgap in a CNT from 0.92 to 0 eV. Similar results were obtained in the case of a flattened "zigzag" BNNT by Kim et al. [68]. In the latter case, the bandgap reduces from ∼5 eV (cylindrical pure BNNT) to ∼2 eV (collapsed or flattened BNNT). Interestingly, this phenomenon was not seen for an "armchair" BNNT. Thus, the BNNT flattening phenomena may open the exciting possibility of smooth tuning BNNT semiconducting properties.

4. CHEMICAL COMPOSITION AND BONDING IN PURE AND C-DOPED BN NANOTUBES

4.1. Electron Energy Loss Spectroscopy

The typical electron energy loss (EEL) spectrum taken on an individual isolated BNNT is depicted in Figure 6 [20]. It displays clear core-loss K-edges of B and N at 188 and 401 eV, respectively. They correspondingly show that the $1s \rightarrow \pi^*$ (left-hand side peak of the edge) and $1s \rightarrow \sigma^*$ (right-hand side band of the edge) transition features are similar to those of layered BN (hexagonal or rhombohedral) [6], implying the existence of a generally sp^2-hybridized structure. On the other hand, Terauchi et al. [69] reported that the valence electron excitation spectra (so-called plasmon loss) of BNNTs has a considerable difference from that of layered BN due to the fact that the bandgap energy of BNNTs decreases with respect to layered BN by an amount of 0.6–0.7 eV due to the curving of a sheet into a nanotube.

4.2. Energy-Filtered Transmission Electron Microscopy

Spatially resolved EELS and energy-filtered electron microscopy becomes the most useful experimental technique as far as atom distribution in C-doped BN and/or ternary B-C-NNTs is concerned [70–76].
Figure 6. Representative EEL spectrum taken from an individual isolated 10-shelled BNNT. The B and N K edges at 188 and 401 eV are visible. The fine structure of the edges corresponds to sp^2-hybridized nanostructure. The calculated atomic B/N ratio is ∼1.0.

For instance, Figure 7 depicts the HRTEM micrograph of a straight, well-ordered four-shelled C-doped BNNT [47]. The wall fringes exhibit bright contrast in the B and N elemental maps and barely visible contrast for the C map. By contrast, inside the tube, an encapsulated C-rich amorphous-like residue is visible. The residue contains fullerene-like molecules, as shown in the inset. Such molecules, whose diameter roughly corresponds to the theoretical diameter of a C_{60} molecule, ∼0.7 nm, were often seen embedded in the B–C–N and BNNTs [47]. So-called peapod structures made of NTs and encapsulated fullerenes have often been observed in pure CNTs [77]. The data presented in Figure 7 serve as solid experimental evidence that encapsulation of fullerene-like molecules may also take place in BN-rich NTs. It is suggested that the present BN-rich NT/fullerene assembly may create a nanostructural molecular device with intriguing and unique electronic properties, especially if one keeps in mind the insulating nature of BNNTs and an exciting possibility of shuffling/moving of C_{60} molecules inside the NT channel.

TEM intensity profile analysis on the B, C, and N maps in the C-doped BN nanotubes [78] led the authors to the assumption that all three species may actually reside in the B–C–N tube walls. This is in striking contrast to the common beliefs on the dominant trend for BN and C shell separation via organization into so-called sandwich-like structures across the NTs [71–75, 79, 80] and/or domains along the NTs of B–C–N. However, the mentioned experimental results remarkably verify several theoretical predictions of homogeneous B–C–N layer stability [70, 74, 81, 82].

The fairly close values of the B and N atomic ratios measured in many EEL spectra [78] taken on B–C–N NTs led the researchers to the assumption that nearly stoichiometric
Figure 7. Zero-loss (HRTEM) and corresponding energy-filtered images of BN-rich MWNT with an encapsulated C-rich amorphous-like residue. The residue contains irregularly shaped and randomly stacked C_{60}-fullerene-like molecules as highlighted in the inset to the zero-loss image. Reprinted with permission from [47], Y. Bando et al., *Chem. Phys. Lett.* 346, 29 (2001). © 2001, Elsevier Science.

BN islands may occasionally form within a given C sheet, but the size of these islands should be well below the resolving power of the Omega filter TEM instrument used (∼0.5 nm) [83]. On the other hand, it is noted that in most EELS runs on B–C–N NTs the N contents prevailed over those of B or vice versa. This implies that the random spatial distribution of B and N atoms in the C sheets via assemblage of complex B–C–N, B–C, and/or C–N containing six-membered rings should also be presumed to exist.

It is considered now that the peculiarities and kinetics (rather than thermodynamics) of a given BN/B–C–N NT synthesis are most important as far as the final elemental distribution is concerned.

For instance, Figure 8a depicts a HRTEM image (zero-energy loss) and B-, C-, and N-elemental maps of a rope synthesized via high-temperature chemical synthesis from aligned CN_x NTs [46, 48]. The B and N contents are seen as dominant ones. A key feature of the Figure 8 is the obvious BN/C domain segregation not visible for the shells of the individual B–C–N NT in Figure 7. The segregation is particularly documented in Figure 8b where intensity profiles of the B, C, and N species across the rope (the cross-section of interest is depicted in the zero-loss image in Fig. 8a) are thoroughly shown. The digits (shown in nm) on the horizontal axis correspond to the distance along the marked line (Fig. 8) starting from its left-hand side. One may immediately note that while the B and N profiles appear to correlate, that of C may either correlate or anticorrelate with the former two. Most importantly, the BN layers are frequently shielded with the C-rich layers (right-hand part of Fig. 8b, ∼60–80 nm range), verifying the appearance of the "sandwich"-like structures. In addition, the B–C–N layers with variable elemental ratios might also present, as the left-hand part of Figure 8b displays (∼40–60 nm range).

Thus, in the latter case, the rope is composed of conducting/semiconducting C-rich and/or B–C–N NTs shielded with insulating BN-rich tubular shells [46, 48] in contrast to the individual B–C–N NTs with homogeneous B, C, and N

distributions across and along the layers, as discussed earlier (Fig. 7).

5. IRRADIATION STABILITY OF BN NANOTUBES

The stability of a given nanotubular structure against various environments is of prime importance as far as its real practical applications are concerned.

The BNNT shells were found to be rather sensitive to the electron beam irradiation. At low dose irradiation the annealing-out of NT growth defects effectively occurs [26]. Figure 9a–d depicts consecutive HRTEM images of a BN MWNT irradiated under normal TEM imaging conditions (10–20 A/cm^2). The time interval between consecutive micrographs is ∼2 min. The initial NT lattice image in Figure 9a exhibits numerous undulating, dangling BN

Figure 8. (a) HRTEM (zero-loss) and elemental maps taken on a BN-rich B–C–N NT rope synthesized at 2046 K from aligned CN_x nanotube mats, B_2O_3 and N_2. The cross-section of interest is marked with the black bars on the zero-loss image. (b) The elemental map intensity profiles across the BN-rich B–C–N rope [along the line shown in the HRTEM image in (a); from left to right], displaying complex assembly of BN-rich, C-rich, and B–C–N layers. Figure 9. (a)–(d) Consecutive HRTEM images of a BN MWNT found in a material laser heated at superhigh nitrogen pressure (11 GPa), taken at intervals of ∼2 min under normal TEM imaging conditions (flux density ∼10–20 A/cm^2). Dangling, undulating BN sheets—a commonly observed growth defect—are indicated by arrows. The MWNT section viewed edge-on contains irregularities in shell spacing, which are marked with a circle and enlarged separately in the insets. Annealing-out of the growth defects occurs under irradiation. Reprinted with permission from [26], D. Golberg et al., *Chem. Phys. Lett.* 279, 191 (1997). © 1997, Elsevier Science.

sheets viewed edge-on in the areas indicated by the arrows, in particular for the innermost NT sheet. The spacing between BN layers in the NT wall is extremely irregular, showing a very poor degree of crystallinity in the direction perpendicular to the NT axis. The observed irregularities caused by an extra atomic plane (i.e., dislocation edge), Figure 9a–c, or transverse shift of upper and lower internal sheet parts, Figure 9d, are marked with a circle and subsequently enlarged in the insets.

With increasing time of irradiation striking changes in the NT morphology take place. BN sheets become straight and align in the direction of the initial growth, while almost complete ordering of the NT shells occurs. The only defect remaining in the NT structure is an irregularity between the third and fourth lattice fringes on the left-hand side of the image. The observed movement of the dislocation edge apparently suggests virtual temporary sp^3-character bonding between shells and a changeable stress gradient in the walls under electron beam irradiation.

An electron beam heats the specimen by energy absorption [84]. A temperature of several hundreds Kelvin can be reached on the thin specimen area. In order to distinguish growth defects from those resulting from electron beam irradiation, the BNNTs were irradiated for longer times, as shown in Figure 10 [85]. The results were similar to those for CNTs: longer irradiation of the entire illuminated NT region (Fig. 10) at an irradiation dose of $\sim$30 A/cm^2 over 90 min leads first to a decrease in the (0002) fringe contrast sharpness and, then, to the complete destruction of the nanotubular morphology, leaving the material with the consecutive appearance of a near-amorphous BN rod and near-amorphous BN rectangle-"onion"-like nanoparticle, a shape which is characteristic in the BN system (see Section 3).
Figure 10. Consecutive HRTEM images demonstrating structural changes of a BN MWMT into a nested, highly defective octahedral-like BN "onion" under electron irradiation with a $\sim$30 A/cm^2 flux density. The irradiation time is shown on the figures. Reprinted with permission from [85], D. Golberg et al., *Mater. Res. Soc. Symp. Proc.* 593, 27 (2000). © 2000, Materials Research Society.

6. METAL-FILLED BN NANOTUBES

In spite of the existing intriguing possibility of making insulating "nanocables" composed of a conducting metal core and an insulating BN shield, a BNNT can hardly be filled with any metal due to its relatively poor wetting properties [6], as opposed to the relative ease in encapsulation of different metals and alloys into conventional CNTs.

The filling of CNTs with metal, metal oxides, or metal chlorides by capillary or wet chemistry methods has been known for a decade [86]. However, all well-established techniques for CNT filling do not effectively work for BNNTs. As a result, to date the research on capillarity-induced filling of BNNTs with metals has not been actively carried out. During conventional laser vaporization or arc discharge accidentally formed metal-based nanoparticles originating from electrode and/or crucible materials have so far been observed at the BNNT tip-ends [1, 16, 50]. Undulating BN tubular fibers with a continuous ceramic core made of SiC were produced using a thermochemical C template method [87]. There have been also recent results on electrochemical deposition of Cu into submicrometer thick BN tubular fibers [88].

The present authors invented the simple, low-cost, and original way of continuous filling BNNTs with 3*d*-transition metal via capillarity using a two-step high-temperature synthesis involving (i) preliminary filling of C-based NTs with the metallic nanoparticles during the standard CVD process, followed by (ii) a high-temperature C $\rightarrow$ BN conversion within NT layers through consecutive chemical reactions [18]. Figure 11a and b depicts TEM micrographs of the resultant BNNTs continuously filled with the Invar Fe–Ni alloy (Fig. 11a) and pure Co (Fig. 11b) nanorods using this innovative technique.

The yield of filled NTs in the resultant products reached $\sim$5 vol%. The diameter of metal-filled NTs ranged between 30 and 300 nm, whereas the filled length reached several micrometers [18]. A "nanocable" shown in Figure 11a exhibits an outer diameter of $\sim$40 nm and contains a nanorod of alloy with a diameter of $\sim$20 nm. That shown in Figure 11b displays an external diameter of $\sim$45 nm and displays a Co nanorod with diameter $\sim$30 nm. The chemical compositions of BN tubular layers and metallic fillings and their orientation relationship were thoroughly verified by EELS, EDX, and electron diffraction [18]. Depending on
Figure 11. (a), (b) TEM images of BN MWNTs with embedded 3*d*-transition metal nanorods through high-temperature chemical syntheses: (a) a Fe–Ni filling and (b) a pure Co filling. Reprinted with permission from [18], Y. Bando et al., *Chem. Phys. Lett.* 347, 349 (2001). © 2001, Elsevier Science.

synthetic route used, composite structures may also be prepared: in the latter case the external BN layers may cover the innermost C layers, which together wrap the innermost conducting metallic nanowire, as was reported by Zhang et al. [79] and Ma et al. [80].

The unique features of the filled BNNT are the insulating properties of the BN tubular shields and conductive properties of the metallic cores (Fe–Ni, Co), which together made the first naturally insulated "nanocable." The unmatched electrical, magnetic, and mechanical properties of the novel nanostructures should find appropriate applications in nanoelectronics, nanoscale thermostats, and/or magnetic storage devices.

In the case of using metallic oxides as a filling medium, discrete metal clusters were also successfully encapsulated into BNNT channels. Golberg et al. [45] for the first time embedded pure discrete Mo clusters into BNNTs (Fig. 12). The clusters were just ~1–2 nm in size and spread over the whole nanotube length of ~0.5 μm. The inset in Figure 12 displays a cluster exhibiting lattice fringes with a separation of ~0.223 nm, which perfectly matches the (110) lattice spacing of a pure crystalline Mo, 0.222(5) nm. Since the clusters do not wet the internal BN shells they freely levitate within the tubular channel which thus may serve as a natural "pipeline" for tiny metallic cluster delivery and/or thermochemical protection.

7. PHYSICAL PROPERTIES

7.1. Thermal Stability

Figure 13a–c shows a comparison between thermal stability in air of the CNTs (grown either by a CVD process or arc discharge) and ropes consisting of BN MWNTs [20]. Differential thermal analysis (DTA) and thermogravimetry (TG) curves are shown. While oxidation of the CVD CNTs and the arc-discharge CNTs start respectively at ~844 and ~1013 K (as revealed by the corresponding DTA peaks and dramatic weight losses for the TG curves in Fig. 13), the reaction temperature of the BNNT ropes with air shifts to a

Figure 13. Comparative DTA and TG curves of BN and C MWNTs. Characteristic temperatures discussed in the text are particularly highlighted. Reprinted with permission from [20], D. Golberg et al., *Scripta Mater.* 44, 1561 (2001). © 2001, Elsevier Science.

much higher temperature range. Thorough modelling of the oxidation process shows that during BN tube oxidation, first, B_2O_3 starts to form above ~1107 K and, then, it vaporizes above 1423 K. To sum up, the BNNTs display much better thermal and chemical stability than their C counterparts. Thus, BN is preferred as far as NT-based device application is expected at high temperature and in chemically active and/or hazard environments. Thermal stability and chemical toughness of BNNTs are also of high importance in performing NT-based field emitters in flat panel displays and in field emission (FE) tips for scanning tunnelling (STM) and atom force (AFM) electron microscopes.

Figure 12. TEM image of a BN MWNT assembled within a rope and filled with Mo clusters of just 1–2 nm in size over the whole NT length. HRTEM image of a representative cluster is shown in the inset. The cluster displays lattice fringes separated by ~0.22 nm which fairly well match the (100) lattice spacing [0.220(8) nm] of a body-centered cubic Mo cluster. Reprinted with permission from [45], D. Golberg et al., *J. Nanosci. Nanotech.* 1, 49 (2001). © 2001, American Scientific Publishers.

7.2. Transport *I–V* Characteristics

Recent striking theoretical predictions with respect to the unique mechanical and electrical properties of BNNTs pave the way to the real property measurements [89–103]. For

instance, Bettinger et al. [101] calculated that a BNNT should have greater yield resistance compared to a CNT, suggesting the promising use of the BNNT in environmentally stable reinforcing nanofibers for various composites. Kral et al. [92] calculated that an electrical current should appear when a BNNT is exposed to the polarized light (i.e., ultrafast optoelectronic and optomechanical devices may be expected). Moreover, thermal conductivity of a given nanotubular structure was calculated to approach the record value among of all materials existing on the Earth [93]; thus efficient use may be found for cooling computer chips performing at ultrahigh frequency (>1 THz) in modern computers. The insulating character of pure BNNTs also made possible electrical insulation of encapsulated metallic nanowires in complex electrical circuits.

The first experiment on practical evaluation of FE for an individual pure BNNT has been reported by Cumings and Zettl [22] during which an electrically insulating (expected *a priori*) BNNT surprisingly demonstrated notable FE currents at relatively low voltages. In order to further evaluate the transport and FE prospects of BN-based NT devices, Golberg et al. [78] performed marginal doping of BNNTs with C (in order to smoothly tune a bandgap) and analyzed the resultant *I–V* and FE characteristics of an individual C-doped BNNT rope in a Fresnel projection electron microscope [so-called low energy electron source microscope (LEEPS)] [78, 107].

The LEEPS images of a representative BN-rich CNT bundle [before (a) and after (b) *I–V* measurements] together with the detected *I–V* characteristics are shown in Figure 14a–c [78]. The shape of the *I–V* curves in Figure 14c is characteristic of a semiconductor with ∼1 eV bandgap. Three consecutive *I–V* curves from [78] (sweeps 1, 2, and 3) that display fairly good reproducibility are shown in Figure 14c.

To date, there have been a few theoretical predictions that layered B–C–N materials may display semiconducting properties intermediate between metallic CNTs and dielectric BNNTs. For instance, Liu et al. [105] calculated a 2.0 eV

bandgap for a BC_2N stoichiometric sheet, while Zhu et al. [106] obtained a 0.2 eV gap for a BCN layered network. There has been an experimental estimate of the bandgap in a mat of ternary $B_{0.34}C_{0.42}N_{0.24}$ undulating highly defective CVD tubular fibers using photoluminescence, stated to be around 1.0 eV [28]. The value of the bandgap experimentally determined for an individual straight perfectly ordered BN-rich B–C–N NT rope was close to ∼1 eV [78]. The small value of the bandgap is due to the global reduction of the ionicity of the C-doped BNNT network compared to pure BNNTs (bandgap of ∼5.5 eV [4]) in the earlier experiments of Cumings and Zettl [22].

7.3. Field Emission Parameters

FE properties of aligned NT mats composed of B, C, and N atoms were found to be mostly governed by the chemical composition [104]. For instance, Figure 15a displays a LEEPS image of a representative individual C-doped BNNT rope, utilized for FE measurements [107]. The image of the same rope after the FE event is also given in Figure 15b. Figure 15c shows consecutively recorded *I–V* FE curves.
Figure 15. LEEPS images of a C-doped BN MWNT rope before (a) and after (b) FE measurements; and (c) consecutive *I–V* curves taken at three distances between the tungsten tip of the LEEPS microscope and the rope: curve 1—indefinitely large distance; curve 2—when notable FE current was first recorded; curves 3–5—consecutive runs taken at a shorter distance. FE current gradually increases while the rope is presumably "sharpened" (3–5). Inset in (c) shows a representative Fowler–Nordheim plot for curve 5. Reprinted with permission from [107], P. Dorozhkin et al., *Appl. Phys. Lett.* 81, 1083 (2002). © 2002, American Institute of Physics.

(a) Before transport measurements, (b) after transport measurements, and (c) consecutive *I–V* curves of an individual C-doped BNNT rope: first sweep; second sweep; and third sweep. All curves are characteristic of a semiconductor with an estimated bandgap of ∼1 eV. Reprinted with permission from [78], D. Golberg et al., *Chem. Phys. Lett.* 359, 220 (2002). © 2002, Elsevier Science.

Curve 1 was taken at a large distance, d, between the microscope tip and the rope and shows only a small leakage current. The tip was then moved closer to the rope until a notable FE current was first detected (curve 2). Then, the tip–rope distance was finally decreased and three consecutive I–V curves (3–5) were recorded at fixed d.

Remarkably, the last recorded curve 5 demonstrated stable FE current up to at least 2.5 μA, which is fairly close to the maximum stable FE current (~ 2 μA) reported for an individual CNT [108]. When plotted in Fowler–Nordheim [109] coordinates (inset to Fig. 15c) curve 5 fits a line at low voltages proving that a conventional FE process is taking place.

To summarize, a C-doped BNNT rope is a good field emitter with emission characteristics comparable to those of CNTs. While its ability to produce high FE currents is similar to that of CNTs, the BN-based NT rope exhibits better environmental stability for FE, opening the new horizon in a wide application of C-doped BNNTs in flat panel displays and/or FE tips for the STM and AFM microscopes of the new generation.

8. APPLICATIONS

8.1. Gas Adsorption

It is noted that investigations aiming to probe gas adsorption properties of BNNTs for potential applications are becoming more and more important. For instance, hydrogen—the cleanest source of energy—holds promise for solving current environment pollution problems with zero-emission vehicles. The research on hydrogen uptake in BN nanotubes was initially promoted by that in counterpart CNTs. Single-walled CNTs were intensively studied and revealed strong interactions between hydrogen molecules and tube walls [110]. However, quite different uptake values were reported by various groups [110–112]. This may be caused by the difference in electronic interactions between hydrogen and CNTs exhibiting various atomic structure; in fact, CNT electrical properties are highly sensitive to its morphology and atomic order which are yet not under control [5]. By contrast, BN nanotubes are quite electrically uniform offering stable insulating properties independent of the atomic structure, diameter, and number of layers. Recently Ma et al. [113] has demonstrated that BN nanostructures may absorb hydrogen at the level equal or even exceeding that for C nanotubes. Multiwalled BNNTs could adsorb 1.8–2.6 wt% of nitrogen under ~ 10 MPa at room temperature. Innovative nanostructures in BN may also be of great importance in the field [114–120]. For instance, Tang et al. [120] has demonstrated that significant hydrogen uptake increase (up to 4.8 wt%) may occur in collapsed BNNTs having highly developed surface area due to breaking of straight tubular shells into hairlike fragments attached to the tubular-like core. High thermal and chemical stability of BNNTs which is superior to that of CNTs [20, 121] may be also an advantageous factor for applications in hydrogen storage NT capacitors, since the latter presumes long-time thermal cycling in nonvacuum conditions.

8.2. Electrical Nanoinsulators

The insulating nature of BNNTs opens up a new horizon in producing electrically insulated embedded nanowires in downsized electrical devices and complex nanocircuits. The problem of poor wetting properties of BN material could be effectively overcome through conducting two-stage filling processes [18, 45], simultaneous growth of a nanowire and BN shells, or substitution of BN coating for the filling procedure [115–122]. Another possible route is production of BNNT insulated C or B–C–N NTs through sandwich-like tubular structure formation [48, 79, 80]. Recently perfect insulating performance of mechanically tough BN tubular shields and excellent conductive properties of the internal tubular B–C–N layers were verified for such eagerly awaited nanostructures during *in-situ* transport and field emission experiments in a LEEPS microscope [123].

8.3. Field-Emitting Devices

Due to the insulating nature of BN material field emission from pure BNNTs may doubtfully be of interest due to naturally high turn-on fields, low current densities, possible arcing, and resistance heating [6, 124]. In fact, high turn-on fields of 15.2 to 8.3 V/μm [125] were measured on microcrystalline BN thin films. For comparison, the best field emitters made of aligned CNTs typically have turn-on fields in the range of 1–3 V/μm. Doping of BNNTs with C seems preferable for lowering turn-on fields and increasing current densities of BNNTs [106]. In fact, turn-on fields of 2–3 V/μm and current densities of ~ 3 mA/cm^2 have recently been achieved on C-doped BNNT films at 5.5 V/μm macroscopic fields [126]. For comparison the best field emitters made of CNTs may reach 10 mA/cm^2 below 4.5 V/μm—thus the better parameters. Particular selection of C or BN–C NT field emitters for a given application thus should be governed by the interplay between the importance of the environmental stability (better for BN–C NTs) and absolute field emission characteristics (better for CNTs).

9. CONCLUDING REMARKS

We conclude that in spite of the significant difficulties in BNNT preparation, structural analysis, and property measurements, the notable breakthroughs in their synthesis and atomic structure determination have been achieved within a few experimental and theoretical research groups, among those Y. Bando's group at NIMS (Japan), A. Zettl's group at the University of California, Berkeley (USA), A. Loiseau's group at CNRS (France), C. N. R. Rao's group at the Bangalore CSIR Centre (India), Y. Saito's group at the Mie University (Japan), M. Terauchi's group at Tohoku University (Japan), A. Rubio's group at the University of Pais Vasco (Spain), D. Tomanek's group at Michigan State University (USA), M. Terrones's group at IPICYT (Mexico), R. Ruoff's group at Northwestern University (USA), and Y. Chen's group at Australian National University may be mentioned.

The main challenge is now to significantly increase the yield of BNNTs to promote their advantageous applications as compared to conventional CNTs and to exploit novel BNNT structures [127–129].

GLOSSARY

Armchair nanotubes   Nanotubes having their axes in parallel with the [11–20] orientation of a graphitic sheet.

Energy filtered elemental maps   Images of nanostructures using electron loss energies characteristic of a band transition of a particular element.

Field emission   Extracting electrons from a substance placed at a particular distance from a positively biased electrode.

Multiwalled nanotube   A nanotube having more than two layers.

Nanotube   A cylinder made of a wrapped graphitic sheet exhibiting diameters down to 4 Angstroms.

Single-walled nanotube   A nanotube having a single atomic shell.

Zigzag nanotubes   Nanotubes having their axes in parallel with the [10–10] orientation of a graphitic sheet.

C$_{60}$-Based Materials

J. G. Hou, A. D. Zhao, Tian Huang, Shan Lu

University of Science and Technology of China, Hefei, Anhui, People's Republic of China

CONTENTS

1. INTRODUCTION

Since the discovery of Buckminsterfullerene C$_{60}$ by Kroto et al. [1] in 1985 and the discovery of large quantity synthesis by Krätschmer et al. [2] in 1990, this molecular allotrope of carbon has attracted intense interest because of its unique physical and chemical properties. Varied novel materials based on C$_{60}$ have been synthesized successfully showing fantastic properties.

C$_{60}$ is a beautiful spherical hollow molecule with a diameter of $\sim$1 nm possessing the highest degree of symmetry of all known molecules. Remarkable potential applications in future nanoscale molecular electronic devices were proposed [3] for C$_{60}$ molecules based on their fantastic properties and structural and chemical stabilities. Moreover, the molecule shows a strong ability to form derivative structures, such as substituted heterofullerenes, encapsulated endohedrals fullerenes, metal-adsorbed exohedral fullerenes, and so on. These novel structures broaden the field of nano-structured carbon materials and stimulated the research on fullerene-based nanotechnology.

Crystalline C$_{60}$, as a new third form of crystalline carbon, along with diamond and graphite, has also exhibited many interesting properties. Solid C$_{60}$ is a typical molecular crystal, it can be intercalated by metal atoms and molecules, polymerized, or composited to form complex solid-state structures. Many novel properties have been discovered such

as high temperature superconductivity in alkali metal intercalated C$_{60}$ compounds, ultrahigh hardness even exceeding diamand in three-dimensional (3D) polymerized C$_{60}$, and high temperature organic ferromagnetism in 2D rhombohedral polymerized C$_{60}$.

In this chapter, we summarize the structure and properties of the single C$_{60}$ molecule and C$_{60}$ based materials, including metal-intercalated, polymerized, doped, composite, and other derivative compounds. Moreover, recent progress in the search for some novel low-dimensional C$_{60}$ derivative structures, such as heterofullerenes, endohedral fullerenes, exohedral fullerene complexes, C$_{60}$ in carbon nanotubes, and $(C_{60})_n$ clusters, is also summarized.

2. C$_{60}$ MOLECULE

2.1. Synthesis

Fullerenes can be extracted from the soot made by either combustion [4–7] or pyrolysis of aromatic hydrocarbons [8–13] or by an arc-discharge process [1]; the latter is now the most commonly adopted and convenient method. It is usually achieved by heating resistively and evaporating carbon (usually graphite) electrodes with a small gap controlled as a constant in a helium or an argon atmosphere by passing a high electric arc-discharge current between them (see Fig. 1). For the carbon arc-discharge method, the best inert gas atmosphere is high-purity helium with preferred quenching-gas pressure in the range 100–200 Torr. Rods of smaller diameter of about 5 mm are most suitable for currents of 100 ampere; larger reactor volumes and high purity rods give higher yields and lower impurity content soot. Since the fullerene containing soot is better able to diffuse away from the hot discharging zone and the intense ultraviolet (UV) light of the arc, it is better that the inert gas is flowed through the arc zone. Either ac or dc discharge may be available and the latter results in consumption of the anode only which gives facilities for the use of anode rod autoloaders and continuous operation. The common yield of fullerenes in soot through this method is about 10%, of which the yields of C$_{60}$ and higher fullerenes (mainly C$_{70}$) are about 75 and 25%, respectively.

During the fullerene formation process, insoluble nanoscale carbon soot is formed together with soluble fullerenes and other soluble impurity molecules. Extraction can now most conveniently be performed with chloroform or toluene. The latter is more rapid but risks reaction brought about by the toluene (or xylene, mesitylene, etc.) solvent due to their susceptibility to electrophilic substantial reaction and degradation. The efficiency of this solvent method for the extraction is tied to the solubility of the fullerene molecules in solvents.

Liquid column chromatography is the main technique used for fullerene purification. Here purification means the separation of the fullerenes to distinguish C_{60}, C_{70}, etc. Earlier experiments used alumina [14] or mixtures of alumina/charcoal with toluene/hexane elution [15, 16]. The simpler and less expensive method employs Norit Elorit carbon granules as the stationary phase with toluene elution for C_{60} and following 1,2-dichlorobenzene for C_{70}, in this way C_{60} can be obtained at a fairly high rate of 10 gram per hour [17]. It is also necessary to wash the samples after purification with acetone to remove traces of hydrocarbons and other impurities.

A recent experiment showed that C_{60} can be synthesized in 12 steps from commercially available starting materials by rational chemical methods [18]. A molecular polycyclic aromatic precursor bearing chlorine substituents at key positions forms C_{60} when subjected to flash vacuum pyrolysis at 1100 °C and no other fullerenes are formed as by-products.

2.2. Structure

For C_{60} there are 1812 possible structures [19], but the most stable isomer and the only one in which all the pentagons are nonadjacent is depicted as a truncated icosahedron cage structure with 90 edges, 60 vertices, and 32 surfaces, 12 of which are pentagonal and 20 are hexagonal (see Fig. 2 [20]). This building principle obeys Euler's theorem predicting that exactly 12 pentagons and an arbitrary number *n* of hexagons are required for the closure of a carbon closed cage. Otherwise C_{60} is the most stable fullerene because it is the smallest possible to obey the isolated pentagon rule (IPR) [21, 22] which predicts fullerene structures with all the pentagons isolated by hexagons to be stabilized against structures with adjacent pentagons. The mean diameter of a C_{60} molecule is
about 7.10 Å [23], or considering the thickness of the electron cloud shell the outer and inner diameters are approximately 10 and 4 Å, respectively.

The point group of C_{60} is icosahedral I_h which comprises 120 symmetry operations consist of identity operation, 12 fivefold axes through the centers of the 12 pentagons, 20 threefold axes through the centers of the 20 pentagons, and 30 twofold axes through the centers of the 30 edges joining 2 hexagons combined with their inversion operations. Thus the C_{60} molecule has the highest degree of symmetry of any known molecule.

The 2D representation of the 3D structure of C_{60} is shown in Figure 3 [24]. It is created by shrinking the polygons of the nearest face and expanding those of the far face to fit all 60 carbon atoms within one plane. Obviously the Schlegel diagrams for C_{60} may have either a pentagon or hexagon at the center, and a pentagon in Figure 3.

2.3. Electronic Structure

A neutral C$_{60}$ molecule has 240 valence electrons; 180 are involved in σ-bonding energy levels lying well below the Fermi level. They brace and stabilize the cage structure. The remaining 60 electrons are involved in π-bonds, contributing to the conduction.

Since C$_{60}$ forms a near-sphere cage structure, the deviation from planarity leads to an admixture of s orbitals character into the p_z orbitals, where z is perpendicular to the (local) surface of the buckyball sphere. An average σ bond hybridization of $sp^{2.278}$ with a fractional s (about 9%) character into the p_z orbitals was estimated [25–29], compared to graphite with pure bond hybridization of sp^2. Geometrically the p_z orbitals extend further outside the cage than inside the cage.

The bonds at the junctions of two hexagons ([6,6] bonds) ($\sim$1.40 Å) are somewhat shorter than the bonds at the junctions of a hexagon and a pentagon ([5,6] bonds) ($\sim$1.45 Å); thus the [6,6] bonds are usually considered to be double bonds and the [5,6] single. The shortening of bonds is caused by the partial localization of the π-orbitals into localized bonds and thus is directly related to the symmetry of C$_{60}$. This ununiformity of bond lengths has been demonstrated by a series of theoretical [30, 31] and experimental investigations [32–34]. As a consequence, the double bonds in C$_{60}$ only lie at the junctions of the hexagons ([6,6] double bonds) and do not lie in the pentagonal rings.

Due to the near-spherical shape of the C$_{60}$ molecules, the fullerene electronic eigenstates can be considerd by spherical harmonics and classified by their angular momentum quantum numbers l (see Fig. 4). Due to the Pauli exclusive principle, 50 π-electrons fully occupy the angular momentum states up through $l = 4$, leaving 10 π-electrons in the $l = 5$ state which can accommodate 22 electrons in full spherical symmetry, assuming that all the $l = 5$ states are filled before any $l = 6$ level becomes occupied. For C$_{60}^{10+}$ with $l = 4$ filled, no significant bond length alternation is expected. But in the case of neutral C$_{60}$ with the symmetry lowered from ideal spherical symmetry to icosahedral symmetry, the $l = 5$ state split into the $(h_u + t_{1u} + t_{2u})$ irreducible representations and the fivefold-degenerate h_u level (the lowest energy level) is completely filled by the remaining 10 electrons (see Fig. 4). This level forms the highest occupied molecular orbital (HOMO) in C$_{60}$. The threefold-degenerate t_{1u} level of $l = 5$ state forms the lowest unoccupied molecular orbital (LUMO) and this low-lying LUMO suggests that the C$_{60}$ is a fairly electronegative molecule. The HOMO–LUMO gap is calculated to be about 1.7 eV.

2.4. Properties of Single C$_{60}$ Molecule

2.4.1. Main Description

The main properties of C$_{60}$ molecule are summarized in Table 1 [23, 30–39]. The comparison of properties of C$_{60}$ with other fullerenes (from C$_{20}$, C$_{36}$, . . . to C$_{106}$) is listed in Appendix A [23, 36, 40–55].

2.4.2. Electronic Transport Properties

Electronic transport properties of individual C$_{60}$ molecules have been investigated using a scanning tunneling microscope (STM) which enables controlled two-terminal measurements or a three-terminal transistor configuration which enables gate-voltage controlled current amplifications.

The resistance of a C$_{60}$ molecule was determined by the study of electrical contact with an individual C$_{60}$ introduced between a STM tip and a clean Au(110)-(1 × 2) surface at 300 K in ultrahigh vacuum [56]. It was revealed that at low applied bias voltages of $\pm$200 mV this system exhibited linear current–voltage (I–V) characteristics at all fixed tip displacement, indicating that the system behaves similarly to a metal–vacuum–metal tunnel junction at low bias voltage within the C$_{60}$ HOMO–LUMO gap. In this sense, the linearity allows us to define the intrinsic electrical resistance of an individual C$_{60}$ molecule. It was observed in

Figure 4. (a) Schematic diagram of the electronic structure for the 60 π-electrons in C$_{60}$ by Hückel theory calculation of the molecular energy spectrum of neutral C$_{60}$. The number l is the orbital angular quantum of the spherical harmonic from which a molecular orbital is derived. (b) Density of states (DOS) for the isolated C$_{60}$ molecule calculated using the discrete variational local density approximation method. Vertical lines denote energy levels of the molecule. The DOS is obtained by broadening the discrete levels with a Lorentz function for better comparison with experimental data.

Table 1. Properties of C$_{60}$ molecules.

Property	Quantity	Ref.
IPR isomers	1	
Symmetry (point group)	I_h	
Double bond length	$\sim$1.40 Å	[30–34]
Single bond length	$\sim$1.45 Å	[30–34]
Average C–C distance	1.44 Å	[33]
Diameter	7.10 Å (mean)	[23]
Volume per molecule (πabc)	1.87×10^{-22}/cm^3	
Number of distinct C sites	1	
Number of distinct C–C bonds	2	
Binding energy per atom	7.40 eV	[35]
Electron affinity	2.65 ± 0.05 eV	[36]
Cohesive energy per C atom	1.4 eV/atom	[37]
Ionization potential	7.95 ± 0.02 eV	[38]
HOMO–LUMO gap	1.7 eV (Dmol3 cal.)	
Heat of formation	(41.8 ± 0.3 kJ per C atom) (at 298 k)	[39]

the current–distance (I–s) characteristics that the tunneling current increases approximately exponentially with tip displacement in the tunnel regime, but this behavior changes significantly as contact is established. A theoretical calculation using the elastic scattering quantum chemistry technique configured for STM (STM-ESQC) [57] considering the full atomic structure and valence orbitals of the tip, the C_{60} molecule, and the Au(110) surface agreed very well with the experimental I–s curve. The deformation of C_{60} was also included in STM-ESQC using the molecular mechanics (MM2) routine with a standard sp^2 carbon parametrization [58], and the C_{60} conformation was optimized for each tip displacement s. The current I through the molecule was then calculated for each conformation. The point of electrical contact was found to be $s = 12.3$ Å, where the van der Waals expansion induced by tip attraction is compensated by tip compression, and the C_{60} molecule may be considered approximately as its original shape. An apparent electrical resistance of 54.80 MΩ for the total junction with C_{60} was determined at this point. In the Landauer formalism [59] of $T = (h/2e^2)R^{-1}$, this value corresponds to the C_{60} electronic transparence (ease of transmission) of $T = 2.3 \times 10^{-4}$.

This experiment of "squeezing" a C_{60} molecule by applying a small force in the nanonewton range with a metallic STM tip also results in a shift of the molecular orbital levels [56]. The mechanically induced shift provides a means to modulate tunnelling through a single C_{60} molecule, even in a nonresonant tunnelling regime, and to change its resistance up to a limiting value approaching the quantum of resistance, $h/2e^2$ (~12.9 kΩ) [56]. The phenomenon, mechanically modulated virtual-resonant tunnelling, has also been used to design an single-molecule electromechanical amplifier, by making use of the ability to mechanically reduce molecular level degeneracy [60].

Electronic transport properties of C_{60} molecules have also been studied in some other systems: The scanning tunneling spectroscopy (STS) investigation of an isolated C_{60} molecule considered as a quantum dot in a double barrier tunnel junction (DBTJ) configuration [61] was carried out showing clear discrete molecular-level spectrum and obvious interplay with single-electron charging effects.

A novel negative differential resistance (NDR) molecular device is realized involving two C_{60} molecules; one is adsorbed on a STM tip and the other is on the surface of the hexanethiol self-assembled monolayer [62]. It was demonstrated that it is the narrow local density of states features near the Fermi energy of the C_{60} molecules that lead to the obvious stable and reproducible NDR effect.

In a single-C_{60} nanomechanical transistor configuration based on an individual C_{60} molecule connected to gold electrodes [63], the transport measurements provided obvious evidence for a coupling between the center-of-mass motion of the C_{60} molecules and a single-electron hopping—a novel conduction mechanism. The coupling is manifest as quantized nanomechanical oscillations of the C_{60} molecule against the gold surface with a frequency of about 1.2 THz which agreed well with a simple theoretical estimate based on van der Waals and electrostatic interactions between C_{60} molecules and gold electrodes [63].

2.4.3. Scanning Tunneling Spectroscopy

Scanning Tunneling Spectroscopy of Isolated C_{60} Molecule The scanning tunneling microscope is a powerful tool for measuring the local density states of surfaces and molecules. STS of an isolated C_{60} molecule can be obtained in a DBTJ system (see Fig. 5a) where the individual C_{60} molecule is coupled via two tunnel junctions to the metal substrate and an STM tip of vacuum and insulating layer, respectively, in order to eliminate the interaction between the metal substrate and C_{60} molecule. Figure 5 shows a schematic view and equivalent circuit of the experimental setup and a typical spectroscopy of C_{60} in this system.

Zeng et al. [62] measured the STS with such a system at a low temperature of 78 K by employing a hexanethiol self-assembled monolayer as the insulating barrier between C_{60} and a gold substrate. Their results exhibited a noticeably larger HOMO–LUMO gap of ~2.8 eV (see Fig. 5), which is about 1 eV larger than the intrinsic HOMO–LUMO gap of ~1.7 eV. Because the size of a C_{60} molecule is about 7 Å, much smaller than other metal or semiconductor quantum dots so far, the charging energy E_C of such a nanojunction, about 1 eV, is significant enough to be comparable with the molecular HOMO–LUMO bandgap (E_g) of a neutral C_{60} molecule. So they attributed the larger gap width they observed to the sum of E_g and E_C. It was also noted that their differential tunneling spectra showed clearly fine peaks at the position of HOMO and LUMO energy regions. The three peaks in the negative bias region and five peaks in the negative bias region were well attributed to the degenerate splitting of threefold degenerated LUMO (t_{1u}) and fivefold degenerate HOMO (h_{1u}) level. The reason for the orbital degeneracy was considered to be the strong local electrical field and the Jahn–Teller effect.

Porath et al. [61] performed similar experiments at a low temperature of 4.2 K by using a polymethyl-methacrylate layer (less than 40 Å thick, determined by X-ray measurements) as the insulating barrier. The tunneling current–voltage spectra they observed also showed both Comlomb blockade and Coulomb staircase behavior and rich fine structures resulting from the discrete levels of a single C_{60} molecule and the splitting of the degenerate energy levels. But the HOMO–LUMO gap in their specra observed was about 0.8 eV (generally less than 1.5 eV), which is much less than that of a free neutral C_{60} molecule. They attributed the
Figure 5. Scanning tunneling spectroscopy of a single C_{60} molecule in a double barrier tunneling junction system. Dashed line is the dI–dV curve; solid line is the I–V characteristic curve.

origin of the smaller gap mainly to the level space between LUMO(C$_{60}^-$) and HOMO(C$_{60}^+$).

Inelastic Electron Tunneling Spectroscopy of Single C$_{60}$ Molecule Inelastic electron tunneling spectroscopy (IETS) is a powerful technique to obtain average vibrational information on condensed molecule species [64]. Combined IETS–STM can provide vibrational information resolved on single molecules [65–72]. It has been demonstrated that when C$_{60}$ is adsorbed on a surface, the structure of the free molecule remains fairly unaltered [73]. Pascual et al. [64] extend the inelastic STS (ISTS) studies to single C$_{60}$ molecules adsorbed on Ag(110) surface; they observed peaks at ± 54 mV in the d^2I/d^2V curves in ISTS spectras on those C$_{60}$ molecules which oriented along one of their symmetry axes upon adsorption (see Fig. 6). In strong coincidence, those fullerenes maintain a resonance structure at the Fermi level that resembles the first unoccupied molecular orbital distribution of a free molecule. The enhanced signal was attributed to the excitation of a fullerene-cage vibrational mode by inelastic tunneling electrons. The vibration was assigned to the $H_g(\omega_2)$ mode (431 cm^{-1}), a fivefold denegerated mode of a free C$_{60}$ molecule corresponding to a "gerade" breathing of the molecular cage with larger radial component along the C_{5v} symmetry axis. Only in those cases where some molecular symmetry survives upon adsorption does some mode degeneracy remain, leading to a detectable contribution in the inelastic signal; for molecules in a non-symmetric orientation, degeneracy splitting, and subsequent mode mixing, may be so extensive that the observation of clear vibrational features in the ISTS spectra is suppressed. They concluded that the nature of the electronic molecular resonances around the Fermi level E_F, which determines the vibrational mode primarily, and the existence of a surviving symmetry on the adsorbed species, which determines the magnitude, were the two principal detection selection rules.

2.4.4. ^{13}C Nuclear Magnetic Resonance Spectroscopy

By using room temperature ^{13}C nuclear magnetic resonance (NMR) spectroscopy, Taylor et al. [14] and several research groups [74–76] obtained the first structure data for C$_{60}$ molecules in solution. In the spectrum, there is only one peak, showing extremely simple character, at a chemical shift of 143.2 ppm relative to tetramethyl silane (the standard reference molecule for ^{13}C NMR spectroscopy). This only-one-peak character confirms that each carbon atom in the C$_{60}$ molecule is equivalent in the solution environment. In comparison with C$_{60}$, the C$_{70}$ molecule has five inequivalent carbon sites out of total atoms in geometry, corresponding to a richer NMR spectrum character of five peaks at 130.9, 145.4, 147.4, 148.1, and 150.7 ppm in a ratio of 10:20:10:20:10. Figure 7 shows typical ^{13}C NMR spectra for the C$_{60}$ and C$_{70}$/C$_{60}$ mixture in benzene solution showing clear peak features [74].

2.4.5. Optical Properties

In gas phase or in organic solutions, optically excited fullerene molecules are influenced relatively weakly by their environments, thus the photophysical properties can be considered as those for near free molecules. The molecular energy level and photophysical behavior of electronically energized states for an individual C$_{60}$ molecule can be well described by using a Jablonski diagram, as shown in Figure 8. In this type of diagram, photoexcited electronic states of molecules include spin triplets ($S = 1$) and spin singlets ($S = 0$). The energy state definitions and transitions between these states are interpreted in Table 2.

The low-lying electronic transitions in C$_{60}$ are only weakly allowed because of the high degree of symmetry in the

Figure 6. Comparison of ISTS spectra measured consecutively on two neighboring C$_{60}$ molecules. The dashed plot corresponds to the spectrum acquired on the bare silver surface. Each spectrum is the average of six bias voltage scans (25 sec/scan). In (a), the peak at 54 mV (-54 mV) represents a normalized change in conductance of 9% (8%). Figure 8. Diagram of electronic energy levels of C_{60} molecule.

closed-shell electronic configuration. The absorption band of C_{60} in the visible is very weak, with the molar absorptivity at the band maximum of only $\sim$950 M^{-1} cm^{-1} [14, 74, 77, 78]. Only a small fraction of the broad visible absorption band in the 430–670 nm region is due to the contribution of the transition to the lowest excited singlet state S_1 [79].

With extensive experimental investigations [79–95], it was well known that both C_{60} and C_{70} are only weakly fluorescent from the lowest singlet S_1 to the ground state, with C_{70} having a slightly higher fluorescence quantum yield. Due to the weak interaction with each other, fluorescence lifetimes and fluorescence quantum yields of the fullerene molecules in solution under ambient conditions are essentially solvent independent.

In fact, upon photoexcitation, the excited singlet state S_1 decays are mainly dominated by nonradiative intersystem crossing to the excited triplet state T_1, with a very large quantum yield of nearly 100% [77, 96–99]. The extremely efficient intersystem crossing produces a high population of the excited triplet state T_1. Phosphorescence emission from the T_1 state to the ground state S_0 is so weak that it could not be detected initially even in a cryogenic sample [100]. The weak

Table 2. Energy states and transitions in a C_{60} molecule.

Energy states	
S_0	ground (singlet) state
S_1 (T_1)	first excited singlet (triplet) state
S_n (T_n)	higher excited singlet (triplet) state
Transitions or decays	
Absorption	including ground state absorption $S_0 \rightarrow S_n$ and excited state absorption $T_n \rightarrow T_m$ ($n, m \geq 1$)
Fluorescence	$S_1 \rightarrow S_0$ (usually)
Phosphorescence	$T_1 \rightarrow S_0$ (usually)
Internal conversion	$S_n \rightarrow S_{n-1}$ and $T_n \rightarrow T_{n-1}$, radiationless transitions
Intersystem crossing (ISC)	$S_n \rightarrow T_m$ for $n > 0$, or $T_m \rightarrow S_n$ for $m > 0$, radiationless transitions

phosphorescence reflects a low radiative rate for $T_1 \rightarrow S_0$ emission, which is both spin and orbitally forbidden, plus comparatively rapid $T_1 \rightarrow S_0$ nonradiative decay of intersystem crossing; see Figure 8. Previous results for the triplet T_1 lifetime of C_{60} in room-temperature solutions range from 37 to 285 μs and even longer [77, 96, 98, 99, 101–105]. Recently Weisman [106] concluded that the wide discrepancies among these values likely reflect the presence of bimolecular decay channels such as self-quenching or unrecognized triplet–triplet annihilation, the effects of impurities in solution, or uncertainties in the kinetic data. He obtained an intrinsic T_1 triplet lifetime of 143 μs by eliminating the self-quenching component of this decay of 0.21%/μM.

Fullerenes and their derivatives were found to be excellent optical limiters in room-temperature solution [107–111]. The first report of the optical limiting (OL) of C_{60} was that C_{60} in toluene possesses the strongest OL response toward a laser at 532 nm. Optical power limiting occurs when the optical transmission of a material decreases with increasing laser fluence [112] which is now attributed to strong triplet absorption [112–115]. C_{60} is an excellent broadband nonlinear absorber for potential optical limiting and optical switching applications [108, 112, 116–119], because of higher triplet–triplet transient absorption cross sections than the ground-state absorption cross sections [101, 108, 120]. However, a recent study suggested that in addition to the strongly absorptive excited singlet and triplet state, other transient species that are most likely associated with photoexcited state bimolecular processes may also be responsible for the observed strong optical limiting responses of fullerene in solution [119, 121]. There have been several mechanisms suggested to account for the optical limiting behavior of C_{60}, including reverse saturable absorption (RSA) [107], nonlinear scattering [122], thermal blooming [108, 123], and multiphonon absorption [108]. RSA was proved by transient absorption spectra to be the dominant mechanism, whereas other processes become important at high input influences [108, 122].

Photoexcited fullerenes are also excellent electron acceptors, exhibiting strong interactions with a variety of electron donors [89, 124, 125]. The unique properties of fullerenes with respect to photoinduced electron transfers include the small solvent reorganization energy [126] and the ability of a single fullerene cage to accept multiple electrons [127]. Photochemical reactions of fullerenes through an electron transfer mechanism often yield products that are different from those expected on the basis of known reactions of typical aromatic systems [128, 129], and in these reactions fullerenes often behave quite differently from polyaromatic compounds and other electron acceptors such as porphyrins. The recent development of cage functionalization methods [118, 130–133] has made it possible to prepare redox active fullerene derivatives for fundamental studies of photoinduced electron transfers and charge separations and for potential technological applications such as solar energy conservation. Fullerene molecules and their derivatives have also been used as charge generators in photoconductive polymer thin films [134–136].

The photophysical quantities for C_{60} molecules in solution are listed in Table 3, corresponding to the physical properties illustrated in Figure 8.

Table 3. Photophysical quantities for C$_{60}$ molecules in solution.

Property	Quantity	Ref.
S_1 energy	2.0 eV	[77]
T_1 energy	1.62–1.69 eV	[77, 137]
S_2 energy	3.4 eV	[120]
T_2 energy	3.3 eV	[120]
Φ_T, ISC quantum yield ($S_1 \rightarrow T_1$)	0.88–0.98 (near 100%)	[77, 96–99]
Φ_F, fluorescence quantum yield	3.2×10^{-4}	[79]
τ_F, singlet (S_1) lifetime (fluorescence lifetime)	1.2 ns	[138, 111]
Φ_F, phosphorescence quantum yield	8.5×10^{-4}	[77]
τ_F, triplet (T_1) lifetime (phosphorescence lifetime)	143 μs	[106]

2.4.6. Solubility Properties of C$_{60}$

Solubility of C$_{60}$ in Various Solvents The solubility of C$_{60}$ in various solvents has been measured extensively in the past 10 years [139–153]. These experimental studies were mainly motivated to improve the efficiency of the separation process of fullerenes. Studying the organic solvents of C$_{60}$ is important for the separation of fullerenes, investigation of their chemical properties, and the synthetic reaction to functionalize fullerene in organic solvents. Moreover, the globular molecule provides a near-ideal model for the theoretical studies of solubility. Full coverage of the solubility properties of C$_{60}$ in various solvents from various literature is given in Table 4. In general, C$_{60}$ has poor solubility in most common solvents. These results include: C$_{60}$ is slightly soluble in alkanes with the solubility increasing with the number of carbons; the solubility in halogen-containing alkanes is generally higher than in alkanes and it is essentially insoluble in polar and H-bonding solvents such as alcohol and water; the solubility in aromatic solvents is generally higher than in other solvents, so increasing the size of the aromatic system (benzene to naphthalene) will increase the solubility. The highest solubilities of C$_{60}$ of about 50 mg ml^{-1} are found to be in naphthalene derivatives.

In recent years, there have also been a number of theoretical studies focused on the decision of the relationship between possible influential factors and solubility parameters [140, 143, 154–158].

No single solvent parameter or property can uniformly predict the solubility. Early studies indicated the composite picture of solvents with high solubility for C$_{60}$: large index of refraction n, dielectric constant ε around 4, large molecular volume, and Hildebrand solubility parameter δ around 19 MPa$^{-1/2}$ [140, 143]. Recently, several theoretical studies were performed in order to develop applicable and suitable influencing factor relationships. Marcus et al. [154, 155] analyzed a comprehensive set of solubility data of C$_{60}$ in various solvents at 298 and 303 K by multivariate stepwise linear regression applied as the linear solvation energy relationships (LSER) approach. Considering the formation of crystalline solvates in a few solvents, they used the calculated "hypothetical solubility" of unsolvated C$_{60}$ instead of the solubility of the solvate in the statistical procedure. Their results showed that increasing molar

et al. [156] examined the solubility of C$_{60}$ in 75 organic solvents and succeeded in developing a solubility model of quantitative structure–solubility relationships by using the quantitative structure–property relationships (QSPR) approach. They used topological indices and polarizability parameters computed from refractive indexes to form the regression models. Kiss et al. [157] utilized a multiparameter artificial neural network (ANN) approach to model the solubility of C$_{60}$ in 126 solvents. The trend of nonlinear fit of the ANN suggested the same results as in the LSER studies: the solubility in a large number of solvents decreases with increasing molar volumes of the solvent and increases with increasing polarizability parameters, saturated surface areas, and average polarizability.

One of the most striking peculiarities of fullerenes in solutions is the extraordinary nonmonotonic behavior of the temperature dependence of the solubility of fullerene C$_{60}$. Experimental results of temperature dependence of the solubility of C$_{60}$ in hexane, toluene, CS$_2$ [139], and xylene [153] in the temperature range 200–400 K showed that, whereas the absolute values of the solubility of C$_{60}$ for different solvents differ over two orders of magnitude, the nonmonotonic behavior of the temperature dependence of the solubility is almost independent of the type of solvent over a wide range of temperature variation. This dependence reaches its maximum magnitude near 280 K and notably decreases at further enhancement of temperature. It is of

interest to note that the nonmonotonic temperature dependence of solubility is inherent only to C$_{60}$ and is not observed for other fullerenes, such as C$_{70}$. The temperature dependences of the solubility of fullerene C$_{70}$ in toluene, xylene, and CS$_2$ [153] are monotonically rising, which is inherent to the majority of solvent–solute pairs. The experimentally found distinctions in the temperature dependence of solubility of different fullerenes may be explained by a cluster mechanism of solubility based on the possibility of formation in solution of clusters consisting of a number of fullerene molecules [159, 160]. This aggregation phenomenon influences the thermodynamic parameters of fullerenes in solutions as well as the solubility; thus the observed lowering in the solubility of C$_{60}$ with rising temperature can be treated as a result of the thermal decomposition of clusters.

C$_{60}$ in Water   Fullerene is not soluble in water. But it can be dispersed in water with the C$_{60}$ concentration >2 mM (1.4 mg/ml) and forms two types of fullerene–water colloidal systems: molecular-colloidal C$_{60}$ solution in water (also called C$_{60}$FWS; here FWS is the abbreviation of "fullerene–water system") [161–164] and typical monodisperse C$_{60}$ hydrosol (also called ChH) [165].

C$_{60}$FWS can be produced by transferring fullerene from organic solution into the aqueous phase with the help of ultrasonic treatment [162], without using any stabilizers and chemical modification. It has been characterized as an aqueous molecular-colloidal solution having properties of both true solutions and colloidal systems simultaneously, which consists of both single hydrated fullerene molecules, C$_{60}$@{H$_2$O}$_n$, and their fractal spherical clusters [161–164]. Tests of C$_{60}$FWS biological activity showed that these hydrated fullerenes appeared to be very promising in the context of their biological and therapeutical applications [166]. ChH is another monodisperse aqueous colloidal system with a particle size of 10 nm [165], it can be obtained by oxidation of the C$_{60}$ anion with oxygen in "tetrahydrofuran-water" solutions. Both C$_{60}$FWS and ChH have the following similar characteristics: (i) high concentration (1 mg/ml and more); (ii) high stability, that is, preservation of their properties within a number of months even more under ambient conditions; (iii) almost identical color of solutions (from pale red to dark brown–red) that depends on C$_{60}$ concentration; (iv) negative charge of colloidal particles; (v) preservation of the same properties in the case of dilution or concentration of both colloidal solutions; (vi) a similar ability to coagulate under the inorganic cation influence [166, 167].

In contrast to well-known reasons of stabilization of typical colloidal systems [168], the main mechanism of FWS stabilization is the hydration of fullerene molecules with formation of the supramolecular complex of C$_{60}$@{H$_2$O}$_n$ type [164] (see Fig. 9). The C$_{60}$@{H$_2$O}$_n$ clusters are stabilized by the weak donor–acceptor interactions of unpaired electrons of H$_2$O oxygen atoms with fullerene molecule to form -OH$\cdots\pi$ hydrogen bonds (such -OH$\cdots\pi$ hydrogen bonds have been found to possess about half the binding energy of -OH$\cdots$O hydrogen bonds with, optimally, the -OH atoms centrally and vertically placed and the distances from the oxygen atom to the aromatic centroid of about 3.1–3.7 Å [169]) and by the formation of the ordered, H-bounded,
Figure 9. (a) A model of C$_{60}${H$_2$O}$_{80}$ cluster, obtained from an icosahedral water cluster with a C$_{60}$ molecule taking the place of its inner water dodecahedron. (b) C$_{60}$ molecules in aqueous solution form colloidal clusters based on 3.4-nm-sized icosahedral arrangements of 13 C$_{60}$ molecules, where the C$_{60}$ molecules are separated by water molecules [164]. The water network is formed by fully tessellated tetrahedral tricyclo decamer (H$_2$O)$_{10}$ structures.

and spherelike H$_2$O molecular shells around the fullerene's surface.

2.5. C$_{60}$ on Surfaces

2.5.1. On Metal Surfaces

C$_{60}$ adsorbed on a noble-metal surface usually form strong ionic bonding via charge transfer [170–179] from the metal near-Fermi-level surface states to the fullerene $5t_{1u}$-derived LUMO. Quantities of charge transfer can be estimated indirectly from the following experimental results: (i) the shift of C$_{60}$ vibrational energies in high-resolution electron-energy-loss spectroscopy (HREELS) (Au(110) [171], Ni(110) [180], and Cu(111) [181]); (ii) the shift of carbon C$_{1s}$ core-level absorption spectra using electron-energy-loss spectroscopy (EELS) (Au(110) [171]); (iii) using near-edge x-ray-absorption spectroscopy (NEXAFS) (Cu(111) [179]) compared to the known shift of alkalidoped compounds [182]; (iv) the anglur dependence in angle-resolved valence-band photoemission spectroscopy (PES) (Au(111) [183]); and (v) direct comparison of relative photoemission intensities (Ag(111) [175] and Cu(111) [179]). But for Al [184, 185] and Pt(111) [186] surfaces, experimental results by NEXAFS, HREELS, or PES show no charge transfer evidence and suggest the interaction of a covalent bonding.

At the initial state the individual C$_{60}$ molecules are readily mobile on most metal surfaces at room temperature, stabilized at the step edges on Au(110) [172], Au(111) [187], Ag(111) [188], and Cu(111) [189], and form two-dimensional islands on Ag(110) [190].

On many low-index metal surfaces, C$_{60}$ forms commensurate monolayers, such as Au(111) (23 × $\sqrt{3}$) [187, 191], Ag(111) [188], Ag(110) [190], Cu(111)-c(1 × 1) [192], and Au (100)-c(5 × 20), with uniaxial stress along the $\langle 110 \rangle$ direction [193]. But C$_{60}$ adsorption on Au(110) [172] and Ni(110) [178] surfaces causes strong substrate reconstructions due to the strong interaction between the substrates and the C$_{60}$ adsorbates. In the case of a high anisotropic Au(110)-p(1 × 2) surface, C$_{60}$ molecules adsorbed on this

surface induce the Au surface atoms to form a (1×5) missing row reconstruction as a precursor for the $p(6 \times 5)$ adsorbate structure and form a hexagonal close-packed corrugated layer [172]. Recent in-plane X-ray diffraction data suggested that a large fraction of Au surface atoms are displaced from their original positions producing microscopic pits to accommodate the C_{60} molecules [194]. In the case of Ni(110) surface, strong interaction between C_{60} and the surface causes a formation of added/missing Ni [001] rows which creates a corrugated structure resulting in formation of (100) microfacets and maximizing the C_{60}–Ni coordination [178]. It is suggested that the small separation between the LUMO of C_{60} and Ni Fermi level located in the d band leads to a strong hybridization interaction (i.e., covalent in character). Generally, the interaction between C_{60} and transition metal surfaces is stronger than that between C_{60} and noble metal surfaces [170, 178].

Images of the intramolecular features of adsorbed C_{60} molecules which are bias dependent have been studied by STM in C_{60}/Cu(111)-$c(4 \times 4)$ [195] and C_{60}/Au(110) [196] systems. X-ray photoelectron diffraction has also been used to determine the molecular orientation of adsorbed C_{60} molecules [196–200].

For C_{60} monolayers on several common metal surfaces, the adsorptive structures as well as their interactions are summarized in Table 5, and a typical $(2\sqrt{3} \times 2\sqrt{3})R30°$ model of the adsorptive structure on M(111) (M = Au, Ag, Al) surfaces is shown in Figure 10 [185].

2.5.2. On Semiconductor Surfaces

The initial state of adsorption of C_{60} on most common semiconductor surfaces shows individual isolated molecules, no island or specific interaction with step edge or defects on the surface. At room temperature the C_{60} molecules are generally immobile, showing strong interactions with the surface.
Figure 10. A model of the $(2\sqrt{3} \times 2\sqrt{3})$ $R30°$ phase. The dashed hexagon encloses an overlayer-induced unit cell, while the solid hexagon encloses a unit cell of the M(111) surface (M = Au, Ag, Al). Adapted with permission from [185], A. J. Maxwell et al., *Phys. Rev. B* 57, 7312 (1998). © 1998, American Physical Society.

Si(111)-(7 × 7) The interaction of adsorbed C_{60} molecules with the Si surface is still not very clear. The Si(111)-(7 × 7) surface is (weakly) metallic due to the surface dangling bonds. Initially, it was suggested [205, 206] that the C_{60}–Si(111) interaction was ionic in character and similar to the C_{60}–noble metal interactions. HREELS data supported this

Note: NDD—nearest neighbor distance, WF—work function, CT—charge transfer, DT—decomposition temperature.

charge-transfer model well with quantitative estimates of the amount of electron transfer to the fullerene LUMO being as high as (3 ± 1) electrons per molecule at the coverage lower than 0.25 monolayer (ML) and (0.7 ± 1) electrons at an average of about 1 ML [207]. But photoemission measurements [208–210] showed that the charge transfer to the fullerene LUMO is negligible, suggesting that the bonding is strongly covalent in character with a clear Si–C-related peak observed in both the C$_{1s}$ core level and valence-band photoemission spectra.

Individual isolated C$_{60}$ molecule adsorption on Si(111)-(7×7) surface is strongly site dependent due to the different surface atom arrangements and dangling bond configurations caused by surface (7×7) reconstruction [205, 211, 212]. STM experiment reveals that about 80% C$_{60}$ molecules are adsorbed on faulted half and unfaulted half sites (sites A and A′), about 13% molecules on corner holes (site B), and only 7% on dimer lines (site C) [212]. Figure 11 gives high resolution STM images of single C$_{60}$ molecules adsorbed on different surface sites showing clear and rich intramolecular features which agree well with the theoretical calculation using the local density approximation with C$_{60}$Si$_m$H$_l$ cluster models [212].

A STS study was also carried out to probe the local electronic structure of individual C$_{60}$ molecules on Si(111)-(7×7) surfaces (see Fig. 12). It was found that the HOMO–LUMO gaps of C$_{60}$ adsorbed at sites A, B, and C are 1.4, 0.8, and 1.3 eV, respectively, much smaller than that of free C$_{60}$ molecules ($\sim$1.8 eV). Thus it was confirmed that the mixing states of the C$_{60}$ orbitals with the local density of states (LDOS) of Si(111)-(7×7) are site dependent due to the strong interaction between the C$_{60}$ and the dangling bonds of the surface and the different surface structures at different sites [213].

As the submonolayer coverage increases to about 1 ML, the adsorbate–adsorbate interaction becomes large enough that two kinds of local ordered structural domains registered with those pinned on the substrate corner holes will form [214]. After the completion of monolayer C$_{60}$ coverage, a R-19° double-domain structure forms in which the

Figure 12. Curves A, B, and C are typical STS results corresponding to C$_{60}$ adsorbed at sites A, B, C (see Fig. x1b), respectively, on a Si(111)-(7×7) surface. Curve D is the average STS result on the bare Si surface. These STS results are represented in a graph of $(dI/dV)/(I/V)$ vs V. Adapted with permission from [213], H. Wang et al., *Surf. Sci.* 442, L1024 (1999). © 1999, Elsevier Science.

two domains exhibit interfacial structures with the C$_{60}$ [$\bar{1}$10] directions $\pm$11° off the [$\bar{2}$11] axis of a Si substrate [215, 216].

Si(100)-(2 × 1) The interaction of C$_{60}$ with Si(100)-(2×1) surfaces is suggested to be weak and van der Waals force like [217, 218] without charge transfer [207]. Annealing the surface at an elevated temperature will cause a rearrangement of surface Si atoms and change the interaction from physical adsorption to a chemical one [90] and cause a hybridization of C$_{60}$ molecular orbitals with the surface states [219].

At room temperature, individual isolated adsorbed C$_{60}$ molecules on the Si(100)-(2×1) surface reside in the valleys between the (2×1) reconstruction dimer rows randomly at the initial state [220]. For monolayers on Si(100)-(2×1) surfaces, C$_{60}$ form two short-range local order structures of $c(4 \times 4)$, and $c(4 \times 3)$, with nearest-neighbor distances of 10.9 and 9.6 Å [217], respectively.

In the case of chemical adsorption of C$_{60}$ on Si(100)-(2×1) surfaces after annealing, the scanning tunneling spectroscopy of individual C$_{60}$ molecules on two different adsorption sites of the Si(100) surface was investigated [221, 222] (see Fig. 13). It was found that the HOMO–LUMO gap of C$_{60}$ molecules at the top of a single dimer (type A molecules) is about 1.8 eV, which is about the same as that of free C$_{60}$ molecules; the HOMO–LUMO gap of these molecules which is usually located at a missing dimer defect (type B molecules) is about 2.2 eV, which is close to the bandgap of SiC [223, 224]. STS results indicated that the interaction between a type B molecule and the Si surface is much stronger than that for a type A molecule; type B molecules form covalent bonds not only with second layer Si atoms but also with the surrounding Si atoms in the first layer.

Figure 11. High resolution STM images of single C$_{60}$ molecule recorded with different bias voltages on an faulted half site: (a1) $V_s = -1.8$ V, (a2) $V_s = 1.5$ V, (a3) $V_s = 1.8$ V, and (a4) $V_s = 2.5$ V; and on corner holes: (b1) $V_s = -1.8$ V and (b2) $V_s = 2.3$ V. The tunneling current is 0.15 nA for positive bias images and 0.1 nA for negative bias images. Adapted with permission from [212], J. G. Hou et al., *Phys. Rev. Lett.* 83, 3001 (1999). © 1999, American Physical Society.

Figure 13. Curves A, B, and C are typical STS results corresponding to C_{60} adsorbed at sites A, B (see Fig. x2b), respectively, on an Si(100)-(2×1) surface. Curve C is the average STS result on the bare Si surface. These STS results are represented in a graph of $(d \ln I / d \ln V)$ vs V. Adapted with permission from [221], X. Yao et al., *Surf. Sci.* 366, L743 (1996). © 1996, Elsevier Science.

Ge(100)-(2 × 1) and Ge(111)-(2 × 8) The C_{60} monolayer adsopted on Ge(100)-(2×1) exhibits uniaxial incommensurate near-ordered lattice close to a structure of $c(3 \times 4)$ in the direction of the dimer rows of the Ge(100)-(2×1) surface [218, 225–227] and preserves the Ge(100)-(2×1) reconstruction [227].

In contrast to Ge(100) and Si(111), the Ge(111) surface undergoes a structural rearrangement upon the adsorption of C_{60} molecules [228]. The C_{60} monolayer on a Ge(111) system exhibits several ordered structures as a function of the annealing temperature [228]. Two stable surface phases, $(3\sqrt{3} \times 3\sqrt{3})R30°$ and $(\sqrt{13} \times \sqrt{13})R14°$, form upon annealing at 450–500 and above 500 °C, respectively, as well as a localized metastable 5×5 phase by suddenly quenching the $(3\sqrt{3} \times 3\sqrt{3})R30°$ phase heated at 500 °C. The interaction of C_{60} with the Ge(111) surface is prevalently covalent and strong [229].

GaAs(110) and GaAs(001) The interaction of C_{60} molecules on the GaAs(110)-(1×1) surface is weak (dominantly via van der Waals force), resulting in well-ordered C_{60} thin film growth and rotating C_{60} molecules. The C_{60} layer on GaAs(110)-(1×1) is stressed due to the competition between the intermolecular interaction and the adsorbate–substrate interaction and the fact that the lattice parameter of the GaAs(110) substrate does not match with those of C_{60} [230, 231].

The interaction of C_{60} molecules on the GaAs(001) surface is weak too and the C_{60} molecules are mobile at room temperature on the surface [232, 233]. Particularly in the case of C_{60} on the As-rich 2×4 substrate, the epitaxial

growth is found to be unique and quite different from other GaAs(001) phases: C_{60} film takes its (110) crystalline axis which cannot be obtained on other substrate. The C_{60} overlayer is highly strained with a lattice expansion of $\sim 13\%$ due to a charge transfer from the As-dangling bonds to C_{60} and a site-specific C_{60}–substrate interaction, and this structure is very stable at least up to 10 ML [233].

3. C_{60} CRYSTAL

3.1. Structure

3.1.1. Main Description

At room temperature (RT), solid C_{60} usually forms black or brownish powder or crystals. C_{60} single crystal forms a molecular crystal through weak van der Waals force C_{60}–C_{60} bonding and adopts a closed–packed face-centered cubic (fcc) structure with a lattice constant of 14.17 Å [234, 235] and a nearest neighbor C_{60}–C_{60} distance of 10.02 Å [236]. It is chemically active but stable in air or at temperatures well above RT. A pure C_{60} single crystal and a schematic view of the fcc structure is shown in Figure 14 [237]. The more physical constant for crystalline C_{60} in the solid state is shown in Table 6. The comparison of properties of solid C_{60} with other fullerene solids (C_{36}, C_{70}, C_{76}, C_{78}, C_{84}) is listed in Appendix B.

3.1.2. Symmetry and Space Group

The symmetry of the space group for fcc C_{60} crystal at RT has been identified by X-ray and neutron diffraction [235, 238, 272, 273] to be O_h^5 or $Fm\bar{3}m$, using the Schoenflies and International Crystallographic nomenclature, respectively.

Solid state ^{13}C NMR [32, 274–276], quasi-elastic neutron scattering [277], and muon spin resonance (μSR) [278, 279] studies showed that the C_{60} molecules in the crystal are rotating rapidly with three degrees of rotational freedom and reorienting rapidly. The rotational reorientation time at RT is about 9–12 ps which is 50% faster than molecular reorientation in solution (about 15.5 ps) [280], so that solid C_{60} may be considered as a nearly ideal close-packed configuration of spheres at room temperature. The rapid reorienting and rotating mechanism is consistent with RT NMR results that all carbon atoms are equivalent although

Table 6. Physical constant for crystalline C$_{60}$ in the solid state.

Property	Quantity
Fcc lattice constant	14.17 Å [234, 235]
C$_{60}$–C$_{60}$ distance	10.02 Å [236]
Tetrahedral interstitial site radius	1.12 Å [236]
Octahedral interstitial site radius	2.07 Å [236]
Mass density	1.72 g/cm^3 [236]
Volume thermal-expansion coefficient	6.2×10^{-5}/K [238]
Molecular density	1.44×10^{21} cm^3 [236]
Compressibility ($-d \ln V/dP$)	6.9×10^{-12} cm^2/dyn [239] (compared with: graphite 2.7, diamond 0.18)
Bulk Modulus	6.8 GPa [240] $\sim$12 GPa [241]
Young's modulus	15.9 GPa [242]
Phase transition temperature (T_{01})	260–261 K [243]
dT_{01}/dP	$\sim$11–16K/kbar [244, 245][a]
Sublimation temperature	$\sim$434 °C [246]
Heat of sublimation	38 kJ mol^{-1} [247]
Cohesive energy	$\sim$1.7 eV [248, 249]

[a] The value varies with different pressure medium.

the point group I_h of C$_{60}$ molecule is incompatible with any crystal space group [14].

Figure 15 shows an X-ray powder-diffraction pattern of crystalline C$_{60}$ compared to that of gold. In these two kinds of materials, both the C$_{60}$ molecules and the gold atoms present a close-packed fcc structure, but in the pattern of C$_{60}$ crystals the (200) and (400) diffraction peaks are missing. The reason for the missing peaks can be attributed to the unique intrinsic properties of C$_{60}$ molecules. Because C$_{60}$ molecules are rotating rapidly at room temperature, all molecules in the fcc lattice can be well approximated by hollow spherical shells filled by electrons. This "hollow-sphere"
Figure 15. X-ray powder-diffraction pattern of crystalline C$_{60}$ compared to that of gold. In both kinds of materials, the molecules (i.e., atoms in case of gold) crystallize in a face-centered-cubic arrangement, corresponding to a closest packing of spheres. Notice the absence of the (200) and (400) diffraction peaks in crystalline C$_{60}$.

scattering introduces additional interference which happens to extinguish just those fcc diffraction peaks [235].

For the RT fcc structure, subsequent studies in very close detail by X-ray [281, 282] and neutron diffraction [282–285] reveal that the molecular rotation is not, in fact, completely free, and provide evidence for pronounced local orientational order with a correlation length $\sim$40 Å [282] which is four times the shortest intermolecular distance and consists of several dozen molecules. The local order seems to be driven by the same nearest neighbor interaction which leads to long range order below the phase transition temperature T_{01} but does not possess the symmetry of the low temperature structure [282].

3.2. Vibrational Modes

3.2.1. Overview

The vibrations of C$_{60}$ molecules can be very well classed into two distinct groups: intermolecular and intramolecular vibrations. For intermolecular molecular vibrations, C$_{60}$ molecules translate or rotate as nearly rigid entities, and the highest measured intermolecular phonon frequency at room temperature is only $\sim$50 cm^{-1}, well below that of the lowest intramolecular frequency, namely 272 cm^{-1} for the $H_g(1)$ "squashing" mode [286, 287].

The intramolecular vibrations of an isolated C$_{60}$ molecule involve changes of the bond distances or bond angles of the carbon atoms on the C$_{60}$ molecule. Starting with $60 \times 3 = 180$ total degrees for an isolated C$_{60}$ molecule and subtracting the 6 degrees of freedom corresponding to 3 translations and 3 rotations results in 174 vibrational degrees of freedom. However, there are only 46 distinct mode frequencies corresponding to the 174 degrees of freedom due to the high symmetry of C$_{60}$ (point group I_h). According to the symmetry of the displacement patterns, the 46 distinct intramolecular vibrations can be classed into several groups as follows:

$$2A_g + 1A_u + 3T_{1g} + 4T_{1u} + 4T_{2g} + 5T_{2u} + 6G_g + 6G_u$$
$$+ 8H_g + 7H_u$$

Here, the subscripts g (gerade or even) and u (ungerade or odd) refer to the symmetry of the eigenvector under the action of the inversion operator. The T-modes are triply, the G-modes are fourfold, and the H-modes are fivefold degenerate. These degeneracies are a consequence of the high symmetry of the C$_{60}$ molecule and lead to the fact that the number of distinct modes (46) is much lower than 174 (the vibrational degrees of freedom). Group theory indicates that only 10 of the 46 distinct mode frequencies are Raman-active ($2A_g + 8H_g$) in first order and 4 (T_{1u}) are infrared (IR)-active in first order. These activated frequencies have been assigned with certainty. The remaining 32 modes ($1A_u + 3T_{1g} + 4T_{2g} + 5T_{2u} + 6G_g + 6G_u + 7H_u$) are optically inactive ("silent") so that the identification of these modes has been difficult. Early calculations of the vibrational frequencies of C$_{60}$ used mainly classical force constant treatments [288–293] or relied on quantum chemistry calculations [294–300]. However, they did not display the accuracy required to use them as a reliable guide for a clear identification of the silent modes. Analysis of the second-order

Raman and infrared spectra for C_{60} provides a good determination of assignments of the 32 silent mode frequencies [301–303]. The results of density functional theory (DFT) calculations can provide a more reliable complete assignment of the C_{60} modes [304–308]. Since Raman and infrared spectra can only provide 14 active mode frequencies, a number of other experimental techniques were developed to probe silent modes, such as inelastic neutron scattering, EELS, and single oxygen photoluminescence (PL). Table 7 gives recommended values for the 46 distinct vibrational frequencies of an isolated C_{60} molecule and their assignments [309]. Several alternative assignments of vibrational frequencies in C_{60} can be found in the literature [301, 303, 310–315].

3.2.2. Raman and Infrared Spectra

First-Order Active Raman and Infrared Modes Raman and IR spectra provide the most quantitative methods for determining the vibrational mode frequencies. Since C_{60} is very nearly an ideal molecular solid, so the Raman and infrared spectra are sensitive for distinguishing C_{60} from higher-molecular-weight fullerenes with lower symmetry (e.g., C_{70} has D_{5h} symmetry). Because most of the higher molecular weight fullerenes have lower symmetry as well as more degrees of freedom, they have many more infrared- and Raman-active modes [316, 317].

Table 7. Recommended values for the 46 distinct normal mode frequencies of an isolated C_{60} molecule [309].

Even modes			Odd modes		
Frequency (cm^{-1})	Assignment	Activated modes	Frequency (cm^{-1})	Assignment	Activated modes
496	A_g (1)	R	984	A_u (1)	
1470	A_g (2)	R			
			526	T_{1u} (1)	IR
568	T_{1g} (1)		575	T_{1u} (2)	IR
831	T_{1g} (2)		1182	T_{1u} (3)	IR
1289	T_{1g} (3)		1429	T_{1u} (4)	IR
553	T_{2g} (1)		342	T_{2u} (1)	
756	T_{2g} (2)		753	T_{2u} (2)	
796	T_{2g} (3)		973	T_{2u} (3)	
1345	T_{2g} (4)		1205	T_{2u} (4)	
			1525	T_{2u} (5)	
485	G_g (1)				
567	G_g (2)		353	G_u (1)	
736	G_g (3)		764	G_u (2)	
1079	G_g (4)		776	G_u (3)	
1310	G_g (5)		961	G_u (4)	
1482	G_g (6)		1309	G_u (5)	
			1422	G_u (6)	
272	H_g (1)	R			
433	H_g (2)	R	403	H_u (1)	
709	H_g (3)	R	534	H_u (2)	
772	H_g (4)	R	668	H_u (3)	
1099	H_g (5)	R	743	H_u (4)	
1252	H_g (6)	R	1223	H_u (5)	
1425	H_g (7)	R	1344	H_u (6)	
1575	H_g (8)	R	1567	H_u (7)	

Note: "R" represents Raman activated mode; "IR" represent infrared activated mode.

The Raman and IR spectra of the pristine monomeric fcc phase of C_{60} are shown in Figures 16 and 17, together with the spectra of the orthorhombic (O), tetragonal (T), and rhombohedral pressure-polymerized (R) phase of C_{60} as well as the pressure-dimerized state for comparation (for comprehensive knowledge on the polymerized C_{60}, please refer to Section 4.2). Raman and IR spectra of solid C_{60} remain almost unchanged relative to the isolated C_{60} molecule. Raman scattering spectra in Figure 16 for solid C_{60} show 10 strong Raman lines, including two "breathing" A_g-modes related to symmetric oscillations of the entire molecule (496 cm^{-1}) and of pentagons (1468 cm^{-1}), and eight H_g-modes: 272, 432, 710, 772, 1100, 1248, 1422, and 1574 cm^{-1} [301, 318–323]. The first-order infrared spectrum for C_{60} contains only four strong lines (see Fig. 17) at 526, 576, 1184, and 1428 cm^{-1}, each identified with an intramolecular T_{1u} mode [303, 318, 324].

Isotopic Effects in the Raman Spectra The natural abundance of ^{13}C isotopes is about 1.1%, with the result that approximately half of the molecules in ordinary C_{60} samples produced from natural graphite contain one or more ^{13}C isotopes. The isotopic distribution within the molecule is random [325]. The truncated icosahedral structure of C_{60} molecule belongs to icsohedral point group (I_h). The $^{12}C_{60}$ molecule shows the highest degree of symmetry and most stringent selection rules and there are 4 infrared-active and 10 Raman-active modes for the molecule. The remaining 32 distinct modes, silent modes, are IR and Raman forbidden. However, the addition of ^{13}C isotopes lowers the symmetry of the molecule. Since the symmetry restrictions against first-order Raman or IR activity for the silent modes have been removed, it is expected that all of the previous silent modes become active. The lowering of the icosahedral symmetry by the presence of ^{13}C isotope has been used to investigate the silent modes in the isotopically pure molecule [310, 326–329].
Figure 16. Raman spectra of the pristine C_{60} (a), polymerized DS (b), and O phase (c), excited by a 1064-nm line; those of the O (d), T (e), and R (f) phases, excited by a 568.2-nm line. Figure 17. IR spectra of the pristine C$_{60}$ (a), and polymerized O (c), T (d), R (e) phases, and DS (b). Adapted with permission from [318], V. A. Davydov et al., *Phys. Rev. B* 61, 11936 (2000). © 2000, American Physical Society.

Besides the symmetry-lowering phenomena due to the presence of ^{13}C, the isotopes can also cause the shifts and splittings of the active modes [330, 331]. This isotope effect on the mode frequencies is due to their dependence on $(\kappa/M)^{1/2}$, where κ and M are the force constants and atomic mass, respectively. Thus in a C$_{60}$ molecule with n ^{13}C isotopes, at first order, the vibrational frequency is expected to be lowered proportional to the mass difference between ^{12}C$_{60}$ and ^{13}C$_n$^{12}C$_{60-n}$, which can be simply written as

$$\frac{\omega(n)^2}{\omega(0)^2} = 1 - \frac{n}{720}$$

where $\omega(0)$ is an eigenmode frequency of ^{12}C$_{60}$ and 720 a.u. is its atomic mass.

A high-resolution Raman spectrum for a C$_{60}$ sample with the natural isotopic abundance is shown in Figure 18. To reduce the natural Raman linewidth, the C$_{60}$ was dissolved in CS$_2$ solution, and the spectrum was taken at 30 K. A fine structure of the high-energy pentagonal-pinch $A_g(2)$ mode near 1470 cm^{-1} was observed. Three peaks in the fine structure could be resolved, associated with ^{12}C$_{60}$, ^{13}C$_1$^{12}C$_{59}$, and ^{13}C$_2$^{12}C$_{58}$, respectively. The measured separation between the first and second peaks is 0.98 ± 0.01 cm^{-1}, while for the second and third peaks it is 1.02 ± 0.02 cm^{-1}. Spectra taken at higher temperatures are shown in the inset [330]. Figure 19 shows Raman and mass spectra for a ^{13}C enriched C$_{60}$ sample, which is produced by enriching the graphite nod
Figure 18. Unpolarized Raman spectrum of a frozen solution of C$_{60}$ in CS$_2$ at 30 K. The solid line is a 3-Lorentzian fit to the experimental data. The highest frequency peak is assigned to the totally symmetric pentagonal-pinch A_g mode in ^{12}C$_{60}$. The other two lines are assigned to the pentagonal-pinch mode in molecules containing one and two ^{13}C isotopes, respectively. The inset shows the evolution of these peaks as the solution is heated. They are no longer resolved as the solution melts above 150 K. Adapted with permission from [330], S. Suha et al., *Phys. Rev. Lett.* 72, 3359 (1994). © 1994, American Physical Society.

with ^{13}C. Comparison between the Raman and mass spectra shows that the two line shapes have a remarkable correlation [330]. The simple correlation was further confirmed by using a variety of first-principle and phenomenological dynamical models [332]. Within the framework of a first-principle calculation, normal modes of vibration of the C$_{60}$ isotopomers ^{3}C$_1$^{12}C$_{59}$ and ^{13}C$_2$^{12}C$_{58}$ have been calculated [333].

3.2.3. Inelastic Neutron Scattering Spectrum

Inelastic neutron scattering (INS) offers the potential to detect all 46 intramolecular distinct modes of C$_{60}$, including those silent for first-order Raman and infrared spectroscopies, because the technique is sensitive to modes of all symmetries. The scattering intensity is proportional to the mode degeneracy, which can be used to identify the vibrations. Although, in principle, inelastic neutron scattering allows one to unambiguously assign all the modes, it has so far not been so ideal. In fact this technique has two main disadvantages, which make it difficult to individually assign all of the modes. First, the determination of eigenvectors is traditionally based on single-crystal samples, but the available C$_{60}$ crystals were too small for inelastic neutron-scattering experiments. Second, the poor spectral resolution
Figure 19. Comparison of the mass spectra and the Raman spectra for a ^{13}C-enriched C$_{60}$ sample. Adapted with permission from [330], S. Suha et al., *Phys. Rev. Lett.* 72, 3359 (1994). © 1994, American Physical Society.

of INS makes it difficult if not impossible to achieve assignments of many of the C$_{60}$ modes, especially those whose frequencies are clustered within a narrow range. A number of workers have measured the intramolecular mode frequencies for C$_{60}$ by INS, and the results are summarized in Table 8. For more experimental and theoretical details and the principal INS technique, one can read several review and original research papers [285, 334–340].

3.2.4. High-Resolution Electron Energy Loss Spectrum

Infrared-active modes can be observed in HREELS measurements because the electric dipole associated with infrared-active vibrations can scatter the incident monoenergetic electrons. An ultrahigh vacuum environment is necessary for HREELS experiments and the resolution of HREELS experiments can not match that of optical measurements. Although HREELS has no obvious advantage in the determination of the infrared mode frequencies, it is very useful for the assignment of vibrational frequencies in C$_{60}$. This is because all modes in C$_{60}$ can induce inelastic scattering of electrons due to the impact scattering mechanism [341, 342]. In the impact scattering mode, the electron

scattering is by short-range components of the electron–molecule interaction.

A few experimental works have performed HREELS experiments on C$_{60}$ films, using a variety of substrates [343–345]. Depending on the substrate used, the films are crystalline or disordered. This has a significant effect on the relative intensity of the different spectral features (see Table 8).

3.2.5. Optical Spectroscopy

Some optical spectra, including singlet oxygen PL [346], fluorescence, and phosphorescence spectra, can also be powerful tools for the identification of intramolecular vibrational modes of C$_{60}$. The applicability of the photoluminescence technique to probe fundamental vibrational excitations of C$_{60}$ is based on the weak vibronic coupling of O$_2$ molecules intercalated into the C$_{60}$ lattice. Thirty-two of the 46 distinct vibrational modes of C$_{60}$ can be observed in the PL spectra, some of which are not Raman and IR first-order active modes. Mode energies determined from this technique show good agreement with those determined from INS, IR, and Raman spectroscopies. At high energies (>700 cm^{-1}), the technique has a significant advantage over INS, since the much sharper peaks can provide very accurate data for mode frequencies [346]. By investigating the vibrational fine structure in the fluorescence [347] and phosphorescence [348] spectra of C$_{60}$ molecules isolated in neon and argon matrices, the unambiguous identification of several vibrational modes of T_{3u}, H_u, and G_u symmetry were obtained.

3.3. Phase Transition

3.3.1. Orientational Phase Transition

On cooling below a temperature of about $T_{01} \sim 260$ K, the nearly free rotation of C$_{60}$ molecules in solid C$_{60}$ will be frozen by losing two of their three degrees of rotational freedom; the four neighboring molecules in an fcc unit cell remain in their positions but become orientationally inequivalent. Their rotation motions are constrained along two standard favorite orientations and become hindered, resulting in an orientational ordering [235, 243, 249, 273, 349], but the random reorientation between the two possible standard orientations for each molecule in the solid still lead to a residue disorder (a so-called "merohedral disorder") [32, 243, 274, 275, 349–352]. The two favorite orientations are corresponding to electron-rich double bonds on one molecule facing the electron deficient centers of hexagons (HF) and pentagons (PF) respectively on its adjacent molecules, obtained by rotating the molecules around the four $\langle 111 \rangle$ axes of the C$_{60}$ molecules through about 38° and 98° (60° jumps) respectively [243, 284, 349, 353–355]. Recently, elastic diffuse neutron-scattering study, considering the optimization of nearest-neighbor orientations rather than long-range orientational order, showed that the actual angles may be closer to 42° and 102° [356]. The PF structure has been indicated to be an idealized ordered structure and the HF structure a "defect structure," because the HF structure has a slightly higher energy than the PF structure. The lower energy configuration is about only 11.4 meV [352, 357] below the higher energy configuration, and the two are

Table 8. Assignment and comparative list of peak positions (in meV) of neutron inelastic scattering, HREELS, and photoluminescence (PL).

Note: The HREELS peak positions observed in an ordered C$_{60}$ film on GaSe(0001) and a crystalline C$_{60}$ film on GeS(001) are italic. The other numbers correspond to the peaks detected in the spectra of an amorphous C$_{60}$ films on Si(100).

separated by a potential barrier of ~235–295 meV [243, 274, 280, 284, 349, 352, 357–361] which has been confirmed by various experiments.

A schematic 3D model of a close-packed (111) plane of C$_{60}$ molecules exhibiting uniaxial reorientation about ⟨111⟩ directions (low temperature phase, 90–260 K) is shown in Figure 20 [243]. The molecules reorientate between a number of different sites but principally perform 60° jumps about [111] residing in the two configurations corresponding to 38° and 98° (or 42° and 102°, using latest data) rotations.

Although the centers of the C$_{60}$ molecules remain in the same places, the four molecules of the conventional fcc unit cell become orientationally nonequivalent. The incompatibility of the icosahedral molecular symmetry of the different molecular orientations and the cubic lattice symmetry lowers the crystal symmetry from fcc into a simple cubic (sc) structure (space group T_h^6 or $Pa\bar{3}$, which is a subgroup of the space group $Fm\bar{3}m$ of an fcc structure) [235, 273, 362]. Thus the C$_{60}$ crystal undergoes a so-called orientational ordering phase transition.

The orientational ordering transition is first order [111]. The occurrence of this transition has been confirmed by various experimental methods such as differential scanning calorimetry (DSC) [235, 273, 363], X-ray diffraction [235, 273], NMR [14, 23, 274–276, 363–366], neutron diffraction [243], dielectric spectroscopy [359]; μSR [279]; specific heat measurements [352, 361, 367, 368], inelastic neutron scattering [33, 277, 369, 370], electron diffraction [371], sound velocity and ultrasonic attenuation [242, 372], and Raman spectroscopy [326, 373–375].

Figure 21 shows a comparative electron diffraction patterns of crystalline C$_{60}$ at room temperature and at 100 K [371]. Additional spots appear at positions which are extinct in an fcc lattice on cooling below T_{01} and correspond to a primitive cubic lattice. The appearance of these spots reveals the low temperature structure in which the molecules are still situated on an fcc lattice but orientationally ordered and also shows that the space group $Pa\bar{3}$ is a subgroup of the space group $Fm\bar{3}m$ of the high temperature fcc phase.
Figure 20. Close-packed (111) plane of C$_{60}$ molecules depicting uniaxial reorientation about ⟨111⟩ directions (low temperature phase, 90–260 K). The "dimples" correspond to the centers of electron-poor hexagonal/pentagonal faces; the equatorial protrusions depict electron-rich 6:6 bonds. The constraints demanded by $Pa\bar{3}$ symmetry imply that the electron-rich and electron-poor regions have well-defined loci corresponding to constant latitudes relative to [111]. These electrostatic considerations are consistent with the assumption that the preferred easy reorientation direction is [111]. Adapted with permission from [243], W. I. F. David et al., *Europhys. Lett.* 18, 219 (1992). © 1992, EDP Science.
Figure 21. Electron diffraction patterns of C$_{60}$ crystallite along [001] (a, c) and along [011] (b, d) at room temperature (a, b) and at 100 K (c, d). Note the appearance of extra reflections at low temperature related to a lowering of symmetry due to orientation ordering. Adapted with permission from [371], G. Van Tendeloo and S. Figure 22 shows the ^{13}C NMR spectra of solid C$_{60}$ at temperatures from 295 down to 77 K [275]. The low-temperature NMR line shape for the C$_{60}$ solid is quite different from that of C$_{60}$ in solution. From RT to low temperature below T_g, the spectra changes from a single line peak at 298 K to a line shape at 77 K. The symmetry of the molecule and the equivalence of all C$_{60}$ carbon atoms in C$_{60}$ crystals are broken by two factors: the presence of the crystal lattice and the applied magnetic field. As the temperature is reduced, the "motionally narrowed" NMR line at 295 K (143 ppm from tetramethyl silane) in the 13C NMR spectrum of C$_{60}$, which proves that C$_{60}$ molecules are rotating rapidly with respect to the NMR time scale at RT, is broadened and the C$_{60}$ molecule's orientation become static on the NMR time scale. At 77 K there is little evidence of the narrow line at 143 ppm, and a fit to this line shape yields an asymmetric chemical-shift tensor with components of 220, 186, and 25 ppm, reflecting the chemical-shift anisotropy of the ^{13}C nuclei averaged over the crystallite orientations.

The phase transition affects various physical properties; the changes of some of these properties at the transition temperature T_{01} are listed in Table 9.

It has also been indicated that both the transition temperature and the size and shape of the transition anomalies are strongly influenced by deformation, impurities, and solvent [354, 378].

3.3.2. Glass Transition

Below about 90 K the molecules in C$_{60}$ crystal are entirely frozen but never order perfectly; the C$_{60}$ crystal undergoes a so-called glass transition. The glass transition of C$_{60}$ crystal is second order [243].

The fraction of molecules in the more stable PF orientation is only about 60% near 260 K but increases to
Figure 22. ^{13}C NMR spectra of solid C_{60} obtained at ambient temperatures of 123, 100, and 77 K. The 13C NMR spectrum of C_{60} is expected to be a broad "powder pattern" resonance (width greater than ~200 ppm) reflecting the chemical-shift anisotropy of the ^{13}C nuclei averaged over the crystallite orientations. The "motionally narrowed" NMR line at 295 K (143 ppm from tetramethyl silane) proves that C_{60} molecules are rotating rapidly with respect to the NMR time scale, which is defined by the inverse of the spectral spread (~10^{-4} s). As the temperature is reduced, the powder pattern is recovered as the molecular motion decreases. At 77 K there is little evidence of the narrow line at 143 ppm, and a fit to this line shape yields an asymmetric chemical-shift tensor with components of 220, 186, and 25 ppm. Adapted with permission from [275], C. S. Yannoni et al., *J. Phys. Chem.* 95, 9 (1991). © 1991, American Chemical Society.

about 84% near $T_g \sim 90$ K, the glass transition temperature [243]. Below T_g, the thermal energy becomes too small compared with the energy barrier between the two states for further reorientation to occur; therefore the C_{60} molecules are frozen in their orientation and the fraction of PF orientation (~84%) or HF orientation (~16%) becomes invariable. The remaining orientational disorder causes an orientational glass phase. Because the nearest-neighbor distance of HF oriented C_{60} molecules is slightly smaller than that of the PF oriented molecules, there is an anomalous increase of volume thermal expansion coefficient in the transition temperature [243].

Evidence for this glass transition at low temperature has been provided by a number of experimental techniques, including velocity of sound and ultrasonic attenuation

Table 9. Physical properties at orientational phase transition temperature T_{01}.

Quantity	Under T_{01}	Above T_{01}	Jump
Structure	sc	fcc	—

studies [242, 372], specific heat measurements [361, 379], thermal conductivity [352, 380], elasticity [242, 358, 372], high resolution capacitance dilatometry [357], dielectric relaxation studies [359], electron microscopy observations [381], and neutron scattering measurements [243, 349]. It has been demonstrated that the measured values of transition temperature T_g varying in a wide range (~90–165 K) rely strongly on the time scale of the measurements [358]. The temperature dependence of the relaxation time may be described by the relation $\tau_t = \tau_{t0} \exp(E_{At}/k_B T)$, where E_{At} is the activation energy for the transition and τ_{t0} is a characteristic relaxation time with values of $\tau_{t0} = 4 \pm 2 \times 10^{-14}$ s and $E_{At} = 300 \pm 10$ meV [358]. For high-frequency measurement probes, the molecules cannot reorient quickly enough to follow the probe frequency, so that the molecules seem to be frozen at a higher transition temperature and a lower transition temperature for low-frequency measurement probes. It is concluded that below T_g a quenched disorder occurs rather than an equilibrium glass phase [358].

3.3.3. Phase Transition in Low-Dimensional Structures

At room temperature, the molecules on C_{60} (111) surfaces are hexagonal close-packed and rotating and reorientating freely corresponding to a (1×1) structure. Below a temperature of surface orientational ordering transition temperature T_{s01} about 230 K [382–386] (about 30 K lower than that of C_{60} bulk), the C_{60} (111) surface exhibits a (2×2) reconstruction [382, 387] due to the four inequivalent frozen molecules in a (2×2) unit cell holding four different orientations. STM study clearly revealed the surface structure and indicated that the orientational configurations of the C_{60} molecules on the surface are similar to those in the bulk, except for some complex details. This similarity indicates that it is the

interaction of the neighboring C$_{60}$ molecules that drives the molecules to an orientational ordered state [387]. Recently, a two-stage rotational disordering mechanism, with a new intermediate regime between a low-temperature ordered (2×2) state and a high-temperature (1×1) disordered phase, has been proposed for this surface phase transition based on Monte Carlo simulations [388].

C$_{60}$ submonolayers adsorbed on a self-assembled mono-layer of an alkylthiol can be considered as ideal two-dimensional hexagonal arrays with a nearest-neighbor distance of ~10 Å [20] due to the weak van der Waals force between C$_{60}$ and the organic monolayer surface. At room temperature the C$_{60}$ molecules at this surface are mobile and rotating freely. At 77 K, the C$_{60}$ molecule appears as a hemi-sphere, a tilted doughnut, or an asymmetric dumb-bell, each being consistent with a rotating pattern around a fixed axis. That is, unlike in the case of bulk C$_{60}$, the two-dimensional rotationally ordered phase persists down to 77 K (already 13 K below the bulk freezing temperature) [20].

Unlike the orientation-related glass phase in bulk C$_{60}$ and the bulk C$_{60}$ (111) surface, the two-dimensional C$_{60}$ array forms orientationally ordered domains at 5 K although the C$_{60}$ molecules are not commensurate with alkylthiol mono-layer [20]. The molecular rotation is frozen and the internal fine pattern of C$_{60}$ with a well-known native cage struc-ture can be clearly revealed by STM, because of the fairly weak interaction between C$_{60}$ and the organic monolayer surface with a negligible influence on the C$_{60}$ molecule by the substrate.

3.3.4. Phase Diagram

Figure 23 gives an equilibrium phase diagram of C$_{60}$ crystal covering a wide range of temperatures and pressures, drawn on logarithmic scales to bring out clearly the low-pressure behavior [389].

The solid lines are derived from experiment, and dashed lines are theoretical or reflect extrapolations from exper-iment. The solid–vapor coexistence line $P(T)$ is given by plotting the equilibrium vapor pressure against temperature. The thermal gravimetric analysis data (shown by solid cir-cles) [247] are fitted to $P(T) = P_0 \exp(-\Delta H/kT)$, which can be derived from the Clausius–Clapeyron equation assuming ideal gas behavior [390]; the low pressure experimental data (shown by a bar and a open diamond) [389, 391] are in good agreement with extrapolation of the solid–vapor coexistence line using the ideal gas relationship. It can be indicated from the diagram that solid fcc C$_{60}$ sublimes on heating without forming a liquid phase at normal pressures.

The fcc–sc coexistence line at the left of the phase dia-gram defines the pressure-dependent temperature of the solid-state orientational ordering phase transition; the data shown by filled squares are measured using DSC [244].

At high temperature or under ultrahigh pressure, the C$_{60}$ molecules will collapse into amorphous carbon. Under higher pressure (>1 GPa) and high temperature, which is not shown in the phase diagram, crystal C$_{60}$ will polymerize, induced by pressure. The pressure-induced polymerization will be introduced in Section 4.2.

3.4. Crystal Growth

3.4.1. Single Crystal

Solvent grown C$_{60}$ crystals may form various structures due to the intercalation of solvent molecules or small atmo-spheric molecules into C$_{60}$ crystal lattices [392–395], such as hexagonal close packed (hcp) structure [2, 396], fcc struc-ture [397], orthorhombic or monoclinic structure [398, 399], and so on, and various shapes, even decagonal crystals with pseudo tenfold symmetry, can formed [392, 400, 401].

C$_{60}$ has an extraordinarily high vapor pressure of strong temperature dependence [246] (at 500 °C, the vapor pres-sure of C$_{60}$ is about 10^{35} times greater than that of the graphite [247]) and solid C$_{60}$ sublimes at relatively low tem-perature (see Table 4) [247]. A vapor transport method is used to grow pure C$_{60}$ single crystal free of solvent or gas in a large quantity and a perfect quality conveniently by slow condensation or deposition of the molecules from vapor [402]. See Table 10.

The vapor growth technique for synthesizing single-crystal fullerenes usually uses a carefully cleaned, dynamically

Table 10. Available rate of weight loss and vapor pressure of C$_{60}$ at selected temperatures [247].

Temperature (°C)	dw/dt (μg/s)	Vapor pressure (mTorr)
400	0.004	0.019
450	0.014	0.069

600	1.75	9.67

pumped, horizontal quartz tube (usually about 50 cm long by 1 cm in diameter) placed in a furnace with a temperature gradient [403–405] (see Fig. 24). The initial C_{60} powder is filled in a gold boat and heated in the vacuum furnace at about 250 °C under dynamic vacuum for 6–72 hours in order to remove the solvent intercalated in the powder. Subsequently the Au boat is heated above the C_{60} sublimation temperature to about 590–620 °C, and high-purity, dry helium flow kept at a flow rate below 5 cc/min is employed to carry the C_{60} vapor to the colder part of the quartz tube. Crystallization starts at the part where the temperature is below 520 °C. The growth rate in this method is expected to be about 15 mg per day. The vapor transport procedure is always kept for several days to yield larger C_{60} crystals.

Several modified techniques based on the vapor transport growth method have been developed to grow larger and more perfect C_{60} crystals such as the vibrating temperature method [406], the double temperature gradient method [407], optimization of temperature distribution [408], use of a vectical furnace with a pulling technique [409], the Pizzarello method [410, 411], very small temperature gradient control [412], and so on.

3.4.2. Thin Films

High-quality crystalline C_{60} thin films have been grown successfully on many substrates and studied extensively for the understanding of growth mechanisms and properties. The potential applications of C_{60} thin films in electronic devices have been explored, such as rectifying electronic diodes [413], photodiodes and solar cells [413], and thin-film field-effect transistors [414–416]. The results showed those fullerene electronic devices have stable, reproducible performances and excellent device characteristics.

Most of the C_{60} thin films are grown under ultrahigh vacuum (UHV) environment using a sublimation-deposition method, such as a simple or enhanced vapor deposition technique [417–419], organic molecular beam epitaxy [420], the hot-wall diffusion method, or the ionized cluster beam deposition technique [421–425]. A schematic sketch of a universal hot-wall diffusion method setup is shown in Figure 25. The diffusion oven (lower part of Fig. 25) employed is composed of three parts. The temperature of each part can be controlled independently to get three different temperature zones (upper part of Fig. 25). The source C_{60} powder and substrate are placed in zone I and zone III in a quartz tube, respectively. The C_{60} molecules are evaporated from zone I, through zone II, then deposited on the substrate in zone III. The temperature of zone II (hot wall) is higher than the other two zones, which can generate a very low growth rate. As an example, the temperatures of zone I and zone II are
Figure 25. A sketch of diffusion oven composed of three independently temperature-controlled zones; T_1, T_2, and T_3 are the temperatures of the C_{60} source: "hot wall" and substrate, respectively. Adapted with permission from [426], J. G. Hou et al., *Thin Solid Films* 320, 179 (1998). © 1998, Elsevier Science.

set to $T_1 = 420$ °C and $T_2 = 440$ °C, respectively [426]. The substrate temperature (T_3) is usually set from 100 to 200 °C.

Most of well-ordered C_{60} thin films or multilayers were grown on substrates including layered substrates, alkali halides surfaces, semiconductor surfaces, and metal surfaces.

But studies showed that crystalline films can grown relatively easily on layered substrates like mica [417, 427–439], graphite [386, 440, 441], MoS_2 [437–439, 442, 443], fluorophlogopite [444], and lamellar substrates such as GeS(001) [445–448], GaSe(0001) [341, 343], and Sb [449]. Because of the natural passivation of these substrate surfaces, the C_{60}–substrate interactions are dominated by van der Waals force which can relax the stringent lattice match condition and result in the formation of fcc (111) oriented C_{60} crystal grains.

Well-ordered crystal C_{60} monolayers and thin films can also be grown on alkali halides and other ion crystals such as NaCl [417, 418, 437, 438, 450, 451], KCl [418, 438, 450, 451], KBr [418, 438, 450–453], KI [245, 246], and CaF_2 [247, 248], due to the very weak surface bonding dominated by the electrostatic force that restricts the diffusion of C_{60} ad-species.

But C_{60} thin films grown on metal substrates are much different from the weak-bonding substrates mentioned. It has been shown that there exist very strong interfacial interactions and charge transfer from the metal substrate to the LUMO of C_{60} [172, 191]. Compared with the nonmetal substrates, the metal substrates are usually less smooth and contain much higher densities of steps, so it is more difficult to grow high-quality single crystal films on metal surfaces. There have been reported high-quality C_{60} (111) oriented films successfully grown on Au [191, 419, 458], Ag [191, 419, 459, 460], Cu(111) [191, 461, 462], as well as $Ni_3Fe(111)$, $Ni_3Co(111)$, and $Ni_3Fe(110)$ [426, 463] using a hot-wall diffusion method.

Several techniques have been attempted to improve the crystallization and quality of C_{60} thin films. Using a self-mediated process [451] or using Sb as the surfactant or buffer layer [464, 465] and the multistep growth method [418], higher quality and larger grain-sized C_{60} can be obtained. Figure 26 shows a transmission electron microscopy (TEM) image as well as diffraction pattern of a high-quality single crystal C_{60} fcc (111) oriented film with a thickness of about 60 nm prepared by using Sb as the surfactant on a freshly cleaved (001) NaCl single crystal surface [465].

3.5. Properties

3.5.1. Electronic Structure

C$_{60}$ solid is a semiconductor with a minimum of the energy gap at the X point of the Brillouin zone. The value of the energy gap is still under debate, which is in the range of 1.43–2.35 eV. In early studies, a typical and widely referenced band calculation for solid C$_{60}$ is based upon the local density approximation (LDA) in density functional theory, in which all many-body effects are collected into the exchange-correlation energy, which is evaluated within a free-electron model. The LDA calculations obtained a bandgap of ∼1.5 eV for fcc C$_{60}$ crystals [466] and a value of 1.18 eV for the bandgap at the X point [467]. The band structure of C$_{60}$ crystals is derivated from the energy level distribution of an isolated C$_{60}$ molecule. Figure 27 shows the electronic structure of the HOMO- and LUMO-derived bands of C$_{60}$ in the solid state obtained from LDA calculations.

By properly treating the electron excitations with an *ab initio* quasiparticle approach, a GW (G represents Green's function and W is a dynamically screened Coulomb interaction) approach was developed. In the GW approach, the Dyson equation is solved within a Green's function formalism using a dynamically screened Coulomb interaction W to obtain the quasiparticle energy spectrum. Because the method includes a treatment of the electron self-energy (in terms of a dynamically screened Coulomb interaction), it predicted a larger value of 2.15 eV [469] for the HOMO–LUMO gap, with bandwidths of 0.9, 0.7, and 0.8 eV for the HOMO-, LUMO-, and (LUMO + 1)-derived bands, respectively. This result is very close to the gap value of ∼2.3 eV given by high-energy spectroscopy experiments like PES and inverse photoemission spectroscopy (IPES) [470–472]. There are also many other experiments carried out by different methods showing different results [473]. A scheme in Figure 28 shows the difference of the gap values given by different methods.

A detailed electronic structure of C$_{60}$ thin films was studied by surface photovoltage spectroscopy [474, 483, 484]. It is illustrated in Figure 29, which includes a mobility gap of 2.25 eV and exponential Urbach tails of states determining the optical gap of 1.65 eV [481, 485]. In addition, there exist two deep gap states: one donor and one acceptor. The acceptor level lies 0.8 eV below the conduction band tail, and the donor level is 1.25 eV higher than the valence band tail. The exponential Urbach tails in the density of gap states may be due to thermal disorder rather than from static structure, topological, or compositional disorder. The donor level arises from the unbound intercalated oxygen and the acceptor level is considered to be the result of chemical reaction of oxygen with fullerene. This detailed electronic structure shows that the optical absorption edge [481] is not simply connected to the HOMO–LUMO gap.

To get a complete description of the electronic structure of C$_{60}$ solids, a number of many-body calculations have focused on calculations of quantities of electron correlation effects. Direct *in-situ* comparison of C 1*s* absorption spectra taken in the gas phase with those from solid C$_{60}$ reveals a close similarity [486]. It can be concluded that solid-state interactions are not important in this new material, and the electron correlation effects are mainly intramolecular. So the Coulomb repulsion (U) of two holes on the same molecule in solid C$_{60}$ is an important quantity, which is nearly independent of the molecular orbital of the hole with a value of 1.6 eV [471]. This value of U leads to Frenkel-type molecular excitons with energy of about 1.5–2 eV corresponding to h_u–t_{1u} intramolecular excitations which correspond to the lowest-energy-observed optical transitions of electronic origin. The calculated values of such Frenkel excitons are 1.58 and 1.30, with experimentally measured values of 1.83 and 1.55 eV [487, 488].

3.5.2. Electrical Transport Properties

At room temperature, pristine C$_{60}$ solids are *n*-type semiconductors with a high resistivity [415, 489]. The electron mobility is considerably larger than the hole mobility. The electron and hole drift mobilities are 1.3 and 2 × 10^{-4} cm^2/V s, respectively, and the recombination lifetime is 1.7 × 10^{-6} s [490]. The dc conductivities in C$_{60}$ follow a purely thermally activated behavior. The conductivity of the crystalline C$_{60}$ is obviously higher than that of the amorphous films. The dc conductivity of C$_{60}$ single crystal is 1.7 × 10^{-8} (Ω cm)$^{-1}$ and the activation energy is 0.581 eV [491]. But for polycrystalline films, the conductivity and activation energy are reported to be 10^{-6}–10^{-8} (Ω cm)$^{-1}$ and 0.3–0.6 eV [492–496], respectively. For amorphous films, these values are within the intervals 10^{-7}–10^{-14} (Ω cm)$^{-1}$ and 0.5–1.1 eV [479, 497–499]. With improving crystallinity of C$_{60}$ films, their conductivity increases, and the activation energy falls [500, 501].

The thermally activated conductivity in fullerene systems [493, 502] obeys the Meyer–Neldel (MN) rule [503]. The MN rule describes an exponential relation between the activation energy E_a and the pre-exponential factor σ_0. The expression of the MN rule for the dc conductivity can be written as $\sigma = \sigma_0 \exp(-E_a/kT)$, and the prefactor σ_0 correlates with the activation energy E_a as $\sigma_0 = \sigma_{00} \exp(-E_a/kT)$, where σ_{00} and T_0 are the Meyer–Neldel parameters. For example, the relationship between the conductivity prefactor σ_0 and activation energy E_a in C$_{60}$ films under different O$_2$ exposure can be described by the MN rule. The obtained σ_{00} and kT_0 are 15.6 (Ω cm)$^{-1}$ and 0.11 eV, respectively [493]. The relationship between the conductivity prefactor and activation energy in C$_{60}$ films at different stages of the growth process also obeys the MN rule with the MN parameters of $\sigma_{00} = 7.7 \times 10^{-19}$ (Ω cm)$^{-1}$ and $kT_0 = 0.012$ eV [493].

High pressure has a strong effect on the conductivity, as well as the width of the gap between LUMO- and HOMO-derived bands of C$_{60}$ solids [504, 505]. The electric conductivity changes four orders of magnitude from 2 × 10^{-6}(Ω cm)$^{-1}$ (below 8 GPa) to 3 × 10^{-2} (Ω cm)$^{-1}$ (around 20 GPa). The bandgap is as follows: 1.6 ± 0.1 eV at 3 and 6 GPa, and 1.2 ± 0.1 eV at 10 GPa. Exposed to air, upon the interaction with oxygen, the conductivity of C$_{60}$ single crystals [506] and films falls [493, 507] by 3–6 orders of magnitude. Such an effect may be caused by trap levels for carriers and neutralizes defects forming localized electronic states, which are created by the intercalated oxygen.

The conduction mechanism at different temperatures has been studied by measuring the ac (1 < f < 50 kHz) conductance of C$_{60}$ polycrystals [508]. In the temperature range of 100–150 K, the ac conductance linearly depends on the temperature and nearly has a power law of $\omega^{0.8}$ dependence on the frequency, which is characteristic of the model of the variable range hopping between midgap localized states around the Fermi level [509]. In this model, the ac conductance can be described as $\sigma(\omega, T) \sim \pi e^2 kT [N(E_F)]^2 \alpha^{-5} \omega [\ln(\nu_{ph})/\omega]^4$. Here, $N(E_F)$ is the density of states at the Fermi level, ν_{ph} is the phonon frequency, and α is a constant. In the temperature range of 200–350 K, the frequency dependence of conductance at a fixed temperature can also be roughly described as a power law $\sigma \sim \omega^s (s = 0.8)$. However, in this temperature range (as the frequency varied from 1 to 10 kHz), the ac conductance increases rapidly with temperature and shows a thermal activated behavior with an activation energy E_a of 0.389 eV below 265 K and 0.104 eV above it. This is proposed to be caused by the hopping process among the tails of localized states, which can be described as $\sigma(T) \propto \exp(-E_a/kT)$. The two activation energies can be ascribed to the coexistence of the crystalline and amorphous phase of C$_{60}$. At very high temperatures approaching the sublimation temperature of about 430 °C, experiments suggest that the mechanism of conductivity of C$_{60}$ changes from hopping conductivity to band conductivity (charge transfer over delocalized states) [510–512]. From these results, it can be concluded that the C$_{60}$ solid conductivity can be described in terms of the conduction mechanism of disordered semiconductors.

3.5.3. Optical Properties

Optical Absorption and Photoluminescence Spectroscopies The optical properties of solid C$_{60}$ in the visible-UV range were investigated by a variable angle spectroscopic ellipsometry (VASE) technique [513–515] and

near-normal-incidence reflection and transmission experiments [516]. UV data above ~7 eV were obtained using EELS [475] by Kramers–Kronig analysis of the EELS loss function. The observed optical properties of C_{60} solids are usually expressed in terms of the complex optical dielectric function $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$. Figure 30 shows the results for $\varepsilon_1(\omega)$ and $\varepsilon_2(\omega)$, obtained from VASE and transmission-FTIR (Fourier transform infrared) studies on thin solid films of C_{60} on KBr substrate at $T = 300$ K [316]. The strong, sharp structure at low energy (below 0.5 eV) is identified with infrared-active optic phonons. The imaginary part of the dielectric constants of C_{60} begins to rise at 1.7 eV, which can be considered the absorption edge. At higher energies in the visible and UV ranges, the spectrum structure is due to allowed optical transitions at 3.5–5.6 eV and to excitons at energies below 3 eV. There are four prominent absorption peaks at ~2.7, 3.6, 4.7, and 5.6 eV for the pristine C_{60} with dipole-allowed electronic transition [480, 481, 517–519]. Optical transitions between the HOMO and LUMO bands are forbidden by symmetry [520].

Luminescence spectra appear to be more sensitive to sample quality and to show wider sample to sample variation than absorption spectra [521] The temperature dependence of the photoluminescence spectra is given in [522]. At a temperature of 7 K, the absorption curve intersects the photoluminescence curve at the point 1.8 eV, which may be the optical gap at this temperature [523].

Transition Assignment An accurate study of optical transition in C_{60} was carried out by comparing the optical spectra of C_{60} films on mica with the transmission of toluene, hexane, and heptane solutions [480]. Experimental spectra were fitted with Gauss–Lorentz (GL) line shapes to determine the energy positions of individual transitions.

The assignment of the electronic transitions given in Table 11 is based on the calculated transition energies of [524–526]. The best agreement of the calculated gap positions with experimental results is provided by the tight-binding models [525, 526]. An overview of the energy levels and optical transitions discussed is shown in Figure 31.

The three leading GL bands D, $E+F$, and G are assigned to the transitions $h_g, g_g \rightarrow t_{1u}$, $h_u \rightarrow h_g$, and $h_g, g_g \rightarrow t_{2u}$,

Table 11. Spectral features for solid C_{60} and C_{60} molecules. All energies are given in eV [480].

Band code	Solid C_{60}	C_{60} molecules	Transition assignment
γ_0	1.918	1.995	$h_u \rightarrow t_{1u} + T_u, H_u, G_u$
γ_1		2.035	$(+H_g, A_g)$
γ_2	1.992	2.070	
γ_3	2.028	2.105	
γ_5	2.097	2.180	
A	2.41		$h_u \rightarrow t_{1g}$
B	2.70		
C	3.2		
D1	3.489	3.58	$h_g, g_g \rightarrow t_{1u}$
D2	3.541	3.732	
E	3.99	4.21	$h_u \rightarrow h_g$
F1	4.36		
F2	4.546	4.6	
G1	5.500	5.437	$h_g, g_g \rightarrow t_{2u}$
G2	5.77	5.73	

respectively [480, 513]. The oscillator strengths of these dipole-allowed transitions are in reasonable agreement with the calculations of [525]. The D band assigned to $h_g, g_g \rightarrow t_{1u}$ transitions is strongly reduced in doped films due to the filling of the lowest state in the conduction band derived from the t_{1u} molecular states [527]. The molecular $F_{1,2}$ band, which originates from the $h_u \rightarrow h_g$ transition, split into $F1$ and $F2$ bands in the solid due to the splitting of the fivefold-degenerate $h_u(h_g)$ levels to the threefold- and twofold-degenerate $t_u(t_g)$ and $e_u(e_g)$ levels, respectively [467]. The weak E band possibly also originates from the $h_u \rightarrow h_g$ transition.

The assignment of the two lowest transitions, $h_u \rightarrow t_{1u}$ and $h_u \rightarrow t_{1g}$, is more delicate. The $t_{1g}h_u^{-1}$ molecular state consists of electron–hole excited states with T_{1u}, T_{2u}, H_u, and G_u symmetry [528]. According to several calculations, the lowest allowed transition $h_u \rightarrow t_{1g}$ to the T_{1u} excited state should be located near 3 eV with an oscillator strength of about 3% of that of the $h_g, g_g \rightarrow t_{1u}$ band at 3.5 eV

[524, 525, 529]; the very small oscillator strength has been attributed to plasmon screening [525]. In addition to this allowed transition, phononinduced transitions of comparable strengths [529] to the T_{2u}, H_u, and G_u excited states [528] should appear in the same energy region. The comparison of the energies and oscillator strengths of the B and D bands is essential for the following assignment of γ, B, B', and D subbands to the electronic transitions (see Table 11).

The A-group is attributed to the $t_{1g}h_u^{-1}$ electron–hole state parity forbidden in an isolated molecule, but becoming partially allowed because of level splitting.

The γ-group results from the forbidden molecular transition $h_u \rightarrow t_{1u}$. These transitions gain nonzero strength through the excitation of an appropriate odd-parity vibrational mode [530] (Hertzberg–Teller coupling) and their upper electronic states can be influenced by Jahn–Teller dynamic distortions [518].

Photoconductivity Experiments confirmed the existence of the photoconductivity in fullerene solids [531, 532]. Photoconductivity spectra of C$_{60}$ are, on the whole, similar to the absorption spectra, apart from the conduction dip at about 350 nm of wavelength. Such a photoconduction dip appears frequently in intense absorption regions in many photoconductors. The photoconduction edge is at about 730 nm (1.7 eV) [523]. The main spectra features are related to excitons rather than to interband transitions. The photoconduction spectra measured at various light-intensity modulation frequencies, light intensities, and applied voltages shows that the photocurrent is proportional to light intensity and applied voltage. Moreover, the photocurrent increases with decreasing light-intensity modulation frequency, which may arise from some deep carrier traps in the energy gap.

3.5.4. Dielectric Properties

Solid C$_{60}$ is a soft dielectric material [533]. The complex dielectric function $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$ of solid C$_{60}$ was studied over a broad frequency range using a wide variety of techniques including ac impedance measurements at low frequencies and optical measurements at high frequencies [259, 391, 475, 516, 517, 534].

The complex optical dielectric function $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$ can be expressed in the terms of the complex refractive index $N(\omega) = [n(\omega) + ik(\omega)]$. Here, n is the refractive index and k is the extinction coefficient. Both n and k are frequency-dependent optical constants. The expression is $\varepsilon(\omega) = [N(\omega)]^2 = [n(\omega) + ik(\omega)]^2$. The optical dielectric function $\varepsilon(\omega)$ of C$_{60}$ was studied over a wide frequency range of 10^{13}–10^{16} Hz (corresponding to 0.05–40 eV, 1 eV = 8066 cm^{-1}). Below 7 eV, it was studied using infrared (between 0.05 and 0.5 eV) [534] and visible-UV (1.5–5.5 eV) [516, 525] spectroscopies. UV data above 7 eV were obtained using EELS by Kramers–Kronig analysis of the EELS loss function [475]. The features of the $\varepsilon_2(\omega)$ dielectric loss spectrum in the infrared range include four strong lines at 526, 576, 1182, and 1428 cm^{-1} due to molecular vibrations. At higher energies in the visible and UV ranges, the imaginary $\varepsilon_2(\omega)$ part of the dielectric constants begins to rise at 1.65 eV and there are four prominent peaks at ∼2.75, 3.55, 4.50, and 5.50 eV in the $\varepsilon_2(\omega)$ spectrum, corresponding to four absorption peaks [269]. An absolute

value of the real $\varepsilon_1(\omega)$ part at 1.5 eV is 4.1. The whole trend of the optical dielectric function of C$_{60}$ is as below. Where there is a loss process represented by a peak in the $\varepsilon_2(\omega)$ dielectric loss spectrum, there is a rise or a resonant oscillation in the $\varepsilon_1(\omega)$ spectrum. This result is consistent with Kramers–Kronig relations. With frequency decreasing to 10^{13} Hz, $\varepsilon_1(\omega)$ is approaching its dc value. The small difference between ε_1 (10^{13} Hz) ≈ 3.9 [517] and ε_1 (10^5 Hz) ≈ 4.4 [391] might be due to the losses associated with C$_{60}$ molecules rapidly rotating (at the rate of ∼10^9 Hz) at room temperature ($T > T_{01}$, $T_{01} = 260$ K is the structure transition temperature).

In the low frequency regime (below 10^5 Hz), polarization mechanisms come into play. The dielectric properties in this regime were investigated by ac impedance measurements, which are usually performed on a sample between closely spaced parallel conducting plates. These M–C$_{60}$–M (M = metal) "sandwich" structures consist of 200-μm-wide aluminum down stripes as base electrodes, a known thickness of C$_{60}$, and 200-μm-wide aluminum cross stripes as counterelectrode [535]. The ac equivalent capacitance $C(\omega)$ and the dissipation factor $D(\omega)$ of the resulting capacitor can be obtained. The real part of the relative dielectric function $\varepsilon_1(\omega)$ can be calculated since the relation between the capacitance and $\varepsilon_1(\omega)$ is known to be $C(\omega) = \varepsilon_1(\omega)\varepsilon_0 A/d$. Here, A is the cross-sectional area of the capacitor, d is the separation distance between the plates, and ε_0 is the absolute permittivity of free space (8.85×10^{-12} F/m). The imaginary part of the dielectric function $\varepsilon_2(\omega)$ can be extracted from measurement of the dissipation factor $D(\omega) = \varepsilon_2(\omega)/\varepsilon_1(\omega)$. To ascertain the intrinsic dc $\varepsilon_1(0)$ of C$_{60}$, the dielectric measurement needs to be performed at frequencies low enough to include the intrinsic relaxation processes of the material, but high enough to escape the effects of impurities (e.g., molecular oxygen). The effects of oxygen and other impurities occupying the interstitial sites of solid C$_{60}$ on the dielectric relaxation of C$_{60}$ films can be ignored only above ∼5 kHz. So the intrinsic dielectric constant was obtained by performing a series of capacitance measurements at 100 kHz. By this method, a value of 4.4 ± 0.2 was obtained for the relative permittivity $\varepsilon_1(0)$ [391].

The plate spacing d of the C$_{60}$ capacitor may change due to the thermal expansion or to phase transition at $T_{01} \approx 260$ K. The interaction of oxygen or other species into the interstitial spaces of C$_{60}$ solid can also lead to such problems. To avoid these problems, a microdielectrometry technique [536, 537] has been employed at low frequencies (from 10^{-2} to 10^5 Hz). In this technique, a coplanar electrode configuration was used as an alternative to the "sandwich" configuration. Both electrodes in the microdielectric measurement are placed on the same surface of an integrated circuit, and C$_{60}$ film is placed over the electrodes by thermal sublimation in vacuum [391]. In comparison with the "sandwich" geometry, this geometry has the advantages as follows. First, the comb electrodes of a coplanar sensor, in contrast to parallel plates, ensure proper calibration of the device even if the material being measured undergoes structure transformations. Moreover, the open-face layout facilitates studies of diffusion of foreign species into the bulk of the material.

By means of capacitance and dissipation factor measurements discussed previously, the temperature dependence of

the dielectric properties of C$_{60}$ single crystals, polycrystalline C$_{60}$, and microcrystalline C$_{60}$ films were studied [359, 538, 539]. On cooling below the first-order structural phase transition at 260 K, a Debye-like relaxational contribution to the dielectric response was observed. From the Debye-like relaxation, the presence of permanent electric dipoles was found, which are unexpected in the centrosymmetric structure of the pure ordered cubic phase C$_{60}$. It is suggested that the high degree of frozen orientational disorder of the C$_{60}$ molecules is responsible for the existence of electric dipolar activity. In addition to the structure phase transition at 260 K, a signature of the glass transition was detected at ~90 K. Studies on the dielectric properties of C$_{60}$ films in the high-temperature region discovered that both the capacitance and dissipation factor curves as a function of temperature have a pronounced feature at 435 K, which confirms the fact that above 400 K a phase transition does occur in the crystal [539].

A small charge transfer between the C$_{60}$ and O$_2$ molecules, which occupy interstitial space of solid C$_{60}$ exposed to oxygen (or ambient air), creates large electrical dipole moments due to the large size of the C$_{60}$ molecules [535]. The dipole moments can be coupled to the applied ac electric field via a diffusion-controlled relaxation mechanism. This leads to a significant increase in the permittivity ε_1 accompanied by a broad dielectric loss peak ε_2 at ~10–100 Hz. For instance, the dielectric function $\varepsilon_1(\omega)$ increases dramatically from 4.4 at 10^5 Hz to 18.4 at 100 Hz due to the polarization caused by the interstitial oxygen [535]. With increasing oxygenation, the interstitial sites are nearly fully occupied. As a result, interstitial hopping is inhibited, and the loss peaks disappear.

3.5.5. Magnetic Properties

Pristine C$_{60}$ solids are diamagnetic materials due to the presence of ring currents in the C$_{60}$ molecule [1]. In comparison with other carbon-based materials [540–543], such as graphite and diamond, C$_{60}$ has an unusually small diamagnetic susceptibility of about -0.35×10^{-6} emu/g [544, 545]. This is because there is an unusual cancellation of ring currents in the C$_{60}$ molecule. There are two kinds of rings in the C$_{60}$ molecule: the aromatic rings and the pentagonal rings. The aromatic rings in C$_{60}$ set up shielding screening currents in a magnetic field [546, 547] which contribute a diamagnetic term to susceptibility χ, while the pentagonal rings contribute a paramagnetic term of almost equal magnitude. Table 12 presents the diamagnetic susceptibility for C$_{60}$ and related materials.

Table 12. The diamagnetic susceptibility for C$_{60}$ and related materials at $T = 300$ K.

Material	χ (10^{-6} emu/g)	Ref.
C$_{60}$	-0.35	[544, 545]
C$_{70}$	-0.59	[544, 545]
Graphite	-21.1 (c-axis)[a]	[548]
Carbon nanotubes	-10.2	[549, 550]
Diamond	-0.49	[551]

[a] The value refers to c-axis susceptibility of graphite. The H in-plane susceptibility of graphite is 0.4×10^{-6} emu/g.

The measurement performed on a C$_{60}$ powder sample shows the temperature dependence of the magnetic susceptibility [544]. At temperatures greater than 180 K the susceptibility is temperature independent with a mass value of $\chi_g = -0.35 \times 10^{-6}$ emu/g, where the subscript g refers to the susceptibility per gram of sample. At low temperatures, due to a relatively small number of electron spins, χ_g increases and becomes paramagnetic, yielding a molar Curie constant $C_M = \chi_M T = 0.75 \times 10^{-4}$ (χ_M is a molar susceptibility), which gives an electron spin value of 1.5×10^{-4} per carbon atom. It is believed that the Curie constant here is caused by a foreign paramagnetic impurity in the C$_{60}$ sample.

Magnetization of a large single C$_{60}$ crystal was measured as functions of applied field and temperature [377]. The sample was carefully prepared and handled to avoid oxygen contamination. The result shows no low-temperature Curie term, from which it is concluded that the low-temperature Curie contribution is likely due to oxygen contamination. In addition, near $T_{01} = 260$ K, a discontinuity with a 1.2% change in susceptibility was observed, with $\chi(T_{01}^-)$ more negative than $\chi(T_{01}^+)$ for the susceptibility at either side of the phase transition. The discontinuity is attributed to the change in the intramolecular geometry at the orientational order–disorder transition. The susceptibility can be considered to be independent of the temperature below and above the structural transition temperature, $T_{01} = 260$ K. The experiment demonstrated that the cooperative phase transition affects the magnetic susceptibility of a single molecule.

Whereas the unpolymerized C$_{60}$ is diamagnetic, a few fullerene-based materials were found to be ferromagnetic. Ferromagnetism has previously been observed in [TDAE]C$_{60}$ [TDAE = tetrakis(dimethylamino)ethylene] below 17 K [552]. It has been reported that hydrogenated fullerene [553], C$_{60}$H$_{24}$, and some palladium fullerides [554], C$_{60}$Pd$_n$, may be ferromagnetic. Recently, the finding of ferromagnetism in pure Rh-C$_{60}$ (rhombohedral phase 2D C$_{60}$ polymer) samples by Makarova et al. [555] appears to be the first report on magnetic ordering in a pure molecular carbon material up to temperatures above 300 K (see Section 4.2.4).

3.5.6. Thermal Properties

Specific Heat Measurement of the temperature dependence of the heat capacity at constant pressure $C_p(T)$ provides the most direct method for the study of the temperature evolution of the degrees of freedom, phase transitions, and the enthalpy change.

The temperature dependence of the specific heat of C$_{60}$ solids is studied mainly by DSC. The overall shape of the C$_{60}$ specific-heat curve in the temperature range of 0.2–400 K is as follows. At very low temperature (below 1 K), the specific heat shows a $C_p(T) = C_1 T + C_3 T^3$ behavior. The T^3 dependence component of $C_p(T)$ yields a Debye temperature $\Theta_D = 80$ K [556–558]. The linear T contribution arises from the tunneling modes in the glassy systems [559]. The contribution saturates above ~5 K and contributes little at high temperatures. In the temperature range $2 \leq T \leq 80$ K, there is an initial rise in the specific heat, followed by a plateau near 80 K [560]. The intermolecular modes of C$_{60}$ contribute

significantly in this range. The plateau is due to the saturation of these low-energy excitations. The low-energy excitations in this range consist of both acoustic (translational) modes and rotations (also called librations) involving the entire C_{60} cage. Because the bonds between cages are weak van der Waals bonds, these low-energy modes saturate below 80 K. With six modes (three translational and three librational) and a molecular number density ($N/60$), the Dulong–Petit limit for the C_{60} molecules is $6(N/60)k_B = 69.3$ mJ/g K, which matches the level of the plateau. Here, N is the number density (per unit mass) of carbon atoms.

Above 100 K, there is a nearly linear rise in $C_p(T)$ curve, and this rise in C_p is caused by the higher energy intramolecular excitations on the ball, which start to be activated and contribute to the specific heat. The Dulong–Petit limit for the carbon atoms is equal to $3Nk_B = 2.08$ J/g K. Based on the highest energy on-ball mode (196 meV), the saturation temperature is expected to be above 2500 K. Since C_{60} sublimes around 300 °C, it could not be observed anyway. It is the large difference in bond strength between the covalent bonds on the cage and the molecular bonds between the cages that leads to the energy separation between the intra- and intermolecular modes [560].

A remarkable feature in the temperature dependence of the specific heat for C_{60} is the large specific heat anomaly near $T_{01} = 261$ K orientational order–disorder transition [368, 561]. The structure of the $C_p(T)$ curve near the phase transition temperature T_{01} is strongly impurity concentration dependent. Moreover, the specific heat of C_{60} depends dramatically on the cooling or heating rate. Extremely slow heating and cooling runs (at rates of the order of 100 mK/h) showed that even at such low scanning rates the results are rate dependent [368]. The material is not in a thermodynamic equilibrium state and behaves as a system with a very long internal relaxation time (order of 10 h) in completing the first-order transition. The lower the scanning rate, the more the ordering transition temperature shifts to lower (higher) temperatures for the heating (cooling) runs. Measurements [368] on high-purity sublimed C_{60} show that for the orientational transformation occurring at 262.4 K during the heating run, the associated $C_p(T)$ peak is remarkably sharp and attains a value of 12,360 J/kg K. The corresponding heat of transition is about 9000 J/kg (6500 J/mol), a value considerably smaller than reported for single crystal of 12,500 J/kg (9000 J/mol) [376]. For the slow cooling run an even larger peak value of 16,730 J/kg K at a transition temperature of 260.6 K is observed.

If the specific heat anomalies associated with phase transitions are removed from the experimental $C_p(T)$ data for C_{60}, then the temperature dependence of the residual specific heat contribution for C_{60} is in good agreement with that of graphite [367, 562] for $T \geq T_{01}$ (261 K).

Thermal Expansion The temperature dependence of the lattice constant a_0 for C_{60} shows a large discontinuity at the structure phase transition temperature $T_{01} = 261$ K, where the lattice parameter a_0 jumps by $+0.044 \pm 0.004$ Å on heating [238]. The fractional jump of the unit cell volume of $\Delta v = (\Delta V)/V$ is $(9.3 \pm 0.8) \times 10^{-3}$. The average isobaric volume coefficient of thermal expansion α both above and below the transition is $(6.2 \pm 0.2) \times 10^{-5}$ K^{-1} [238, 349]. It is

surprising that measurements of α taken to high temperature (1180 K) show a lower value of 4.7×10^{-5}/K than for the lower temperature range [563]. The thermal expansion coefficient of C_{60} films with thickness t were investigated. As t decreases α increases and is described well by the relation $\alpha = 17 \times 10^{-6}$ K$^{-1} + 8.3 \times 10^{-5}$ nm K$^{-1}t^{-1}$ [564].

Thermal Conductivity Because C_{60} is a van der Waals–bonded molecular solid, its Debye temperature θ_D due to the intermolecular phonon modes is low with a value of about 70–80 K [350, 556]. Above the Debye temperature the specific heat due to propagating modes is independent of temperature. Consequently, the thermal conductivity κ is an ideal probe of the phonon mean free path through the kinetic expression $\kappa = Cv_s\lambda/3$, where C is the specific heat, v_s is the sound velocity, and λ is the phonon mean free path. Experiments showed that $\kappa \sim 0.4$ W/mK at room temperature and is approximately temperature independent down to 260 K [380, 352]. At 260 K, κ takes a sharp jump from 0.4 to 0.5 W/mK with a transition width of ~2 K. Because the heat capacity due to intermolecular modes is constant at 260 K, the 25% jump in κ must be due to a sudden increase in the phonon mean free path. Upon further cooling, the thermal conductivity increases. At about 85 K, the thermal conductivity shows a shoulderlike structure. The temperature and time dependence of the thermal conductivity below 260 K can be described by a phenomenological model that involves thermally activated jumping motion between two nearly degenerate orientations, separated by an energy barrier of ~260 meV.

3.5.7. Mechanical Properties

Primary C_{60} is fcc molecular crystal formed by Van der Waals interaction between rigid C_{60} molecules. It is a soft and friable material showing low strength and high-elastic compliance. Information on the temperature dependence of the elastic moduli is incomplete and partially contradictory [242, 358, 372, 565–567]. The elastic constants of single-crystal C_{60} at room temperature have been established [568, 569]. Since solid C_{60} at room temperature is cubic, the matrix of the elastic constants has three independent components: C_{11}, C_{12}, and C_{44}. The elastic moduli C_{11}, C_{12}, and C_{44} were obtained experimentally on the basis of sound velocity and the density ρ by using the well-known relations between the elastic moduli and sound velocity in cubic crystal: $\rho v_T^2 = C_{44}$, where v_T is the velocity of transverse ultrasonic waves in the [100]-direction, $\rho v_T^2 = (C_{11} - C_{12} + C_{44})/3$, where v_T is the velocity of transverse ultrasonic waves in the [111]-direction, and $\rho v_L^2 = C_{11}$, where v_L is the velocity of longitudinal waves in the [100]-direction. These values of the elastic moduli determined by the experiments are presented in Table 13.

Table 13. Experimental and theoretical values of the elastic moduli C_{ij} (GPa) of the fcc phase of solid C_{60} (300 K).

C_{11}	C_{12}	C_{44}	C_{11}–C_{12}	Ref.
14.9 ± 0.9	8.8 ± 1.0	6.6 ± 0.18	6.1 ± 0.45	Experiment [571]
13.8	6.6	7.0	7.2	Theory [570]

For comparison, the theoretical values of the elastic stiffness constants obtained in terms of the model intermolecular interaction are also given in Table 7 [570]. In the theory approach, the interatomic Buckingham potential was used for calculating the intermolecular interaction and the electrostatic interaction was taken into account.

To compare the previous results of a single crystal with the measurements of the elastic properties performed on compact samples and polycrystalline films of C$_{60}$, the isotropic moduli of polycrystalline C$_{60}$ were estimated by averaging the elastic constants C_{ij} of a single crystal. By regarding the anisotropy in polycrystalline C$_{60}$ as a result of the disordered orientation of individual single-crystal grains, the bulk modulus K is determined from the equation $K = (C_{11} + 2C_{12})/3$ and the shear modulus G from the relation $G = [(C_{11} - C_{12})/2C_{44}]^{2/5}$. All other elastic constants of the polycrystal material (Young's modulus E, the longitudinal modulus C_L, and the Poisson ratio ν) can be estimated from G and K using the well-known relations between the elastic moduli of an isotropic medium. Isotropic moduli obtained from single-crystal, compacted samples and polycrystal films are presented in Table 14.

4. C$_{60}$-BASED MATERIALS

4.1. Intercalated Compounds

4.1.1. Alkali Metal Doped C$_{60}$

M$_3$C$_{60}$ (M = K, Rb, and Cs)   When the alkali metals (M = K, Rb, and Cs) are doped in C$_{60}$, stable crystalline phases M$_1$C$_{60}$, M$_3$C$_{60}$, M$_4$C$_{60}$, and M$_6$C$_{60}$ are formed. The M$_3$C$_{60}$ system is the most widely studied of the doped C$_{60}$ compounds because of the discovery of superconductivity [574].

K$_3$C$_{60}$ and Rb$_3$C$_{60}$

(i) *Synthesis* The usual way to produce M$_3$C$_{60}$ compounds is the vapor transport technique which is most suitable for intercalation of heavy alkali metals into C$_{60}$ lattice. A wide variety of methods based on this technique have been employed to prepare the samples with different crystalline forms (thin film [575], powder [576, 577], and single crystal [578, 579]).

For preparing powder samples, the alkali metals are measured out using precision inner-diameter capillary tubes. The quantity of the metal is controlled by cutting an alkali metal-filled capillary tube to the required length in a dry box. The capillary tube is then placed in a 5–10 mm Pyrex (or quartz) tube along with the C$_{60}$ powders. Then the Pyrex (or quartz) tube is sealed under high vacuum and heated to a temperature of 200 to 450 °C for several days. The alkali metals

appear to be completely absorbed by the C$_{60}$. After that, the sample tube is held at 200–300 °C for a period between 24 and 72 hours to ensure complete diffusion of the metal into the C$_{60}$ sample.

For preparing single-crystalline samples, the intercalation process can be controlled by measuring the conductivity of the samples *in-situ*. Electrical contacts to the pristine C$_{60}$ samples are made prior. Then the conductivity apparatus is sealed together with fresh alkali metal in a Pyrex glass apparatus under high vacuum. Uniform doping is accomplished using a repeating high-temperature dope–anneal cycle. Both the sample and dopant are heated uniformly from room temperature to ~200 °C in a furnace first while the sample resistance is continuously monitored. At the point where the resistance of the sample reaches a minimum, the alkali-metal end of the tube is cooled to room temperature and the sample alone is annealed for several hours. Then the metal end is reheated and the sample was further doped until a new resistivity minimum point is reached. The sample alone is then again annealed for several hours. This doping and annealing process is repeated until the resistance reaches an equilibrium state. A method similar to this is also applied to obtain thin film M$_3$C$_{60}$ samples [575].

In order to obtain M$_3$C$_{60}$ samples with more certain chemical compositions, two methods based on vapor transport are used. One is the azide technique, in which the metal azides (i.e., MN$_3$, M = K, Rb) are used as the metal sources [580–582]. A mixture of C$_{60}$ powders and stoichiometric amounts of azides is loaded into a quartz tube and heated slowly under dynamical vacuum. At 550 °C for a couple of hours, the azide of any alkali metal decomposed into free alkali metal and N$_2$, during which C$_{60}$ is doped. After completion of the reaction, the sample is cooled to room temperature and sealed to avoid exposure to air. In the other method, stoichiometric control is markedly improved by reacting pristine C$_{60}$ with the saturation-doped product [577]. Two aliquots of C$_{60}$ are weighed outside the drybox first. A weighed amount of C$_{60}$ is treated with a large excess of alkali metal at 225 °C under vacuum to produce M$_6$C$_{60}$. The air-sensitive product is then diluted with the C$_{60}$ in the dry box. After heating and annealing under vacuum, the single-phase K$_3$C$_{60}$ and Rb$_3$C$_{60}$ are prepared.

Metal fullerides can also be prepared in solution at low temperatures [583]. The solvents usually used are THF, liquid ammonia, or CS$_2$. The compounds are obtained by dissolving proportional molar amounts of the metal and the C$_{60}$ powder in the solvent and then heating at ~300 °C to remove the solvents.

(ii) *Crystal structure* In K$_3$C$_{60}$ and Rb$_3$C$_{60}$ compounds, the structure of K$_3$C$_{60}$ and Rb$_3$C$_{60}$ is still fcc although the lattice constants become larger than that of pristine C$_{60}$. Table 15 summarizes some of the structural parameters of K$_3$C$_{60}$ and Rb$_3$C$_{60}$.

M$_3$C$_{60}$ have a merohedral disorder which means the individual C$_{60}$ molecules have two different possible orientations in the fcc lattice. Except this disorder, the symmetry of the C$_{60}$ molecule is not further reduced by the doping from C$_{60}$ to M$_3$C$_{60}$. Vibrational properties have been studied by Raman scattering [586–590] and IR spectroscopy in the mid-IR and the far-IR spectral range [324, 591].

Table 14. Isotropic moduli obtained from different samples.

K (GPa)	G (GPa)	E (GPa)	C_L (GPa)	ν	Sample
10.8 ± 0.75	4.85 ± 0.18	12.6 ± 0.45	17.2 ± 0.45	0.306 ± 0.012	a
8.4 ± 0.5	3.75 ± 0.1	9.8 ± 0.4	13.4 ± 0.4	0.305 ± 0.02	b
6.4 ± 0.5	4.1 ± 0.2	12 ± 1	13.3 ± 0.8	0.18 ± 0.04	c

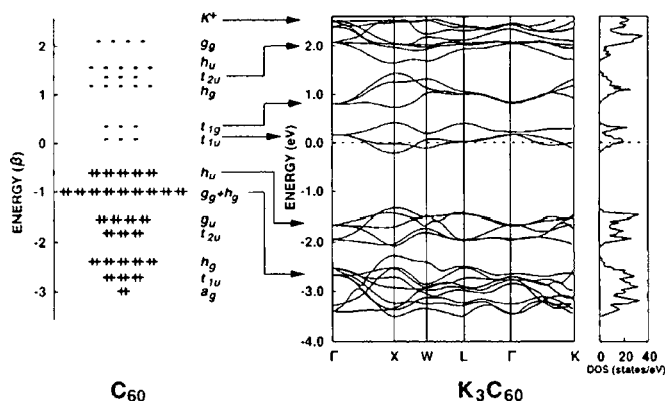
(iii) *Normal state properties*

Electronic structure In M$_3$C$_{60}$, the alkali metal is expected to donate its electron to the t_{1u}-derived conduction band. Hence M$_3$C$_{60}$ is expected to be a metal, with a half-filled t_{1u} band. In the solid, molecular orbitals on neighboring molecular sites mix to form bands. The band structure and density of states for K$_3$C$_{60}$ using the LDA in DFT are shown in Figure 32 [592, 593]; the electronic structure of C$_{60}$ is also shown in the figure for comparison.

In the M$_3$C$_{60}$ solids (M = K, Rb), the C$_{60}$ molecules have binary (merohedral) orientational disorder, and the statistical occupancy of the two molecular orientations remains disordered even at low temperatures [236]. This disorder was predicted to have significant effects on the band structure of the materials [594], with a smearing out of the fine structure in the t_{1u}-derived conduction band density of states (DOS), whose width remains unaffected by the disorder [595]. However, despite the disorder, the electronic states near E_F are best described using an effective Bloch wave vector, and the states localized due to disorder lie only at the bottom or top of the band [596].

The calculated t_{1u}-derived bandwidth is ~0.5 eV for K$_3$C$_{60}$ [597]. The LDA-DOS clearly supports a rigid-band picture. In this rigid band model, the band structure of M$_x$C$_{60}$ (M = alkali) remains roughly the same as that of pure C$_{60}$, expect that the Fermi level is shifted due to the filling of electrons donated by the alkali atoms [598]. Many other calculations of the electronic properties of M$_3$C$_{60}$ were performed at different levels of accuracy [594, 599–606]. Whereas the


effect of the intermolecular binding on the molecular geometry itself can be represented reasonably within LDA at any level, the band structure depends more significantly on the level of accuracy of the calculations. The band dispersion is also determined by the weak interaction between the chains, which cannot be expected to be correctly described within the LDA.

PES and EELS were widely used to investigate the electronic structure of the C$_{60}$ compounds [382, 607–618]. The metallic nature of M$_3$C$_{60}$ has been reported from PES studies [182, 610, 611, 619] as well as from conductivity measurements [620, 621]. The PES result indicated the metallic ground state for K$_3$C$_{60}$ through a considerable density of states at the Fermi level and a clear Fermi cutoff in the spectra [608, 609]. The C$_{1s}$ excitation spectrum results of K$_3$C$_{60}$ and C$_{60}$ implied the half-filling of the t_{1u}-derived band [622, 623]. The bandwidth observed for the half-filled t_{1u}-derived conduction band is about 1.2 eV and is much larger than the band structure calculations [624]. A clue to the explanation of this observation can be gained from high resolution PES studies of Rb$_3$C$_{60}$ and K$_3$C$_{60}$ [609, 610] at low temperature. PES profiles of M$_3$C$_{60}$ calculated within a model [609, 625] showed that good agreement can be obtained by taking into account relatively strong coupling of the electronic system to the molecular A_g and H_g vibrational modes, together with an additional coupling to the charge carrier plasmon observed at about 0.5 eV in the loss function.

Electrical resistivity The electrical resistivity (ρ) of M$_3$C$_{60}$ was measured on various samples using different methods such as dc four-point measurement [578, 579, 626–632] and other contactless techniques [627, 633–635]. Temperature dependences of the $\rho(T)$ of single crystal K$_3$C$_{60}$ and Rb$_3$C$_{60}$ have been measured under conditions of constant sample pressure [578, 579]. The measurement results are typically metallic as the sharp drop of resistivity at T_c and $\rho(T)$ varies as $(a + bT^2)$. Results on pellets (pressed from polycrystalline powders and subsequently annealed) obtained with a contactless technique such as optical excitation spectrum and microwave techniques also showed that $\rho(T)$ varies as $(a + bT^2)$ [627, 635]. Early $\rho(T)$ measurement for underdoped granular film showed that $\rho(T)$ increases with decreasing temperature [626]. However, it has been confirmed with new measurements on crystalline films that the transport properties of both K$_3$C$_{60}$ and Rb$_3$C$_{60}$ exhibit metallic behavior up to 500 K and a T^2-like dependence at temperatures from 50 to 250 K [631]. The granularity of the thin films is most probably the reason for the discrepancy. Although the electron–phonon (el–ph) scattering mechanism is expected to result in a linear temperature dependence of the resistivity, however, the T^2-like dependence behavior cannot be the evidence for other scattering mechanism because the volume of sample varies along with the temperature during the constant pressure measurements and this change will affect the temperature dependence of ρ significantly. The measurement of ρ vs T under conditions of constant sample volume can help to find the real scattering mechanism. A linear temperature dependence $\rho(T) \sim T$ on Rb$_3$C$_{60}$ was reported [630] and this linearity is consistent with the picture that the scattering mechanism is simply of the electron–phonon type with a coupling constant $\lambda_{tr} \sim$ 0.65–0.80. Table 16 lists some values of ρ.

(iv) Superconductivity

T_c and superconductivity gap It is widely believed that M$_3$C$_{60}$ (M = K, Rb) are *s*-wave BCS-like superconductors, driven by the coupling to the intramolecular H_g phonons and probably with some strong-coupling effects [636]. Transition temperature (T_c) as a function of the lattice constant *a* has been widely studied for M$_3$C$_{60}$ superconductors [272, 637–639]. In these studies the constant *a* was changed either by chemical substitution or by applied pressure. It was found that T_c is increased by substituting Rb for K and the authors speculated that an elastic response of the lattice to the large ionic size of Rb would lead to a narrowing of the conduction band and a subsequent increase in $N(E_F)$ which has the general effect of raising T_c [640].

A linear relationship between T_c and pressure P was observed with $dT_c/dP = -6.3 \pm 0.8$ K GPa^{-1} performed up to 0.6 GPa [641] and with $dT_c/dP = 7.8$ K GPa^{-1} performed up to 2 GPa respectively for K$_3$C$_{60}$ [637]. A similar result has also been obtained in Rb$_3$C$_{60}$ with $dT_c/dP = -9.7$ K GPa^{-1} [642]. The authors considered that applied pressure causes band broadening, which leads to both a smaller $N(E_F)$ and a smaller T_c.

In the BCS theory for a system with only one type of ion with mass M, the transition temperature behaves as $T_c \sim M^{-\alpha}$, where $\alpha = 0.5$. The isotope effect when ^{12}C is substituted by ^{13}C in M$_3$C$_{60}$ has been investigated in order to establish the mechanism of superconductivity. Various values of α were obtained by different groups [643–646] and it was indicated that $\alpha = 0.3$ should be the best available experimental result [645, 646].

The superconductivity energy gap (Δ) was first measured by point-contact tunneling spectroscopy using a scanning tunneling microscope [647], which gave a reduced energy gap $2\Delta/k_B T_c = 5.3$ for Rb$_3$C$_{60}$. NMR measurements were also performed to obtain $2\Delta/k_B T_c$ and were found to be in good agreement with the BCS value of 3.53 for the gap [648]. Moreover, the data has been obtained using other methods such as muon spin relaxation [649], optical methods, [634, 650], and photoemission [651]. It is noted that the data obtained from different experiments show substantial variation ranging from the BCS value of 3.53 up to about 4.2 (see Table 17). The value of the reduced gap that is substantially larger than the BCS value indicates that strong coupling effects are important.

Upper critical field and coherence length A large number of experiments was performed to determine the upper critical field for crystal [184, 578, 651, 655–657], powder [642, 658–663], and thin film [626] samples of M$_3$C$_{60}$ using different techniques such as magnetization [642, 659], ac susceptibility [660, 661], transport [626, 663], and radio frequency (rf) absorption [662].

Early measurements were usually carried on powder samples. Field-cooled curves from dc magnetization are first used to obtain the temperature dependence of the upper critical field [$H_{c2}(T)$]. Measurements on powder K$_3$C$_{60}$ [659] and Rb$_3$C$_{60}$ [642] samples in this way both showed that the temperature dependence of H_{c2} is linear at temperatures not far below T_c. Due to the experimental limitations of the magnetic field window (5–8 T in superconductivity quantum interference device (SQUID) magnetometers), measurements of H_{c2} by this method are usually performed at temperatures close to the transition temperature. Therefore a large uncertainty will occur in the extrapolations of $H_{c2}(T)$ to $T = 0$ K which depend on the fitting scheme significantly. Using the standard theory of Werthamer–Helfand–Hohenberg (WHH) [664], the critical field extrapolated to $T = 0$ K is $H_{c2}(0) = 49$ T for K$_3$C$_{60}$ [659] and $H_{c2}(0) = 78$ K for Rb$_3$C$_{60}$ [642], respectively.

Ac susceptibility [660, 661] and rf absorption [662] technique measurements also show linear temperature dependence of H_{c2} near T_c. These two measurements can obtain the data under high fields (the ac susceptibility technique can be performed up to 30 T [660, 661] and the rf absorption technique can be performed up to 60 T [662]). Therefore the $H_{c2}(T)$ curves can extend near 0 K and this will reduce the uncertainty in the extrapolations of $H_{c2}(T)$ to 0 K. More accurate values of $H_{c2}(0)$ are obtained in these experiments (28 T for K$_3$C$_{60}$ and 40 T for Rb$_3$C$_{60}$ [660], 30–38 T for K$_3$C$_{60}$ [661], 38 T for K$_3$C$_{60}$, and 76 T for Rb$_3$C$_{60}$ [662]). Good agreements of the experimental $H_{c2}(T)$ curves with the WHH predictions are obtained [660, 662], demonstrating that this theory is successful in describing fullerene superconductors. However, a result of an enhancement of $H_{c2}(T)$ compared to theory has also been found [661]. A likely mechanism proposed by the authors is the dirty-limit effect which showed that the high upper critical fields might partly result from a reduction of the mean free path by different types of defects and the limitation of the mean free path could be the reason for the strong scatter of the experimental data for $H_{c2}(0)$ [661]. The magnetoresistance of K$_3$C$_{60}$ samples with different granularity has been measured in fields up to 7.5 T and showed that $H_{c2}(T)$ is dependent on the grain size of the K$_3$C$_{60}$ regions within the sample. $dH_{c2}(T)/dT$ varies from -2.18 to -2.8 T/K near the superconducting transition temperature [663].

Upper critical fields in single-crystalline samples have been obtained using various methods. All of these results

showed a linear temperature dependence of H_{c2} near T_c [655, 656, 665, 666]. The $H_{c2}(0)$ has first been estimated from transport measurements, with the results 17.5 T for K_3C_{60} [655] and 62 T for Rb_3C_{60} [656], and later from dc magnetization measurements, with the results 28.5 T for K_3C_{60} [665] and 43 T for Rb_3C_{60} [666].

A upturn of $H_{c2}(T)$ at temperatures very close to T_c has been observed in almost all experiments on all superconducting compounds. Different authors suggested different explanations for this effect and the best possible explanation [657] is that the upturn is a consequence of the anisotropy of the Fermi surface of fullerene superconductors [599].

From $H_{c2}(0)$, the coherence length ξ can be calculated using Ginzburg–Landau relations. Despite a large scatter (see Table 18) arising from the large scatter of $H_{c2}(0)$, it is clearly seen that the coherence length of M_3C_{60} is very small (a few tens of nanometers) and comparable to the short ξ of high-T_c superconductors.

Lower critical field and penetration depth A large number of experiments were performed to determine the lower critical field using various methods [642, 659, 665, 667–671].

Results on H_{c1} for powder K_3C_{60} [659] and Rb_3C_{60} [642] samples were first obtained from a dc magnetization method. In this method H_{c1} was defined as the field at which a deviation from linearity in $M(H)$ first appeared. The result show that the values of $H_{c1}(0)$ lies in the range 10–16 mT and $H_{c1}(T)$ follows the simple empirical formula $H_{c1}(T)/H_{c1}(0) = 1 - (T/T_c)^2$ [642, 659].

However, different from the ideal superconductor, the measurements of $M(H)$ in K_3C_{60} and Rb_3C_{60} usually do not exhibit ideal linearity and only have a smooth positive (even a negative) curvature. The deviation is so small that it is very hard to get the point of first deviation from such a curve. Therefore this method may not provide the "intrinsic" values of the H_{c1}. Politis et al. [667] measured the reversible magnetization at high external fields and calculated H_{c1} from Ginzburg–Landau relations. The value of H_{c1} obtained by this method is slightly smaller (9–11.4 mT at zero temperature) than the data obtained by the first method.

In the second method based on direct measurements of the reversible magnetization, the quantitative calculation is uncertain, especially in case of powder sample with a large distribution of grain sizes. Therefore a method based on measurement of the trapped magnetization was used to evaluate H_{c1} [668]. This measurement was performed on powder and single crystalline K_3C_{60} and Rb_3C_{60} samples [665, 668]. Much smaller values of H_{c1}, which are about 1 mT at zero temperature, were obtained in these studies. It is considered that wave functions between adjacent C_{60}^{3-} ions overlap relatively weakly leading to the smallness of H_{c1} [668].

Using Ginzburg–Landau relations, the penetration depth λ has been calculated and the value of the coherence length used in the calculations was obtained from independent measurements. These values of λ are listed in Table 19.

Moreover, the penetration depth has also been estimated from muon spin resonance, with the results 480 nm for K_3C_{60} and 420 nm for Rb_3C_{60} [672, 673], from optical conductivity, with the result 800 nm for both K_3C_{60} and Rb_3C_{60} [674], and from NMR data, which give 600 nm for K_3C_{60} and 460 nm for Rb_3C_{60} [654].

Critical current density The critical current density (J_c) in the M_3C_{60} system has been obtained from magnetization measurements by using Bean's critical state model [675]. Based on this model, J_c is determined simply from the dc magnetization curve by the equation $J_c = A(M_+ - M_-)/R$. In the equation, A is a coefficient which is dependent on the sample geometry, M_+ and M_- denote the magnetization measured in increasing and decreasing fields at a certain magnetic field, and R is the sample radius [675, 676].

In the case of powders which can be approximated as a collection of spheres, R is set by the average grain size which can be measured in various ways. Different values of J_c for M_3C_{60} powders are obtained from magnetization measurements which showed substantial hysteresis up to high enough fields (higher than 5 T) [642, 659, 677–679]. However, the values of J_c in the order of 10^{10} A m^{-2} indicate substantial flux pinning and high values of the critical current density.

For single crystalline samples, certain assumptions about the internal microstructure must be made to obtain R. J_c of single crystal K_3C_{60} and Rb_3C_{60} obtained from magnetization measurements by using Bean's critical state model [670] was of the order of 10^7 A m^{-2}, that is, much smaller than the value of J_c for powdered samples ($\sim 10^{10}$ A m^{-2}).

The qualitative character of the temperature and magnetic field dependence of J_c has been acquired. J_c shows a near logarithmic dependence on H and does not correspond

to a simple analytic functional form [670] in single crystalline K$_3$C$_{60}$ and Rb$_3$C$_{60}$ samples. The temperature dependence of J_c was first found to follow the empirical equation $J_c \sim J_c(0)[1 - (T/T_c)^2]^n$, with $n = 3$–5 [680] in Rb$_3$C$_{60}$ powders. Subsequently, similar results for K$_3$C$_{60}$ [681, 682] and Rb$_3$C$_{60}$ powders [681] were obtained with $n = 1.3$–5. This temperature dependence was confirmed by measurements on single-crystalline K$_3$C$_{60}$ [657] and Rb$_3$C$_{60}$ [670]. The higher the magnetic field, the more rapidly J_c decreases with increasing temperature.

Cs$_3$C$_{60}$ Cs$_3$C$_{60}$ cannot be synthesized by vapor transport reaction because of its thermodynamic instability above ∼200 °C which will cause the phase to segregate into the more stable CsC$_{60}$ and Cs$_4$C$_{60}$. Stable Cs$_3$C$_{60}$ was synthesized in solution using liquid ammonia as solvent [683]. Raman measurement showed the Cs$_3$C$_{60}$ has a single sharp Ag mode centered at 1447 cm^{-1} with a linewidth of 11 cm^{-1} [683]. This indicated that all the fullerene molecules are in the 3$^-$ state. X-ray diffraction data showed that the compound consists of two phases: a body-center tetragonal (bct) Cs$_3$C$_{60}$ and an A15 cubic Cs$_3$C$_{60}$. The lattice parameters are $a = 12.057$ and $c = 11.432$ Å for the bct phase, and $a = 11.77$ Å for the A15 phase. It was reported that the Cs$_3$C$_{60}$ had a T_c of 40 K under high pressure [683], but this result has not yet been reproduced.

M$_{3-x}$M$'_x$C$_{60}$ Structures (M, M' = K, Rb, Cs) A series of ternary alkali doped C$_{60}$ have been synthesized with the general formulae of M$_{3-x}$M$'_x$C$_{60}$ [272, 684, 685]. All of these compounds are fcc structures. Most of these M$_{3-x}$M$'_x$C$_{60}$ compounds are superconductors. Table 20 lists some of these compounds as well as their structural parameters and T_c's.

M$_{3-x}$M$'_x$C$_{60}$ has merohedreal orientational disorder like M$_3$C$_{60}$. The relations of T_c and lattice constants in these compounds are similar to M$_3$C$_{60}$ (see Fig. 34). The overall trend is an increase in T_c with increasing lattice constant, which is interpreted in terms of a decrease in the LUMO-derived bandwidth and hence an enhancement of the Fermi energy density of states $N(E_F)$ at constant band filling [272, 639, 684–687].

M$_x$C$_{60}$ (M = K, Rb, and Cs, x = 1, 4, 6)

MC$_{60}$ MC$_{60}$ can be synthesized by reacting an appropriate amount of pristine C$_{60}$ with the saturation-doped product (M$_6$C$_{60}$) using the vapor transport technique [688–690]. The existence of a crystal phase with stoichiometric MC$_{60}$ was first indicated by Raman [688], photoemission [691, 692], and X-ray diffraction (XRD) [690] studies.

Table 20. Structural parameters and T_c of M$_{3-x}$M$'_x$C$_{60}$.

M$_{3-x}$M$'_x$C$_{60}$	Dopant location^a	a (Å)	T_c (K)	Ref.
KRb$_2$C$_{60}$	K(t)Rb(t)Rb(o)	14.243	23.0	[686]
K$_{1.5}$Rb$_{1.5}$C$_{60}$	K(t)K(o)Rb(t)Rb(o)	14.253	22.2	[272]
K$_2$RbC$_{60}$	K(t)K(t)Rb(o)	14.243	23.0	[686]
K$_2$CsC$_{60}$	K(t)K(t)Cs(o)	14.292	24.0

Rb$_2$CsC$_{60}$	Rb(t)Rb(t)Cs(o)	14.431	31.3	[272]

^{a} (o) = Octahedral site, (t) = tetrahedral site.

(i) *High temperature MC$_{60}$* Above 400 K the XRD pattern showed that MC$_{60}$ has a fcc rocksalt structure in which C$_{60}$ molecules are orientationally disordered [690]. M ion occupies an octahedral site in the fcc lattice (shown in Fig. 33). This phase is nonmetallic. The lattice parameters of MC$_{60}$ are listed in Table 21. This phase is nonmetallic.

(ii) *(MC$_{60}$)$_n$* When the fcc MC$_{60}$ is gradually cooled, new metallic polymeric phase forms [692–694]. Covalent bonding is formed between neighboring C$_{60}$ ions and results in the short interfullerene distance along the distorted orthorhombic ***a***-axis (also shown in Fig. 33). The linkage is through a [2 + 2] cycloaddition [695]. Therefore MC$_{60}$ phase exhibits a quasi-one-dimensional polymer character as in the case in pristine C$_{60}$ [693–697]. The (MC$_{60}$)$_n$ is used to denote this phase. These polymer phases are stable in air, in contrast to the vast majority of fulleride salts which are extremely sensitive in air [696]. Polymerization is reversible; heating the sample recovers the monomer fcc phase. XRD studies indicated that (MC$_{60}$)$_n$ phase has a body-centred orthorhombic (bco) lattice with space group *Pnnm*. The lattice parameters of (MC$_{60}$)$_n$ are listed in Table 21.

^{13}C NMR spectroscopy gave the direct evidence for the presence of sp^3 hybridized carbon atoms in (MC$_{60}$)$_n$ [698, 699]. Another piece of direct spectroscopic identification of the intermolecular bridging C–C modes in (MC$_{60}$)$_n$ (M = Rb, Cs) has been achieved by neutron inelastic scattering measurements [700, 701]. A first-principles quantum molecular dynamics model was developed [702] to describe the vibrational properties of polymerized fullerenes. Rigid ball–ball chain modes are predicted to occur in the energy range 10–20 meV in good agreement with the measured low-temperature neutron spectra.

Only few DFT-based calculations have been performed on the (MC$_{60}$)$_n$ to obtain the band structures [703, 704].

(iii) *Metastable structure MC$_{60}$* Moreover, depending on the cooling rate from the high temperature rocksalt fcc phase, a variety of other metastable phases are encountered. A medium quenching rate to just below room temperature leads to the stabilization of a low-symmetry insulating structure which has been characterized by synchrotron XRD studies to comprise (C$_{60}^-$)$_2$ dimers, bridged by single C–C bonds [705, 706]. The RbC$_{60}$ dimer phase crystallizes in the monoclinic space group $P2_1/a$ with lattice parameters $a = 17.141$ Å, $b = 9.929$ Å, $c = 19.277$ Å, and $\beta = 124.4°$ at 220 K [706] and transforms back to the polymer phase on heating. Another metastable conducting phase of RbC$_{60}$ and CsC$_{60}$ was reported with very rapid quenching by immersing the high-T sample in liquid nitrogen [707]. In this case,
Figure 33. The left: high-T fcc phase of MC$_{60}$; the middle: bco polymer phase stabilized by slow cooling from the fcc phase. The thick lines represent polymer chains; right: the linkage of C$_{60}$ in (MC$_{60}$)$_n$.

Table 21. Crystal structure and parameters for M_xC_{60} ($x = 1, 4, 6$).

M_xC_{60}	Crystal structure	Lattice constants (Å)	Ref.
KC_{60}	fcc (rock salt)	$a = 14.07$	[690]
RbC_{60}	fcc (rock salt)	$a = 14.08$	
CsC_{60}	fcc (rock salt)	$a = 14.12$	
$(KC_{60})_n$	bco	$a = 9.11, b = 9.95,$ $c = 14.32$	[693, 694]
$(RbC_{60})_n$	bco	$a = 9.11, b = 10.10,$ $c = 14.21$	
$(CsC_{60})_n$	bco	$a = 9.10, b = 10.21,$ $c = 14.17$	
K_4C_{60}	bct	$a = 11.867,$ $c = 10.765$	[711]
Rb_4C_{60}	bct	$a = 11.969,$ $c = 11.017$	
Cs_4C_{60}	bct (orthorhombic distorted)	$a = 12.15, b = 11.90,$ $c = 11.45$	[710]
K_6C_{60}	bcc	$a = 11.38$	[724, 725]
Rb_6C_{60}	bcc	$a = 11.54$	
Cs_6C_{60}	bcc	$a = 11.79$	

the 3D isotropic character of the structure is retained while orientational ordering of the C_{60}^- ions leads to a simple cubic structure with $a = 13.9671$ Å at 4.5 K. Upon heating, it returns to the most stable polymer phase.

M_4C_{60} K_4C_{60} and Rb_4C_{60} were synthesized by a vapor transport technique [584, 585, 708, 709]. XRD results showed that they have a bct structure with a space group $I4/mmm$ [709]. The early experiments suggested that Cs_4C_{60} is isostructural with K_4C_{60} [584, 708]. Single phase Cs_4C_{60}, which has an orthorhombic distortion of the ideal bct structure, was later synthesized by the low-temperature liquid ammonia route [710]. Cs_4C_{60} is not as well studied as K_4C_{60} and Rb_4C_{60} due to problems in stabilizing single phase samples. The structure parameters for M_4C_{60} are listed in Table 21.

M_4C_{60} compounds have an insulating, nonmagnetic ground state [620, 712] although their t_{1u}-derived bands are only partly (2/3) filled, which would lead one to expect a metallic behavior within a one-electron description. Detailed LDA calculations predict that M_4C_{60} is a metal [713]; this indicated that the insulativity does not come from the gap created by tetragonal symmetry split of the conduction band. Furthermore, electron paramagnetic resonance (EPR) [714], NMR [715] and EELS [716] measurements imply that orientational disorder is not a key ingredient in the insulating behavior of the M_4C_{60} phases. The scenarios proposed to explain this insulativity have included the suggestion of a Mott–Hubbard ground state for M_4C_{60} [471, 717, 718] and a description of these compounds as Jahn–Teller insulators [719, 720].

A systematic study of the optical conductivities of M_4C_{60} has provided strong evidence for a Mott–Hubbard ground state of these compounds [716]. Low-temperature NMR showed the development of a Koringa-like term under pressure, indicating that a metal–insulator transition occurs above 8 kPa [721]. Either a Mott insulator or a Jahn–Teller distortion is consistent with this NMR observation. It seems that a complete understanding of the electronic properties of M_4C_{60} requires a unique combination of both electron

correlation and Jahn–Teller effects which may lead to a Mott insulator without a magnetic ground state.

No superconductivity has been observed in M_4C_{60} down to 2 K.

M_6C_{60} The alkali metal-saturated compounds M_6C_{60} were synthesized by a vapor transport technique [709]. Synchrotron XRD data indicated that the M_6C_{60} compound has a bcc structure and corresponds to the space group T_h^5 or $Im\bar{3}$ [722]. In the M_6C_{60} structure, the alkali metal ions all occupy equivalent distorted tetrahedral sites, which are surrounded by four C_{60} anions, two with adjacent pentagonal faces and two with adjacent hexagonal faces. NMR spectra of M_6C_{60} are quite similar and in good agreement with the X-ray studies [723]. From the result it is apparent that the C_{60} molecules are ordered at all temperatures. The structural parameters for M_6C_{60} are given in Table 21.

M_6C_{60} has completely filled electronic levels which results in its observed insulating nature. No superconductivity was observed in M_6C_{60}.

Na and Li Doped C_{60}

Na Doped C_{60}

(i) Na_xC_{60} The Na_xC_{60} compounds were synthesized by a vapor transport technique [684]. All of the Na_xC_{60} phases except Na_4C_{60} have intercalated fcc structures. In Na_2C_{60}, the dopants fill the tetrahedral sites, leaving the octahedral sites unoccupied [726]. In Na_6C_{60}, two Na ions occupy tetrahedral sites and four Na atoms (not ions) go into octahedral sites [684]. It was reported that Na_3C_{60} tends to phase separate (disproportionate) into Na_2C_{60} and Na_6C_{60} [684, 727, 728]. The small size of the Na atom also allows the intercalation of Na to high concentrations. The saturated phase is $Na_{10}C_{60}$ in which Na atoms are located at the tetrahedral and octahedral sites, and at the general point with fractional occupancies [728]. Later a new Na_4C_{60} polymer phase which has a body-centered monoclinic unit cell was identified [729, 730]. Superconductivity has not been observed in any Na–C_{60} binary compounds. The structural parameters for Na_xC_{60} are listed in Table 22.

(ii) Na_2MC_{60} (M = Alkali, $Cs_{1-x}Rb_x$, Hg_x)   The vacant octahedral site in Na_2C_{60} allows this unique phase to act as a host lattice for further intercalation of dopants into the vacant octahedral site. The crystal structure and lattice parameters of Na_2MC_{60} are list in Table 23.

Superconductivity was observed in Na_2MC_{60} with $M = K$, Rb, Cs and $Cs_{1-x}Rb_x$. The T_c-lattice parameter correlation

in this class of fulleride superconductors is different from the case in M$_3$C$_{60}$ (see Fig. 34) [735].

Li Doped C$_{60}$

(i) *Li$_x$C$_{60}$* The Li–C$_{60}$ system is the least investigated among all alkali doped C$_{60}$ because of the difficulties in synthesis of single-phase samples. Li$_x$C$_{60}$ compounds can be synthesized by thermal decomposition of alkali metal azides or reaction of Li metal and C$_{60}$ powder in liquid ammonia or by electrochemical doping [736–738]. Structural parameters for some of the Li$_x$C$_{60}$ compounds are listed in Table 24. No superconductivity was observed in Li fullerides.

(ii) *Li$_x$MC$_{60}$ (M = Cs and Rb)* For smaller alkali metal K and Na, Li$_2$MC$_{60}$ phase is not stable and phase separates [739]. The crystal structure and lattice parameters of Li$_2$MC$_{60}$ (M = Cs and Rb) are listed in Table 25.
Figure 34. T_c as a function of the lattice parameter a for the $Fm\bar{3}m$ (triangles, circles, and open squares) and $Pa\bar{3}$ (filled squares) superconductors. For K$_3$C$_{60}$ and Rb$_3$C$_{60}$ the lattice parameter was varied by changing the pressure, while for M$_x$M'$_{3-x}$C$_{60}$ (with M, M' = K, Rb, Cs) the lattice parameter was varied by changing the composition. Ammoniated M$_x$C$_{60}$ The ammoniated alkali metal fullerides have been prepared by either exposing preformed metal fullerides to ammonia vapor or reaction of metal and C$_{60}$ in liquid NH$_3$. Ammoniation induces structure expansion and often changes the symmetry. Table 26 lists some of these compounds and their structural parameters. Some of these ammoniated M$_x$C$_{60}$ are superconductors under pressure. Table 26 also lists the T_c of them.

4.1.2. Alkaline–Earth Metal Doped C$_{60}$

Alkaline–earth fullerides show complicated structures and interesting properties [234, 746–751]. They are more difficult to synthesize and are less understood compared to the alkali–metal fullerides. Their electronic properties show a departure from the simple band-filling picture of the fulleride bands [750–754].

Ca$_x$C$_{60}$ The Ca$_x$C$_{60}$ compounds were synthesized by solid phase reaction. The mixture of high-purity Ca and C$_{60}$ powder was heated at 550 °C under a vacuum of 10^{-6} Torr for several hours to obtain Ca$_x$C$_{60}$ [234].

Ca$_5$C$_{60}$ X-ray diffraction studies indicated the formation of a simple cubic phase at $x = 5$. The proposed structural model involves multiple occupancy of the octahedral sites by Ca^{2+} ions [234]. The lattice constant of Ca$_5$C$_{60}$ is 14.01 Å [234, 755, 756].

Calcium intercalation into single-crystal C$_{60}$ thin films was studied with scanning tunneling microscopy and their real-space images were obtained [757]. A model of the Ca$_5$C$_{60}$ structure was deduced in which octahedral sites of the fcc lattice are occupied by four Ca ions while one of the tetrahedral sites is filled. The other tetrahedral site is filled at higher concentration, but these later-filled sites are arranged in rectangular or triangular lattices so that their distances are maximized.

Measurements of microwave loss, magnetic susceptibility, and Meissner effect first showed that Ca$_5$C$_{60}$ becomes superconducting below 8.4 K [234]. The T_c for Ca$_5$C$_{60}$ follows the same relation between T_c and the C$_{60}$–C$_{60}$ separation found in the alkali–metal compounds. However, the

Note: Although (NH$_3$) K$_3$C$_{60}$ exhibits no superconductivity at ambient pressure, superconductivity can be induced by hydrostatic pressure with an onset at 28 K.

pressure dependence of T_c of Ca$_5$C$_{60}$ is quite different. Schirber et al. [758] found that opposite to that observed in the alkali fullerides, the T_c of Ca$_5$C$_{60}$ increases with increasing pressure.

Band calculations using the local density approximation [752–754] showed that the t_{1u} level is totally filled, while the t_{1g} level of C$_{60}$ is half-filled. These half-filled t_{1g}-hybridized levels are the ones responsible for the conductivity and superconductivity in Ca$_5$C$_{60}$. Experimental evidence for the partial filling of the t_{1g} level comes from both photoemission spectra [755] and transport measurements [759, 760]. Electron energy loss [761] and inverse photoemission [755] studies showed that the completely filled t_{1u} band for $x < 3$ is below E_F, giving nonmetallic character.

Ca$_{2.75}$C$_{60}$ Studies by Ozdas et al. showed that Ca$_{2.75}$C$_{60}$ is the only stable phase for $1.8 < x < 2.8$ [737]. X-ray patterns and calculated results showed that the structure is a 2 × 2 × 2 supercell with space group *Pcab*, a direct subgroup of *Pa$\bar{3}$*, and the lattice parameters are 27.93 × 28.03 × 27.95 Å (at 298 K). Ca cations are located in both the tetrahedral (T) and octahedral (O) interstitial sites of the cubic close-packed C$_{60}$ lattice. All of the O-sites are occupied by single Ca cations, which are displaced off-center. By contrast, one out of every eight T-sites in the subcell is vacant.

The Ca$_{2.75}$C$_{60}$ phase is not superconducting down to 2 K under ambient pressure. Electron energy loss [761] and inverse photoemission [755] studies showed that the completely filled t_{1u} band for $x < 3$ is below E_F, giving nometallic character.

AE$_x$C$_{60}$ (AE = Ba, Sr) In contrast to calcium fullerides which are fcc at all compositions, Ba$_x$C$_{60}$ and S$_x$C$_{60}$ only exist in bcc-based structures at $x = 3$, $x = 4$, and $x = 6$ [746–749]. All of these compounds have been synthesized by solid phase reaction [746]. Their crystal structure and lattice constant are listed in Table 27.

No superconducting transition is observed down to 1.5 K in Ba$_3$C$_{60}$ and Sr$_3$C$_{60}$ [763, 762]. Early investigations show that both of the Ba$_6$C$_{60}$ and Sr$_6$C$_{60}$ are superconductors, with transition temperatures of 7 and 4 K, respectively [746, 762]. However, later studies indicate that AE$_4$C$_{60}$(AE = Ba, Sr) is the actual superconducting phase rather than AE$_6$C$_{60}$(AE = Ba, Sr) as originally proposed [747–749]. In contrast to Ca$_5$C$_{60}$, T_c of Ba$_4$C$_{60}$ decreased with increasing pressure. High magnetic susceptibility measurements show that AE$_6$C$_{60}$ phases are metallic, even though they are not super-conducting [749]. Moreover, these magnetic susceptibility measurements and calculated [752] results combined with the different lattice constants dependence of T_c for Ba$_4$C$_{60}$ [764] and Ca$_5$C$_{60}$ [758] indicate that there is no clear relation between T_c and $N(E_F)$ in AE$_x$C$_{60}$ compounds.

Alkaline–Earth Substituted M$_x$C$_{60}$

M$_{3-x}$Ba$_x$C$_{60}$ ($0 < x < 2$) Direct synthesis of alkali–alkaline earth fullerides by vapor transport is impractical due to huge differences in vapor pressures. This can be avoided by using azides BaN$_6$ and MN$_3$ (M = alkali metal) as metal source. Direct reactions with BaN$_6$ and MN$_3$ yielded complicated mixed phases [763]. Stable compounds were eventually synthesized by reacting BaN$_6$ powder with the fcc M$_1$C$_{60}$ phase

Table 27. Structural parameters of AE$_x$C$_{60}$ (AE = Ba and Sr, x = 3, 4, 6).

AE$_x$C$_{60}$ (AE = Ba and Sr)		Synthesis	Crystal structure	Lattice constant	Ref.
AE$_3$C$_{60}$	Ba$_3$C$_{60}$	solid phase reaction	simple cubic A15	11.34 Å	[763]
	Sr$_3$C$_{60}$		fcc and A15 coexistence	14.144 Å (fcc) 11.140 Å (A15)	[762]
AE$_6$C$_{60}$	Ba$_6$C$_{60}$		body-centered cubic	11.171 Å	[746]
	Sr$_6$C$_{60}$			10.975 Å	[762]
AE$_4$C$_{60}$	Ba$_4$C$_{60}$		orthorombic (bco)	11.25 × 11.69 × 10.90 Å	[747, 748]
	Sr$_4$C$_{60}$			—	[749]

prepared by the azide decomposition method [582, 624,765–767]. This process worked well for all MBa$_2$C$_{60}$ with M = K, Rb, or Cs. But the M$_2$BaC$_{60}$ cannot be obtained following the same process. However, starting from CsC$_{60}$ ensuring octahedral Cs and then adding BaN$_6$ and AN$_3$ together in the second step yielded single-phase products MBaCsC$_{60}$ for M = Na or K, while phase separation occurred for M = Rb or Cs. X-ray diffraction and Raman scattering showed that these compounds are fcc with pentavalent and quadrivalent C$_{60}$'s, respectively [768]. Table 28 lists the structural parameters of these compounds.

No superconductivity was observed in these compounds down to 0.5 K [624]. Electron spin resonance (ESR) indicated weakly metallic behavior [769]. ^{13}C NMR indicated strong dynamical disorder above room temperature, which may be related to the anisotropic crystal field induced by cations of different valence [624, 770].

M$_{3-y}$M'$_y$Ba$_3$C$_{60}$ (M, M' = K, Rb, Cs) Samples of M$_{3-y}$M'$_y$Ba$_3$C$_{60}$ were typically synthesized by intercalation of alkali metals into preformed Ba$_3$C$_{60}$ [765–767]. XRD for the samples show single phase bcc patterns with space group *Im*-3. Simulation of diffraction patterns indicates the random occupation of the interstitial sites by M and Ba. The lattice parameter in M$_3$Ba$_3$C$_{60}$ is controllable by changing linearly with the alkali ionic radii. Moreover, by changing the y in K$_y$Rb$_{3-y}$Ba$_3$C$_{60}$, the lattice parameter can be tuned quasi-continuously between K$_3$Ba$_3$C$_{60}$ and Rb$_3$Ba$_3$C$_{60}$ [765]. The structural parameters of these compounds are listed in Table 29.

M$_3$Ba$_3$C$_{60}$ is a half-filled metal in which the Fermi energy exists at the center of the next lowest unoccupied molecular orbital with the t_{1g} symmetry [767]. Superconductivity was observed in all compounds except for Cs$_3$Ba$_3$C$_{60}$ in which superconductivity was absent down to 0.5 K [765]. T_c decreased with increasing lattice parameter in M$_3$Ba$_3$C$_{60}$ [765]. This T_c–lattice parameter correlation is in striking contrast with the positive correlation between T_c and the fcc cell parameter in M$_3$C$_{60}$ superconductors.

4.1.3. Rare-Earth and Lanthanide Metal Doped C$_{60}$

Yb$_{2.75}$C$_{60}$ Yb$_{2.75}$C$_{60}$ was successfully synthesized by solid phase reaction [771]. X-ray diffraction studies showed that Yb$_{2.75}$C$_{60}$ has an orthorhombic unit cell with *Pcab* symmetry and lattice constants of $a = 27.87$ Å, $b = 27.98$ Å, and

$c = 27.87$ Å [771]. Near-edge X-ray absorption measurements show that all of the Yb cations are divalent, meaning that the average negative charge of the C$_{60}$ anions is 5.5 [772, 773]. EXAFS and Raman measurements also reveal that the C$_{60}$ anions are distorted in shape, despite their well-ordered local structure around the Yb cations [773]. Yb$_{2.75}$C$_{60}$ becomes superconducting below 6 K.

Sm Doped C$_{60}$ The Sm$_x$C$_{60}$ compounds have been synthesized by solid phase reactions [774]. The unit cell structure of the nominal Sm$_3$C$_{60}$ phase is identified as orthorhombic ($a = 28.17$ Å, $b = 28.07$ Å, and $c = 28.27$ Å) derived from the fcc M$_3$C$_{60}$ (M = Alkali metal) cell by doubling the cell dimension in each direction, analogous to that of Yb$_{2.75}$C$_{60}$ [774]. However, the exact structure of the Sm$_3$C$_{60}$ phase is still an open question. The quality of the diffraction data has prevented a full structure determination. Sm$_3$C$_{60}$ is superconducting at $T_c = 8$ K [774].

Temperature dependent resistivity measurements of Sm$_x$C$_{60}$ samples have been reported. The results show that the resistivity decreases with increasing Sm concentration x [775, 776]. The temperature coefficient of resistivity is negative for all compositions and the absolute value decreases with increasing x.

Eu Doped C$_{60}$ Eu$_x$C$_{60}$ compounds can be synthesized by either high-temperature solid state reaction [777, 778] or through the liquid ammonia route [779].

The Eu$_x$C$_{60}$ prepared by ammonia route was found to be amorphous by XRD [779]. Crystalline phases prepared by solid state reaction with the compositions of $x \sim 3$ and 6 are stabilized [777, 778]. The structure of the $x \sim 3$ phase is complicated. Experimental data show the coexistence of a minor A15 phase and a majority phase that has the same structure as Yb$_{2.75}$C$_{60}$.

The Eu$_6$C$_{60}$ phase has the same bcc structure of the saturation M$_6$C$_{60}$ (M = alkali metal) compounds [777, 778]. The experiments reveal the presence of both Eu^{2+} and Eu^{3+} ions. Furthermore, it is found that at $T = 65$ K ferromagnetic Eu pairs form through a superexchange mechanism via the C$_{60}$ molecules [777].

4.1.4. Halogen Intercalated C$_{60}$

I$_2$ Intercalated C$_{60}$ Iodine-doped C$_{60}$ C$_{60}$I$_4$ was synthesized by vapor phase reaction of iodine with pure C$_{60}$ under helium gas of 10 Torr at 250 °C for several days in evacuated Pyrex tubes [780]. XRD results show than C$_{60}$I$_4$ has a simple hexagonal cell with $a = 9.962$ and $c = 9.984$ Å. In this structure the C$_{60}$ host material exhibits a sequence of (AAA...) layers, interleaved with guest iodine layers

Table 28. Structural parameters and T_c of M$_{3-x}$Ba$_x$C$_{60}$ ($0 < x < 2$) compounds.

M$_{3-x}$Ba$_x$C$_{60}$	Crystal structure	Lattice constant	Atom position	T_c	Ref.
KBa$_2$C$_{60}$	fcc	14.173 Å	K(o)Ba(t)	no T_c	[624]
RbBa$_2$C$_{60}$	fcc	14.185 Å	Rb(o)Ba(t)		
CsBa$_2$C$_{60}$	fcc	14.206 Å	Cs(o)Ba(t)		
KbaCsC$_{60}$	fcc	14.215 Å	Cs(o),K and Ba randomly occupy (t)		

Note: (o) = Octahedral site, (t) = tetrahedral site.

Table 29. Structural parameters and T_c of M$_{3-y}$M'$_y$Ba$_3$C$_{60}$ (M, M' = K, Rb, Cs) compounds.

M$_{3-y}$M'$_y$Ba$_3$C$_{60}$	Crystal structure	Lattice constant	Atom position	T_c	Ref.
K$_3$Ba$_3$C$_{60}$	bcc	11.24 Å	Randomly	5.6 K	[765]
Rb$_3$Ba$_3$C$_{60}$	bcc	11.34 Å	occupy	1.9 K	
Cs$_3$Ba$_3$C$_{60}$	bcc	11.47 Å		no T_c	

between the host layers, as in a graphite intercalation compound. The {111} planes of the fcc C_{60} become the {001} planes in the compound by relative shear motions which transform the layer stacking sequence from ABCABC... in fcc C_{60} to A/A/A/... in $C_{60}I_4$, where "/" denotes an iodine guest layer in the $C_{60}I_4$ compound. The shortest I–I (in-plane) distance is 2.53 Å, which is close to the value of 2.72 Å for the molecular solid I_2 [780].

Another intercalation compound of C_{60} with iodine was also prepared under fairly similar conditions [781] with a final composition of $C_{60}I_{1.6}$ [782]. The XRD pattern was interpreted in terms of a C-centered orthorhombic cell with $a = 17.33$, $b = 9.99$, $c = 9.97$ Å, containing two formula units. Iodine atoms were placed in sites slightly shifted from the centers of the trigonal prisms, with near-neighbor and next-near-neighbor distances of 3.9 and 7.21 Å, respectively [781, 782].

Iodine intercalated C_{60} is nonmetallic and has a resistivity at 300 K of 10^9 Ω cm. In addition, no superconductivity is observed down to 4 K. Photoemission [783], X-ray absorption [784], and ^{13}C NMR [785] results confirm the insulating (clathrate) nature (i.e., the absence of guest–host charge transfer).

Halogenation of C_60   Halogenation reactions of $C_{60}X_n$ (X = Br, Cl, F) have been reported for various n values. In these reactions the halogen is attached to a carbon atom on the fullerene shell through a single radial covalent band that is formed by using one electron provided by the fullerene and the other by the halogen.

The species $C_{60}F_{36}$ have been reported by several groups [786, 787]. Complete fluorination of C_{60} ($C_{60}F_{60}$) has also been reported [788]. A very high chlorine content has been found in a photochlorinated fullerene sample which was found to fit the average formula $C_{60}Cl_{40}$ [789]. Bromination of C_{60} has also been observed in chemical reactions carried out in the 25–55 °C range. X-ray crystallographic evidence indicates the existence of $C_{60}Br_6$, $C_{60}Br_8$, and $C_{60}Br_{24}$ [790, 791]. These X-ray studies showed that the attachment of Br is accomplished by placing Br at symmetrically bonding vertices of the C_{60} molecule. These Halogenated fullerenes can be used in substitution reactions to attach aromatic groups sequentially to the fullerene shell.

4.1.5. Molecules Intercalated C_60

Intercalation of Gases into Solid C_60   Various gases such as H_2, N_2, H_2O, CH_4, CO, and O_2 can be intercalated into solid C_{60}. These neutral gas molecules can be intercalated into the interstitial sites of the C_{60} lattice without drastically altering the host structure. The intercalants occupy octahedral sites of the C_{60} lattice and depress the C_{60}'s fcc–sc transition temperature (T_m). These compounds have possible potential applications such as gas separation, sensors, hydrogen storage, etc. Table 30 lists some of these compounds along with a few structural properties.

Intercalation of Larger Species into Solid C_60   When the guest species are larger than the voids in the C_{60} solids, a change in stacking of the fullerene molecules from cubic to hexagonal usually occurs. Structures of these compounds are different from C_{60}. In most of these phases, C_{60} molecules

Table 30. Synthesis and structural properties of gas intercalated C_{60}.

Compound	Synthesis	Structural properties	Ref.
$(N_2)_x C_{60}$	Powder and pellets samples of pure C_{60} were separately subjected to nitrogen and oxygen, at 0.15 kbar for 7 days at room temperature.	$0 < x < 1$, $T_m \sim 255$ K	[792]
$(O2)_x C_{60}$		$0 < x < 1$, $T_m \sim 240$ K	[792] [793]
$(H_2)_x C_{60}$	Pellet samples of pure C_{60} were separately subjected to hydrogen gas, at 750 atm for 5 h at 323 K and soon was cooled below 150 K, thereby "freezing" the interstitial H_2 inside the C_{60} lattice.	$0 < x < 1$, out gas at $T \sim$ 260 K, nearly free quantum rotor at all T	[794] [795]
$(CH_4)_x C_{60}$	The powdered C_{60} was loaded into a high-pressure gas cell filled with CH_4 and heated to ~ 400 °C up to 70 h. The cell was quenched in running cold water. The pressure at temperature in the cell is estimated to be between 1 and 2 kbar.	$0 < x < 1$, $T_m \sim 241$ K	[796]

form triangular planes as in the case of graphite sheets and the intercalants go between them. This is the case in simple systems such as $C_{60}(P_4)_2$, $C_{60}(S_8)_2$. Larger organic and organometallic molecules, like benzene and ferrocene, can also be intercalated to give $C_{60}(C_6H_6)_4$ and $C_{60}(ferrocene)_2$, respectively. In addition, reacting C_{60} with protonic acids, Lewis acids $SbCl_5$, AsF_5, $InCl_3$ [797–799] also produce different compounds. Table 31 lists some of these compounds and their structural parameters.

Table 31. Structural parameters of larger species intercalated C_{60}.

Compound	Structural properties	Ref.
$C_{60}(P_4)_2$	hexagonal, $a = 10.084$ Å, $c = 10.105$ Å	[800, 801]
$C_{60}(S_8)_2$	monoclinic, $a = 20.867$ Å, $b = 21.062$ Å, $c = 10.508$ Å, $\beta = 111.25°$, four formula per cell.	[802]
$C_{60}(ferrocene)_2$	triclinic, $a = 9.899$ Å, $b = 10.366$ Å, $c = 11.342$ Å, $\alpha = 90.96°$, $\beta = 90.96°$, $\gamma = 118.33°$ (at 143 K)	[803]
$C_{60}(AsF5)_{1.88}$	tetragonal (bct), $a = 12.794$ Å, $c = 12.426$ Å	[797, 798]
$C_{60}(C6H6)_4$	triclinic, $a = 9.938$ Å, $b = 15.031$ Å, $c = 17.425$ Å, $\alpha = 65.38°$, $\beta = 88.30°$, $\gamma = 74.83°$ (at 104 K)	[804, 805]

The TDAE intercalated C$_{60}$ organic molecular system raised much interest owing to its ferromagnetic-like phase transition at $T_c = 16$ K [552]. Furthermore, the TDAE-C$_{60}$ material has the highest T_c of any molecular organic ferromagnet [552]. An X-ray diffraction study first established that TDAE-C$_{60}$ is a stoichiometric material with a TDAE:C$_{60}$ ratio of 1:1 [806]. The diffraction data were interpreted in terms of a centered monoclinic unit cell, $a = 15.807$ Å, $b = 12.785$ Å, $c = 9.859$ Å, and $\beta = 94.02°$ [806].

4.2. Polymerized C$_{60}$

4.2.1. Synthesis and Preparation

Photopolymerization of C$_{60}$ First evidence for polymerization [534] showed that oxygen-free thin films of C$_{60}$ can be polymerized by the irradiation of intense visible or ultraviolet light with photon energies greater than the optical absorbtion edge ($\sim$1.7 eV) [534, 807]. Because of the strong light absorption of C$_{60}$, only films thinner than 0.1 μm can be photopolymerized efficiently. The photopolymerized C$_{60}$ no longer dissolves in many common organic solvents compared to pristine C$_{60}$. Dioxygen diffused into C$_{60}$ films seem to be inhibitors during the photopolymerization process [534, 808] and CCl$_4$ can promote the process [809]. The photopolymerization process found to occur only in the fcc phase above 260 K, the orientational transition temperature of pristine C$_{60}$ crystals [808], goes by the [2 + 2] cycloaddition mechanism [534] with the double intramolecular bonds broken and a four-atom ring formed by covalent C–C bonds (i.e., accompanied with rehybridizations from sp^2 to sp^3). Direct evidence for the covalent intermolecular bonds confirms the photopolymerization from laser desorption mass spectroscopy measurements [534, 810]. On heating above $\sim$400 K polymerized C$_{60}$ reverts to normal monomeric C$_{60}$ by breaking up the intermolecular bonds and reforming the intramolecular bonds. Recent Raman [811] and atomic force microscopy studies [812] also suggested that two different photopolymerized states might exist. Photopolymerization at temperatures above 350 K seems to produce mainly dimers, while material polymerized at 320 K and below contains larger oligomers. The photopolymerization of C$_{60}$ usually forms one-dimensional linear-chain structured polymers.

Pressure-Induced Polymerization of C$_{60}$ Pressure-induced polymerization has been studied extensively under various temperatures and pressures in recent years [813]. Several polymerized fullerites have been synthesized from the fcc C$_{60}$ by applying moderate pressures at elevated temperatures [814–816]. Three different phases possessing one- or two-dimensional C$_{60}$–C$_{60}$ networks have been identified: one-dimensional orthorhombic phase (O-phase) [816], two-dimensional tetragonal phase (T-phase) [816], and two-dimensional rhombohedral phases (3R-phase, also called Rh-C$_{60}$) [814–816]. Recently single crystals of these three structures have been successfully synthesized (O-phase [817, 818], T-phase [819–823], and 3R-phase [824, 825]). The one-dimensional and two-dimensional pressure-induced polymerization of C$_{60}$ goes by the same cycloaddition mechanism of the photopolymerization.

Under ultrahigh pressure and a higher temperature ($\sim$13 GPa, 820 K), evidence for the existence of 3D

polymers has been observed [826]. But high purity 3D polymers with uniform structure have not been synthesized efficiently.

Other Polymerization Methods Polymerization of C$_{60}$ can also be accomplished by plasma treatments [827, 828], ion bombardments at a low does [829], a low-energy electron injection from STM probe tips to C$_{60}$ films [830], or electron-beam bombardments from an electron gun [560]. The latter process has been successfully used for chlorine-based reactive ion beam etchng in electron beam lithography where a C$_{60}$ film acts as a negative-type electon beam resist mask [831].

4.2.2. Structures and Phase Diagram

Structures

1D Orthorhombic Phase The orthorhombic phase forms a one-dimensional linear molecular-chain structure along the $\langle 110 \rangle$ direction of the original fcc phase (see Fig. 16a) [813, 833]. The smaller value ($\sim$9.1–9.2 Å, compared to the value of 10.02 Å of pristine C$_{60}$) of the nearest-neighbor distance observed by XRD experiment provides the evidence for a covalent bonding between the C$_{60}$ cages. The space group has been identified as *Pmnn*, corrected from the earlier proposed *Immm* space group [818, 834].

2D Tetragonal Phase The tetragonal phase forms a two-dimensional tetragonal molecular-network layered structure via [2+2] cycloaddition in the (001) plane of the original fcc phase (see Fig. 16b) [813, 833]. The most recent study identified the "tetragonal" phase representing a pseudo-tetragonal packing model with an orthorhombic space group *Immm* [823] although with a very small higher energy (4 kJ mol^{-1}) [835] than another possible packing model with a truly tetragonal space group $P4_2/mmc$.

2D Rhombohedral Phase The rhombohedral phase forms a two-dimensional hexagonal molecular-network layered structure via [2 + 2] cycloaddition in the (111) plane of the original fcc phase (see Fig. 16c) [813, 833]. The hexagonal layers are proposed to be stacked in a close-packed arrangement of the type ABCABC with space group $R\bar{3}m$ [816]. There are three possible packing modes of the hexagonal layers proposed [835]; recent XRD studies confirmed most stable modes, which suggest a trigonal symmetry in individual layers but not a hexagonal one [818, 825].

3D Polymers and Superhard Phase The structure of 3D C$_{60}$ polymers is still ambiguous due to the complex structure and bonding mechanism. There are several theoretically and experimentally suggested structures under nonhydrostatic or hydrostatic compression and high temperature treatment [836–839]. Recently one surperhard phase of 3D polymer treated under 13 GPa, 820 K has been characterized to be a body-centered orthorhombic structure (space group *Immm*), with [3 + 3] cycloaddition bonding between the [2 + 2] cycloaddition bonded tetragonal layers from a 2D polymer [826, 840].

Figure 35 gives the geometric structural diagrams of C$_{60}$ polymers. The crystallographic data from different authors for the 1D and 2D C$_{60}$ polymers are listed in Table 32.
Figure 35. Geometric structures of C_{60} polymers: (a) 1D C_{60} polymer (orthorhombic phase), (b) 2D C_{60} polymer (tetragonal phase), (c) 2D C_{60} polymer (rhombohedral phase).

Phase Diagram There have been several tentative phase diagrams under pressure–temperature treatments of C_{60} presented in some of the literature [318, 813]. Since the phase formation and purity of polymerized C_{60} depend strongly on the temperature and pressure as well as the time of the treatment, those phase diagrams are still under discussion. The typical detailed conditions for the formation of pressure-polymerized C_{60} have been reported as follows: 1D orthorhombic phase 1–1 2 GPa, 550–585 K, about 5 hours [318, 818]; 2D tetragonal phase: 2–2.5 GPa, 700–873 K 0.5–4 hours [318, 822, 823]; 2D rhombohedral phase 5–6 GPa, 773–873 K, 0.5–1 hours [318, 825]. It has also been reported that after a 1000 s treatment under conditions of temperature of ~1.5 GPa and pressure of ~423 K, most of the pristine C_{60} will form dimer phase with a $(C_{60})_2$ content of about 80 mol% [318] (to learn more about C_{60} donors. See Section 5.2).

4.2.3. Electronic Structures and Energetics

Electronic Structures Polymerization of fullerene C_{60} results in the narrowing of the HOMO–LUMO gap that is caused by the splitting of the degenerated molecular orbitals of the icosahedral C_{60} due to its distortion and the formation of intermolecular bonds. The electronic structures of 1D and 2D C_{60} polymers have been studied theoretically using tight-binding calculation and LDA in the framework of the DFT.

From tight-binding calculation, a linear C_{60} chain has been found to be semiconductive with a finite band gap of 1.148 eV and almost pure s-type intermolecular bonding [843]. Assuming the weak van der Waals interlayer interaction in the rhombohedral and tetragonal polymers, a theoretical prediction on stability and conducting properties has been made according to the tight-binding calculation of a single layer [844]. Different numbers of intermolecular covalent bonds in the tetragonal and rhombohedral structures were found to cause the distinction of bandgap values, which were estimated to be 1.2 and 1.0 eV, respectively. The investigation of the electronic structure of the rhombohedral and tetragonal 2D C_{60} polymers has been carried out using the LDA [845, 846]. These phases were found to be elemental semiconductors having indirect gaps of 0.35 and 0.72 eV and three-dimensional electronic structures due to the short interlayer distance. Although the LDA generally underestimates the energy gap, its value is consecutively reduced from the C_{60} to the rhombohedral phase, which correlates well with the result of tight-binding calculations [844].

Recently, empirical tight-binding calculations showed that all 1D and 2D polymers are semiconductors with the smallest energy gap for the rhombohedral phase, and the greatest energy stability for the 1D polymer [847].

Energetics and Stabilities DSC study [848] showed that all polymers are more stable than monomers because the stabilization energy decreases with increasing number of intermolecular bonds per molecule. Formation of polymer bonds lowers the total energy [844]. The stability sequence of a distinct polymerized phase of C_{60} is dimer (C_{120}) > 1D polymer > 2D polymer > Pristine C_{60} (monomer). All polymers depolymerize into pristine C_{60} on heating to 300 °C and the depolymerization reaction is endothermic, indicating that the monomer form is the least stable phase [848].

Table 32. Crystallographic data for C_{60} polymers.

Polymer phase	Space group	a (Å)	b (Å)	c (Å)	V (Å³), Z	d (g/cm³)	Ref.

	Immm	8.69	8.74	12.71		2.43 (X-ray) 2.5 (exp.)	

Compared to the most stable phase, graphite, the energies of diamond and C$_{60}$, reckoned from the graphite level, are, respectively, 0.020 and 0.42 eV per carbon atom. The total energy of distinct phases of C$_{60}$ occur within a very narrow energy range of about 0.01 eV per carbon atom and the difference between the polymer and monomer forms of C$_{60}$ is rather small [848].

4.2.4. Physical Properties

Electrical Properties   Generally, the conductivity of polymerized C$_{60}$ increases with the polymerization degree and depends on their structure and the ratio of the number of sp^2 to sp^3.

Field effect transistor investigations indicate that the 1D plasma-polymerized C$_{60}$ acts as a *p*-type semiconductor in contradiction to the *n*-type semiconductor behavior of pristine C$_{60}$ [849]. The gas and photosensitivity of transport properties of a C$_{60}$ polymer thin film are promising for a sensing device [849]. In addition, it is known that the alkali-metal doped $(AC_{60})_n$ 1D polymer will formed spontaneously below 400 K from the monomer AC_{60} salts. It was found that $(KC_{60})_n$ has metallic conductivity; $(RbC_{60})_n$ and $(CsC_{60})_n$ are also conducting at high temperatures but have a metal–insulator transition at 50 and 40 K, respectively [850].

2D C$_{60}$ high-oriented C$_{60}$ polymer shows a gigantic conductivity anisotropy. Conductivity in the polymerized planes exhibits a metallic-like behavior and the out-of-plane one is semiconductor-like [851]. The anisotropy is temperature dependent and lies in the range of 10^3–10^6. A randomly oriented polymer shows a semiconductor behavior and obeys the Arrhenius law [852]. The observed in-plane conductivity has been explained by a theoretical calculation which considered the formation of distinguishable intermolecular bondings of 66/66, 56/66, and 56/65 models. The calculated results indicated that the occurrence of regions containing 65/56 bonded molecules within a 66/66 connected hexagonal layer may cause variations of in-plane conductivity from a semiconducting behavior to a metallic behavior [853]. If a 2D polymer is formed at a temperature above the collapse temperature of the C$_{60}$ molecular cages (about 800 °C), the conductivity increases intensively by four orders of magnitude [824].

Both semimetallic, variable range hopping (VRH) and semiconducting behaviors have been observed in the electrical resistivity measurement on samples with disordered structures synthesized from pure C$_{60}$ at pressures in the range 8–12.5 GPa and temperatures of 900–1500 K [854]. Particularly, the temperature dependence of resistivity in a disordered crystalline 3D-polymerized C$_{60}$ obtained after 9.5 GPa and 900 K treatment fits Mott's VRH law $\rho = 0.07[\exp(1/T)^{1/4} - 1]\ \Omega$ cm in the range 270 K down to 5 K for hopping conductivity [854].

Optical Properties   Optical absorption and PL spectra of polymerized fullerenes have noticeably broader bands than those in pristine C$_{60}$ [855], and the optical absorption ranges and PL peaks are shifted to the lower energies [522]. Oxygen-containing polymerized fullerene films show strong photoluminescence in the near-IR and visible ranges (1.50–2.36 eV) at room temperature, and the photoluminescence

decrease in intensity after being annealed at different high temperatures [856].

The inverse transmission spectra for 1D and 2D polymers indicate that raising the polymerization temperature shifts the absorption edge to lower energies [857], showing that the polymers are semiconductors with energy gaps $E_g \sim 1.4$ and 1.1 eV which agree well with the theoretical calculations for the orthorhombic and rhombohedral phases ($E_g \sim 1.2$ and 1.0 eV, respectively) [844].

The Raman and infrared spectroscopies of polymerized has also been studied; the spectra are given as comparisons with those of pristine C$_{60}$ crystals in Section 2.2.2.

Magnetic Properties   Among all the 1D and 2D C$_{60}$ polymers, the 2D rhombohedral polymer is the only phase known that shows ferromagnetic features such as saturation magnetization, large hysteresis, and attachment to a small samarium–cobalt magnet at room temperature (shown in Figure 36) [555]. The temperature dependences of the saturation and remanent magnetization indicate a remarkably high Curie temperature about 500 K higher than that of the other known organic ferromagnets [555, 858]. The discovery of ferromagnetism in Rh-C$_{60}$ has opened up the possibility of a whole new family of magnetic fullerenes.

Elastic   Properties   Ultrasonic   measurements   have revealed that the elastic module of C$_{60}$ polymer increases with the polymerization degree which depends on the polymerization pressure and temperature [859]. Table 33 gives the elastic properties of C$_{60}$ polymers compared to pristine C$_{60}$ and polycrystalline diamond [859]. Remarkably, the disordered 3D polymer and amorphous C$_{60}$ synthesized at a temperature higher than the collapse temperature of C$_{60}$ cages shows comparable and exceeding bulk moduli with diamond, respectively.

It has been shown that amorphous C$_{60}$ synthesized at very high pressure and temperature ($\sim$13 GPa, 1850 K) can scratch the diamond surface easily [860, 861], with hardness exceeding that of diamond making the ultrahard C$_{60}$ among the hardest known materials.

4.3. Metal/C$_{60}$ Composites

For metals other than alkali or alkali earth ones, which have much higher cohesive energy, it is energetically unfavorable for them to diffuse into the interstitial sites of the C$_{60}$

Figure 36. 2D rhombohedral polymerized C$_{60}$ attached to a small samarium–cobalt magnet at room temperature.

Table 33. Measured values of sound velocities and elastic moduli in 1D and 2D polymerized C$_{60}$ samples.

Material	p(GPa)/T (K)	ρ (g/cm^3)	c_L (km/s)	c_T (km/s)	K (GPa)	G (GPa)	σ	Structure (X-ray results)
Pristine C$_{60}$		1.68			10.8	4.85	0.31	polycrystalline
1D polymer	8/500	1.75	6.0	3.70	30	24	0.19	orthorhombic
			7.4	4.8	42	40	0.14	
2D polymer	8/900	1.9	6.8	4.1	45	30	0.20	rhombohedral

3D polymer	9.5/970	2.62	18.5	11.4	450	340	0.20	disordered (fcc + bcc)
Amorphous C$_{60}$	13/1770	3.30	18.4	8.7	790	250	0.29	one halo
Diamond		3.74			490	350		polycrystalline

Note: c_L and c_T are longitudinal and transverse sound velocities. K and G are bulk and shear elastic moduli; σ is Poisson ratio. Accuracy of ultrasonic measurements is ~5% [859].

lattice and form a M$_x$C$_{60}$ compound similar to M$_x$C$_{60}$ alkali fullerides [170, 862]. Therefore M/C$_{60}$ composites (phase-separated solids of M/C$_{60}$) were obtained and investigated to study the metal–C$_{60}$ interaction. The most common composites are multilayer films [863–865] and the nanodispersion films [865–871]. Both of them can be easily obtained by the co-deposition method using metals and pure C$_{60}$ (>99.9%) under high vacuum [865, 869].

In the M/C$_{60}$ nanodispersion films, metal nanocrystallites are well dispersed in the C$_{60}$ polycrystalline matrix and the grains of M are very small [866–869]. The volume fraction of the metal and the grain size of the metal particles can be controlled by adjusting the deposition rates of C$_{60}$ and the metal, and the temperature of the substrate, respectively [869].

4.3.1. Al, Cu, Ag/C$_{60}$ Composites

Al/C$_{60}$ Al–C$_{60}$ interaction was first studied in mutilayers [863]. *In-situ* resistivity measurements showed that the presence of underlying layers of C$_{60}$ reduced the critical thickness at which Al became conducting from ~35 to ~20 Å and there was a sudden increase in resistance that occurs when each Al layer was covered by a monolayer of C$_{60}$. A downward shift of 40 cm^{-1} in frequency of a considerably broadened Raman-active $A_g(2)$ pentagonal-pinch mode was observed. A charge transfer model in which up to six electrons per C$_{60}$ were transferred from the Al to the C$_{60}$ layer across the planar Al–C$_{60}$ interface was proposed to explain these experimental results [863].

However, the PES and C 1s X-ray-absorption spectra of C$_{60}$ monolayers on Al(111) surfaces indicated that Al–C$_{60}$ bonding is covalent [184]. Therefore Raman spectra were measured on Al/C$_{60}$ nanodispersion films in order to get some insight into the Al–C$_{60}$ interfacial interactions [868, 872]. The $A_g(2)$ pentagon-pinch mode of C$_{60}$ splits into two peaks, one pristine mode which still remains at 1468 cm^{-1}, and one softened mode with a shift of ~6 to 9 cm^{-1}. The presence of the pristine mode of C$_{60}$ demonstrates that Al–C$_{60}$ interaction is a localized interface effect. In addition, the shifts of the softened $A_g(2)$ mode depend weakly on the Al/C$_{60}$ ratio and the microstructures of the films. The distinct relative increase in intensity of the $H_g(7)$ and $H_g(8)$ modes compared to $A_g(2)$ mode has also been observed. This result as well as the local effect of Al–C$_{60}$ interaction

suggest that covalent bonding may play a major role in the interaction between Al/C$_{60}$ as that reported by Maxwell et al. [184].

Cu/C$_{60}$ Hebard et al. found that C$_{60}$ covered on the surface of a Cu layer showed a metallic characteristic [863] and a similar result was also observed by STM research on a C$_{60}$ layer covered upon the surface of a Cu substrate [14]. Moreover, it was reported that the cover of C$_{60}$ on a layer of metal can effectively affect the conductivity of metal films [3, 15]. Cu/C$_{60}$ nanodispersion films grown by a co-deposition method were obtained and the structures were observed by TEM [869, 870, 874, 875]. The uniformly granular microstructure and the small clusters or grains in Cu–C$_{60}$ films might form a kind of doped fullerene nanostructure so that electrons could be transferred from metal atoms to the surface layers of C$_{60}$ at the interface [869].

The temperature dependence of the conductivities has been measured *in-situ* [874]. The linear relationship $\ln(\sigma/\sigma_{RT}) \propto (1/T)$ was observed when the temperature was lower than 250 K, and the relation $\ln(\sigma/\sigma_{RT}) \propto (1/T^{1/4})$ was observed for temperatures higher than 260 K. The values of conductivity of these films (typically in the range of 10^{-2}–10^2 S cm^{-1}) are much higher than that of the pristine C$_{60}$ solid (~10^{-7} S cm^{-1}). The conduction of Cu/C$_{60}$ interface compounds is dominated by the electrons hopping between the localized states [874].

A Raman backscattering spectra method was performed on Cu/C$_{60}$ as-grown films [869, 875]. The peak width of the pentagon-pinch mode [$A_g(2)$] becomes wider and the peak position shifts to the lower frequency as the atomic ratio of Cu/C$_{60}$ increases. The vibrational frequencies of the softened modes are about 6 cm^{-1} lower than that of the pristine mode so it can be inferred that about one electron is transferred to C$_{60}$.

Ag/C$_{60}$ Ag/C$_{60}$ nanodispersion films have been prepared by the co-deposition method [866]. Linear relationships of $\ln \sigma$ versus $1/T$ were observed in electrical conductivity measurement from ~200 to ~300 °C and the conductivities are in a range similar to those in Cu/C$_{60}$ films [869]. The shift of the soft $A_g(2)$ mode in Raman spectra indicated that about 1–1.5 electrons are transferred from Ag to C$_{60}$. Moreover, Although the peak positions of the $H_g(7)$ and $H_g(8)$ modes are about the same as that of C$_{60}$, the relative intensities of them increase significantly in the Ag–C$_{60}$ film and

this increase is difficult to interpret with the charge transfer model. A plausible explanation is that Ag atoms may diffuse into the C_{60} lattice to form a limited dilute interstitial solid solution under high temperatures similar to the result observed in the Al–C_{60} system [863]. The conductance of discontinuous granular Ag films covered by C_{60} was measured *in-situ* during C_{60} covering [876]. An anomalous peak of conductivity was observed when the thickness of the C_{60} overlayer was around 1.6 nm. This result indicates that 1–2 monolayer(s) of C_{60} covered upon the granular Ag films are "metallic," which is attributed to the charge transfer between Ag and C_{60} [876].

Charge transfer has also been observed in Ag deposited C_{60} films grown on the Si(111)-(7 × 7) surface by using scanning tunneling microscopy [877]. It is found that for individual Ag atoms and very small Ag clusters, the charge transfer is inhibited or less effective, and there is no chemical bonding between Ag and C_{60}. Only after the Ag atoms aggregated to form Ag clusters larger than a critical size will the charge transfer will become effective. From the lateral size distribution of the Ag/C_{60} clusters, the critical size is concluded to be no more than 4 nm. Furthermore, the results indicate that the growth of the Ag/C_{60} clusters should be limited to sizes smaller than 10 nm. This self-limiting growth process and the critical size effects provide a possible method to control the growth of metal clusters with a narrow distribution size.

4.3.2. Magnetic-Metal/C_{60} Composites

Ni/C_{60} Ni/C_{60} granular films were also prepared by the co-deposition method [878]. High-resolution transmission electron microscopy (HRTEM) results show that Ni nanoparticles are well isolated and embedded in an amorphous C_{60} matrix in the films. Raman spectra indicated that the charge transferred to each C_{60} molecule in an N(Ni):N(C_{60}) = 30 film is ~4 electrons, and that in N(Ni):N(C_{60}) = 1.5 and 6 films are ~2 electrons. The charges transferred from Ni to C_{60} reduce when the Ni nanoparticles become smaller (the average sizes of Ni particles in N(Ni):N(C_{60}) = 1.5, 6, and 30 films are 2.6, 3.3, and 6.6 nm, respectively). This is attributed to the quantum size effects of Ni nanoparticles [878].

Measurements of the surface magneto-optical Kerr effect show that the coercivities (H_C) of Ni/C_{60} films are enhanced significantly. In other words, the critical size of superparamagnetic transition (3.3 nm) is much smaller compared to Ni nanoparticles embedded in graphite (13.6 nm) [879] or SiO$_2$ matrix [880]. It was suggested that the enhancement of H_C may be attributed to surface spin disorder of Ni particles induced by the strong interfacial interaction between Ni and C_{60}.

Fe, Co/C_{60} Unlike the C_{60} based materials we discussed, Fe, Co/C_{60} composite films obtained by adding C_{60} as a minor component into Fe, Co matrix have also been investigated [881]. The concentrations of the as-deposited thin films were expressed in a formula of B$_x$C$_{60}$ (M = Fe, Co). TEM images showed that the grains are extremely uniform in the film. Raman spectroscopy shows that most of the fullerenes are stable in the films and the electronic diffraction shows no

graphite phase; the carbon interfacial phase is mainly composed of fullerenes.

Out-of-plane hysteresis loops for the Co$_{162}$C$_{60}$ films show that both the remanence and the coercivity increase significantly in the films. These values are comparable to the promising perpendicular recording media, Co–Cr and Co–CrTa [882]. These C_{60} comprising media have the potential to achieve ultrahigh storage density because the C_{60} molecules limit grain growth, reside at grain boundaries, and reduce the magnetic coupling between grains which can lower media noise [883].

The in-plane major hysteresis loops and the virgin magnetization curve of the Fe$_{73}$C$_{60}$ film display a fast switching property, which suggests this material had the potential to be used in magnetic memory, magnetic switches, spin valves, magnetic springs, and other magnetic devices. The uniformity of the grains and distribution of C_{60} may contribute to this fast switching ability.

5. LOW-DIMENSIONAL STRUCTURES

5.1. Heterofullerenes

5.1.1. Introduction

Heterofullerenes ("dopeyballs," "heterohedral" fullerenes) are fullerenes in which one or more carbon atoms in the cage structure are substituted by a noncarbon atom (i.e., a heteroatom). In this case, heterofullerene formation is a kind of "on-ball" or "in-cage" doping of the fullerene cage. First spectronscopic evidence for heterofullerenes was observed in gas phase of heterofullerene ions produced by laser vaporization of a graphite pellet containing boron nitride powder [884].

Through modification of the cage structure of heterofullerene, significant modification of geometry, chemical functionality, and electronic character of the fullerenes would occur. So it was anticipated that these heterofullerenes should exhibit a variety of properties and lead to formations of various derivatives due to the in-cage introduction of guest atoms.

5.1.2. $C_{59}N/(C_{59}N)_2$

The aza[60]fullerene $C_{59}N$ is formed by substituting a nitrogen atom for a carbon atom in the C_{60} cage structure. Neutral $C_{59}N$ is an open shell molecule due to the trivalency of nitrogen leaving a "dangling bond" on an adjacent carbon atom in the cage (see Fig. 37a). Aza[60]fullerene in the first oxidized state is sometimes called aza[60]fulleronium, for which one resonance structure is shown in Figure 37b. $C_{59}N$ radical is highly reactive and it easily bonds to form $(C_{59}N)_2$ dimer, the most stable form of azafullerene (see Figure 38), or is hydrogenized to form hydroazafullerene $C_{59}NH$.

Synthesis Up to now, the azafullerenes are the only known heterofullerenes which can be isolated as pure substances.

Nitrogen-doped fullerenes can be synthesized basically by vaporization of graphite in nitrogen containing atmosphere [885, 886] or by laser ablation of fullerene derivatives which possess organic ligands bound to the carbon cage through
Figure 37. Important resonance structures of (a) aza[60]fullerene radical and (b) aza[60]fulleronium.

a nitrogen atom [887], or by condensed-phase organic synthesis. But the latter which yields aza[60]fullerene dimer is proved to be the only efficient method leading to the isolation of macroscopic quantities of azafullerenes so far. There are two different methods succeeding organic synthesis.

In 1995 it was found to occur by the effective formation of azafulleronium C59N$^+$ in the gas phase during fast atom bombardment mass spectrometry of a cluster opened *N*-methoxyethoxy methyl ketolactam, so Hummelen et al. applied this process in solution in the presence of strong acid and isolated $C_{59}N$ as its dimer $(C_{59}N)_2$ [888]. In 1996, Grösser et al. succeeded in converting a bisazahomofullerene [889] to the aza[60]fullerene dimer $(C_{59}N)_2$ in a different way [890]. By both these methods high-purity $(C_{59}N)_2$ samples can be obtained after high performance liquid chromatography (HPLC) purification.

Properties

Structure Properties It was found that the C_{59} dimer is formed by linking two cages in a *trans*-configuration by one single bond to minimize the repulsion of the nitrogen atoms and to optimize the whole structure (see Fig. 38). The link is made by the two carbon atoms (C, C′) each of which joins two hexagons together with the N atom in a $C_{59}N$ molecule. The molecule has C_{2h} symmetry. The C–C′ dimer bond was calculated to be 1.609 Å, (i.e., 0.05 Å longer than that between two average sp^3 cabon atoms) [891]. The binding energy was calculated to be ~18 kcal mol^{-1} [891].

The bonding energy is relatively low and the dimer can be cleaved both thermally and photochemically into two $C_{59}N^{\bullet}$ radicals [892]. Light-induced ESR measurement of a solution of $(C_{59}N)_2$ in 1-chloronaphthalene, using 532 nm laser pulses, yielded a spectrum with three equidistant lines of equal intensity, indicative of ^{14}N hyperfine interaction [893]. The hyperfine coupling constant is 3.73 G. The reported values for the g factor of $C_{59}N^{\bullet}$ are 2.0011(1) and 2.0013(2), higher than that of C_{60} radical anion, 1.9991 [894]. This
unusually low g value of $C_{60}^{\bullet -}$ can be explained in terms of Jahn–Teller distortion that splits the triply degenerate t_{1u} states, thus leading to quenching of angular momentum.

Electronic Properties Based upon the extended SSH model for $C_{59}N$, the calculated results are very consistent with those from the SCF-MO method. The lattice structure of $C_{59}N$ is different from that of pure C_{60} due to effects of the dopant ion, but the deformations of the substituted fullerene cage for the $C_{59}N$ are mainly limited in the vicinity of the dopant ions [895]. As one electron is doped into the LUMO of C_{60} in $C_{59}N$, it was changed so significantly that the energy level near the Fermi level and the corresponding smaller bandgap between HOMO and LUMO was about 0.3 eV [895, 896]. The calculated gap was much smaller than that for C_{60}. The HOMO states are mainly localized on the N–C double bonds and the excessive electron density is concentrated on the impurity sites. The excessive electron density of the N atom is 0.27, which implies that electronic charge accumulates on the doped N site and the N atom exists as an acceptor [895].

The electronic properties of $(C_{59}N)_2$ in thin films have been studied by using PES and EELS [897, 898]. It was found that the HOMO of $(C_{59}N)_2$ is located mainly on N atoms and the intermolecular C–C′ bond. In contrast, the LUMO has mainly a C-character. The optical gap of the dimer is ~1.4 eV, some 0.4 eV smaller than that of C_{60} (1.7–1.8 eV). It was obtained from the energy-loss functions that the static dielectric constant $\varepsilon_1(0)$ of $(C_{59}N)_2$ is about 5.6, which is larger than that of C_{60} [$\varepsilon_1(0) \sim 4$], reflecting the smaller energy gap of the heterofullerene dimer.

Properties of $(C_{59}N)_2$ Solid Solid structural investigation of $(C_{59}N)_2$ using X-ray powder diffraction techniques showed that samples of $(C_{59}N)_2$ obtained by recrystallization from CS_2 exhibit a hexagonal structure (space group $P6_3/mmc$ or a subgroup). The hexagonal phase remains stable under hydrostatic compression to 22 GPa, signifying it is somewhat less compressible than pristine C_{60} [899]. The diffraction patterns point to a CS_2 content of about 1/2 molecule per formula unit. The CS_2 can be removed by sublimation of the material *in vacuo* at temperatures of 500–600 °C. This leads to a monoclinic structure with the space group of at most probably $C2/m$, where the $C_{59}N$ dimers sit on the sites of a monoclinic c-centered Bravais lattice with lattice parameters $a = 17.25$ Å, $b = 9.96$ Å, $c = 19.45$ Å, and $\beta = 124.32°$, $T = 295$ K [900]. $(C_{59}N)_2$ are observed to be unstable at temperatures higher than 200 °C in UHV.

5.1.3. Other Heterofullerenes

Borafullerenes Borafullerenes were the first reported heterofullerenes observed in 1991 [884]. In 1996, the macroscopic preparation of borafullerenes was realized by using the arc-evaporation method on graphite rods doped with either boron nitride, boron carbide, or boron [901]. Extraction and enrichment were used for the heterofullerene content of the soot, involving pyridine extraction and subsequent treatments of the extract with CS_2 and pyridine. XPS spectra of the extract showed a peak at 188.8 eV that was assigned to boron (1s level) in borafullerene ($C_{59}B$ mainly). The extracted materials appeared to be moisture sensitive, leading to the formation of boron oxide or boric acid [901].

Figure 38. Schematic 3D structure for a $(C_{59}N)_2$ molecule.

There is another method to synthesize borafullerene by high-temperature laser ablation of a B_4C-graphite composite rod under an argon atmosphere. The product was analyzed with a laser desorption/ionization mass spectrometer, revealing that $C_{59}B$ ($m/z = 719$) was formed together with the C_{60} molecule [902].

Azafullerenes with Multinitrogen Atoms The synthesis of $C_{58}N_2$ is possibly complicated if the formations of the two N sites are not simultaneous, which may cause an open shell intermediate as found in the synthesis of $(C_{59}N)_2$, giving rise to an undesired reaction route. Synthetic route toward $C_{58}N_2$ starting from C_{60} [903] has been proposed; recently, (1,3,5)pyridinophanes having [4.3.2]propellatriene units were synthesized as precursors to macrocyclic polyyne $C_{58}H_4N_2$ and diazafullerene anion $C_{58}N_2^-$ was detected in the laser desorption mass spectrum of the pyridinophanes [904].

A new fullerene-like material, consisting of cross-linked nano-onions of C and N, was reported [905]. Growth of the onion shells takes place atom by atom on a substrate surface and yields thin solid films during magnetron sputter deposition. The N content in the onions, up to 20%, is the highest measured for an azafullerene in the solid phase. Total energy calculations of $C_{60-2n}N_{2n}$ molecules suggest the existence of a novel $C_{48}N_{12}$ molecule.

Azaborafullerenes Recently, it was reported that $C_{58}BN$ can be produced by a BN substitution reaction of fullerene C_{60} upon irradiation by a KrF excimer laser at room temperature [906] and isolated by HPLC. Mass spectra and X-ray photoelectron spectroscopy analysis confirmed the substituted formation of $C_{58}BN$ ($m/z = 721$).

Heterofullerenes with Heteroatoms Other than N, B Early theoretical calculation of Si in-cage doped heterofullerenes ($C_{59}Si$, 1,2-, 1,6-, and 1,60-$C_{58}Si_2$) predicted that these structures are stable and show a steady decrease of the bandgaps with an increasing number of Si atoms [907]. First evidence for the possible existence of silicon heterofullerenes is provided by analyzing the products from pulsed-laser vaporization of silicon–carbon composite rods by time-of-flight mass spectrometry (TOF-MS) [908], which showed small peaks that would match the masses of SiC_n^+ clusters ($61 \geq n \geq 56$). Recently, silicon heterofullerenes have been synthesized in a laser vaporization source from targets processed as mixtures of graphite and silicon powders [909] or Si_xC_{1-x} mixed composition targets [910, 911]. Another method to generate silicon in-cage doped fullerenes is laser-induced photofragmentation of parent clusters of composition $C_{60}Si_x$ which are produced in a low pressure condensation cell, through the mixing of silicon vapor with a vapor containing C_{60} molecules [912]. It was indicated from the analysis of photofragmentation mass spectra that at least three Si atoms can be incorporated in fullerenes, the Si atoms are located close to each other in fullerenes, and Si doping was also predicted to increase the fullerene chemical reactivity [911]. *Ab initio* calculation of optimized geometrical structures of $C_{59}Si$ and $C_{58}Si_2$ isomers showed that the geometrical modifications of the heterofullerenes occur in the vicinity of the Si dopant atom [913].

In the case of oxygen, there is some possible evidence for the existence of O heterofullerenes in the form of $C_{59}O^+$ ions in gas-phase experiments [914] or $C_{59}O^{-1}$ anions produced via collision-induced dissociation of oxy-fullerene anions $C_{60}O_{2-4}^-$ [915].

Evidence for the existence of $C_{59}P$ has been identified in mass spectroscopy. The formation of these heterofullerenes was achieved by evaporating phosphorus and carbon simultaneously but at different positions in a radio frequency furnace (i.e., at different temperatures) [916].

Existence of substitutionally doped fullerenes $C_{59}M$ has also been identified by mass-spectrometric evidence, where M represents the atom of the transition metals such as Fe, Co, Ni, Rh, and Ir. These in-cage doped fullerenes were produced by the photofragmentation of precursor metal–fullerene clusters $C_{60}M_x$ [917]

5.2. C_{120} (C_{60} Dimer)

Since the discovery of the photopolymerization of C_{60} via [2+2] cycloaddition [534, 807], there have been a lot of theoretical studies [918–924] on the smallest subunit of a C_{60} polymer: C_{120} (C_{60} dimer), a dumb-bell-shaped all-carbon molecule polymerized from two individual C_{60} molecules (see Fig. 39). The most stable isomer of C_{120} is confirmed to be polymerized via the same [2+2] cycloaddition mechanism of C_{60} polymers (i.e., the double intramolecular bonds broken and a four-atom ring formed by covalent C–C bonds, accompanied with rehybridizations from sp^2 to sp^3).

5.2.1. Synthesis

C_{120} can be synthesized by many methods, such as photopolymerization [534, 808], solid-state mechanochemical reaction [925–927], quasihydrostatic compression of C_{60} [928], and squeezing of a C_{60} compound [929].

The photopolymerization method gave the first evidence for the existences of C_{60} dimer and polymer [534, 808]. It was observed that solid C_{60} exposed to visible or ultraviolet light forms a polymerized phase which is no longer soluble in toluene.

The solid state mechanochemical reaction of C_{60} with KCN by the use of a high-speed vibration milling (HSVM) technique is the first efficient method to synthesize bulk C_{120} [925, 926]. In a standard procedure, a mixture of C_{60} and 20 molar equivalents is placed in a capsule and vigorously vibrated under HSVM conditions for 30 min in a glovebox filled with nitrogen. Separation of the reaction mixture by flash chromatography on silica gel, eluted with hexane/toluene and then with toluene/o-dichlorobenzene (ODCB), gives 70% of recovered C_{60} and 18% of C_{120} [925, 926]. It was found that this reaction can take place efficiently also by the use of potassium salts such as K_2CO_3

Figure 39. Schematic 3D structure for a C_{120} (C_{60} dimer) molecule.

and CH$_3$CO$_2$K which contain nucleophilic anions, metals such as Li, Na, K, Mg, Al, and Zn (while Ni and Cu are not effective), and organic bases such as 4-(dimethylamino)- and 4-aminopyridine [925, 927]. Single crystals of C$_{120}$ can grown in an ODCB solution since it is hardly soluble in most common organic solvents but has a reasonable solubility in ODCB [925, 926].

The quasihydrostatic compression method for the dimerization of C$_{60}$ is achieved under a high-pressure, high-temperature treatment [928, 930, 931]. It was shown that the dimerization occurs even at room temperature in the entire pressure range above ~1.0 GPa. However, the formation of a dimer phase as a stable modification is at least at temperatures above 400 K. No condition was found that may yield pure C$_{60}$ dimers so far. A typical condition with the pressure, temperature, and treatment time of 1.5 GPa, 423 K, and 1000 s yields about 80% C$_{60}$ dimers [930].

Squeezing of a C$_{60}$ compound was reported to be a high yield selective synthesis method of C$_{60}$ dimers [929]. Squeezing the organic molecular compound crystal (ET)$_2$C$_{60}$ [ET = bis(ethylenedithio)tetrathiafulvalene] at 5 GPa and 200 °C followed by removing unreacted ET molecules by sonication in CH$_2$Cl$_2$ produces C$_{60}$ dimers, with a yield of about 80%. Most of the product is soluble in *o*-dichlorobenzene, while there remains a small amount of insoluble material, which may be one-dimensional oligomers or ladder polymers.

5.2.2. Structure

The isolated C$_{120}$ forms a dark brown powder. The ^{13}C NMR spectrum exhibited 15 signals (including one overlapped signal) in the sp^2 region and one signal at 76.22 ppm in the sp^3 region, which are fully consistent with the assigned structure with D_{2h} symmetry [925]. It was also indicated that C$_{120}$ is indeed the essential subunit of these polymers by comparing the data with the ^{13}C NMR spectra of C$_{60}$ polymers.

The single crystal structure was determined by X-ray crystallography; it was found that there is no obvious difference in the length of the four bonds in the [2 + 2] cycloaddition four-atom ring. The intracage bond length was determined to be 1.575(7) Å, and intercage bond length was found to be 1.581(7) Å [925]. In single crystals grown in an ODCB solution, the C$_{120}$ molecules are arrayed in highly order layers, which is different from the face-centered cubic structure of C$_{60}$ [925].

5.2.3. Electronic Structure

The lowered symmetry of the C$_{120}$ as a consequence of dimerization molecule will result in an increased splitting of energy levels and a narrowing of the optical bandgap [920]. The presence of sp^3 intermolecular bonds and the caused distortion of the C$_{120}$ molecule also change its electronic structure.

The electronic DOS confirms universal expectations about the electronic and vibrational energy levels. Due to the dimerization of C$_{60}$, the LUMO t_{1u} states split into a quasi-doublet and singlet state but the HOMO h_u state mixes strongly with the lower g_g and h_g levels leading to a generally broader DOS [932].

5.2.4. Properties

Far-infrared vibrational property investigation of the C$_{60}$ dimer showed that all the modes are nondegenerate. $H_g(1)$-derived modes are allowed in the dimer and appear as a weak quadruplet near 250 cm^{-1} [933]. The number of $T_{3u}(1)$-derived modes is three, in agreement with group-theory predictions for the D_{2h} symmetry of the dimer.

In room-temperature solution, a systematic study of the photophysical properties and nonlinear absorptive optical limiting responses of the C$_{60}$ dimer was given [934]. It was found that the absorption, fluorescence (spectrum, quantum yield, lifetime), and photoinduced electron-transfer properties of the C$_{60}$ dimer are somewhat different from those of C$_{60}$ but qualitatively similar to those of other C$_{60}$ derivatives, indicating that the dimer may be considered as a pair of 1,2-functionalized C$_{60}$ derivatives. The triplet–triplet absorption of the C$_{60}$ dimer is noticeably weaker than those of C$_{60}$ and other C$_{60}$ derivatives, corresponding to lower optical limiting responses of the C$_{60}$ dimer at 532 nm. It was also concluded that the C$_{60}$ dimer is photochemically stable since there is no meaningful change in both absorption and fluorescence spectra of the dimer solution after 10 h of continuous photoirradiation.

The thermal behavior of the C$_{60}$ dimer was investigated in the range 80–220 °C at a rate of 1 °C min^{-1} using differential scanning calorimetry [925]. An endothermic peak from 150 to 175 °C and centered at 162 °C was found in the heating process, while no such peak was observed in the cooling scan. It was also found that the C$_{60}$ dimer could dissociate quantitatively into C$_{60}$ by heating its ODCB solution at 175 °C for 15 min. C$_{120}$ should have equal chemical reactivity to C$_{60}$ considering their close reduction potentials.

5.3. Endohedral C$_{60}$

Endohedral fullerenes are novel forms of fullerene-based materials in which the fullerenes are encapsulated by atom(s) (even some small molecules) in their inner hollow space (see Fig. 40). These new fullerene derivatives are usually described using the symbol "@" conventionally and conveniently with the encaged atom(s) listed to the left of the "@" symbol. For example, a C$_{60}$-encaged metal species (M) is written as M@C$_{60}$ [935]. In recent years endohedral fullerenes have attracted a lot of interest due to their fascinating properties and novel electronic structures.

Figure 40. Schematic 3D structure for an endohedral fullerene molecule.

5.3.1. M@C$_{60}$, M = Metal

The first evidence for endohedral metallofullerenes based on C$_{60}$ (M@C$_{60}$) was proposed from a magic number due to LaC$_{60}$ in a mass spectrum prepared by laser vaporization of a LaCl$_2$-impregnated graphite rod [936]. Further evidence showing that the La C$_{60}^+$ ions did not react with H$_2$, O$_2$, No, and NH$_3$ confirmed that the active metal atoms are indeed encapsulated inside the C$_{60}$ cage [937].

Original soot containing M@C$_{60}$ (M = Y, Ba, La, Ce, Pr, Nd, Gd, Er, Eu, and Dy) is usually produced by arc-discharge-heating of an M$_x$O$_y$/graphite (M$_x$O$_y$ = Y$_2$O$_3$, BaO, La$_2$O$_3$, CeO$_2$, Pr$_6$O$_{11}$, Nd$_2$O$_3$, Gd$_2$O$_3$, Er, and Eu$_2$O$_3$) composite rod under a 50–100 Torr He atmosphere [938–941]. But the extraction of M@C$_{60}$ from the soot is difficult because of almost all known M@C$_{60}$ so far showing high reactivity and they are insoluble and unstable in normal fullerene solvents such as toluene and carbon disulfide (CS$_2$). Ca@C$_{60}$ has been extracted by pyridine or aniline [942], M@C$_{60}$ (M = Y, Ba, La, Ce, Pr, Nd, Gd, and Sr) can be extracted by aniline [943], and Li@C$_{60}$ prepared by an ion implantation technique can be extracted by CS$_2$ [942, 943].

Pure samples of Eu@C$_{60}$, Er@C$_{60}$, and Dy@C$_{60}$ have obtained by combining sublimation and HPLC with aniline as an eluent [939–941]. The X-ray-absorption near edge structure spectrum showed that the valence of Eu atom in Eu@C$_{60}$ was +2 [939], while the Raman spectrum indicated that the valence of Dy atom in Dy@C$_{60}$ is +3 [941] with 3 electrons transferring from the Dy atom to the C$_{60}$ cage. It has also been indicated that the Dy in Dy@C$_{60}$ is located at an off-center position 1.25–1.30 Å from the center of the C$_{60}$ cage, and the UV-visible–IR spectrum suggested that the HOMO–LUMO gaps of Dy@C$_{60}$, Er@C$_{60}$, and Eu@C$_{60}$ molecules are small [939–941].

5.3.2. R@C$_{60}$, R = N, P

Endohedrals of group-V elements N@C$_{60}$ and P@C$_{60}$ can be prepared by an ion implantation method [944, 945]. The C$_{60}$ fullerene is continuously evaporated onto a substrate and simultaneously bombarded with low-energy (40 eV) nitrogen or phosphorous ions. The resulting film is subsequently scratched from the substrate and dissolved in toluene and filtered. The soluble part contains only intact fullerenes, with the ratio of encapsulated to empty fullerenes typically on the order of 10^{-4}. HPLC techniques are used to obtain pure endohedral fullerenes. These two systems are soluble in organic solvents and stable at room temperature while As@C$_{60}$ is calculated to be unstable [946]. Experimentally, ESR studies [944, 945, 947–950] revealed that the encapsulated nitrogen and phosphorus are located at the center of the cage, the N or P atom is in quartet electronic spin ground state $S = 3/2(^4S_{3/2})$, and the highly reactive ^4S spin states of N and P do not interact with the C$_{60}$ cage. The fact of well-isolated electron spin of group-V atoms encapsulated in fullerenes and the easy positioning of endohedral C$_{60}$ offer a very flexible possible implementation of quantum-information bits for a promising spin quantum computer [951].

5.3.3. X@C$_{60}$, X = Noble Gases

Noble gas atoms can also be trapped in C$_{60}$ cages. In fact, the C$_{60}$ molecule cage is large enough to enclose all of the noble gases including helium, neon (Ne), argon (Ar), krypton (Kr), and xenon (Xe) [952, 953].

The noble-gas endohedral fullerenes are usually prepared by treating the fullerene with the gas under high temperature and pressure [952, 953]. Treatment at ∼650 °C and ∼3000 atm yields a C$_{60}$/X@C$_{60}$ (X = He, Ne, Ar, Kr, Xe) mixture with the ratio of encapsulated to empty fullerenes only on the order of 10^{-3}. Recently, remarkable enrichment of Ar@C$_{60}$ (with a purity of 40%) [954], Xe@C$_{60}$ (with a purity of 31%) [955], and Kr@C$_{60}$ samples [956] with a purity as high as 90% has been realized by HPLC using a semipreparative PYE[2-(1-pyrenyl)ethylsilyl] column (10 × 250 mm) with toluene as the eluent [957].

The fact that noble gases with smaller masses do not interact significantly [952, 953] (the interaction is suggested to be van der Waals force mainly) with the inner parts of π-orbitals of the C$_{60}$ cage implies that the chemical and physical properties of these compounds will not differ much from those of empty C$_{60}$ molecules. But ^{129}Xe NMR spectroscopy study shows that in the case of Xe, the $5p$ electrons of the Xe are much closer to and interact much more strongly with the π-electrons of the C$_{60}$ [955].

5.4. C$_{60}$M$_n$

The exohedral metal complexes of C$_{60}$, usually written as C$_{60}$M$_n$, where M is the metal species, can be categorized as the third type of C$_{60}$ complex compared to the hetero- and endohedral fullerenes (see Fig. 41). The study of gas phase C$_{60}$M$_n$ compounds has been stimulated by the discovery of the superconductivity of alkali doped fullerites. C$_{60}$M$_n$ complexes are suitable model systems for studying the electronic properties of nanostructures and understanding the fundamental interactions between two nanosystems, particularly metal–covalent interfaces.

5.4.1. Alkali Metals and Alkaline Earth Metals

In a pioneering experimental work, Wang and co-workers first studied the photoelectron spectra of C$_{60}$K$_n^-$ clusters, $n = 0$–3, and they found evidence for charge transfer from the alkali atoms to the C$_{60}$ molecules [958]. The electron affinities of the species were found to have a linear relationship

Figure 41. Schematic 3D structures for two types of exohedral metal–fullerene clusters (C$_{60}$M$_n$). (a) A "wet" structure where metal atoms spread over the fullerene cage. Here a C$_{60}$M$_{12}$ molecule with one metal atom on each 12 pentagon facet. (b) A "dry" structure where metal atoms form an adsorbed droplet on C$_{60}$.

with the number of K atoms. This indicated that C$_{60}$K$_n$ are quite ionic because each K atom donates its outer 4s electron to the t_{1u} LUMO of C$_{60}$. A dipole-supported state is found in KC$_{60}^-$, yielding an inter-K-C$_{60}$ stretching vibration of 140 cm^{-1}.

Zimmermann et al. have given a systematic study on alkali metal–fullerene clusters by using photoionization time-of-flight mass spectrometry [959]. The C$_{60}$M$_n$ clusters were produced by coevaporation of fullerenes and metal in a gas aggregation cell. It was suggested that the stability of the alkali metal–fullerene clusters seems to be determined primarily by the electronic rather than the geometric configuration. The C$_{60}$M$_6$ clusters are found to be particularly stable formations for any alkali metal. Coating a fullerene with more than seven alkali metal atoms led to an even–odd alternation in the mass spectra, which signals the beginning of metal–metal bonding [959]. But C$_{60}$Li$_{12}$ was found to be an exception to the electronically determined cluster stability. It retains the iscosahedral symmetry of the C$_{60}$ molecule because each Li atom was found to be stable when above one of the pentagonal faces. C$_{60}$Li$_{12}$ is very stable both in the singly and the doubly ionized state. The origin of the enhanced stability might be interpreted to be of geometric origin [959, 960]. Alkaline earth metal covered fullerenes C$_{60}$M$_n$ ($n = 0$–500; M = Ca, Sr, Ba) were also studied in these works [959, 961]. It was suggested that these clusters are formed by the completion of metal layers around a central C$_{60}$ molecule; the first layer is complete when one metal atom is situated above each of the 32 facets of the C$_{60}$ cage.

Recently, the electronic and geometric properties of C$_{60}$Na$_n^-$ and C$_{60}$Au$_n^-$ cluster anions were investigated by TOF-MS and PES [962]. The C$_{60}$–Na and C$_{60}$–Au clusters were produced in a double-rod laser vaporization source. Both the adiabatic electron affinity and the vertical detachment energy, extracted form the PES spectra, exhibit even–odd alteration with the successive addition of Au atoms on C$_{60}$. So odd-n species have high relative stability. C$_{60}$Au$_n$ takes a "dry" structure where Au atoms aggregate as a cluster (see Fig. 41a). In contrast, C$_{60}$Na$_n$ adopts the direct binding of the Na atoms into stable trimers, each sodium atom lying above a pentagonal ring; thus C$_{60}$Na$_n$ takes a "wet" structure where the Na atoms spread over the fullerene cage (see Fig. 41b). For C$_{60}$Na$_n$ clusters, strong periodical oscillations are observed with a high cluster stability at smaller sizes ($n = 3, 6, 9$, and 12). When $n > 12$, the sodium atoms begin to exhibit a metallic layer behavior considering the much smoother adiabatic electron affinity (AEA) and vertical detachment energy (VDE) variations [963]. Additional PES experiments, performed with a 5.83 eV photodetachment energy, have shown that for $n = 1$ to 3 the charge transfer from the valence orbital of the Na atoms to the fullerene LUMO is approximately complete, whereas at $n = 4$ this charge transfer is only partial. This result not only points out the specificity of Na compared with the larger alkali elements but also suggests a full rearrangement of the cluster geometric configuration at the intermediate sizes.

In contrast to the previous work, another individual study based on the measurement of the polarizability and dipole of isolated C$_{60}$Na$_n$ ($n = 1$–34) molecules in a static electric field showed the existence of a permanent electric dipole for every size with increasing n from 1 to 34; these results

cannot be explained by a metal shell around the C$_{60}$ with a regular distribution but are in agreement with a sodium cluster bound to the C$_{60}$ molecule (i.e., a sodium droplet on C$_{60}$) [964]. For clusters with more than one sodium atom ($n > 2$), it was suggested that there is a strong decrease in ionization potential as the sodium cluster size increases, and a full electron transfer from sodium atoms to the C$_{60}$ molecule is expected.

The electric dipole moment of isolated single-alkali-atom-C$_{60}$ molecules (C$_{60}$Li, C$_{60}$Na, C$_{60}$K, C$_{60}$Rb, and C$_{60}$Cs) has been measured by molecular beam deflection experiments [965]. It was shown that the dipole increases from 12.4 D for C$_{60}$Li to 21.5 D for C$_{60}$Cs. These results indicated a strong electron transfer from the alkali atom to the C$_{60}$ cage, which is partial for Na and almost complete for K and Cs. It was also found that the C$_{60}$K molecules have a giant polarizability at room temperature, equal to 2506 ± 250 Å^3, but no permanent dipole by using the molecular beam deflection technique [966]. The addition of a potassium atom enhances by more than a factor of 20 the polarizability of a pure C$_{60}$ molecule. This giant polarizability is caused by the free skating of the K atom on the C$_{60}$ surface. C$_{60}$K behaves like a paraelectric system with an electric dipole of 17.7 ± 0.9 D.

5.4.2. Transition Metals

In the case of transition metals, the compound clusters C$_{60}$M$_x$ ($x = 0, \ldots, 150$; M = Ti, Zr, V, Y, Ta, Nb, Fe, Co, Ni, Rh) have been produced using modified laser vaporization of a transition metal target in a low-pressure inert gas condensation cell [917, 967, 968]. It was found that the metals form complete layers around the central fullerene molecule (i.e., forming transition metal coated fullerenes). Mass spectrometric studies on these free metal–fullerene clusters showed that upon heating with a intensive laser pulse, these metal–fullerene clusters transform into metal carbides (M = V, Ti) and bulklike metallo-carbohedrene clusters (M = Nb, Ta where $x < 2$) [967]. Photofragmentation mass spectra of metal–fullerene clusters C$_{60}$M$_x$ (M = Fe, Co, Ni, Rh; $x = 0, \ldots, 30$) reveal the existence of a reaction channel which yields clusters having the composition of metal in-cage doped heterofullerenes C$_{59-2n}$M ($n = 0, \ldots, 10$) [917]. Additional tandem TOF experiments on mass selected C$_{59}$M indicated that the initial fragmentation step of this new kind of substitutionally doped fullerene is the loss of a neutral MC molecule [917]. Recently, evidence for the existence of C$_{60}$M$_x$ (M = Sm, Pt) has also been observed in photofragmentation study by excimer laser ablation-TOF mass spectrometry [969].

5.5. C$_{60}$@Carbon Nanotubes

C$_{60}$ can be encapsulated into carbon nanotubes in the form of self-assembled one-dimensional chains and form a new type of self-assembled hybrid structure called "bucky-peapods" (see Fig. 42). The novel structure may give potential applications in data storage [970] and promising high-temperature superconductors [971].

Pulsed laser vaporization of graphite with certain metallic catalysts can produce both carbon nanotubes and C$_{60}$ molecules [972]. To obtain nanotube production, most of
Figure 42. Schematic 3D view for C$_{60}$@carbon nanotubes.

the C$_{60}$ is removed by purification and annealing. Nevertheless, HRTEM observation showed that C$_{60}$ encapsulated in single-wall cabon nanotubes (SWCNTs), usually written as C$_{60}$@SWCNTs, can also be obtained via the same method. The encapsulated fullerenes can coalesce into longer capsules under the action of the electron beam [973] or under a high temperature treatment [974, 975].

The encapsulated C$_{60}$ molecules are positioned in a way that a preferred van der Waals separation (0.3 nm) was maintained between the cages and the nanotubes. The presence or absence of encapsulated cages was strongly correlated with the tubes' diameters, mostly observed to be 1.3–1.4 nm [976]. In a row of encapsulated C$_{60}$ molecules concentric with a tube axis, the center-to-center distance between two C$_{60}$ molecules was observed to be 1.0 nm [973], whereas for paired C$_{60}$ molecules, this distance was 0.9 nm [976]. In another study using electron diffraction, it was found that the intermolecular spacing of adjacent fullerenes in SWNTs is 0.97 nm, smaller than that of the three-dimensional bulk C$_{60}$ crystal but larger than that of polymerized C$_{60}$ crystal [977].

Yields of almost 100% C$_{60}$@SWCNTs have been obtained by heating SWCNTs in dry air for 50 hours at 400 °C [978]. Another individual work which yielded ∼90% C$_{60}$@SWCNTs in abundance by a vapor phase method was confirmed by HRTEM observation indicating a simple lattice of 1.0 nm of the encapsulated one-dimensional C$_{60}$ molecules [979]. Both experimental results based on HRTEM observation [974] and theoretical results using molecular dynamical calculation [980] suggested an optimum temperature range from 350 to 450 °C and that the filling mechanism is most likely through the defect on the surface of SWCNTs but not through the ends of them.

EELS experiments study on C$_{60}$@SWCNTs showed that the electronic and optical properties of the encapsulated C$_{60}$ molecules are very similar to fcc C$_{60}$ with only small changes suggesting a weak van der Waals interaction between the SWCNTs and the C$_{60}$ molecules [981].

Refined measurements of electrical resistivity, thermopower, and thermal conductivity of highly C$_{60}$-filled SWCNTs and unfilled controls from 1.5 to 300 K have been performed recently [982]. It was shown that additional conductive paths form via the filling of interior C$_{60}$ chains, which can effectively bridge defects on the tube walls, reduce the electrical resistivity, and also reduce the effects of charge carrier localization at low temperature [982]. It can also be indicated from the measurements that the filling of C$_{60}$ also increases the photon scattering, enhances the thermal conductivity in some sense, and effectively prevents other molecules (such as oxygen molecules) from doping into SWCNTs [982]. Another direct-current electric resistance measurement carried out by the four-probe method using the matlike films of C$_{60}$@SWCNTs showed somewhat different results in that, for the temperature range $5 < T < 300$ K, the resistances in logarithmic scale exhibit linear temperature dependence when the abscissa is represented by $T^{-1/4}$, suggesting an electron transport associated with three-dimensional VRH [978]. Hongo et al. measured the transport properties and their temperature dependences of C$_{60}$@SWCNTs bundles on a membrane structure consisting of a 50–100 nm thick silicon nitride on a Si wafer and Pt/Ti(30/30 nm) gap electrodes [983]. Their results showing high resistances of the peapod bundles, with two kinds of temperature dependence characters: one exhibits linear temperature dependence with respect to $T^{-1/4}$; the resistance increases as temperature decreases, which agrees with the VRH aforementioned mechanism. The other shows resistance saturation at low temperature, which suggested the existence of weak localization or disorder [984].

A variety of fullerenes were found to exist inside SWCNTs, including C$_{60}$ molecules and 0.7 nm diameter fullerene capsules of various lengths [976]. Many of the hybrid structures spontaneously jump during observation. Under the present experimental conditions, chains containing 2–5 C$_{60}$ melecules are most often seen to jump and each jump is typically 1–10 nm. This dynamic behavior could be driven by beam–specimen interactions.

5.6. (C$_{60}$)$_n$

In a (C$_{60}$)$_n$ cluster, C$_{60}$ molecules interact with each other by weak van der Waals forces. Because the interaction has a very short range, investigations of C$_{60}$ clusters are focused on structure behavior. Experimental studies of fullerene clusters indicate they probably have icosahedral structure, similar to inert gas clusters [985]. Systematic optimization of the lowest energy structures of the (C$_{60}$)$_n$ ($n \leq 57$) clusters has been carried out with a genetic algorithm and database conjugate-gradient method [986]. These structures show transitions at $n = 17$ from icosahedral to decahedral and at $n = 38$ from decahedral to fcc. The second energy difference curve indicates that $n = 13, 38, 55$ (C$_{60}$)$_n$ clusters are especially stable. However, taking account of the thermal effect, the icosahedral structure instead of decahedral and close-packed ones is the most stable structure when the cluster is cooled from a high-temperature state by a molecular dynamics simulation.

$$k = C v_s \lambda/3 \tag{15}$$

$$\rho v_T^2 = C_{44} \tag{16}$$

$$\rho v_T^2 = (C_{11} - C_{12} + C_{44})/3 \tag{17}$$

$$\rho v_L^2 = C_{11} \tag{18}$$

$$K = (C_{11} + 2C_{12})/3 \tag{19}$$

$$G = [(C_{11} - C_{12})/2C_{44}]^{2/5} \tag{20}$$

$$H_{c1}(T)/H_{c1}(0) = 1 - (T/T_c)^2 \tag{21}$$

$$J_c = A(M_+ - M_-)/R \tag{22}$$

$$J_c \sim J_c(0)[1 - (T/T_c)^2]^n \tag{23}$$

$$\rho = 0.07[\exp(1/T)^{1/4} - 1] \tag{24}$$

GLOSSARY

Buckminsterfullerene Or buckyball, C$_{60}$, hollow cage carbon molecule consisting 60 carbon atoms named for R. Buckminster Fuller because of the resemblance of its molecular structure to his geodesic domes. Buckminsterfullerene (C$_{60}$) was originally detected in soot in 1985; isolation was first reported in 1990.

C$_{120}$ Also called C$_{60}$ dimer. A dumb-bell-shaped all-carbon molecule consisting of two C$_{60}$ molecules connected by two single C–C bonds via cycloaddition.

Endohedral C$_{60}$ Novel C$_{60}$-based complex in which the fullerene molecule (C$_{60}$) is encapsulated by atom(s) or some small molecules in the inner hollow space of its carbon cage. These kinds of molecules are usually written as M@C$_{60}$; M is the endohedral species.

Exohedral C$_{60}$ Novel C$_{60}$-based complex in which the fullerene molecule (C$_{60}$) is adsorbed by exohedral atoms (usually metal atoms, including alkali metals, alkaline earth metals, and transition metals), forming gas-phase stable compounds.

Fullerene superconductivity Some kinds of metal doped C$_{60}$ compounds have superconductivity. The M$_3$C$_{60}$ (M = alkali metal) system is the most widely studied of them. The highest T_c found in M$_3$C$_{60}$ is about 30 K (Rb$_3$C$_{60}$). It is widely believed that M$_3$C$_{60}$ are s-wave BCS-like superconductors, driven by the coupling to the intramolecular H_g phonons and probably with some strong-coupling effects.

Fullerene Any of a class of carbon molecules in which the carbon atoms are arranged into 12 pentagonal faces and 2 or more hexagonal faces to form a hollow sphere, cylinder, or similar figure. The smallest possible fullerene molecule may have as few as 32 atoms of carbon, and fullerene-like molecules as few as 20 carbon atoms. The most common and stable fullerene is buckminsterfullerene (C$_{60}$).

Fullerite Solid state form of fullerene; usually means solid state C$_{60}$. It usually forms black powders or black–brownish crystals.

Heterofullerene Fullerenes in which one or more carbon atoms in the carbon cage structure is substituted by a noncarbon atom (heteroatom), also called "dopeyballs" or heterohedral fullerene, including borafullerenes (C$_{59}$B, ...), azafullerenes (C$_{59}$N, C$_{58}$N$_2$, C$_{69}$N, ...), and heterofullerenes with heteroatoms other than N, B.

Metal doped C$_{60}$ compound Or metal doped fullerite. A kind of material formed by intercalating metal atom into the interstitial sites of C$_{60}$ host lattice. The metal usually used includes alkali metal, alkaline earth metal, and some lanthanide metals. Some kinds of these materials have superconductivity.

Metal/C$_{60}$ composite A kind of phase-separated solid of M/C$_{60}$. These metals (such as Al, Cu, Ag, etc.) usually have high cohesive energy and cannot be intercalated C$_{60}$ lattice. The most common composites are multilayer films and the nanodispersion films.

Polymerized C$_{60}$ Solid C$_{60}$ can be polymerized by irradiation of intense visible or ultraviolet light, or under high-temperature, high-pressure treatment. During polymerization, some of the internal C–C bonds of C$_{60}$ molecules are broken and connected via intermolecular cycloaddition.

Calixarenes

Chebrolu P. Rao, Mishtu Dey

Indian Institute of Technology, Mumbai, India

CONTENTS

1. INTRODUCTION

1.1. Genesis of Calixarenes

About 150 years ago, Adolph von Baeyer demonstrated the formation of a hard, resinous, and noncrystalline product from the reaction of aqueous formaldehyde with phenol that remained essentially uncharacterized for almost 70 years. However, three decades later, Leo Baekeland smartly designed a process for this product, which he marketed under the name "bakelite," with tremendous commercial success [1]. In 1942 Zinke and Ziegler researched the products of the reaction of phenol and its substitutes with formaldehyde.

Phenol itself reacts with formaldehyde in acid or base at the *ortho-* and *para*-positions to form a highly cross-linked three-dimensional polymer in which each phenolic residue is attached to three other neighbors as shown in Figure 1. On the other hand, *para*-alkylphenol can react only at its two *ortho*-positions and thereby forms a linear one-dimensional polymer (Fig. 2) by reducing the cross-linking possibilities, in addition to the formation of several macrocylic oligomers. However, the same reaction in the presence of base at high temperatures yielded high melting and high molecular weight substance to which Zinke assigned a cyclic tetrameric structure [2], where the product was proven to be a mixture later on as shown in Figure 3. This problem was not overcome until late 1970s when Gutsche became intrigued by the emerging area of enzyme mimics where he explored the Zinke cyclic tetramers as cavity-containing substances appropriate for enzyme mimic building blocks. He later showed that a careful control of reaction conditions could provide good yields of pure compounds of various ring sizes, calix[*n*]arenes.

1.2. Scope of the Chapter

The main aim of this chapter is to bring into focus the newer developments of calixarenes and its derivatives and the many applications exhibited by these systems. In order to fulfill such a focus, the authors take the approach of showing the developments that took place since the realization of simple calixarenes and their putative applications in biology and materials leading to the nanoscience of such supramolecular systems. Since the work carried out as well as the understanding of calix[6 & 8]arenes is rather limited in the literature, we confine our discussions mostly to calix[4]arenes.

1.3. Nomenclature

The name calixarene is of Greek origin (Greek calix, a *chalice* or *cup*; arene referring to the aromatic ring), having recognized the cyclic tetramer in the conformation in which all of its four aryl groups are oriented in the same direction of a chalice or cuplike shape [3–7] similar to that of a Greek crater vase (Fig. 4). The substitution at the *para*-position preceeds calix[*n*]arene in order to accommodate the number of aryl groups present by giving a numerical value to [*n*]. For example, the cyclic tetramer derived from *p-tert*-butylphenol is written as *p-tert*-butylcalix[4]arene. For a more systematic application of the calixarene nomenclature, the basic name calix[*n*]arene is retained, and identities of all substituents are indicated and their positions are specified by a number (e.g., calixarene is derived from *p-tert*-butylphenol and formaldehyde is named as 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrahydroxycalix[4]arene as shown in Fig. 5).
Figure 1. Schematic view of a highly cross-linked three-dimensional polymer, *bakelite*, obtained from the condensation of phenol with formaldehyde.

Figure 2. Schematic view of one-dimensional polymer formed from the linear condensation of *para*-substituted phenol with formaldehyde. R = any alkyl group.

Figure 3. Cyclic condensation of *p-tert*-butyl phenol with formaldehyde resulting in the formation of highly ordered structures referred to as calixarenes. Ring size can be controlled based on the reaction conditions, leading to *p-tert*-butyl calix[4, 6, 8]arenes [*m* = 1, 3, 5].

Figure 4. Structure of calix[4]arene resembling Greek crater vase. Adapted from [3], V. Bohmer and J. Vicens, "Calixarenes: A Versatile Class of Macrocyclic Compounds." Kluwer Academic, Dordrecht, 1991. © 1991, Kluwer Academic Publishers.

Figure 5. Structure and numbering scheme for calix[*n*]arenes, where *n* = 4, 6, and 8.

As this nomenclature is very inconvenient, in this chapter we have also used the appropriate short form as used by others in the literature.

2. CALIXARENE CONFORMATIONS

Calixarenes generally show conformational mobility in solution and are frozen into a particular conformation only upon crystallization. X-ray crystallographic structures have been established for simple and functionally modified calixarenes. Simple calixarenes have many conformational isomers because of two possible rotational modes of phenol units, the *para*-substituent and the oxygen through the annulus rotation (Fig. 6), and hence shows fluxional behavior [8]. Functionalized calixarenes, at either the lower or upper rim, would have further influence on the conformational mobility and in some derivatives such mobility is frozen. Calix[4]arene shows four conformers and these are designated by Gutsche and co-workers as the "cone" (C_{2v}, C_{4v}), "partial-cone" (C_s), "1,2-alternate" (C_{2h}), and "1,3-alternate" (D_{2d}) forms [9] as shown in Figure 7. All the four conformations are accessible by rotation about the bridging methylene groups. In the cone conformation all four phenolic OH groups are involved in circular hydrogen bonding.

On the other hand, calix[6]arene can assume 8 up–down conformational isomers, designated as cone, partial-cone, 1,2-alternate, 1,3-alternate, 1,4-alternate, 1,2,3-alternate, 1,2,4-alternate, and 1,3,5-alternate. Because of the increased flexibility of this system, additional conformations are possible in which one or more aryl rings assumes a position approximately in the average plane of the molecule designated as an out alignment and named a winged conformation by Gutsche. In *p-tert*-butylcalix[8]arene, the molecule

Figure 6. Annulus rotation in calixarenes. R = any substituent including *tert*-butyl group.
Figure 7. Conformations exhibited by calix[4]arene: (a), (b), (c), and (d) represent cone, partial-cone, 1,2-alternate, and 1,3-alternate conformations respectively. R_1 = any group and R_2 = any group including the *tert*-butyl group.

exists in a pleated loop form. For calix[8]arene, there are 16 up–down forms, as well as many others in which one or more aryl groups assume the out alignment [10].

3. ORGANIC FUNCTIONALIZATION

Since the pathway for conformational inversion in the calix[4]arene involves rotation of the aryl groups in a direction that brings the OH groups through the annulus of the macrocyclic ring, the most obvious way to curtail this motion is by derivatization. Thus, functionalization of calixarenes at the lower rim (phenolic OH groups) or at the upper rim (*para*-position of the aromatic moiety) often produces derivatives with reduced conformational mobility (Fig. 8). It is indeed possible to selectively introduce organic functionalities both on the lower rim as well as on the upper rim of calix[4]arenes. Due to chemical modifications, calixarenes and their derivatives can act as useful receptors or baskets for a range of guests including neutral, cationic, and anionic species. In these modifications the calix[4]arene acts as a platform to which an array of functional groups is attached resulting in the cone conformation and hence is capable of acting as the primary binding site.

3.1. Lower Rim Functionalization

The lower rims of the calixarenes are already functionalized with hydroxyl groups which provide excellent sites for the introduction of other functional groups, by either direct acylation or alkylation (Williamson method) by bringing in groups such as $-CH_2C(O)R$ (R = alkyl [11, 12], or aryl [13], or $N(alkyl)_2$ [14, 15], or $-NHCH(R')COOH$ (gly, ala, asp, glu) [16] or $-NH-CH_2Py$ [16], $-CH_2CH_2OR$ [17, 18], $-CH_2P(O)Ph_2$ [19, 20], CH_2–pyridyl [21, 22], CH_2CN [12, 23], $-CH_2C\equiv CH$) [23]. Further, selective alkylation in terms of the degree as well as the site specificity can be achieved by appropriately manipulating the

Figure 8. "Lower rim" and "upper rim" in calix[4]arene where R = *tert*-butyl.

experimental conditions [24, 25]. In the literature, strategies are reported for di-functionalization of distal (1,3) and proximal (1,2) positions in *p*-R-calix[4]arenes [26]. We have recently obtained 1,3-di-derivatives built through amide linkages originating from amino acids, heterocyclic amines, and saccharide amines and further derivatized so that 2,4-OH groups are methylated [27, 28]. The conformational freezing can also be achieved by bridging between transannular oxygens at the lower rim resulting in crown etherlike structures [29, 30].

3.2. Upper Rim Functionalization

The *p-tert*-butyl group attached to the phenyl ring is removed by de-alkylation using $AlCl_3$-phenol as catalyst [31, 32]. A variety of methods are available to selectively or totally introduce functional groups into the *p*-position of the phenyl ring, which includes electrophilic substitution, such as halogenation (Cl, Br, and I) [33, 34], nitration [35], sulphonation [36, 37], acylation [31], and formylation [38–40]; *para*-Claisen rearrangement [41]; chloromethylation [42] and subsequent replacement of chloride, resulting in the formation of a variety of potential ligands; and Mannich reaction with dialkylamines followed by conversion of nitrogen into quaternary structure and then treatment with nucleophiles [43].

4. METALLOCALIXARENES

Calixarenes and their functionalized derivatives provide the basic structural framework for developing coordination chemistry, and when properly tuned with appropriate functional groups to provide biomimetic model systems. Both simple (parent) and functionalized calixarenes possessing O, S, N donor groups either at the upper rim or at the lower rim have been used as ligands to complex the transition metal ions.

4.1. Metal Ion Complexes of Simple Calixarenes

Simple calixarenes can bind to metal ions via deprotonated phenolate moieties at the lower rim. Neutral complexes of *p-tert*-butyl-calix[4]arene (metal to ligand ratio) using Ti(IV) (2:2), Fe(III) (2:2), Co(III) (3:2), Nb(V) (1:1 with Nb=O), Ta(V) (1:1 with Ta=O), Mo(VI) (1:1 with M=NR), and W(VI) (1:1 with W=O or W(Cl)$_2$) were reported in the literature as shown in Figure 9a–f [44–49]. Harrowfield et al. [50–54] have reported a series of lanthanide metal ion complexes of europium, terbium, and cerium with *p-tert*-buytl-calix[4]arene. The two europium ions were coordinated to the calixarene either as a 2:2 metal/calix[4]arene complex (Fig. 9g) or as a 2:1 metal/calix[8]arene complex.

4.2. Calixarenes Possessing Pendant Binding Sites

Introduction of appropriate functional groups on either the upper or lower rim leads to the derivatives of a versatile nature and would be of great use in a variety of applications. Calixarenes possessing different donor groups (N, P, S)
Figure 9. (a)–(f) Transition and (g) lanthanide metal ion complexes of *p-tert*-butyl calix[4]arene, where dmf = *N*,*N*-dimethylformamide; thf = tetrahydrofuran; R = *t*-Bu, H; S = CH₃CN.

including pendant acids have been synthesized [16]. Some of these molecules and their coordination chemistry aspects are summarized in this section.

4.3. Coordination Chemistry Aspects of Calixarenes with Pendant Nitrogen Donors

Nitrogen containing donor groups have been introduced at either the lower or upper rim of the calix[4]arene as shown in Figure 10 [55, 56]. Interaction of ligand (a) with Ni(II), Cu(II), Pd(II), Co(II), and Fe(II) metal salts yields no complexes attributable to the presence of four mobile ethylamine arms that prevented the formation of rigid and/or closed cavities. However, when ligand (b) is reacted with Ni(ClO₄)₂·6H₂O and NaN₃, it yields a binuclear complex (d) and when ligand (c) is reacted with Ru(bipy)₂ complex, it results in the formation of a (bipy)₂Ru(bipy-calixarene) complex.

4.4. Coordination Chemistry Aspects of Calixarenes with Pendant Sulphur Donors

A limited number of thio-derivatives of calixarenes, viz., tetra mercaptocalix[4]arene and dihydroxy-di mercaptocalix[4]arene, were reported in the literature [57–61]. The former exists in 1,3-alternate conformation both in the free

state as well as in its complexed state. The complex with Hg(acetate)₂ yielded 2:1 with tetra-mercaptocalix[4]arene and 1:1 with dihydroxy-dimercaptocalix[4]arene, and in both cases the calixarene exists in 1,3-alternate conformation as shown in Figure 11.

5. PHYSICAL PROPERTIES OF CALIXARENES

A few physical properties, such as melting point, solubility, and pKa's, are discussed in this section both for the organic derivatives as well as for their inorganic ones.

5.1. Melting Temperatures of Calixarenes

Melting point is a characteristic property of many calixarenes. The parent calixarenes containing the free hydroxyl groups melt at high temperatures and increase progressively going from calix[4]arene to calix[6]arene to calix[8]arene and the melting points are generally in the range 340–450 °C. It has been noticed that even the nature of the substituent present in the p-position affects the melting point (Table 1, compounds 1, 4, 6). It is understood from the literature that [62] calix[6]arenes produced from p-n-alkyl-phenols exhibit melting points as low as 110 °C when the substituent is p-n-octadecyl. The melting point is also known to be affected by the position of the substituents on the "upper rim" of the calix[4]arene (Table 1, compounds 7a–7c). The effect of substituents on the melting points has been observed in the case of isomeric compounds that differ only in the arrangement of identical groups around the "upper rim" of the calixarene. Thus Bohmer's compounds [63] 7a, 7b, and 7c in Table 1 have melting points 185–190, 270, and 368 °C respectively. Hence derivatization of the calixarenes greatly affects the melting point. Lower rim calixarene derivatives of esters and ethers generally melt at temperatures lower than the parent compound (Table 1). For example, 8 and 9 melt at 226–228 and 230–231 °C, respectively (Table 1). However, there are exceptions where the trimethylsilyl ether of p-tert-butylcalix[4]arene at the lower rim melts at 411–412 °C and the tetraacetate melts at 383–386 °C. Among the calix[4]arene derivatives 12–17 (Table 1), the esters melt at lower temperatures than their carboxylic acid counterparts indicating a decrease in the hydrogen-bond interactions. Generally the decrease in the melting point upon derivatization at the lower rim is consistent with a decrease in hydrogen bonding interactions and a similar trend observed with the derivatives at the upper rim is consistent with an increase in the hydrophobic nature.

Table 1. Melting points and solubilities of calixarene derivatives.

Codes	Compounds	Melting point (°C)	Solubility
1	p-tert-butylcalix[4]arene	342–344	less soluble in CHCl$_3$
2	p-tert-butylcalix[6]arene	380–381	
3	p-tert-butylcalix[8]arene	411–412	
4	p-phenylcalix[4]arene	407–409	
5	p-phenylcalix[8]arene	>450	
6	p-n-octadecylcalix[4]arene	110	more soluble in CHCl$_3$

5.2. Solubility

Simple calixarenes are insoluble in water and aqueous base and are only slightly soluble in organic solvents; however, they are sufficiently soluble in chloroform, pyridine, or carbon disulfide [64]. It is this feature that makes some of the calixarenes difficult to isolate, purify, and characterize. Alkyl groups in the *para*-position of a calix[4]arene affect the solubility in organic solvent and the solubility increases as the chain length increases (Table 1, compounds 1 and 6) [65]. Lower rim derivatives of esters and ethers of calix[4]arenes show increased solubility and the difference in solubility may be used to separate the components from a mixture. For example, No et al. [66] separated the product, *p*-acetylcalix[4]arene, from its reactant, calix[4]arene tetraacetate, which is soluble in hot benzene.

Water soluble calixarenes were developed due to their ability to interact with ions and molecules and also due to their catalytic properties. A first water soluble calixarene, tetracarboxymethyl ether of *p-tert*-butylcalix[4]arene, was synthesized by Ungaro et al. [67] whose solubility was found to be in the range 5×10^{-3} to 5×10^{-4} M depending upon the accompanying cation. *p*-Carboxy-calix[4–8]arenes were found to be soluble in 10^{-3} M aqueous base as reported by Gutsche et al. [33, 42, 43]. However, *p*-sulphonato calix[4–8]arenes were much more soluble than the counter-carboxy-derivatives and the former is soluble up to an extent of 0.1 M as reported by Shinkai et al. [36, 37]. However, the upper rim aminocalixarenes are moderately soluble in dilute aqueous acid [42, 43, 55].

5.3. pK$_a$

Due to their low solubility it was difficult to obtain the dissociation constants for the OH groups of the *p-tert*-butylcalixarenes. The pK$_1$ values were found to be 6.0 and 4.3 for the mono-nitrocalixarenes (Figure 12a and b) in 1:1 water:methanol by measuring their ultraviolet absorption as a function of pH as reported by Bohmer et al. [68]. Thus these nitro-calixarenes are somewhat more acidic than *p*-nitrophenol. The pK difference of 1.7 units between the two compounds that differ only in a single *p*-alkyl substituent is attributed to the conformational effects arising from the relative sizes of the methyl and *tert*-butyl groups.
6. SPECTRAL PROPERTIES OF CALIXARENES

Spectral properties, such as vibrational, electronic, nuclear magnetic resonance (NMR), and mass, of both organic and inorganic derivatives of calixarenes are discussed in this section by taking several examples. Luminescence spectral studies are presented in Sections 8.5 and 8.6.

6.1. Vibrational Spectroscopy

One of the most distinct features in the infrared spectra of the calixarenes is the observation of very low frequency for ν_{OH}, viz., 3150 cm^{-1} in the case of calix[4]arene and 3300 cm^{-1} in case of calix[5]arene, which is attributed to the strength of intramolecular hydrogen bond interaction involving the –OH groups at the lower rim in these calixarenes [69, 70]. In the fingerprint region between 1500 and 900 cm^{-1}, the spectra look almost similar in all the calixarenes. However, in the 900–500 cm^{-1} region, the patterns vary to some extent depending upon the derivative.

As shown in Scheme 1, the parent, *p-tert*-butylcalix[4]arene **1**, shows a band at 3186 cm^{-1} for ν_{OH}. Esterification of **1** resulted in **2** and in the spectrum of **2** the ν_{OH} and $\nu_{C=O}$ appear at 3425 and 1757 cm^{-1} indicating the disruption of the circular hydrogen bond to some extent upon derivatization. The base hydrolysis of **2** resulted in the corresponding diacid **3**, where ν_{OH} and $\nu_{C=O}$ appear at 3424 and 1747 cm^{-1} respectively. In case of **3**, ν_{Phe-OH} overlaps with the carboxylic ν_{OH} and thereby exhibits a broad band as compared to its precursor, **2**. Upon treating with SOCl$_2$, the acid is converted to acid-chloride, **4**, where both peaks have shifted to

higher frequencies (Fig. 13). The reaction of acid-chloride, **4**, with the amino acid esters [71] yields the corresponding amides (**5a–5d**) that exhibit characteristic ester and amide bands in the ranges 1741–1754, 1679–1685 (amide I), and 1531–1539 cm^{-1} (amide II, δ_{NH}). Thus the data are indicative of the formation of the pendants with peptide linkages. Conversion of these by base hydrolysis to the corresponding carboxylic acids (**6a–6d**) resulted in a frequency shift of amide bands to lower values shown in Figure 14.

6.2. Ultraviolet Spectroscopy

The linear and cyclic oligomers show two absorption bands at 280 and 288 nm in the ultraviolet spectra. The ratio of the absorptions at these two wavelengths is a function of the size of the ring. Conforth and co-workers [2] carried out the lower rim alkylation of calixarenes by monitoring the disappearance of the absorption at 300 nm (characteristic of the free phenol) and the growth of absorption at 270–280 nm arising from the ether.

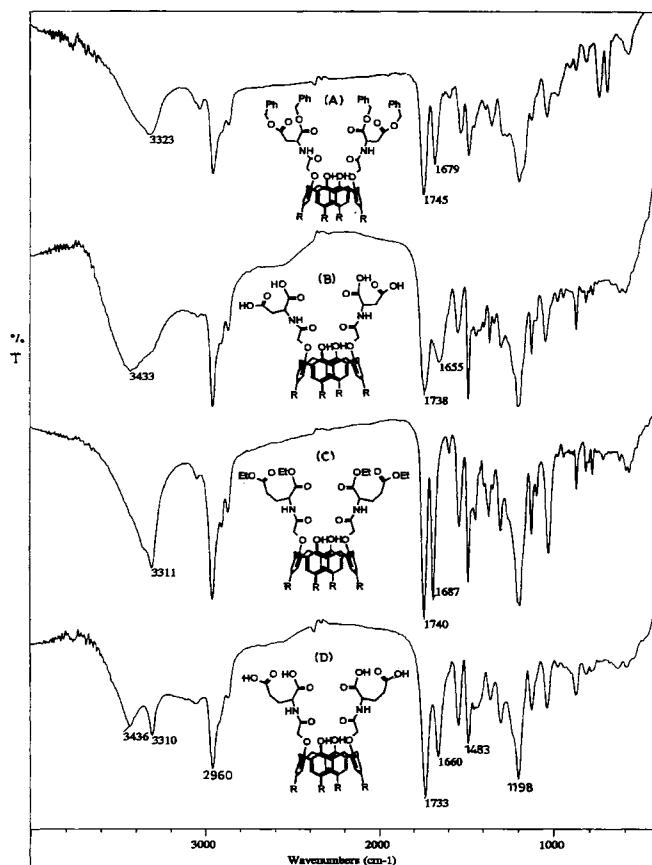

Figure 14. FTIR spectra corresponding to the structures shown under each spectrum. (A), (B), (C), and (D) respectively correspond to the compounds **5c**, **6c**, **5d**, and **6d** which were given in Scheme 1.

6.3. Nuclear Magnetic Resonance Spectroscopy

In the ^{1}H NMR spectrum of *p-tert*-butylcalix[4]arene at room temperature, resonances from the aromatic protons, the *tert*-butyl protons, and the hydroxyl protons are observed as singlets, and those from the CH$_2$ protons are observed as a pair of doublets. However, these doublets collapse to a singlet when the temperature is raised from 20 to 60 °C in chloroform [72]. On the basis of nuclear Overhauser effect experiments, Ungaro et al. [67] assigned the higher field doublet to the equatorial protons (closer to the aromatic rings) and the lower field doublet to the axial protons (closer to the hydroxyl groups). Gutsche et al. [73, 74] have shown that calix[8]arenes behave in a similar manner but calix[6]arenes show only a singlet resonance even at room temperature and split at lower temperature. Calix[4]arene and calix[8]arene can be differentiated [75] by the fact that in pyridine the former retains the pair of doublets at 0 °C whereas the latter shows only a singlet at temperatures as low as −90 °C.

Rao et al. [16] reported that the ^{1}H NMR spectra of **1** (Scheme 1) shows a single *tert*-butyl signal at 1.26 and an AB quartet for bridged methylene group at 3.50 and 4.30 ppm and a singlet for aromatic protons at 7.05 ppm. The phenolic proton appeared as a singlet at 10.30 ppm that disappears upon D$_2$O exchange. The ^{1}H NMR spectra of

1,3-di-derivatives (**2**, **3**, and **4**) exhibited doubling of peaks for *tert*-butyl groups (0.93–1.05 and 1.26–1.27 ppm) and aromatic protons (6.78–6.93 and 7.06–7.08 ppm), one each corresponding to the substituted part and the unsubstituted one. Spectra of these also exhibited an AB quartet for the bridged methylene group in the ranges 3.32–3.41 and 4.13–4.45 ppm. A singlet for the methylene group arising from O–CH$_2$–CO was observed in the range 4.66–5.03 ppm. The spectrum of **2** shows signals corresponding to the ethyl ester group which is absent in **3** and **4**. Thus the data suggest that the substitution in the di-derivatives is of 1,3-alternate type and the calix[4]arene exists in the cone conformation. The splitting pattern observed for the bridged –CH$_2$ group in ^{1}H NMR spectra provides a signature for the type of conformation present.

In case of the 1,3-di-derivatives built using peptide linkages, **5** and **6**, the protons and/or carbon (in ^{13}C NMR) as well as that of calixarene resonances were assigned by correlation spectroscopy (COSY) and hetero multiple quantum coherence experiments. The ^{1}H NMR data corresponding to these derivatives are given in Table 2. In the ^{1}H NMR spectra, the amide N–H proton signals appeared in the range 9.27 to 9.63 (CDCl$_3$) and 8.97 to 9.20 ppm (DMSO-d_6) for **5a**–**5d** and 8.72 to 9.14 ppm for **6a**–**6d** (DMSO-d_6). These chemical shifts were comparable with those observed in case of the tetra-substituted amino acid ester derivatives [76]. The positions of amide proton signals were confirmed through the cross-coupling peaks of C$^\alpha$H in COSY experiments. While the amide –NH protons were not exchanged upon addition of D$_2$O in the case of **5**, these were found to be exchanged in the case of **6** due to the changes in the confirmation of the pendant groups. From these results it can be concluded that there exists strong intramolecular hydrogen bonding in **5** in CDCl$_3$. However, **5** when measured in DMSO-d_6 showed upfield shifts of amide proton signals indicating the disruption of intramolecular hydrogen bond interactions present in the molecule. However, the phenolic –OH proton signals disappear upon D$_2$O exchange. The aromatic protons (Ar–H) in **5a** (gly- derivative) appeared as two singlets whereas **5b**–**5d** (ala-, asp-, and glu- derivatives) showed two doublets due to the presence of pendant chiral amino acid units. For the same reason, the axial and equatorial calixarene bridged CH$_2$ protons showed two pairs of doublets in **5b**–**5d**. This chiral effect is also seen in the signals of OCH$_2$CO protons as two doublets. In case of **6a**–**6d**, a similar splitting pattern was observed. All the spectra were

indicative of the presence of cone conformations of these 1,3-di-derivatives.

6.4. Mass Spectrometry

Rao and co-wokers [16] have reported mass spectral data for the calixarene 1,3-diderivatives of amino acid and their esters formed through peptide linkage. The molecular weights were confirmed by the presence of molecular ion peaks in the mass spectra obtained by the FAB mass method or the EI method.

7. STRUCTURES BY X-RAY CRYSTALLOGRAPHY

Single crystal X-ray diffraction provides a powerful means of determining the molecular and crystal structures. The lower rim derivatives of the calix[4]arenes can exist in any one or more of the possible four conformations as given in Section 2. Undoubtedly, X-ray crystallography is the most confirmative way to ascertain the conformations exhibited by the calixarenes and their derivatives. In several cases the solid state structural studies were further augmented by NMR conformational analysis in solution.

7.1. Crystal Structures of Calixarenes and Their Derivatives

The earliest example was reported by Rizzoli et al. [77], wherein the tetraacetate of *p-tert*-butylcalix[4]arene was shown to exist in partial-cone conformation as shown in Figure 15. Ester and ether derivatives, such as **1b**–**1f** (Fig. 12), exist in cone conformation [14, 29, 78, 79] for which X-ray structures have been obtained. The synthesis of 25, 27-dimethoxy-26, 28-dimethylester-*p-tert*-butylcalix[4]arene was reported and its structure was established wherein it is observed that the calixarene asssumes a partial-cone conformation [80]. The corresponding potassium salt of this ester exists in 1,3-alternate conformation whereas in the sodium salt the calixarene is in a distorted cone or flattened partial-cone conformation (Fig. 16). The crystal structure of a tetra(benzyl)amide of calix[4]arene exhibits a distorted cone conformation [81]. Syntheses of lower rim substituted aryl ethers of *p-tert*-butylcalix[4]arene were reported [82] where the crystal structure of one of the 1,2-disubstituted compounds exists in a partial-cone conformation. One of the aryl ether pendants is sandwiched

between two neighboring O-unsubstituted phenyl rings within the calixarene cavity. Synthesis and structure determinations of thiacalix[4]arenes bearing four keto-groups and four amido-groups on the lower rim have been reported. All three derivatives have been found to adopt 1,3-alternate conformation [83]. A calix tube is formed when two thia-bridged calix[4]arenes were connected at their lower rim phenolic oxygens through four ethylene linkers [84]. This is shown to adopt a flexible C_{2v} flattened cone arrangement as shown in Figure 17. Zinic et al. [85] reported the synthesis of chiral calix[4]arene derivatives with four O-(*N*-acetyl-phenylgly-OMe) or O-(*N*-acetyl-Leu-OMe) strands. X-ray structure analysis of the glycine derivative revealed distorted cone conformation with C_2 symmetry and the structure is organized into infinite chains by intra- and intermolecular hydrogen bonds. The solid and solution structures of the corresponding sodium complex were identical with cone conformation having C_4 symmetry.

A number of lower rim O-alkylated derivatives of mono-, di-, tri-, and tetra-substituted picolyl ones with or without *p-tert*-butyl groups were synthesized and their conformations
were established [21]. It has been found that the type of base used during the synthesis [20 equivalents of the picolylchloride (HCl), NaH (70–80% cone), K_2CO_3 (36% of partial cone, 55% of 1,3-alternate, and 9% of cone), or Cs_2CO_3 (54% of partial cone, 18% of 1,3-alternate, and 9% of cone)] influences the conformation of the tetra-substituted picolyl derivative of calix[4]arene obtained. Such influence of the base used in the reaction on the conformation of the tetraalkylated calix[4]arenes was also reported by Reinhoudt and co-workers [86]. This group also reported that the tetraethyl ether of *p-tert*-butylcalix[4]arene exists in a fixed 1,2-alternate conformation [87] for which the X-ray structure was determined as shown in Figure 18.

The reaction of *p-tert*-butyl calix[4]arene with a flexible and reactive sebacoyl chloride yielded the singly intrabridged calix[4]arene derivative [88]. The crystal structure of this compound showed a distorted cone conformation (Fig. 19). Selective functionalization of calix[4]arenes at the

upper rim led to the formation of 26,28-dimethoxy-11,23-dinitrocalix[4]arene, the crystal structure of which (shown in Fig. 20) reveals that the macrocycle is in a flattened cone conformation [89]. A series of bridged calix[4]arenes with two opposite phenolic units connected by an aliphatic chain were synthesized [90]. The length of the chain was varied from 5 and 16 carbon atoms. ^{1}H NMR spectra support that the cone conformation is fixed in these compounds. X-ray analysis also revealed a distortion of the ideal cone conformation with shorter connecting chains, which is attributed to the weaker intramolecular hydrogen bonds.

7.2. Structures of the Metal Ion Complexes of Calixarenes and Its Derivatives

The treatment of calixarenes and its derivatives with inorganic salts and/or compounds results in the formation of the complexes, whose three-dimensional structures can be established by X-ray crystallography. Power and co-workers established the first crystal structure of a calix[4]arene–transition metal ion complex by the reaction of *p-tert*-
butylcalix[4]arene with Ti(NMe$_2$)$_4$ [44]. The structure shows two titanium ions sandwiched between two calixarene units and the calixarene exists in a partial-cone conformation with the titanium centers in tetrahedral coordination geometry. Similarly, iron and cobalt complexes of calix[4]arene were synthesized and their structures were determined by X-ray crystallography. The iron assumes a distorted trigonal pyramidal geometry and that of cobalt is irregular (Fig. 9).

Andreeti and co-workers [91] treated *p-tert*-butylcalix[6]arene with Ti(OPr)$_4$ and the resultant product exhibited a structure consisting of two calixarene units in a cone conformation coordinated with two titanium centers as a Ti–O–Ti unit, with distorted trigonal bipyramidal geometry around each titanium center.

Harrowfield et al. [92] have synthesized an europium complex of *p-tert*-butylcalix[8]arene whose crystal structure was found to contain two europium atoms in a pinched conformer of the cyclic octamer. Ripmeester and co-workers have reported [93] that xenon is encapsulated in the *p-tert*-butylcalix[4]arene cavity and behaves both as a guest and as a cavity probe. [129]Xe NMR and X-ray diffraction data show that the Xe occupies two cavity sites (Fig. 21). Oxomolybdenum (VI) binds four oxygen atoms from a calix[4]arene with cone conformation, and in the lattice this unit is co-crystallized with a free calix[4]arene by trapping a nitrobenzene between these two units [47]. Reaction of mercury(II)acetate with *p-tert*-butyl-1,3-dihydroxy-2,4-disulfanylcalix[4]arene yielded a mononuclear complex in which the Hg(II) ion is coordinated linearly to two arenethiolate groups [61] and the calixarene adopts a 1,3-alternate conformation (Fig. 22). Calix[4]arene–W(VI)–(OAr)$_2$ complex is exhibited in the lattice self-assembly of these, resulting in a columnar structure as reported by Floriani's group [94].

Reaction of a 10-fold excess of NaH and LiH with *p-tert*-butylcalix[4]arene in THF results in the formation of the corresponding salts of mono-oxyanion and di-oxyanion calixarenes respectively [95], where the additional metal coordination sites are filled by MeOH and H$_2$O to result in tetra-coordination around Li$^+$ and penta-coordination around Na$^+$ as shown in Figure 23a and b. Reaction of the hexamethyl ether of *p-tert*-butylcalix[6]arene with TiCl$_4$ in toluene [96] resulted in crystals of [(calix[6]arene)–(Cl$_3$TiOTiCl$_2$)$_2$] (Fig. 24).

Reactions of aluminium alkyls with a number of cal-ixarene methyl ethers have been established [97, 98]. The reaction of tetramethyl ether of *p-tert*-butylcalix[4]arene with Me$_3$Al in benzene–toluene solution resulted in crystals, the structure of which shows that the calixarene is in 1,2-alternate conformation with two molecules of Me$_3$Al per calixarene. On the other hand the reaction with MeAlCl$_2$ or EtAlCl$_2$ resulted in a complex having the same compo-sition but the calix[4]arene takes up an 1,3-alternate rather than the 1,2- conformation observed in the previous case. The 1,3-bis(trimethylsilyl)ether of *p-tert*-butylcalix[4]arene has been synthesized and used as a dianionic ligand for com-plexing Ge and Sn [99]. The crystal structure of the Ge complex exhibits exo/endo isomerism (Fig. 25a and b).

Transition metals can be used for shaping and electron-ically enriching the calix[4]arene cavity so that the π-basic cavities can be adapted to alkali–metal cation complex-ation in the hydrophobic zone [100]. Thus the structure of the calixarene–alkali metal cation was determined by X-ray diffraction (XRD) wherein the calixarene assumes

a flattened cone conformation. Complexes of Fe(III) and Er(III) of a calix[4]arene diamide were reported [101] to form 1:1 complexes where the calix[4]arene is found to be in cone conformation.

Two extended-array metallocalixarenes derived from the ring opening of imido-molybdenum precursors have been synthesized and their structures were determined [102]. It is observed that the metallocalixarenes are organized in a "cup-to-cup" arrangement that gives rise to a calixarene "socket" and this potentially hosts guest molecules.

A calix[4]arene derivative, 1-carboxylic acid-3-diethyl amide, exhibited efficient extraction properties toward rare-earth ions and the crystal structure of a neutral 1:1 uranyl complex of dinuclear nature was determined [103]. Synthe-ses and X-ray crystal structures of neutral dimeric europium (Fig. 26), samarium, and monomeric lutetium complexes and the selective extraction properties of the 1,3-acid-diethyl amide substituted calix[4]arene ligand have been deter-mined [104]. While the monomeric lutetium complex is seven-coordinated (Fig. 27), both the dimeric complexes exhibit eight-coordination around each metal ion. The struc-tures show that the substituted calix[4]arene exists in cone conformation.

Complexes of La(III), Eu(III), Gd(III), Tb(III), and Lu(III) with the lower rim functionalized tetrakis[2-(diethylcarbamoyl-methoxy)ethoxy]calix[4]arene have been synthesized and the crystal structure of the Lu complex was established where Lu(III) is 9-coordinated in which the calixarene is in the cone conformation [105]. Calixarene derivatives of phosphine oxide moieties [calix-$(OCH_2CH_2POPh_2)_n$, where $n = 4, 6, 8$] attached to the lower rim have been reported to exist in distorted cone conformation [106]. These act as receptors for the extraction of Eu(III), Th(IV), Pu(IV), and Am(IV) in nuclear waste treatment.

The reaction of 5,11,17,23-tetra-*tert*-butyl-25,27-dihydroxy-26,28-bis[{*N*-(2-diphenyl phosphino)phenyl} carboxyamidemethoxy]calix[4]arene with [Cu(CH₃CN)₄]ClO₄ and Pt(COD)Cl₂ formed complexes whose structures were determined by X-ray analysis. The copper complex has two seven-membered metallocycles, the platinum complex
has one five-membered metallocycle, and both complexes assume the cone conformation [107].

X-ray studies reveal that the dimeric supramolecular assemblies of water-soluble calix[4]arenes are formed by a combination of hydrophobic effects and either hydrogen bonding or secondary bonding [108]. It is observed that for copper complex, the dimeric association is based on a secondary bonding interaction between the copper(II) ion and a sulfonato oxygen atom combined with hydrophobic interactions.

The coordination form and hence the cavity of the calix[4]arene ligands can be controlled by other ligands in transition-metal calix[4]arene complexes, if strong directing co-ligands such as oxo groups are used. Radius [109] described the synthesis and structure of Ti(IV) and Mo(VI) complexes of 1,3-dimethoxy-calix[4]arene where TiCl₂ and MoO₂ moieties arising from TiCl₄ and MoO₂Cl₂ control the coordination form and hence the cavity. While the ligand adopts an elliptically distorted cone conformation in TiCl₂ complex as shown in Figure 28, the same adopts a partial-cone conformation in the molybdenum complex (Fig. 29).

Transition-metal complexes of 5,11,17,23-tetra-*tert*-butyl-25,26,27,28-tetrakis(diethyl-carbamoylmethoxy)calix[4]arene in the cone conformation have been synthesized and the crystal structures of Fe(II), Ni(II), Cu(II), Zn(II), and Pb(II) complexes have been established by Ogden and co-workers [110]. The structures of the complexes of Fe(II), Zn(II), and Pb(II) are almost similar with the metal ions coordinated to all eight oxygen atoms of the ligand as can be seen in Figure 30. The copper complex is somewhat different with four bonds slightly shorter than the remaining four. On the other hand, the nickel structure is completely different where the ligand has undergone rearrangement to accommodate the metal cation in a distorted octahedral environment (Fig. 31). The same group also reported Fe(III) complexes of 5,11,17,23-tetra-*tert*-butyl-25-hydroxy, 26,27,28 tris(diethylcarbamoylmethoxy)-calix[4]-arene whose structure was determined by XRD [111]. The structure shows that Fe(III) is bound to all seven oxygen atoms of calix[4]arene with Fe–O_phenolic distance being the shortest (Fig. 32).

8. APPLICATIONS

Parent calixarenes are insoluble in water, have generally low solubility in most organic solvents, and are characterized by their high melting points. However, through appropriate derivatization these exhibit good solubility in either medium [112]. Aqueous solutions (0.1 M) can be prepared with *p*-sulphonato-calix[4]arene. The acylated calixarenes possess antioxidant and heat stabilizing properties that are useful for the plastics. Thus simple calixarenes, their functionalized

derivatives, and the metal ion complexes of all these offer a number of applications having impacts in chemistry, biology, and materials. Details of some such applications are presented in this section.

8.1. Supramolecular Formation

Undoubtedly the most useful property of calixarenes and its derivatives is their ability to function as molecular baskets and bind neutral and/or ionic guests resulting in supramolecular arrays. Rapid and extensive developments have taken place through exploration of the receptor property of the simple calix[4]arene and its functionally modified derivatives, thereby contributing to the area of analytical devices. Inclusion complexes of neutral guest molecules, such as toluene, benzene, xylene, anisole, and pyridine, in the chalicelike molecular cavity of calix[4]arene have been reported [113]. Attractive $CH_3 \cdots \pi$ interactions may contribute to the binding. Based on the X-ray diffraction studies, Atwood [114] and co-workers demonstrated a water inclusion complex of an upper rim sulphonated calix[4]arene (Fig. 33). The water molecule occupies a distorted conical cavity with its two hydrogen atoms directed toward the two nearest juxtaposed benzene rings. Structures of this type may provide important clues about how water molecules interact with aromatic moieties in biological systems. A 1:1 clathrate complex of calix[4]arene–tetracarbonate and acetonitrile is reported to have C_{4v} symmetry. In this clathrate, the acetonitrile resides in the hydrophobic cavity with nitrogen atom protruding from the lower rim.

8.2. Calixarenes as Receptors

Calixarenes can function as ion receptors by selective transport of alkali cations from one aqueous phase to another through a chloroform membrane containing the *p-tert*-butyl-tetramer, -hexamer, or -octamer [115]. When the source phase was neutral, practically no transport was observed, but when the source phase was made basic to allow ionization of the hydroxyl groups ion transport takes place, the octamer showing the fastest rate with cation selectivity order $Cs^+ > Rb^+ \gg K^+ > Na^+ > Li^+$. The presumption that neutral alkali phenoxides contain the cation in or near the cavity has received support from a recent X-ray analysis of neutral cesium salt of the tetramer [116]. Here the cation is found in the center of the cavity. The four phenolic C–O bonds are completely equivalent, indicating a rapidly exchanging network of hydrogen bonds around the four oxygen atoms. It is reported that the calix[4]arene was selective for sodium as compared to the other group I and II metal ions [117]. The studies also showed that there was a size selective effect manifested by a peak extraction of

cesium by the ester derivative of calix[6]arene. Thus, among the alkali cations, calix[4]arene derivatives have the highest affinity for Na^+.

Some advantages of calixarene as receptors are evident from the complexation of UO_2^{2+} species because the uranyl ion requires hexagonal coordination unlike many competing heavy metal ions that have an octahedral coordination sphere. Shinkai and co-workers [118] have found stability constants for UO_2^{2+} with sulphonic and carboxylic acid derivatives of calix[6]arene, up to 10^{19} mol^{-1} and selectivity factors of 10^{11}–10^{19} when compared to the divalent cations, viz., Mg^{2+}, Zn^{2+}, Ni^{2+}. Though most of the complexation studies with calixarenes deal with alkali and alkali earth cations, the derivatives containing soft donor atoms like N and S act as effective receptors for a range of transition-metal ions. Therefore, changing the nature of the substituents/pendants at the lower rim can produce dramatic changes in the selectivity. For instance, if the ester moiety at the lower rim of *p-tert*-butyl calix[4]arene is substituted by soft donors, like thio and thioamide groups, the selectivity is shifted from Na^+ to Ag^+. Similarly, phosphine derivatives have been synthesized to study their complexation with lanthanide and actinide ions for the selective extraction of radioactive elements from nuclear waste.

8.3. Calixarenes as Ion-Selective Electrodes

Calixarenes containing cation complexing groups at the lower rim possess the molecular requirements for the type of ionophores used in ion-selective electrodes. This is so, because calixarenes possess rigid cavities that are predisposed to selectively complex with cations and the high lipophilicity associated with the *t*-butyl groups prevents the organic derivative and its cation-complexed product from leaching nonpolar membrane into aqueous solution. Ion selective electrodes for K^+ and Cs^+ have been successfully developed using dioxacalix[4]arene [119] and calix[6]arene [120] respectively. Calix[4]arene derivatives containing S and N donor groups have been developed as ion selective electrodes as well as used to make chemically modified electrodes suitable to determine Hg^{2+}, Pb^{2+}, Ag^+, and Cu^{2+} [121]. Ion selective field effect transistors containing a calixspherand as the ionophore enable the quantitative determination of K^+ in the presence of even a large excess of Na^+ [122].

8.4. Calixarenes as Biosensors

A tetra-ester derivative of calix[4]arene, **1** (Fig. 34), has been used to make bench and miniaturized Na^+ selective electrodes [123] and for Na^+ detection in flow injection analysis [124]. These devices have been used to determine Na^+ in human blood plasma [125]. This sensor has also been used along with several other sensors in an array giving accurate assays of ions in blood [126] and mineral water [127].

8.5. Calixarenes as Optical Sensors

The signal in potentiometric sensors is generated by selective exchange of cations into the membrane phase, which is mediated by a calixarene ligand. However, for optical

transduction, an optically responsive mechanism must be coupled with the ion–ligand complexation process. This can be achieved by co-immobilizing a lipophilic, acido-chromic dye in the membrane with the ligand. The complexation of the metal ion by the ligand results in the expulsion of a proton from the dye to the sample phase, which maintains overall charge neutrality [128]. This approach has been used to design a series of ion-selective optical sensors (optodes), based on the same type of calixarene ligands (Fig. 34) that is used for ion-selective electrodes. The dyes, such as acridine derivatives, can produce optodes with longer lifetimes [129]. It is also possible to attach acidochromic groups directly on the upper or lower rim of the calixarene [130]. A calix[4]arene derivative [131] containing the nitrophenol-azaphenol chromophore, **3** (Fig. 34), in chloroform changes color upon addition of Li⁺ in the presence of tri-n-dodecylamine (TDDA). On complexation of Li⁺, the labile proton of the dye is transferred to TDDA, and the color changes from a pale yellow to deep brownish red by shifting the absorption maximum from ~380 to ~530 nm. A mixture of tetraester of calix[4]arene, **2** (Fig. 34), Girard's reagent P derivative of butyraldehyde, and chromoionophore ETH5294 has been used to detect low molecular weight aldehydes. 1,1′-Binaphthyl (at the lower rim) as well as the bis(indolphenol) (at the upper rim)-derived calix[4]arene crown ether derivative (Fig. 35) was developed as a sensor to differentiate the entiomers of host amines and amino acids through color change. While one of the enantiomers respond through change in visual coloration, the other does not when these are interacted with this calix[4]arene derivative [132].

Some of these chromogenic calixarene derivatives reported are novel and have important analytical applications, such as light-switching properties, where the derivative possesses a fluorescent pyrene group in the 1-position and a p-nitrobenzyl quencher in the 3-position as shown in Figure 36 [133]. Fluorescence is absent in the cation-free form of the calixarene, but the presence of a cation guest in the cavity forces the lower rim into a more open conformation, with quencher and fluorophore spatially separated, thus allowing fluorescence to occur. Thus, these receptors are of use in fluorescence-based ion sensors. Also, calixarenes functionalized on their lower rim to contain luminescent ruthenium(II) trisbipyridal complex [134] are found to act as potential amine sensors.

Y= CH₂COOC₂H₅
Figure 36. Schematic representation of the structure of calix[4]arene derivative possessing pyrene group on the lower rim as sensor that is suitable for fluorescence studies.

8.6. Electrochemiluminescence of Calixarenes

Upper rim carboxylic acid derivatives of calixarenes shown in Figure 37, when coated on a porous silicon electrode surface, exhibited interesting luminescence properties [135, 136] in 1.0 M H_2SO_4 electrolyte solution through anodic oxidation of the calixarene derivative. It was found that both the duration as well as efficiency of the light emission are affected depending upon the nature of the calixarene derivative used. Electrochemiluminescence can be generated for longer periods of time for these coated porous Si junctions relative to the untreated porous Si ranging from up to 3 h for calix[4]arene-coated porous Si to about 30 min for the calix[n]arene (n = 5, 7, 8) derivatives. These observations are attributed to packing differences between different calixarene carboxylic acid derivatives as thin films and subsequent bias-induced Si nanoparticle oxidation in the porous matrix. The studies also focused on the effect of electrochemiluminescence on the size of the calixarene as well as on the chain length of the carboxylic tether to the rim.

8.7. Calixarenes as Catalysts

Shinkai and co-workers [137, 138] have studied kinetics with a series of sulfonato-calixarene derivatives shown in Figure 38 as catalysts for the reaction of addition of water to 1-benzyl-1, 4-dihydronicotinamide to form 1-benzyl-6-hydroxy-1,4,5,6-tetrahydronicotinamide. The results showed that the calixarenes having a protic lower rim (a and b) are better catalysts than those lacking this feature (c and d). The same reaction was carried out using p-(carboxyethyl)calixarenes [43] (Fig. 37, with n = 6), and it was found that p-sulphonato calix[6]arene is about four times more effective as a catalyst than p-(carboxyethyl)calix[6]arene. This is attributed to the greater concentration of negative charge at the upper rim of the calixarene, the six sulfonato groups being held more rigidly in place than the more flexible carboxyethyl moieties.

8.8. Biomimetic Catalysis

Although calix[4]arene-based molecular receptors have been reported [139, 140], calix[4]arene-based enzyme models have hardly been developed [141–146]. A Ba(II) complex of crown ether attached to the lower rim of calix[4]arene was

Figure 38. Addition of water to 1-benzyl-1,4-dihydronicotinamide catalyzed by sulphonato calix[6]arenes in the presence of acid (AH).

reported to exhibit *trans*-acylase activity in the methanolysis of p-nitro phenyl acetate [147].

Calix[4]arene-based binuclear complexes (Fig. 39) have been shown to efficiently catalyze phosphate diester cleavage with a high degree of cooperation between the two Zn^{II} or the two Cu^{II} centers [139–143]. It has been observed that the binuclear zinc complex 3-Zn_2 having calixarene moiety exhibits a very high activity in the *trans*-esterification of the RNA model substrate HPNP (2-hydroxypropyl p-nitrophenyl phosphate). The catalytic activity of mononuclear calix[4]arene 2-Zn and the reference complex 1-Zn, lacking the flexible calix[4]arene backbone, are low by a factor of 50 and 300 respectively [144, 145]. The binuclear Zn^{II} complex of the bis(aminomethyl)pyridine ligand **3** shows a higher catalytic rate than its Cu^{II} analog 3-Cu_2. This is in

Figure 37. Schematic representation of the structure of calixarene carboxylic acid derivatives (n = 5–8) at the upper rim used in electrochemiluminescence.
Figure 39. Calix[4]arene based model systems for metallophosphodiesterases [R = –$CH_2CH_2OCH_2CH_3$].

contrast to the dinucleating bisimidazolyl ligand 5, which forms a highly active Cu^{II} complex, 5-Cu_2, and a weakly active Zn^{II} complex, 5-Zn_2. Comparison of dinuclear Cu^{II}-calix[4]arene 5-Cu_2 with binuclear Zn^{II} shows that the high catalytic activity of 5-Cu_2 in HPNP *trans*-esterification is mainly a result of a high turnover rate (k_{cat}) combined with a moderate substrate-catalyst binding constant (K_{ass}). However, the observed low activity of 3-Zn_2 is mainly due to strong substrate-catalyst affinity along with a relatively moderate turnover rate. This agrees well with the reported higher phosphate affintiy of Zn^{II}. The differences observed in the reactivity between the Zn^{II} complexes (3-Zn_2 and 5-Zn_2) and the Cu^{II} complexes (3-Cu_2 and 5-Cu_2) are reflective of their preferential coordination geometries [142, 143]. It was therefore concluded that the tether length and the geometry of the binding arms of the ligands determine the catalytic activity and the mechanism of catalysis. Proposed mechanisms for HPNP cleavage by calix[4]arene complexes of 3-Zn_2 and 5-Cu_2 are shown in Figure 40. Hence these calix[4]arene based binuclear complexes can be used as models for binuclear metallo-phosphodiesterases [141–145]. Extension to systems with a third metal ion binding site afforded a trinuclear Zn^{II} complex 4-Zn_3 (Fig. 39) that mimics trinuclear Zn^{II} phosphodiesterases [142, 146] due to the cooperative action of three Zn^{II} centers resulting in an enhanced reactivity.

8.9. Calixarenes as Liquid Crystals

Tungsten complexes with 8 and 12 dodecyloxy side chains on lower rim were found to exhibit liquid crystalline phase [148]. Swager et al. reported a new type of columnar liquid crystal with a rigid bowlic core based on tungsten–oxo calix[4]arene complexes which is stable over a very wide temperature range. These complexes display mesophases of unusually high stability and novel host–guest effects, which suggests that head-to-tail organization occurs in the mesomorphic state.
Figure 40. Proposed mechanism for 2-hydroxypropyl *para*-nitrophenyl phosphate cleavage by calix[4]arene based model complexes, 3-Zn_2 (left) and 5-Cu_2 (right) [R = $-CH_2-CH_2-O-CH_2-CH_3$].

8.10. Calixarenes in Nonlinear Optics

Organic molecules with π electron systems and unsymmetrical charge distributions are useful in nonlinear optics, for frequency-doubling of laser light and electro-optic switching [149, 150]. Reinhoudt and co-workers [151] reported that the tetranitrocalix[4]arene, shown in Figure 41, contains four nonconjugated D-π-A dipoles within a single molecule and it can be present in four idealized conformations with different relative orientations of the intramolecular nonlinear optic-phores. The high μ value of the tetranitrocalix[4]arene enables a high degree of orientation upon poling in a polymeric matrix [152]. It is reported that calix[4]arene based chromophore, calix[4]stilbazole, forms densely packed, highly ordered monolayers on silica surfaces [153]. The second order nonlinear optical properties of calix[4]arene for its different conformations have been investigated theoretically [154]. For further details on this subject, one may refer a recent textbook [155], *Nonlinear Optics of Organic Molecules and Polymers*.

8.11. Nanocavities

The design and synthesis of nanoscale molecular containers such as cavitands [156–158], hemicarcerands [159], and capsules [160–162] result in the selective binding, separation, and sensing of smaller molecules and ions, molecular transport and delivery, stabilization of reactive intermediates, and catalysis through encapsulation [163]. They also mimic the hydrophobic pockets of enzymes [164]. Synthetic calixarene derivatives having cavities of 15–20 Å contribute to molecular recognition thus giving new directions into nanotechnology, microfabrication, and molecular biology [165, 166]. The nanocavities can be used for the encapsulation of drugs and their active transport/delivery through cell membranes. In calix[4]arenes, the aromatic rings were fixed in the perfect cone conformation through the covalent bridging of proximal phenol oxygens with diethylene glycolic chains [167]. Thus the calix-cavitands formed are more rigid and show better affinity toward guest molecules. The crystal structures of calixarenes and the smaller cavitands derived from them showed that the guest molecule is positioned above the plane of the four carbon atoms of the cyclic polyaromatic skeleton [165, 166, 168–170]. The cavity's depth is generally less than 4 Å and this space is just sufficient for one methyl-sized fragment to be included. Several approaches have been developed to enlarge the cavity and achieve better guest entrapment. For example, triethylene glycol footed deep cavitands are functionalized with four *m*-amidinium groups
Figure 41. *para*-Nitro-calix[4]arene where phenolic oxygens are alkylated with *n*-propyl group.

at the upper rim in order to effectively bind mono- and dinu-cleotides in buffered aqueous and methanol solutions [171]. In addition to charged interactions and hydrogen bonding, the cavity also contributes to the overall binding process. A proposed adenosine monophosphate complex of this cavi-tand is shown in Figure 42. ^{1}H NMR and molecular mod-eling studies suggest that the adenine part is located deep inside the host cavity [172].

The cavitand shown in Figure 43 is a much deeper and open ended container molecule with a nanoscale cavity ∼14 Å deep and 12 Å wide reported to date [173]. Accord-ing to molecular modelling, such a cavity is able to accom-modate up to three benzene or chloroform sized molecules. However, its complexing ability toward small organic guests in nonpolar solutions appeared to be poor. The electron-rich interior resulted in considerable interactions with electron deficient fullerene C_{60} in toluene as shown in Figure 43. The open-ended nature of the cavitand is responsible for its host–guest properties.

An alternative strategy to make deep cavitands is to employ self-assembly through intermolecular hydrogen bonding. Multicomponent cavitands have been constructed by MacGillivray in the solid state by co-crystallization of resorcinarene (R = Me) and 4,4′-bipyridine from ethanol in the presence of an aromatic or polycyclic guest. This resulted in an one-dimensional wavelike polymer structure (guest = ferrocene, 1,1′-diacetyl ferrocene, p-chlorotoluene, adamantanon, and [2.2]paracyclophane), where the guest molecules interact with the aromatic walls through multiple C–H···π contacts as shown in Figure 44 [174–176].

8.12. Clamshell-Shaped Molecular Containers

Geometrically, clamshell-shaped hosts impose more con-strictive binding than cavitands and their inner cavities are still exposed to the bulk exterior. Unlike self-assembling

Figure 43. Deep cavitand with nanoscale cavity having electron rich interior provides considerable interaction for filling with fullerene, C_{60}. Adapted from [173], F. C. Tucci et al., *J. Org. Chem.* 64, 4555 (1999). © 1999, American Chemical Society.

capsules, their cavities are constructed through cova-lent bonding. Reinhoudt et al. reported the synthesis of large clamshell-shaped hydrophobic surfaces by linking two calix[4]arenes with one resorcinarene or one calix[4]arene with two resorcinarenes as shown in Figure 45 [177]. Four strong intramolecular hydrogen bonds between the bridging acetamide $CH_2C(O)$–NH and the oxygens of the cavitand acetal bridges were found to significantly rigidify the struc-ture of these extended surfaces. The resultant hosts (Fig. 45) bind corticosteroids, carbohydrates, nucleosides, and alka-loids in $CDCl_3$ solutions.

8.13. Self-Assembling Nanocapsules

Self-assembly represents an alternative way to construct nanocavities and their host–guest complexes [160, 161]. With appropriate curvature and carefully designed posi-tioning of interacting sites, calixarene-based self-assembling systems generate capsules. Capsules have been organized through hydrogen bonding and metal–ligand interactions. An example of self-assembling cavities is the calix[4]arene tetraurea dimer shown in Figure 46 [178, 179]. This has an internal volume of only 50–250 Å^3 and can entrap a single guest molecule of moderate dimensions [180, 181].

8.14. Spheres and Tubular Structures

The *p*-sulfonatocalix[4]arene has been reported to assemble in an up–up fashion to result in curved structures by Atwood and co-workers [182], using a reaction system consisting of Na$_5$[*p*-sulfonatocalix[4]arene, pyridine *N*-oxide, and La(NO$_3$)$_3$·6H$_2$O in 2:2:1 ratio. The hydrophobic regions of the calixarenes are assembled in an up–up radial symmetric fashion along the surface of a sphere, where they constitute an organic shell around an aqueous polar core. This spherical assembly measures ∼28 Å across and has a volume of ∼11,000 Å^3. The interior of the sphere consists of two Na(H$_2$O)$_6$ ions surrounded by an additional 24 water molecules. The cavities of the calixarenes are situated just below the polar surface of the sphere and constitute a series of hydrophobic pockets. Twelve pyridine *N*-oxide molecules penetrate the polar surface of the sphere and are bound within the hydrophobic pockets via π-stacking interactions. Their oxygen atoms extend outward and coordinate to La^{3+} ions above the surface of the sphere. The hydrophilic interstitial regions between the spheres contain, in addition to La^{3+} ions, an array of water molecules and hydrated Na$^+$ ions. The core of each sphere has a diameter of ∼15 Å and a volume of ∼1700 Å^3. Adjacent spheres are tethered to one another by coordination of sulfonate oxygen atoms to interstitial lanthanum ions. Thus these La(III) ion centers are both first- and second-sphere coordinated to the calixarene molecules.

When the three components are taken in a molar ratio of 2:8:1, crystals obtained revealed a tubular assembly of ∼28 Å in diameter. The calixarene molecules are arranged along the surface of a cylinder that is analogous to the spherical assembly in that there is a polar core, a hydrophobic midregion constituting the tube, and a polar outer shell. However, the organic shell is not composed of purely calixarene molecules but contains pyridine *N*-oxide molecules intercalated between the aromatic rings of adjacent macrocycles. The calixarene and the pyridine *N*-oxide molecules form a chiral helical assembly along the length of the tube. The helix consists of a single strand of alternating calixarene and pyridine *N*-oxide molecules and there are 4.5 such units per turn. Both the hydrophilic core and the hydrophilic interstices between the tubules contain complex arrays of sodium, lanthanum, and water molecules.

8.15. Synthetic Nanotubes

Calix[4]arenes in 1,3-alternate conformations have a π-basic benzene hole or interlayers through which metal ions can easily pass with the help of cation–π interaction [183]. This plays a crucial role in metal ion transport across ion channels, metal ion inclusion in fullerenes, and intercalation of metal cations into graphite layers [184]. Nanotubes of 1,3-alternate calix[4]arenes having a well-defined inner diameter for the metal tunneling have been reported (Fig. 47) [185].

Figure 47. Synthetic *nanotubes* of 1,3-alternate-calix[4]arene having a π-basic hole for metal tunneling.

to suit special applications of these based on their intrinsic properties. Properties such as metal ion binding and the capacity to hold and/or recognize molecules or species of calix[4]arenes have been guided and thoroughly refined by the rational design followed by the development. The metal ion complexation chemistry of calix[4]arene derivatives is still going on at a very slow pace. While the biomimetic chemistry of calix[4]arene derivatives is in its early phase, their ability to host organic and/or inorganic species in their neutral, cationic, or anionic form seems to have grown very rapidly during the past few years. Characterization of both the organic and the corresponding inorganic derivatives of calixarenes by different spectral and crystallographic methods has become an important feature in the current literature on calixarenes. Very recent studies have shown the putative utility of carefully designed calix[4]arene derivatives to act as catalysts, hosts, receptors, sensors, cavitands, and nanomaterials as reported in this review chapter. Based on the rate at which the studies are going on with the calixarenes in the literature, it is logical to draw a conclusion that the smartly designed derivatives of calix[4]arene would be occupying a pivotal role in molecular recognition, analytical devices, and materials science and technology that leads to the enrichment of the knowledge of nanoscience in order to eventually get into nanotechnology of calixarenes in the very near future.

GLOSSARY

Arene cavity   The cavity formed by the enclosure of the aromatic rings in a calixarene.

Calix[*n*]arenes   A group of phenolic macrocyclic molecules resulting from the condensation of *para*-substituted phenol and formaldehyde (*n* refers to the number of phenolic units).

Crystal structure   Three-dimensional arrangement of atoms derived from single crystal X-ray diffraction that provides information about the structure, conformation, and geometry of the molecule.

Functionalization   Chemical modification on the lower or upper rim leading to the formation of derivatives containing appropriate functional groups.

Lower rim   The rim containing the phenolic –OH groups in a *para*-substituted calixarene.

Metalloenzymes   Those enzymes that exhibit their function as a result of the presence of a specific metal ion.

Receptor   A molecule that possesses the ability to bind to neutral or ionic species through recognition.

Upper rim   The rim containing the groups present at the *para*-position in a calixarene.

9. CONCLUSIONS

It is evident from the literature that the field of calixarenes has been going through rapid phase changes during the past two decades ever since these were synthesized in pure and in large quantities. During the initial period, the literature was primarily focused on developing methods for organic derivatization, particularly of calix[4]arenes, at both its lower and upper rims. As a result of this, the literature of calix[4]arenes on one hand became very rich with a spectrum of organic derivatives; on the other hand, such an outcome led to the rational design of calix[4]arene derivatives

Cantilever-Based Sensors

D. Then, C. Ziegler

University of Kaiserslautern, Kaiserslautern, Germany

CONTENTS

1. INTRODUCTION

The invention of scanning force microscopy (SFM) by Binnig et al. in 1986 [1] was a first bridge between microscopy and micromechanics. SFM measures the interaction forces between two surfaces from the micrometer level down to the atomic scale. Intermolecular forces are not the only forces that can be detected by this technique. A wide variety of different signal domains such as magnetic [2], electrical [3], electrochemical [4], elastic [5], thermal [6], biological [7], and chemical [8] signals can be detected with high sensitivity and (moderate) speed through transduction into a mechanical motion of a cantilever beam. SFM measures the small forces acting on a sharp tip at the apex of a thin beam clamped at one side, the cantilever. The force on the tip bends the cantilever, which acts as a force transducer. The support of the cantilever is mounted into a holder and the motion of the beam is measured via the tunneling effect, with an interferometer, or via the optical lever deflection technique, the latter being the most commonly used method in commercially available SFMs due to its high resolution and its low costs. Newly developed smart force sensors use micromachined devices with integrated piezoresistive, integrated piezoelectric, and integrated capacitance detection of the cantilever deflection.

It is possible to produce inexpensive force sensors in a reproducible way by taking advantage of the batch silicon micromachining techniques developed for integrated circuit (IC) process technology. Miniaturization and mass production are the main reasons for the success of SFM in research laboratories and industrial applications. These lead to cantilevers with low spring constants for a high sensitivity to the applied forces or high resonance frequencies for faster response times and insensitivity to external disturbances. The commercial cantilevers are typically made of silicon, silicon nitride, or silicon oxide and are available in a great variety of different shapes, dimensions, and force sensitivities [9–14]. Recent developments combine the newest IC and complementary metal oxide semiconductor (CMOS) technologies to get intelligent cantilevers [15–23], extremely small cantilevers [24–31], or large arrays [32–39].

In the last few years a second evolution in the world of nanoscience was seen, and cantilevers were applied in scenarios other then detecting surfaces. Because of their above-mentioned benefits of high sensitivity, small dimensions, short response times, and low prize they were used to detect changes in temperature, surface stress, and mass in picogram amounts of analyte without touching the surface any more. Cantilevers were used in sensor systems to get a completely new type of miniaturized transducer based on fundamental principles of physics such as the bimetallic effect, surface stress, or the harmonic oscillator. With cantilever sensors it is possible to push "the powers of 10" into a region in which otherwise only time-consuming and expensive analytical tools can be applied or which is completely inaccessible by means of macroscopic techniques.

In this chapter the fundamental physics of microcantilever sensors will be described as well as recent methods, experiments, and prospective directions of the newest sensing systems. The discussion is limited to chemical and/or biological sensors as well as radiation sensors. Physical sensing devices such as accelerometers [40, 41], gyroscopes [42], or flow sensors [43, 44] with beam architecture will be excluded, but micromachined cantilevers show interesting abilities to enhance the power of these devices, too.

2. SENSORS AND BIOSENSORS

(Bio-)chemical sensors are miniaturized devices that convert a chemical state into an electrical signal. The chemical state is determined by different concentrations, partial pressures, or activities of particles such as atoms, molecules,

ions, or biologically relevant compounds to be detected in the gas, liquid, or solid phase [45]. A sensor can be divided into three main components. The first is the *recognition site* with a sensitive or selective layer that recognizes the signal of interest. In some cases there is also a preprocessing element (e.g., filter, temperature, catalyst, or preconcentration) that can add further selectivity or sensitivity. The second part of a sensor system is the signal *transducer*. It converts the chemical or biological information into the physical signal (e.g., mass change into frequency change of a quartz crystal microbalance [46]) which then can be detected, filtered, amplified, and displayed by a *readout system* as the third part (Fig. 1). There are a huge variety of transducer principles, but in the present context only acoustic (often called mass-sensitive) transducers are of importance. The advantage of using acoustic sensors compared with classical analytical techniques or most optical sensors is the possibility of working label-free.

An optimal sensor system should be highly selective, stable, and sensitive to the analyte ("sss"). It should be able to work continuously and time-resolved to allow for on-line or in-line detection of changes in concentrations. This is only possible if the sensor response is completely reversible. By the combination of several different sensors into arrays with pattern recognition and multicomponent analysis of the complex data pattern the challenge to analyze complex mixtures could be met successfully. Such arrays are often called "electronic nose" [47] or "electronic tongue" [48] although there are only a few similarities to the functions of a human nose and tongue. In an ideal electronic nose or tongue, each single sensor should respond to only one analyte with a signal proportional to the analyte concentration, ensuring complete reversibility. The vector space spanned by such sensor signals would consist of orthogonal basis vectors, which would make the required data processing easy and the sensor response unique. In reality, sensor signals are never unique and cross-sensitivities occur. The scientist or user has to select the best sensors with respect to the application, that is, sensitive layers that cover the range of possible interactions.

A biosensor is often defined as a compact analytical device incorporating a biological or biologically derived sensing element either integrated within or intimately associated with a physicochemical transducer [49]. Its recognition layer therefore consists of an enzyme, antibody, nucleic acid, microorganism, cell, or tissue. However, biological molecules can also be detected unspecifically on a nonbiological sensor surface, which will also be covered in this review.

The detection elements may be divided into three groups: In catalytic biosensors enzymes catalyze a reaction. In affinity sensors a specific recognition reaction between a receptor and a ligand, that is, a key–lock interaction, is detected. This includes antibody–antigen, nucleic acid–nucleic acid, enzyme–enzyme inhibitor, and other receptor systems. The third class includes all other principles, for example, membrane transport through specific pores or whole-cell sensors, in which one or more of the above-mentioned interactions can occur.

In this chapter only those systems in which mass changes take place are relevant. Therefore, mainly affinity sensors will be stressed in the following. One problem in the definition of an affinity biosensor is the antagonism of specificity and reversibility. A rule of thumb is that with increasing strength of the chemical interaction between sensitive layer and target analyte, sensitivity and selectivity are enhanced whereas the reversibility of the sensor decreases. Reversibility can be achieved either by selecting an appropriate chemical interaction (e.g., solubility interactions) or by refreshing cycles of the system (e.g., purging with reference/neutralizing gas/solution, adsorbing/desorbing steps) [50]. This reversibility is in strong contrast to the highly specific binding process of, for example, antibodies and antigens with high-affinity constants. Therefore, most affinity biosensors are not sensors according to the defintion given above but can be better described as dosimeters because the biomolecules pile up on the surface with exposure time.

3. TRANSDUCTION PRINCIPLES

In general there are three different methods to transduce the recognition event into a micromechanical motion. First, the frequency change due to additional mass loading or a change in the force constant can be measured; that is, the cantilever is used as a microbalance. Second, the bending of a bimetallic cantilever can be used as temperature sensor. In addition, cantilevers can work as stress sensors by measuring the bending due to changes in the surface stress at one side of the cantilever. The transduction principles are shown in Figure 2.

3.1. Resonant Behavior of Cantilever Beams

A basic understanding of the mechanical behavior of cantilever beams is crucial to develop cantilever sensors with optimized sensitivity and geometry. (However, those readers only interested in the general subject may skip this section.) The spring constant, resonance frequency, and corresponding quality factor will be derived in this section using the one-dimensional Euler–Bernoulli differential equation of an initially flat, thin, homogenous cantilever beam [51]:

$$\widehat{E}I \frac{\partial^4 w(x,t)}{\partial x^4} + (\rho A + \chi) \frac{\partial^2 w(x,t)}{\partial t^2} + \xi \frac{\partial w(x,t)}{\partial t} = q(x,t) \quad (1)$$

$\widehat{E}$ and ρ denote the apparent Young's modulus [see Eq. (2)] and specific mass density of the beam material, $A = hb$, the cross-sectional area, and I is the moment of inertia. ξ is the damping coefficient per unit length per unit velocity,

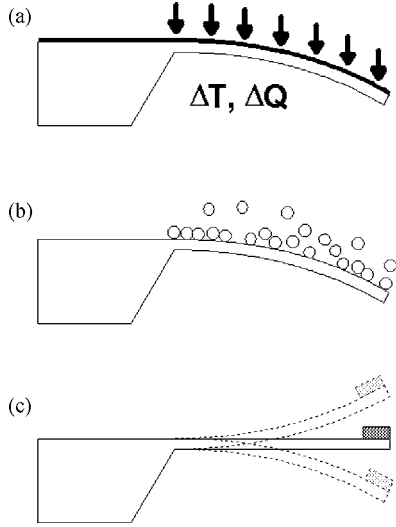
Figure 1. Schematic drawing of a sensor system. The information about the chemical nature and concentration of the analyte will be transduced into an electrical signal that can be displayed and stored.


Figure 2. Schematic drawings of the possible cantilever transduction principles: (a) bimetallic temperature and heat sensor; (b) surface stress sensor; (c) microbalance due to additional mass loading.

and χ is an additional mass per unit length. $q(x, t)$ represents the driving load in N/m. The additional mass χ can either exist due to adsorbing molecules on the surface or describe the mass of molecules of the surrounding media that are accelerated by the vibration of the beam. This leads to dependence of the resonance frequency, respectively, the resonance behavior, in general from the surrounding media. Effects of rotary inertia and shear deformations are not included in Eq. (1) nor are nonlinear terms due to a large vibration amplitude. Under the assumption of a beam structure with $b \gg h$, the apparent Young's modulus is given by

$$\widehat{E} = \frac{E}{1 - \nu^2} \qquad (2)$$

where ν is the Poisson's ratio and E is the Young's modulus of the beam material. The moment of inertia for a rectangular beam can be calculated as

$$I = \int_0^b \int_{-h/2}^{h/2} z^2 \, dz \, dy = \frac{1}{12} bh^3 \qquad (3)$$

By assuming a harmonic time dependence a variable separation with $w(x, t) = W(x)T(t)$ can be performed. For the case without an additional driving load this leads to [52]

$$\frac{\widehat{E}I}{\rho A + \chi} \frac{\partial^4 W(x)}{\partial x^4} \frac{1}{W(x)} = -\frac{\xi}{\rho A + \chi} \frac{\frac{\partial T(t)}{\partial t}}{T(t)} - \frac{\frac{\partial^2 T(t)}{\partial t^2}}{T(t)} \equiv \omega_0^2 = \text{const} \qquad (4)$$

The time variable can be written as

$$\frac{d^2 T(t)}{dt^2} + \frac{\xi}{\rho A + \chi} \frac{dT(t)}{dt} + \omega_0^2 T(t) = 0 \qquad (5)$$

The solution is a function of time which is equal to that of the model of the one-dimensional harmonic oscillator with $T(t) = Be^{-\gamma t} \sin(\omega_0 t + \varphi)$.

The variable of position can be written as

$$\frac{\widehat{E}I}{\rho A + \chi} \frac{d^4 W(x)}{dx^4} - \omega_0^2 W(x) = 0 \qquad (6)$$

The solution of a homogenous fourth-order differential equation is the sum of four linear independent solutions,

$$W(x) = c_1 \cos\left(\frac{\lambda}{L}x\right) + c_2 \sin\left(\frac{\lambda}{L}x\right) + c_3 \sinh\left(\frac{\lambda}{L}x\right) + c_4 \cosh\left(\frac{\lambda}{L}x\right) \qquad (7)$$

with the constants c_1, c_2, c_3, and c_4 assuming the boundary conditions

$$W(0) = 0 \quad \left.\frac{dW(x)}{dx}\right|_{x=0} = 0 \quad \left.\frac{d^2 W(x)}{dx^2}\right|_{x=L} = 0$$

$$\left.\frac{d^3 W(x)}{dx^3}\right|_{x=L} = 0 \qquad (8)$$

with L as the length of the cantilever and the nondimensional parameter, λ, defined by

$$\left(\frac{\lambda}{L}\right)^4 := \frac{\rho A \omega_0^2}{\widehat{E}I} \qquad (9)$$

The first two boundary conditions are due to the fact that one end of the beam is clamped. The third excludes any bending moment at the free end of the cantilever and the fourth excludes any torsion [53]. By assuming the boundary conditions, a characteristic equation can be calculated:

$$\cos \lambda \cosh \lambda = -1 \qquad (10)$$

with discrete values λ_a for λ for the first four modes [54]

$$\lambda_0 = 1.875, \quad \lambda_1 = 4.69, \quad \lambda_2 = 7.86, \quad \lambda_3 = 11.00 \quad (11)$$

By inserting these parameters into Eq. (9) the resonance frequency of a clamped beam with rectangular cross-section can be calculated as

$$\omega_{a,0} = 2\pi f_{a,0} = \frac{\lambda_a^2 h}{\sqrt{12}L^2}\sqrt{\frac{E}{\rho(1 - \nu^2) + \chi}} = \frac{\lambda_a^2}{L^2}\sqrt{\frac{\widehat{E}I}{\rho A + \chi}}$$

$$\text{with} \quad a = 0, 1, 2, \ldots. \qquad (12)$$

With the introduction of the quality factor

$$Q = \frac{\omega(\rho A + \chi)}{\xi} \qquad (13)$$

the resonance frequency of a cantilever beam can then be expressed as

$$\omega_a = \omega_{a,0} \cdot \left[1 + \frac{1}{4Q^2}\right]^{-1/2} \qquad (14)$$

$\omega_{a,0}$ is the resonance frequency in the undamped case $\xi = 0$. From Eq. (13) one can expect the quality factor to increase linearly with the resonance frequency of the cantilever beam.

Looking at Eq. (12) one can use the model of the one-dimensional harmonic oscillator

$$f = \frac{1}{2\pi}\sqrt{\frac{k}{m \cdot n}} \qquad (15)$$

with $n = 0.24$ as a geometrical parameter for the fundamental mode of a rectangular cantilever beam and k as the force constant:

$$k = \widehat{E}\left(\frac{h}{L}\right)^3 \frac{b}{4} \qquad (16)$$

An additional mass uniformly distributed over the surface can be correlated with a frequency change by

$$\Delta m = -\frac{k}{4\pi^2 n}\left(\frac{1}{f_0^2} - \frac{1}{f_m^2}\right) \qquad (17)$$

where f_m is the frequency of the loaded beam

$$f_m = \frac{1}{2\pi}\sqrt{\frac{k}{m^* + n\Delta m}} = \frac{f_0}{\sqrt{1 + \frac{\Delta m}{m}}} \qquad (18)$$

A Taylor series taking into account only the first order and $f_m = f_0 + \Delta f$ results in

$$f_m \approx f_0\left(1 - \frac{1}{2}\frac{\Delta m}{m}\right) \Rightarrow \frac{\Delta f}{f_0} \approx -\frac{1}{2}\frac{\Delta m}{m} \qquad (19)$$

By using the material parameters the sensitivity per unit area can be written as

$$\frac{\Delta m}{A} \approx -4\pi\sqrt{n} \cdot L^2 \cdot \sqrt{\frac{\rho^3(1 - \nu^2)}{E}} \cdot 2\Delta f \qquad (20)$$

The minimum detectable mass is given if one takes the minimum measurable frequency change. By considering that all material parameters are constant, the only variable parameter is the length of the cantilever. To achieve a better mass resolution and therefore a higher mass sensitivity the length of the cantilever has to be reduced. However, the length reduction is usually accompanied by a reduction of area also. The second possibility for getting a higher frequency change for a given mass change is to operate the system at higher modes.

Besides the frequency characteristics, the force constant is another important parameter. According to Eq. (17) the force constant has to be known if a quantitative calculation of the mass change due to the frequency change is performed. In the literature the mechanical behavior and the determination of spring constants is well described for various methods [55–61]. In Eq. (16) the force constant can be calculated from the material parameters. In reality the material parameters are unknown variables because of the production process of the cantilevers. The length and the width of the cantilever can be controlled quite well during the etching process, but the thickness of the cantilever is the critical parameter. In addition, the Young's modulus of the bulk material can change due to reflective coatings on one side of the cantilever. This could be calculated, too, but there are more elegant possibilities to calculate the force constant.

One possibility is to measure the static deflection of the cantilever because of the influence of defined forces [62, 63] or pressing with a reference spring [64, 65]. Dynamic methods will use the mean square amplitude of the thermal noise [53, 66] or the frequency shift due to adding a known mass at the apex [67] of the cantilever. For the thermal noise method especially, an easy and fast method for determination of the spring constant of soft cantilevers, the sensitivity of the optical detection system has to be known. The most common method for the determination of this lever sensitivity is that the cantilever is brought into contact with a hard surface and then moved a known distance. The slope of the resulting cantilever deflection versus distance yields the sensitivity, assuming that the piezo scanner driving the cantilever is calibrated. A method without touching the surface by using the drag forces of a moving cantilever is presented in [68].

The third important parameter to characterize the movement of a cantilever is the quality factor Q. The quality factor of a resonator is defined as

$$Q = 2\pi\frac{W_0}{\Delta W} \qquad (21)$$

where W_0 is the stored vibrational energy and ΔW is the total energy lost per cycle [compare Eq. (13) for Q described by material parameters]. The frequency stability of a resonator depends on different parameters. One is the noise acting on the resonator as well as the ability to store the energy that is applied to it. The minimum detectable frequency shift $\delta\omega$ of a cantilever with resonance frequency ω_0 under the influence of a thermal noise $k_B T$ can be estimated to be [69]

$$\delta\omega = \sqrt{\frac{\omega_0 k_B T B}{k Q\langle A^2\rangle}} \qquad (22)$$

where B, k, k_B, and T denote the bandwidth, spring constant of the cantilever, Boltzmann constant, and absolute temperature respectively. $\langle A^2\rangle$ is the mean square vibrational amplitude. From Eq. (22) it becomes obvious that an improved frequency resolution of the resonator is associated with an improved quality factor. The dissipation mechanisms that contribute to ΔW can be distinguished as internal damping due to the physical structure of the resonator and external damping caused by viscous and turbulent flow of the surrounding media. The inverse quality factor can then be written as [70]

$$\frac{1}{Q} = \sum_i \frac{1}{Q_i} = \frac{1}{Q_{\text{int}}} + \frac{1}{Q_{\text{ext}}} \qquad (23)$$

Q_{int} represents all dissipation effects due to the internal structure of the cantilever, whereas Q_{ext} includes all external effects (like viscous media) that act on the cantilever.

The gas damping in microstructures can be accessed by a finite-element simulation and is described in [71]. Another approach uses the model of a moving string of beads [72] instead of a beam-shaped geometry. The resulting drag force is the sum of the drag forces of the individual spheres. By assuming that the motion of the cantilever is in a viscous medium (e.g., liquids) the Reynolds numbers are not small

and the drag force becomes not only proportional to the speed but also to the acceleration. The damping can then be expressed as

$$\xi = 6\pi\eta R\left(1 + \frac{R}{\delta_L}\right) \tag{24}$$

The additional or induced mass can be expressed as [73]

$$\chi = \left(\frac{2}{3}\right)\pi R^3 \rho_L\left(1 + \frac{9}{2}\frac{\delta_L}{R}\right) \tag{25}$$

whereas R is the radius of the sphere, η is the viscosity of the medium, and ρ_L is the density. $\delta_L = \sqrt{(2\eta/\rho_L\omega)}$ can be derived from the Navier–Stokes equation and equals the thickness of an additional layer of molecules sticking at the sphere that have to be moved during the oscillation. The mass of the cantilever can therefore be described by a virtual mass $m' = m^* + m_I$ (m_I describes the additional mass of the accelerated molecules) [74].

The relative frequency change due to damping can be approximated by

$$\frac{\Delta\omega}{\omega_0} = -\frac{\pi R^3 \rho_L}{3\rho Lb}\left(1 + \frac{9}{2}\frac{\delta_L}{R}\right) \tag{26}$$

The change in resonance characteristics leads to a change in the quality factor [75]

$$Q = \frac{\lambda_a b h^2 \sqrt{\rho E/12}}{6\pi\eta R L(1 + R/\delta_L)} \tag{27}$$

where ρ and E denote the mass density and the Young's modulus of the beam material and δ_L is again the width of the boundary layer perpendicular to the direction of motion around the sphere. This result indicates an increasing quality factor with decreasing length or increasing resonance frequency. For more information on this complex theme, see, for example, [74, 76–78].

It can be seen from Eq. (22) and the above derivations that the quality factor is an important parameter in the resonance characteristics of a cantilever. An increased quality factor indicates a decreasing minimum detectable frequency change and therefore a better resolution (and sensitivity) of the sensor system. To increase the quality factor the method of active feedback can be used (Fig. 3). This was first introduced in [79] and is normally used for increasing speed and resolution in tapping-mode atomic force microscopy [80, 81].

The active feedback electronic consists of a variable phase shifter ϕ and a gain amplifier G. The equation of motion of a damped feedback system can be written as

$$\ddot{z}(t) + \gamma\dot{z}(t) + \omega^2 z(t) = F_0 e^{i\omega t} + F_2 \tag{28}$$

where k is the force constant, γ is the damping constant, and F_2 is a second periodic force generated by the feedback circuit. The original signal of the oscillator $z(t) = Ae^{i\omega t}$ is amplified with G and phase shifted with $\frac{\pi}{2}$ and fed back into the original system:

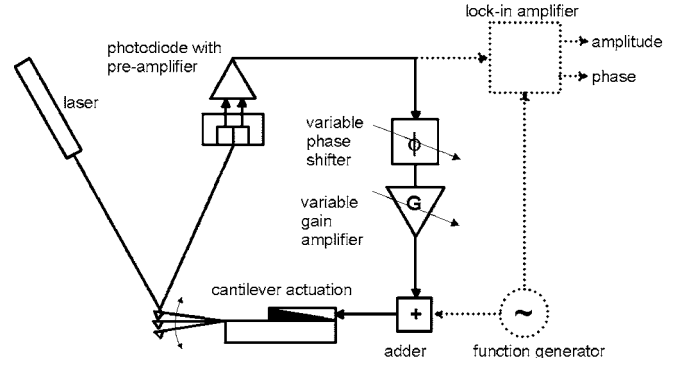
$$F_2 = G \cdot Ae^{i(\omega t + \pi/2)} = Ge^{i\pi/2}z(t) \tag{29}$$


Figure 3. Schematic drawing of an active feedback circuit with a variable phase shifter and gain amplifier (black and dotted lines) first presented by [79] and a self-oscillating system (only black lines).

The first-time derivative

$$\frac{dz}{dt} = i\omega e^{i\omega t} = \omega z e^{i\pi/2} \Rightarrow F_2 = \left(\frac{G}{\omega}\right)\frac{dz}{dt} \tag{30}$$

leads to an effective reduced damping constant by inserting Eq. (30) into Eq. (28):

$$\gamma_{\text{eff}} = \gamma - \left(\frac{G}{\omega}\right) \tag{10}$$

The reduced damping leads to a reduced full width at half-peak maximum and therefore to a smaller minimum detectable frequency shift.

Besides the actively driven system the electronic feedback circuit can be designed in a way that the system is self-oscillating and no further actuation has to be done. The electronic circuit has to be designed in a way that only the resonance frequencies of the cantilever are amplified and fed back and that the environmental noise is high enough to start the oscillation; that is, it has to contain the resonance frequency. This principle is well known from quartz crystals driven by an oscillation circuit to build a microbalance [82, 83]. Examples of cantilever sensors driven by a self-oscillating system will be discussed later.

3.2. Bending Behavior of Cantilever Beams

A uniform surface stress acting on an isotropic material increases (compressive stress) or decreases (tensile stress) the surface area. If this stress is not compensated for at the opposite side of a thin plate or beam, the whole structure will bend (Fig. 4). Between the areas of compressive stress and tensile stress there is a neutral plane that is not deformed. Because of the bending, a force F is acting at the distance x and in the neutral plane results in a bending moment $M = F \cdot x$. Therefore the radius of curvature R is given by

$$\frac{1}{R} = \frac{d^2 z}{dx^2} = \frac{M}{\widehat{E}I} \tag{31}$$
Figure 4. Side view of a thin beam. The beam bends around a neutral plane N with a curvature R due to a force F. The origin of the bending can be also be a change in the surface stress (see text).

where $\widehat{E}$ is the apparent Young's modulus and I is the moment of inertia, which is given by Eq. (3) for rectangular beams.

The change in the surface stress at one side of the beam will cause a static bending and the bending moment can be calculated [84] by

$$M = \frac{\Delta\sigma b h}{2} \tag{32}$$

$\Delta\sigma = \sigma_1 - \sigma_2$ is the differential surface stress with σ_1 and σ_2 as surface stress at the upper and lower sides of the cantilever, respectively. Inserting this into Eq. (31) yields Stoney's formula [85]

$$\frac{1}{R} = \frac{6(1-\nu)}{Eh^2}\Delta\sigma \tag{33}$$

By taking into account the boundary conditions of a cantilever ($R \gg L$) [86], Eq. (33) can be solved and the displacement of the cantilever s can be written as

$$s = \frac{3L^2(1-\nu)}{Eh^2}\Delta\sigma \tag{34}$$

Changes in surface stress can be the result of an adsorption process or electrostatic interactions between charged molecules on the surface as well as changes in the surface hydrophobicity and conformational changes of the adsorbed molecules.

In addition to surface stress-induced bending, the volume expansion of bimaterial cantilevers can result in a static bending. A bimaterial cantilever undergoes bending due to gas adsorption if the volume expansion coefficients of the two materials are different [87].

3.3. Thermal Effects on Cantilevers

By assuming a beam with a constant cross-section consisting of only one material, a change in the surrounding temperature will change the physical dimensions of the beam due to thermal expansion and the elastic properties of the beam material. In considering Eq. (12) the length L, width b, height h, and the Young's modulus $\widehat{E}$ show a temperature

dependence. With the assumption of a constant Poisson's ratio the relative change of the resonance frequency with temperature can be written as

$$\frac{1}{f_0}\frac{\partial f}{\partial T} = \frac{1}{2}\left(3\frac{1}{h_0}\frac{\partial h}{\partial T} - 3\frac{1}{L_0}\frac{\partial L}{\partial T} + \frac{1}{b_0}\frac{\partial b}{\partial T} + \frac{1}{E_0}\frac{\partial E}{\partial T}\right) \tag{35}$$

The subscript zero indicates the variable to be at the starting temperature T_0. The isotropic thermal expansion coefficient is given by

$$\alpha = \frac{1}{h_0}\frac{\partial h}{\partial T} = \frac{1}{L_0}\frac{\partial L}{\partial T} = \frac{1}{b_0}\frac{\partial b}{\partial T} \tag{36}$$

and the temperature coefficient of the Young's modulus by

$$\beta = \frac{1}{E_0}\frac{\partial E}{\partial T} \tag{37}$$

If these equations are inserted into Eq. (35), the temperature-dependent relative frequency change will be

$$\frac{1}{f_0}\frac{\partial f}{\partial T} = \frac{1}{2}(\alpha + \beta) \tag{38}$$

These considerations do not take into account different beam materials in a sandwich structure cantilever. A composite beam of two materials with two different thermal expansion coefficients undergoes a static bending if the temperature changes. For uniform heating the bending z is proportional to the adsorbed heating power and is expressed by the differential equation [88]

$$\frac{d^2z}{dx^2} = 6(\alpha_1 - \alpha_2)\frac{h_1 + h_2}{h_2^2 K}(T - T_0)L^2 \tag{39}$$

with

$$K = 4 + 6\left(\frac{h_1}{h_2}\right) + 4\left(\frac{h_1}{h_2}\right)^2 + \frac{E_1}{E_2}\left(\frac{h_1}{h_2}\right)^3 + \frac{E_2}{E_1}\left(\frac{h_2}{h_1}\right) \tag{40}$$

By assuming λ as the thermal conductivities of layers 1 and 2 and P as the total power on the sensor, the bending is derived as

$$z = \frac{5}{4}(\alpha_1 - \alpha_2)\frac{t_1 + t_2}{t_2^2 K}\frac{L^3}{(\lambda_1 T_1 + \lambda_2 T_2)b}P \tag{41}$$

Devices can be calibrated *in-situ* by following the bending of the sensor for a known power transduced into heat at the sensor [89].

Because of the above explanations, on the one side the cantilever can be used as a highly sensitive temperature sensor, but on the other side every temperature change will cause trouble if another parameter like the frequency change is the measured quantity.

3.4. Cantilever Deflection Detection Techniques

The most common method to measure the deflection of a cantilever is the optical lever technique [90]. This technique works with a focused laser diode beam at the free end of the cantilever, which is reflected into a split photodiode or a position-sensitive detector. When the cantilever bends, the reflected light moves on the photodetector surface. This movement is proportional to the cantilever deflection.

Another optical detection method is based on the interference effect [91–93]. The interference occurs between a reference laser beam and the reflection from the cantilever. This can be realized with a cleaved end of an optical fiber brought close to the cantilever [94]. One part of the light is reflected at the interface fiber/surrounding media and the other part is reflected at the cantilever back into the fiber. These two beams interfere inside the fiber and the interference signal can be measured with a photodiode. Interferometry is very sensitive and provides a direct and absolute measurement of the displacement, but it is limited by the wavelength of the laser light and therefore works only for small deflections.

If the distance between two parallel plates is changed, the capacitance between these plates is changing, too. This is used in capacitive sensors to measure the distance between the plates. If one of the plates is a cantilever, small changes in distance can be measured [95–97]. This technique is highly sensitive and provides absolute displacements, but it is unable to measure large displacements and does not work in electrolyte solutions because of the Faradaic currents between the capacitor plates [98]. It is therefore only of limited use in biosensor applications.

Alternative approaches use interdigital cantilevers as an optical diffraction grating. The reflected laser light forms a diffraction pattern, where the intensity is proportional to the cantilever deflection [99, 100]. This can be used for atomic force microscopy and infrared detection [101, 102] and is proposed for chemical sensing [103].

An alternative method uses piezoresistive cantilevers. If a piezoresistive material is set under stress, it changes its electrical conductivity. Implemented into cantilevers this effect can be used to monitor stress and therefore the bending of the cantilever. Such stress sensors can be integrated on a cantilever structure with a Wheatstone bridge measuring the resistivity [104–107]. A lot of developments are under way in the field of piezoresisitive cantilevers to gain better resolution and error-free measurements. The advantage compared to standard optical techniques is that neither additional optical components nor laser alignment is needed. Also the readout electronics can be integrated on the same chip using CMOS fabrication [16, 17], and they are unaffected by optical artifacts arising from distributions of the surrounding medium. The disadvantage of most piezoresistive cantilevers is that they only can be used in nonliquid environments because of Faradaic currents that will resut in a short circuit. Recent improvements allow the fabrication of thin, passivated resistors on cantilevers that can be used in electrolyte solutions [108]. Drift compensation is possible due to the development of a symmetrical configuration where the output signal is the difference between a sensing and a reference cantilever [23]. Piezoresistive cantilevers can also vary

their surface temperature by increasing the electrical current flow through the resistor layer. This is proposed to be implemented as a tool for breaking ligand–receptor bindings for the regeneration process of the sensing layer in biosensor applications [98].

3.5. Cantilever Actuation Methods

For cantilever sensors based on the measurement of the frequency change it is necessary to drive the cantilever. Without any external actuation the cantilever is only driven by the thermal noise $k_B T$. At room temperature the thermal energy is very low, and long measurement times are the consequence. A better way to drive the cantilever is to apply an external force. In the most commercially available scanning probe microscopes this is done by an external driving piezo mounted near the cantilever. The excitation takes part through mechanical stimulation by shaking the cantilever as well as the complete measurement setup. In a liquid environment the disadvantage of this method is that a lot of standing waves are generated through the acoustic stimulation of the medium. This can be avoided by direct driving of the cantilever using a piezoresistive layer similar to the piezoresisitive readout [22, 106, 109–112]. Lorentz forces can be used for the actuation of a cantilever either by evaporating a magnetic layer on the cantilever and applying an external magnetic field [113–117] or by a conductive pathway on the cantilever with an alternating current and the application of an constant external field [118–121]. Instead of magnetic actuation it is also possible to drive the cantilever with electrostatic forces [118, 122–125] or by an additional heater at the bottom of the cantilever [16, 18, 126].

4. SENSOR APPLICATIONS IN THE GAS PHASE

As is described above two basic operation principles are possible for micromachined beams: measurement of the frequency change or measurement of the static bending. In this section an overview from the first experiments to recent developments in the field of sensor applications in the gas phase is given.

First, experiments with the deflection detection will be introduced. The bending of a cantilever is very sensitive to changes in the environment of the cantilever and, more interesting, is very sensitive to changes at the surface of the cantilever. Even the smallest changes of the material properties due to adsorbing molecules will cause a static bending. One problem is that the changes have to occur only on one side of the cantilever and that the processes are very complicated and often not completely understood. Often a bending that occurs cannot be explained in full detail and therefore it is nearly impossible to make quantitative measurements. The other problem of the bending measurements compared to frequency measurements is that they are very prone to disturbances in the environment such as temperature changes (if one does not want to measure them) or vibrations.

Measuring the frequency changes seems to be better because one can easily quantify mass changes and the operation is a lot more stable. But there are other problems to

deal with: First of all the measurement setup is more complicated because of the active driving of the cantilever and one needs a complicated electronic device for the frequency feedback. In addition, the frequency change can arise from temperature changes and/or changes in the force constant.

This shows that each method has advantages and disadvantages and one has to decide upon the nature of the task that one has chosen. It is best to measure both the bending and the frequency change at one time. In this case the surface effects can be separated from mass effects. Most modern sensor systems measure the bending and the frequency change simultaneously.

4.1. Deflection Detection

The first experiments with microcantilevers beams published in 1994 dealt with temperature measurements and surface stress-induced deflections. Tiny heat fluxes were detected with bimetallic cantilevers by measuring the static deflection of the apex of a cantilever due to temperature changes. In [127] the observation of a chemical reaction with a sensitivity of 1 pJ and a temperature limit of $\sim 10^{-5}$ K was published, whereas in [128] thermal and ambient temperature-induced deflections were described. Then calorimeters and photothermal spectroscopy were presented with bending cantilevers as sensors. The use as a calorimeter for investigating surface catalytic reactions was achieved by coating the sensor with a thin Pt layer, which catalyzes the exothermic conversation of H_2 and O_2 to form water [88]. The thermal analysis of picoliter volumes was shown with the enthalpy change detection during the phase transition of n-alkanes [129–131]. The measurement of heat transfer during a chemical reaction was also described in [132].

By coating the sensor with a specific photon-absorbing material, it was possible to monitor heat effects as a function of wavelength [133]. With a multilayer architecture cantilevers could be used for photothermal spectroscopy as well [134]. In [135] a radiation dosimeter was presented with ultraviolet cross-linking polymers coated at one side of a cantilever as optical detectors. The exposure to radiation causes a bending in the cantilever. Sensing infrared radiation with high sensitivity and resolution was already shown in [136–139]. In [140] cantilevers were introduced as vibration sensors to control the power between two optical fibers.

The capability of micromachined cantilevers as stress sensors was shown with the adsorption of molecules to a freshly cleaved gold surface. The unspecific adsorption of ambient molecules like water or hydrocarbons [128] could be seen as well as the forming of self-assembled monolayers of thiols on the gold surfaces [141–144]. The alkanthiols formed a monolayer producing a compressive stress, which can be time-resolved, monitored, and fitted with a Langmuir kinetic. Cantilevers can be used to monitor thin film growth processes [84, 145] too. Good overviews of early cantilever sensor achievements are given in [89] and [146]. By measuring the electric field emanating from a charged-particle collecting sphere, cantilevers can be used as charged-particle flux detectors [147].

Bending microcantilevers can be used as chemical sensors by coating one side with a sensitive layer. This layer will amplify the bending effect compared with an uncoated cantilever. This was shown for the water adsorption of an uncoated and a gelatine-coated cantilever [148].

For (specific) chemical sensing a sensitive or selective layer is necessary to get any kind of signal, because without coating there will not be any interaction between the cantilever and the analyte. Polymer-coated cantilevers can be used to monitor concentration changes of different volatile organic compounds [149, 150]. It is easy to apply the polymers to the sensor surface with spray coating, a polymer solution with an airbrush pistol, or the use of a patch-clamp pipette and a micromanipulator. The polymer sticks due to physisorption at the surface and no further modification is necessary.

By using array architectures with sensitively coated cantilevers and uncoated reference cantilevers, it is possible to distinguish between a real signal and an error signal and to improve the signal-to-noise ratio. Cantilever arrays with differently coated cantilevers have been realized by a number of different groups. In [151–156] a system with a sequential optical readout was described for an array of eight cantilevers. Through coating with different polymers a great variety of organic compounds could be analyzed using multivariate data analysis techniques. The qualitative and quantitative analysis of mixtures of different organic solvents, perfume oils, flavors, and whiskies was performed. A multiple input chemical sensing unit with coated cantilevers, which are produced by including microelectromechanical system (MEMS) processes, was presented in [157, 158]. In [159] a complete microcantilever system with coated cantilevers was described. In [103] chemical sensing using optical diffraction from an array of microcantilevers was proposed. The micromachined cantilevers contained embedded deformable diffraction gratings and are functionalized with polymer coatings.

The latest inventions use array techniques combined with the high resolution of bending cantilevers for radiation detection arrays such as quantum well photon detectors [160] or electromagnetic and nuclear radiation [161]. A new field of investigation and invention for microcantilevers is array infrared detectors for building uncooled infrared devices [37, 102, 162–165] or thermal nanoprobes [33, 166]. Another approach in chemical sensing combines the adsorption-induced stress and the photoinduced stress of target molecules in one device. Microcantilevers that have adsorbed molecules will undergo photoinduced bending that depends on the number of adsorbed molecules on the surface. Also, when microcantilevers undergo photoinduced bending, molecules will adsorb on their surface differently. Depending on the wavelength and cantilever material used, the bending direction can be altered. By combining this with a chemically sensitive coating, a tunable selectivity is achieved [167–170].

A last approach of a microcantilever sensing device brings an array of piezoresistive cantilevers in contact with a sensitive layer. The swelling of the sensitive layer due to analyte exposure is measured directly by measuring the bending of the cantilever [171].

4.2. Frequency Detection

Mass-sensitive devices are well established in the wide field of sensors. One of the most popular representatives is the quartz crystal microbalance (QCM) device. They are well

described in the literature, work in gaseous and liquid environments, and are relatively cheap and easy to handle. They are driven by an oscillation circuit and are therefore very insensitive against external disturbances, providing very good mass sensitivity [172–174]. The reason for new mass-sensitive devices based on microcantilevers is the low mass of cantilevers compared with that of quartz crystal systems. If one calculates the mass sensitivity of a commercially available QCM with 10 MHz compared with that of a cantilever made of single crystal silicon with a fundamental frequency of 100 kHz, one gets a 1000 times higher mass resolution for the cantilever [175]. The mechanical properties together with the low price and fast response times make vibrating beams ideal candidates for new sensor systems. The first use of a coated beam structure as a chemical sensor was reported in [176], and it was first shown in practice with scanning probe microscopy cantilevers in [128], probing the resonance frequency shift due to water adsorption on the cantilever surface. The first CMOS processed beams for sensor purpose were presented in [177]. With these early devices a mass resolution ranging from nanograms to picograms was predicted. The sensitivity of the humidity sensing device could be enhanced by coating with gelatine or phosphorous acid [148, 178]. An early experiment for testing cantilevers as mass-sensing devices was the adsorption of mercury vapors to gold-coated cantilevers [146, 148, 179]. The first interactions between adsorption, force constant change, and frequency change were described in [84]. If the evaporated mercury layer is too thick, the change in the elastic properties of the beam material will completely compensate for the mass effects due to adsorption. A way to enhance the sensitivity of microdevices to mass loading is the use of materials with a high surface-to-mass ratio as a coating material. This was shown for humidity sensing with a few zeolite single crystals attached to a cantilever sensor [180–182]. Good overviews of the first experiments with cantilever sensors are given in [89] and [146]. A microchanical sensor for charged-particle flux detection is demonstrated in [147] with α particles. Frequency and damping rate variation due to electrostatic force gradients were measured. In [30] cantilevers are used as a low-cost detector in molecular beam experiments to measure the ratio of neutral to ionized clusters and the molecular beam profile with an array architecture of cantilevers.

In all these experiments no additional electronic circuit for active feedback was integrated. They were all driven either by the thermal energy or with an additional piezoelectric crystal as is used in scanning probe microscopes for the tapping mode.

A typical application of cantilever sensors is the detection of volatile organic compounds with an array of differently coated cantilevers. The selective coating consists of polymers that have shown their versatility in QCM systems [183]. The effect is based on a solubility interaction between an adsorbed analyte and the polymer. The closer the chemical properties of the analyte and the polymer, the more analyte is solved in the polymer matrix. This effect increases the density and the polymer gets heavier and starts to swell. With these effects and the chemical selectivity of different polymers it is possible to build a sensor array for analyzing mixtures of organic solvents.

A chemical sensor based on a micromechanical cantilever array consisting of eight differently coated cantilevers with a sequential readout system using a time multiplexing scheme was introduced in [154, 184]. In this setup the cantilever motion is detected via beam deflection with an array of vertical cavity surface-emitting lasers and a position-sensitive detector. The time-multiplexing scheme allows only one cantilever at a time to be monitored. In the dynamic mode the cantilever is driven by a piezoelectric actuator and the frequency change is controlled with a phase locked loop (PLL) controller. This system enables the simultaneous detection of the frequency change and the static bending.

A different approach uses an array of piezoresistive cantilevers with an integrated microheater for calorimetry and mass detection [33]. For microbalance purposes the frequency change during the outgasing process of photoresist due to ultraviolet exposure was monitored.

In [185–188] the parallel frequency readout of an array of polymer-coated mass-sensitive transducers for sensor applications is described. The coated cantilevers were exposed to vaporized organic solvents. Parallel detection of the thermal noise of the cantilevers was possible with an optical beam deflection technique. By adding a cylindric lens in front of the laser diode a line focus is formed, which can be used to illuminate a whole array of cantilevers. The light is reflected from the beams and collected in a split photodiode. The Fourier spectrum of the detector signal represents the response of the cantilever array to thermal excitation and reveals the resonance frequencies of each individual cantilever. The advantage is the simultaneous detection of several cantilevers and the improvement of the sensitivity by measuring higher eigenmodes. However, this method is very time consuming (the Fourier analysis requires long recording times), and it is impossible to monitor the bending of the cantilever at the same time. The data were evaluated with principal component regression (partial least squares, one method of the multivariate data analysis) for quantitative and qualitative analysis. Therefore, the prediction of unknown concentrations in a binary mixture was possible.

A new way to enhance sensitivity is the use of bridge structures, which are both-ends-supported beams. In [189] the fabrication of a micromechanical mass-sensitive resonator using silicon-on-insulator substrates was presented. Bridge structures have a 6.3 times higher fundamental frequency compared with one-end-supported beam structures and therefore have a higher mass sensitivity. The resonators are driven electrostatically and read out optically by means of the beam deflection method.

In all these experiments no additional electronic circuits for active feedback have been integrated. They were all driven either by the thermal energy or with an additional driving system (piezoelectric crystal or electrostatical) as is used in scanning probe microscopes for the tapping mode. As described in Section 3.1 the sensitivity can be enhanced by enhancing the quality factor. The quality factor is related to damping and an active feedback loop reduces damping. This was realized in the latest cantilever sensor systems where one can find stable self-oscillating cantilevers with extremely enhanced sensitivity.

In [190] a feedback driven system was developed. In this approach an additional feedback circuit is added and PLL device actively drives the frequency. Due to the magnetic actuation this system can be used in a liquid environment as well (see Section 5.3).

A promising approach for microcantilever applications is the combination of the sensitivity of micromachined beams with CMOS technology. By including the CMOS process in cantilever fabrication, it is possible to integrate the electronics on the substrate and to get extremely compact devices. A CMOS resonant beam gas-sensing system with on-chip self-excitation was presented in [38, 50, 121, 191–194]. In these devices the cantilever is thermally excited with two heating resistors in the cantilever base that are heated periodically. The temperature increase on the cantilever generates a bending moment due to the difference in thermal expansion coefficients. The cantilever motion is detected with a piezoresistive Wheatstone bridge at the base of the cantilever. The active feedback circuit is integrated on-chip. The output signal of the Wheatstone bridge is filtered and amplified, and the phase shift is controlled by a Schmitt trigger that can be adjusted externally. The phase is shifted to ensure positive feedback. The result is an integrated oscillator operating at the cantilever resonance frequency with short-term stability of better than 0.1 Hz [38, 195]. The cantilever has an on-chip thermal actuation and a closed feedback loop preamplifier circuitry (Fig. 5). For sensor test purposes the cantilevers were coated with different polymers for the identification of organic vapors. With multivariate data analysis it is possible to analyze quantitatively and qualitatively a binary mixture of two different organic solvents. Advantages of this system are the high sensitivity, its compact design, the array architecture, and the integrated electronics. The disadvantages are the limitations with a gaseous environment (the CMOS circuits have not been stable in liquids so far) and the fact that the simultaneous detection of static bending is not possible.

Another approach for the use of scanning probe microscopy cantilevers as transducers in gas sensor systems was described in [175]. The cantilevers were either actuated electrostatically or magnetically and read out optically with the beam deflection technique. For the electrostatic actuation they were integrated in a capacitor-like circuit in which either the cantilever or the counter electrode was supplied with alternating current voltage and the other electrode with direct current voltage or vice versa. For magnetic actuation the cantilevers were coated with a magnetic material like iron or cobalt and premagnetized normal to the cantilever axis. An array was built up of two times three cantilevers at each substrate with different polymer coatings. The measurement chamber was integrated in a gas-mixing station to provide different gases and gas mixtures to the measurement system. The readout can only be done sequentially so far. The cantilever system was integrated in a closed-loop feedback system in which the signal from the cantilever is filtered, amplified, and fed back. The closed loop setup provides stable self-oscillation at the resonance frequency of the cantilever with a short-term stability of 0.005 Hz for the electrostatic and 0.01 Hz for the magnetic actuation [196]. The quality factor can be enhanced for a cantilever with 100 kHz from ∼200 with vibrating in air driven by the thermal energy up to 400,000 driven actively. This enhancement provides a 1000 times higher frequency stability compared with the systems actuated with thermal energy (Fig. 6). With this measurement electronics it is possible to measure frequency changes and the static bending of the cantilever simultaneously.

For gas-sensing purposes different polymers were chosen so that with multivariate data analysis it was possible to analyze quantitatively and qualitatively a ternary mixture of three different organic solvents. A qualitative principal component analysis of the mixture after normalizing the data set is shown in Figure 7. In a principal component analysis (PCA), a high dimensional vector space (one dimension from each cantilever sensor if only one variable like maximum frequency change is evaluated) can be projected to two (or at least less than the original) dimensions, which nonetheless contain nearly the whole information. In the so-called scores plot of a PCA, data points which reflect similar properties cluster in a certain region. The more similar the properties, the closer two points are together.

Figure 5. Micrograph of a 150 μm long resonant cantilever with an on-chip feedback circuit, piezoresistive Wheatstone bridge, and thermal actuation. Reprinted with permission from [38], D. Lange et al., *Anal. Chem.* 74, 3084 (2002). © 2002, American Chemical Society.
Figure 6. Frequency spectrum of a cantilever driven by thermal noise (upper curve, triangles) and of the same cantilever driven with a closed feedback loop and magnetic actuation (lower curve, squares), measured with the spectrum analyzer function of a hp4195A [175].
Figure 7. PCA scores plot for the calibration of an array of six polymer-coated cantilevers showing the first two principal components for qualitative and quantitative analysis of a ternary mixture of organics solvents (before calculation of the PCA the data were normalized).

Which property leads to the clustering depends on the particular system. Here, data points cluster if interactions with the sensors and hence their chemical natures are similar. As can be seen in Figure 7 the data points rearrange in clusters. The larger the distance between two clusters the better the sensor array is able to separate the two analytes. After the system was calibrated with a training set of different ternary mixtures, a linear regression model with the partial least squares (PLS) method was applied and a prediction of unknown concentrations could be done. In Figure 8 the predicted values are plotted against the true concentration values of an organic solvent. The concentration is given in parts per million of the carrier gas (synthetic air). Obviously, an acceptable prediction is achieved.

Advantages of this system are the high short-term stability, the easy setup, and the possible use in liquid environments. The disadvantage is that so far a parallel readout is not possible.
Figure 8. Predicted concentrations vs. true concentrations for 1-butanol. The model used for this prediction was a linear regression model (PLS2). The ternary mixture was evaluated for only one unknown concentration after training the model with the data from Figure 7.

5. SENSOR APPLICATIONS IN THE LIQUID PHASE

In biosensing applications there is a need for fast, easy to use, cheap, and highly sensitive methods for the recognition of biomolecules. A high grade of parallelization is a must because of the demand of the pharmaceutical industry for high throughput screening. All these points can be fulfilled by micromachined cantilever sensors, and therefore they are the ideal candidates for biosensing applications.

5.1. Surface Modification

As defined in Section 2 a liquid sensor or, more specifically, a biosensor has as its main part a transducer combined with a recognition unit. The recognition element is in most cases a single-strand DNA, a protein, or an antibody. These molecules usually will not stick at the surface themselves. Their long-term stability on the surface is in most cases not given. Therefore, a chemical surface functionalization has to be applied to deposit a receptor layer on a cantilever surface. The ideal case of a surface functionalization is a closed, uniform monolayer of the receptor that is covalently anchored to the surface with enough space to interact with the specific ligand. The receptor activity should be maintained over time and resist several regeneration cycles.

To anchor a molecule covalently to a surface the sensor has to be modified and functionalized. Most cantilevers are made of silicon, silicon nitride, or silicon dioxide. Such a surface can be activated and functionalized with silanes [197]. The silanes form a dense polymer covalently linked to the surface with free functional side groups. These groups can react with other side groups of the target molecule. Another popular method for surface functionalization is the evaporation of thin layers of noble metals like gold. Alkane chain molecules with thiol side groups form ordered self-assembled monolayers (SAM) on gold substrates [198]. These uniform, densely packed, and covalently linked monolayers can be synthesized with different chain lengths and end groups. The end groups are used to link other molecules to the functionalized surface. With the chain length one can vary the spacer length between the surface and the active site in the recognition layer and therefore guarantee the best possible activity. Because of their variability SAMs are one of the most popular methods used for biosensor applications.

From the application point of view, one has to decide which surface modification technique is required. Among others, the following parameters are involved in the choice of the chemical surface modification protocol: type of substrate (e.g., plastic, glass, silicon, gold, or ceramics), the functional unit that has to be attached (e.g., polymers, antibodies, or other proteins or lipids), the type of sample (e.g., DNA, DNA–protein mixtures, pure proteins, or cells), and the type of liquid transport (e.g., pressure driven or electroosmotic). Additional introductions to surface coating techniques and reviews can be found in [199, 200].

If one wants to use the deflection detection method for cantilevers, only one side has to be functionalized. Using thiol monolayers this can be done by evaporating gold only on one side of the cantilever or incubating only one side

of a double-sided gold-coated cantilever in the thiol solution. Incubating only one side always causes stress that has to be taken into account [143]. In [201] a procedure is described for coating each side of the cantilever with a different thiol. Nevertheless, surface functionalization is as easy as it sounds, but if deflection detection is used the experimenter has to ensure that the specific interaction occurs only at one side of the cantilever and, even more important, unspecific interaction is blocked. One easy way to block surfaces against unspecific adsorptions is treatment with bovine serum albumin (BSA), a protein with the ability to adsorb on nearly every surface and to be very resistant to a wide variety of chemical and physical conditions such as changes in salt concentration, weak acids and alkaline solutions, and temperature changes. Besides the property of blocking surfaces, the unspecific protein adsorption can be used for surface modification too. By using functionalized BSA a surface can easily be modified biologically with a close, uniform, and compact layer. One example is the modification with biotinylated BSA to get a biotin surface coverage [202]. Another way to modify surfaces with adsorbing proteins is protein A. Protein A has nearly the same adsorbing characteristics as BSA, and it is able to bind the F_c fragment of most immunoglobulin G antibodies [203], which comprise the largest class of antibodies. With this method an antibody-coated surface can be prepared. Besides blocking the surface against unspecific adsorption with BSA or other proteins, the surface can be covered with a monolayer of nonreactive macromolecules or polymers. Polyethyleneglycols have proven their suitability for protecting surfaces against the unspecific absorption of proteins [204, 205].

Organic layers can be created on solid substrates without the need for reactive surface sites with Langmuir–Blodgett (LB) film transfer. The LB deposition transfers ordered layers of amphiphilic molecules from the water/air to the solid/air interface and allows the precise control of multilayer formation [206]. Sol–gels can be used for surface functionalization too [207]. They allow the creation of layers of porous materials with controlled pore size [98]. An increase in the active area can act as a catalyst with the pores serving as a mechanical filter to improve the specificity of the interaction [208].

5.2. Deflection Detection

With the deflection detection method in liquids it is possible to use cantilevers as stress sensors by performing electrocapillary curves with gold- or platinum-coated cantilevers as working electrodes [209]. The change in voltage causes a static bending and enables the study of the thermodynamics of the electrode–electrolyte interface. Similar electrocapillary curves were reported in [89, 210]. In [211] the bending of a cantilever due to the electrochemical deposition of polyaniline to one side of the cantilever is reported. By cyclic oxidation and reduction of the polymer the cantilever is reversibly deflected and restored to its original position.

Changes in surface energy can also be measured with bending microcantilevers. In [212] a cantilever deflects due to changes in the pH value or salt concentration of the surrounding liquid. This effect could also be shown for thiol-modified cantilevers [201]. Differences in the

pH dependence of a mercaptohexadecanoic acid-coated cantilever and a hexadecanethiol-covered reference cantilever were reported in [213]. Additional experiments have been presented with metal-modified and aminosilane-modified surfaces. Only the change in the pH value influences the bending; negligible bending was found for variations in salt concentrations [214]. Trace amounts of Hg^{2+} can be detected by using a gold-coated microcantilever [215]. The bending occurs due to accumulation of the Hg^{2+} on the gold surface. Coating the surface with a SAM of a long-chain thiol compound could improve the sensitivity. The detection of cesium and calcium ions was possible with the modification of the surface with an ion-selective SAM. A method for *in-situ* monitoring of ions in the range 10^{-7}–10^{-11} M was developed in [216, 217]. In addition, the use as a temperature sensor in liquid environment was shown in [89]. A polymer-coated cantilever can be used for the detection of different amounts of ethanol in water. It was proposed in [150] that the bending of the cantilever due to a change in ethanol concentration is caused by a swelling of the polymer matrix. In addition, the adsorption-induced variation in the spring constant of microcantilevers due to Na^+ ions was proposed in [218].

All of these experiments based on the measurement of the bending of the cantilever and a wide range of signal domains such as pH value, salt concentration, temperature, and electrochemical activity can and will be transduced by a static deflection of the cantilever. During the measurement of a biological affinity reaction all these parameters have to be kept constant or the result is ambiguous. This problem and the difficulties in the quantification of the results are always present during the experiments.

It is possible to build a chemical sensor based on polymer-coated microcantilevers in a liquid environment. In [219] thiolated β-cyclodextrins form a SAM on the cantilever surface, which enables an unspecific interaction with analyte molecules such as a naphthalene derivative. Similar results could be obtained for other cyclodextrin layers on smooth and nanostructured gold surfaces.

Since the introduction of microcantilevers many biological experiments using static deflection have been presented. In [220–222] a so-called force-amplified biological sensor was used to take advantage of the high sensitivity of scanning probe microscope cantilevers to detect the presence of small magnetic particles bound to a cantilever by a sandwich immunoassay technique. The magnetic particles were functionalized with a specific biological species whose counterpart is on the cantilever surface. To detect the binding event the deflection of the cantilever is measured while the magnetic particles amplify the deflection through magnetization of a strong permanent magnet and a modulated additional magnetic field. With this technique concentrations down to 10^{-18} M were proposed to be detectable.

An important field of investigation is the unspecific adsorption of proteins and cells. In [223] the interrogation of living cells grown directly on the cantilever surface to external chemical stimuli was proposed. The unspecific adsorption of proteins such as BSA on one side of the cantilever causes stress and therefore a static bending of the cantilever [153, 212, 224]. The differentiation between the adsorption of a low-density lipoprotein and its oxidized form on heparin

was monitored in [225] as well as the surface stress induced by slow conformational changes of proteins in [226].

Besides the field of unspecific adsorption, the field of specific binding events is very promising. In [146] the variation in an antibody-coated microcantilever deflection as a function of time due to interactions with antigens was reported. The adsorption kinetics and mechanical properties of thiol-modified DNA oligonucleotides on gold were investigated with microcantilever sensors [227, 228]. The sensor used had an integrated piezoresistive readout and is integrated in a microliquid handling system. The specific detection of two forms of prostate-specific antigen over a wide range of concentrations in a background of different proteins was reported in [229]. The antigen–antibody interaction of biotin and streptavidin or the binding of a herbicide to its monoclonal antibody with a bending cantilever as transducer is described in [201, 230]. This enables the label-free detection of an antigen–antibody interaction with a miniaturized micromechanical system.

With cantilever sensors one can also enter the field of genomics. A first example of an array of cantilevers detecting DNA hybridization was presented in [231]. The hybridization of complementary oligonucleotides showed that a single mismatch between two 12-mer oligonucleotides is clearly detectable. The principle of this hybridization reaction is shown in Figure 9. These promising results were obtained in
Figure 9. Schematic illustration of a hybridization experiment. Each cantilever is functionalized on one side with a different 12-mer oligonucleotide base (red or blue) differing in only one base. (a) The differential deflection signal is set to zero. (b) After injection of the first complementary oligonucleotide (green), hybridization occurs on the cantilever providing the matching sequence (red) and increasing the differential signal Δx. (c) Injection of the second complementary oligonucleotide (yellow) causes the cantilever functionalized with the second oligonucleotide (blue) to bend. Reprinted with permission from [231], J. Fritz et al., *Science* 288, 316 (2000). © 2000, American Association for the Advancement of Science.

[232] with a 10-mer oligonucleotide. It is possible to measure with cantilever sensors single nucleotide polymorphisms fast and easily.

5.3. Frequency Detection

All of the previously mentioned examples of cantilever liquid sensors are based on the bending of the micromachined beam. The most important problem that has to be solved if the frequency change in liquids should be the measured value is the damping in liquids. As described in Section 3.1, in liquids high damping occurs with a decreasing resonance frequency and, even more important, a decreasing quality factor. Generally the quality factor decreases by 2 orders of magnitude if the surrounding medium is changed from air to water. Because of these effects it is nearly impossible to measure frequency changes below 10–20 Hz.

The damping is caused by changes in the density and the viscosity in the surrounding medium and can be explained by an increase of the effective mass due to an added mass of the liquid being dragged with the cantilever. The resulting frequency change can be used for quantitative measurements of the density/viscosity of different liquids [74, 233].

In [146] the hybridization of an 8-mer DNA oligonucleotide is proposed to be measured with the frequency change of a resonating cantilever, but no data have been published. With a cantilever operated in the resonating mode in [234] the adsorption of bacteria was investigated. The number of bacteria adsorbed onto an antibody-coated surface could be weighed and counted. The measurements were not only measurements in the liquid phase, they were also performed on a dry cantilever in air to get a higher frequency resolution. In [235] cells were been immobilized, but measurement of the frequency change was not reported.

The main problem in all these measurements is the high damping, not the biological preparation. A solution to this problem is to take advantage of the closed feedback loop described earlier. If it is possible to design a closed feedback loop that will work in liquids in an appropriate manner, the damping could be reduced and the quality factor enhanced. This was done in [190] to measure ethanol in water with a polymer-coated cantilever and the antigen–antibody interaction STAR71-BRAC30. In this measurement setup the cantilever is driven with a PLL-controlled oscillator connected to a feedback loop with a variable phase shifter and gain amplifier. The results obtained are a first step in the direction of measuring biological interactions in the liquid phase with resonating microcantilevers. Another promising result is described in [175]. In this setup a self-oscillating system is designed that needs no further actuation. This easy design enables the stable oscillation of cantilevers in the liquid environment. The versatile use of this system was proven with the quantitative measurement of the viscosity and density changes in different ethanol/water mixtures. The short-term frequency stability obtained is approximately 0.3 Hz and therefore an enhancement of the quality factor of 2 orders of magnitude was possible.
Figure 10. Optical microscope images of a sensor chip which consists of 10 piezoresistive cantilevers in a channel and 4 inlets/outlets. The piezoresistor, which serves as a readout mechanism to detect the bending of the cantilever, is fully encapsulated and can be used in liquids. Reprinted with permission from [227], J. Thaysen et al. "International Conference of Microelectromechanical Systems," pp. 401–404, 2001. © 2001, IEEE.

6. SUMMARY AND FUTURE TRENDS IN MICROCANTILEVER SENSORS

In this chapter it was shown that most of the fundamental problems in cantilever sensor technology are solved in the laboratory state. It is possible to fabricate small cantilevers with low force constants that are very sensitive to bending moments. On the other hand, stiff cantilevers can be produced with high frequencies that are very sensitive to mass changes or changes in the force constant. There are a large variety of different methods for measuring the movement of the cantilever, starting with optical techniques and ending with CMOS-manufactured piezoresistive cantilevers. A few different methods for coating the surface with different polymers for gas sensing purposes and with biological layers for biosensing purposes were introduced. First approaches to work with arrays of cantilevers for reference measurements and pattern recognition to improve signal quality were presented. In addition, some methods based on closed feedback loop operations for the enhancement of the quality factor in gaseous and liquid environment were shown.

Most of these measurements are promising approaches to a completely new class of miniaturized sensor systems. However, under real conditions sensors have to be stable long-term with low power consumption in an extremely small housing for low cost. Ease of use and reproducibility are additional factors for an industrial sensor system. In biomedicine and biotechnology only small amounts of reagents are available and high sensitivity and high throughput screening are requirements. Furthermore, the preparation of high amounts of reproducible biofunctionalized surface modifications in an easy-to-use liquid handling system is necessary for biosensing applications.

At present there are several approaches to solving these problems. In Figure 5 CMOS-processed cantilevers combined with subsequent CMOS-compatible micromachining

were presented with the complete electronic circuitry for cantilever driving and signal conditioning [38, 195]. With this industrial technique it is easy to mass produce large and compact arrays of integrated cantilevers for the detection of gaseous analytes.

Besides an integrated readout and driving system it is necessary to combine sensing systems with the requirements of biotechnology. One approach is an array of 10 cantilevers with a piezoresistive readout for deflection detection integrated into a microfluidic handling system onto a silicon chip as shown in Figure 10. These cantilevers are completely encapsulated and can be operated stably in liquid environments.

Another development focuses on larger arrays. At the moment an array of 2 to 10 cantilevers is state of the art, but this is not enough for the requirements of the industry for extremely high parallelization. Large sensor arrays with 1024 cantilevers combined with MEMS technology are used in [34, 236, 237] as ultra-high density storage devices. Besides the piezoresistive readout of these large arrays, new optical readout techniques are being explored [37, 103, 165, 238] for parallel optical detection.

One next step will be to go to smaller cantilevers with higher frequencies and therefore better mass resolution in the dynamic mode of operation. These approaches are presented in [24–31] for an optical detection system. Nanometer-sized cantilevers with frequencies in the megahertz range and integrated CMOS circuitry are the newest steps in the future direction of high resolution mass sensitivity [239, 240].

GLOSSARY

Biosensor Often defined as a compact analytical device incorporating a biological or biologically derived sensing element either integrated within or intimately associated with a physicochemical transducer.

Complementary metal oxide semiconductor (CMOS) Special semiconductor technology, standard process for most integrated circuits.

Integrated circuit (IC) Semiconductor device (e.g., amplifier, oscillator, or microprocessor), in which all resistors, capacitors, and transistors which perform the desired function of the circuit are processed together.

Multivariate data analysis Methods for dealing with large tables of data by displaying the data in a few meaningful plots that contain the most important information. Methods for displaying are, for example, principal component analysis for an overview over groups and trends, the classification or discriminant analysis for analyzing the groups, and the multiple regression analysis or partial least squares projection to build quantitative models for prediction of unknown analytes.

Scanning force microscopy (SFM) A method to measure the interaction forces between two surfaces for getting a three-dimensional picture of the surface.

Sensor A miniaturized device that converts a chemical state into an electrical signal. It mainly consists of three parts: the recognition site, the transducer, and the readout system.

Carbon Nanomaterials

Maheshwar Sharon

Indian Institute of Technology, Mumbai, India

CONTENTS

1. INTRODUCTION

The element carbon occupies a special place in nature. The whole living world is built of carbon, which makes a huge number of (organic) compounds. This is possible because of the electronic structure of the carbon atom, resulting in different chemical bonds. Though carbon belongs to the same group as silicon, thanks to the carbon bonding degeneracy, unlike silicon, carbon can exist in various allotropic forms, starting from sp^2 bonded graphite, across a whole variety of carbon materials including glassy carbon, amorphous sp^2 bonded carbon, polymeric materials, fullerenes, nanotubes, amorphous diamond-like carbon with majority of sp^3 bounded atoms, to diamond with strong sp^3 tetrahedral bonds.

Carbon has been accepted by the power source industry because of its unique properties of good electronic conductivity, good intercalation capability, chemical inertness, low cost, wide availability, ease of fabrication, and availability in many different forms. One of the earliest uses of carbon in a commercial battery was in 1841, when Robert Bunsen proposed replacing the expensive platinum current collector of a Grove cell with a more cost-effective carbon one.

Nowadays the unique properties of carbon make it a preferred constituent of virtually all power source technologies. Better performance of carbon in lithium battery is achieved using Chevron acetylene black, which has a surface area of 40 m^2 g^{-1}, instead of graphite (5 m^2 g^{-1}). High-surface-area carbons, such as Ketjenblack (1000 m^2 g^{-1}) or Black pearl 2000 (2000 m^2 g^{-1}), could further improve its performance. Various forms of carbon have been considered as hydrogen storage media, such as carbon nanotubes or carbon nanofibers [1]. If the high storage capacity of nanofibers can be realized in a practical system, it could revolutionize hydrogen storage for fuel cell application. Carbon in supercapacitors is also being developed as a rechargeable power source for electric vehicles and consumer electronics. Carbon is one of the most common electrode materials, either in powdered form or as woven cloths with surface areas in the range of 1000 to 2000 m^2 g^{-1} and pore size from <2 nm to >5 nm. Intense research is being conducted worldwide into development of carbon nanomaterials for lithium battery technology, hydrogen storage, and fuel cells.

Carbon has also been gaining importance for its ability to induce different properties and to form composite materials. The term composite materials is often taken to mean continuous fiber-reinforced polymer-matrix composites. This family includes glass fiber-reinforced polyester resins, used for boats and large tanks, and carbon fiber-reinforced epoxy resins, used on many aircraft. They offer a very good combination of high stiffness and low density. Another form of commercial carbon is "whiskers," which are fibrous single crystal and which have been produced commercially since 1962. Relatively inexpensive silicon carbide whiskers can be formed by the pyrolysis of rice husk. The husk of rice is rich in silica. During pyrolysis the cellulose dehydrates to carbon; this reduces the silica to silica monoxide. Silicon carbide whiskers are apparently formed by the interaction of silicon monoxide vapor with carbon [2].

Prior to 1985, it was known that two allotropic forms of carbon exist: diamond and graphite. However, after the discovery of the fullerene family by Kroto et al. [3], and their microscopic preparation by Kratchmer et al. [4], it has become well known that carbon has three allotropic forms, namely diamond, graphite, and the fullerene family. But is it really so? In addition to these forms, we have many other

forms of carbon such as active carbon, black carbon, carbon beads, nanobeads, nanotubes, fibers, etc. Which class of carbon should these materials therefore be considered as? For example, has the classification of carbon as diamond and graphite led us to think of the existence of the fullerene family? Certainly not. Moreover, does the classical classification give us any impetus to think of the possibility of developing any new forms of carbon? The answer is No.

Thus, there is a need to evolve a new classification of carbon which on one hand, can give us an insight for developing new forms of carbon, and on the other, should be able to classify all the existing forms of carbon. For this purpose, perhaps it would be advisable to examine some of the properties of carbon, which are distinctly different from other forms of carbon. We shall discuss this aspect here in more detail.

However, it would be a difficult task to cover all aspects of carbon in this small review, since each aspect of carbon can form a book in itself. Hence, in this review, an inquiry is made into the suitability of the conventional classification of various allotropes of carbon and whether classification gives an insight into developing newer forms of carbon. This is followed by a brief description of conventional types of synthesis, properties, and applications of carbon, which have been discovered lately. In order to keep the list of references to a minimum number, references appearing within a given paper are, as far as possible, not included in the list of references.

2. CLASSIFICATION OF CARBON

Conventionally carbon has been classified in two forms: diamond and graphite. Has this type of classification given us any help in searching for newer allotropes of carbon? After the discovery of the fullerenes family, a third allotrope of carbon, "fullerenes," was adopted. Hence there is a need to reconsider the classification procedure for carbon to evolve a classification which can help to discover newer carbon materials. A classification of carbon based on the nature of carbon atoms present in the carbonaceous material perhaps may be more appropriate and may open a Pandora's box for developing many new varieties of carbon than what we have been able to even think of. For example, diamond has atoms with 100% sp^3 type of carbon, while graphite has 100% sp^2 carbon atoms. The former is an insulator due to its very large bandgap (5.5 eV) while the latter is a conductor (bandgap being in vicinity of 0.25 eV or low). These two examples immediately give us a clue that there is a possibility of millions of permutations and combinations of sp^3 and sp^2, giving an innumerable variety of carbon with varied bandgaps in the range of 0.25 to 5.5 eV. Diamond-like carbon (DLC) and glassy carbon are two examples of such combinations. Neither of them can be classified as diamond or graphite. Therefore, a classification of carbon on the basis of ratio of sp^3 and sp^2 carbon atoms present in the material may be more appropriate than the conventional classification. We can thus classify carbon again in three forms: (i) diamond (100% sp^3), (ii) intermediate carbon (with different ratios of sp^3/sp^2 carbon atoms), and (iii) graphite (100% sp^2). All forms of carbons will fall in one of these three categories. This classification also gives us an opportunity

to understand the reasons for carbon showing its novelty. Carbon nanobeads, carbon nanotubes, carbon fibers, active carbon, charcoal, and fullerenes all fall in the intermediate group of carbon because they contain different ratios of sp^3/sp^2. Perhaps it may be a good idea to devote some time to discuss structural aspects, applications, and properties of carbon belonging to these three new groups of carbon.

3. DIAMOND-TYPE CARBON WITH PURE sp^3 CONFIGURED CARBON ATOMS

3.1. Structural Aspect

Material containing 100% sp^3 bonded carbon is classified as "diamond." Carbon in the form of diamond belongs to the cubic system and is the hardest material known. It has the same space lattice as zinc blend (Fig. 1a) except that alternate tetrahedral sites and all octahedral sites are filled with carbon atoms instead of sulfur and zinc, respectively.

The essential point of this structure is that every carbon atom is surrounded by four other carbon atoms situated at the corners of a regular tetrahedron. Thus, all carbon in diamond has the sp^3 configuration. The distance between the centers of two adjoining atoms is 1.54 Å which, strangely, corresponds very closely to the distance between two carbon atoms attached to each other by a single covalent bond in aliphatic organic compounds. This agreement, together with the fact that each carbon atom in diamond has four others situated around it at the corners of a rectangular tetrahedron, suggests that every atom is joined to four others by covalent linkages. It will be noticed from Figure 1b that the carbon atoms form a series of hexagonal "puckered" rings similar to those in cyclohexane, where the carbon atoms
Figure 1. (a) Zinc sulfide (zinc blend) lattice and (b) space lattice of diamond forming hexagonal "puckered" ring like cyclohexane. (c) Carbon atom surrounded by four other carbon atoms forming channels in diamond structure.

are joined by single linkages. This figure, however, clearly shows the possibility of the existence of many interlocked hexagonal nanochannels, and the diameter of the channel would have a dimension similar to the hexagonal cyclohexane ring (Fig. 1c). Hence diamond can also exist in hexagonal form (lonsdaleite) with a wurtzite crystal structure where the C—C bond length is 1.52 Å. The crystal density of both types of diamond is 3.52 g cm^{-3}.

3.2. Synthesis of Diamond and Diamond Films

Until the 1950s, nature was the only source of diamond, because of the extreme conditions required for its formation. Since at room temperature and atmospheric pressure the trigonal bond is more stable, a very high temperature (greater than 2500 K) and high pressure (around 100,000 atm) are required to induce the formation of tetrahedral bond. In the 1950s, scientists simulated these conditions in the laboratory to produce synthetic diamond.

Two decades later, in the 1970s, scientists showed that diamond could be produced at lower temperature (1000 K) and subatmospheric pressure by thermal dissociation of hydrocarbon gases, for example, methane, ethane, acetylene, etc. This process involves dissociation of hydrocarbon, typically methane-hydrogen mixture, with the addition of small amount of oxygen. Techniques such as hot filament, flame (acetylene torch), or microwave excitation are used for the dissociation process. The growth process consists of a competition between the tetrahedral and trigonal bonds where the former are promoted and the latter suppressed by their etching generated by atomic hydrogen and oxygen or internal rearrangement of carbon atoms [5]. It was believed earlier that the substrate's temperature in excess of 1000 K was necessary to get a diamond film, but now it has been shown that diamond film can be grown at 700 K or less also. Sharon and co-workers [6] have been able to prepare diamond by chemical vapor deposition of soot of camphor (Fig. 2).

The standard free energy changes for the process C$_{gas}$ → graphite and C$_{gas}$ → diamond are −671.26 and −668.36 kJ mol^{-1} at 298 K, respectively. This comparison suggests that the thermodynamic driving forces for forming graphite and diamond from vapor phase are similar. Hence large numbers of chemical vapor deposition (CVD) diamond deposition techniques have been developed. The following are the essential requirements for deposition of diamond film by CVD process:

(i) A carbon source gas that is rich in hydrogen but dilute (typically ∼1.0 vol%) in the carbon-containing gas. The gas mixture may contain oxygen in form of CO.

(ii) A process to activate the gas to produce free radicals, excited molecular species, or plasma.

(iii) A temperature-controlled substrate (typically at 500–900 °C).

CVD processes can be classified as thermal methods (e.g., hot filament methods) and plasma methods (direct current, radio frequency, and microwave). Film deposition rates range from less than 0.1 μm h^{-1} to ∼1 mm h^{-1} depending upon the method used, although over a small area,
Figure 2. (a) Diamond thin film deposited over quartz glass from the soot of camphor. (b) Magnified SEM view of the diamond film. Reprinted with permission from [6], K. Mukhopadhyay et al., *Mater. Chem. Phys.* 49, 252 (1997). © 1997, Elsevier Science.

high deposition rates of 100 mm h^{-1} or more have been reported. Thinner films with good adhesion to substrates (e.g., silicon wafer) have been achieved, but in thicker films spalling or delamination occurs because of built-in-stress [7].

CVD diamond films can be deposited on a wide range of substrates (metals, semiconductors, insulators, single crystals and polycrystalline solids, glassy and amorphous solids). Most of the CVD diamond films reported to date have been grown on single-crystal Si wafers, mainly due to availability, low cost, and favorable properties of Si wafers. However, one could use any other substrate for deposition of diamond provided it meets the following requirements [8]:

1. Substrate must have melting point higher than the temperature required for diamond growth. This precludes the use of plastic, aluminum, and glasses, GaAs, etc.

2. Thermal expansion of substrate material must be comparable to that of diamond. Otherwise, diamond film will experience compressive stresses from the shrinking substrate, leading to bowing of the sample and/or cracking, flaking, or even delamination of the entire film.

3. In order to form adherent films, it is a requirement that substrate material be capable of forming a carbide layer to a certain extent. The carbide layer can be pictured as the "glue" which promotes the growth of diamond and aids the adhesion. Therefore, material which does not have many tendencies to form carbide (e.g., Cu, Sn, Pb, Ag, Au, and Ge, sapphire, alumina) forms only few

layers of carbide. This layer of carbide helps the growth of the subsequent layer of diamond as well as helps to form a strong adhesion with the substrate. But those materials which have greater ability to form carbide (e.g., Pt, Pd, Rh, Ni, Ti, and Fe) promote the growth of a thicker layer of carbide over the substrate. These materials, in addition to helping the growth of diamond, also modify the property of deposited diamond. There are some materials which form carbide easily (e.g., metals like Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W, Co, Ni, Fe, Y, Al, etc., and nonmetals like B), and when these materials are used as substrate, most of the layers of the diamond are in form of carbide; thus the property of diamond is completely changed.

It is believed that mechanical polishing with diamond grit ranging from 10 nm to 10 μm aids nucleation by creating appropriately shaped scratches in the surface, which act as growth templates, or by embedding nanometer-sized fragments of diamond into the surface, which then act as seed crystals, or a combination of both [9].

Diamond thin films have been grown from a diluted mixture of a hydrocarbon gas (e.g., methane) in hydrogen. For example, a gas mixture consisting of methanol and hydrogen introduced at pressure of 10 Torr gives a deposition of diamond on the substrate maintained at 800 °C. Atomic hydrogen prevents the surface reconstruction from a saturated sp^3 diamond to sp^2 graphite microstructure. Hydrogen also helps in abstracting hydrogen from hydrocarbon surface sites and gas-phase hydrocarbon species to form reactive radicals. Sharon and Chaterjee [10] have been able to get diamond film by pyrolysis of turpentine oil with iron catalyst at 650 °C under argon gas (Fig. 3).

The purity and the property of the film are strongly controlled by the graphitic carbon content in diamond film. Doping by phosphorus gives n-type diamond. This was achieved by carrying vapor of phosphorus/methanol mixture into the reactor from a solution of P_2O_5 in methanol [11]. Microwave plasma-assisted CVD from a mixture of H_2S in 1% CH_4/H_2 on a Si substrate [12] has also given n-type diamond. Diamond has also been doped with nitrogen by allowing vapor of urea into the reactive chamber where n-type diamond is being formed [13]. For this purpose a saturated solution of urea and methanol in acetone is vaporized and
Figure 3. SEM micrograph of diamond film obtained at 650 °C from pyrolysis of turpentine oil in presence of ferrocene catalysts.

carried into the hot-filament chemical vapor deposition unit along with acetone and hydrogen. Nitrogen could be doped to $\sim 3.5 \times 10^{20}$ N atoms per cubic centimeter into the diamond. Such a high concentration of N is usually difficult to incorporate in diamond when using nitrogen or ammonia as the dopants. Boron doping of diamond has been achieved by dissolving B_2O_3 in methanol [14]. This process gives volatile trimethylborate $(CH_3O)_3B$. Ferreira et al. [15] prepared boron doped diamond by hot-filament technique. CH_4 flow (0.5 s cm^{-3}) was maintained along with flow of hydrogen through a solution of B_2O_3 in methanol. Boron could be carried by hydrogen from this mixture. Furnace temperature was maintained at 800 °C.

3.3. Properties of Diamond Thin Films

Although the standard enthalpies of diamond and graphite only differ by 2.9 kJ mol^{-1}, a large activation barrier separates the two phases, preventing interconversion between them at room temperature and pressure. Ironically, this large energy barrier, which makes diamond so rare, is also responsible for its existence, since diamond, once formed, cannot spontaneously be converted to the more stable graphite phase. Thus diamond is said to be metastable, that is, kinetically stable but thermodynamically unstable.

Diamond possesses several technologically important properties, including extreme hardness, high electrical resistance, chemical inertness, high thermal conductivity, high electron and hole mobility, and optical transparency (Table 1).

As per the solid-state concept of vacuum scale, electrons present in or above the vacuum scale are expected to be free electrons. Since the conduction band of diamond lies above the vacuum scale, this means that if electrons of diamond are excited from valence band to conduction band, they will behave like free electrons. This condition is different from a state of any other material whose conduction band lies below the vacuum scale. With such material, although electrons excited from its valence band to conduction band are free, they still belong to the same material, whereas with diamond, they become nonbound free electrons. This also suggests that if diamond were heavily doped such that its Fermi level shifted to about 0.1 eV below the conduction band, diamond would become a free electron emitter. Unfortunately, it has not been possible to dope diamond with donor atoms to this extent so far.

It is interesting to observe that naturally occurring diamond, though in pure form (intrinsic diamond), is p-type. The reasons for intrinsic diamond being the p-form are not very well understood, though many explanations have been given. The author of this chapter would like to propose the following arguments to explain this behavior. Conversion of material into either n- or p-type depends upon the nature of dopant added into the materials. If dopant has a greater number of electrons than the host atom, the material becomes n-type, and if the dopant has a smaller number of valence electrons than the host, the material becomes p-type. This behavior is quite reasonably understood. Why diamond in pure form should exist in p-form is not very well understood. Perhaps, this strange behavior of diamond can be explained by considering the electronic configuration of carbon atoms bonded into the structure.

Table 1. Some outstanding properties of diamond.

Property	Value
Atomic mass	12.01
Crystalline structure	fcc
Symmetry	Fd3m
Chemical bond	covalent sp^3
Lattice parameter	3.56
Density	3.51 g cm^{-3}
Melting temperature	4000 °C
Highest bulk modulus	1.2×10^{12} N m^{-2}
Hardness	6000–10000 kg mm^{-2}
Linear expansion coefficient at 300 K	1.18×10^{-6} deg^{-1}
Lowest compressibility	18.3×10^{-13} m^2 N^{-1}
Highest room temperature thermal conductivity	2.0×10^3 W m^{-1} K^{-1}
Thermal expansion coefficient at room temperature	1.0×10^{-6} K
Highest sound propagation velocity	17.5 km s^{-1}
Room temperature resistivity (undoped)	8.3×10^{-13} m^2 N^{-1}
Bandgap	1.5 eV (indirect)
Breakdown voltage	10×10^7 V cm^{-1}
Biological compatibility	yes
Mobility (electron) at 300 K [27]	1000–2200 cm^2 V^{-1} s^{-1}
Mobility (hole) at 300 K	1400–1600 cm^2 V^{-1} s^{-1}
Raman shift	1332 cm^{-1}
Work function	4.7 eV (close to graphite)
Dangling bond	~1.4 eV above valence band
Boron doping	acceptor level at 0.38 eV above E_v
Phosphorus doping [28]	donor level 0.46 eV below E_c
Nitrogen doping	creates two levels, one at 1.7 eV below E_c and the other one doubly occupied just above E_v due to quasi-N lone pair
Electron affinity of the bare surface of diamond [29]	+0.37 eV
EA for hydrogenated C (111):H surface [30]	−1.27 eV. Thus E_v lies between 5.9 eV and 4.2 eV below vacuum level

The combination of one *s* orbital with two *p* orbitals leads to the formation of three sp^2 hybridized orbitals. Each of these orbitals has one large and one small lobe. All these hybridized orbitals lie in the same plane (the plane containing the two *p* orbitals from which they were formed) and point toward the corners of an equilateral triangle. Each sp^2 hybridized carbon atom has one electron in a *p* valence orbital that is perpendicular to the plane of the σ bonds. These *p* orbitals can overlap to form π bonds. This type of bond places electron density above and below the line joining the bonded atoms (i.e., above or below the plane in which σ bond lies). In contrast to this, the mixing of the *s* and all three *p* orbitals yields four sp^3 hybridized orbitals. Again, each of these orbitals has a large and a small lobe. The large lobes point at the corners of the tetrahedron. Unlike sp^2 hybridized carbon atoms, due to absence of π bonds, the charge density in sp^3 carbon atoms can be

assumed to be zero; that is, the plane perpendicular to the plane containing σ bonds will have no charge (Fig. 4).

Therefore, in contrast to diamond, graphite should have some charge density in space, perpendicular to the σ bonds of diamond. In other words, removal of this charge from π bond by addition of hole should lead to a structure of diamond. If we assume the existence of some kind of equilibrium between the graphite and diamond (based on the charge density), then the following equilibrium between sp^2 and sp^3 carbon atom can be conceived:

sp^3-C-C-sp^3 + h$^+$[missing of electron charge in plane ⊥
    to σ bond (Fig. 4b)]

$$\uparrow\downarrow$$

sp^2-C-C-sp^2 + e$^-$[addition of electron charge due π
    bonds ⊥ to σ bond (Fig. 4a)]
If this concept is accepted, then diamond should intrinsically exist as p-type material and graphite should exist as n-type material. This is what is normally observed with these materials. The conversion of graphite to diamond can therefore be viewed as substitution of sp^3 configured into sp^2 configured carbon atoms. This explanation also suggests that while pure diamond and pure graphite should exhibit p- and n-type character, respectively, materials containing carbon-bonded atoms of some suitable ratio of sp^3 and sp^2 should exhibit a true intrinsic character. Sharon et al. [16] observed that pyrolyzing camphor under inert atmosphere and sintering it under inert atmosphere for different time, changes the ratio of sp^2/sp^3 carbon. They also observed that if this ratio is 33%, the resulting carbon behaves like true intrinsic material. If this ratio is greater than 33%, pyrolyzed carbon shows n-type character, and if it is less than this value, pyrolyzed carbon shows p-type character. This change in behavior is observed only due to change in the ratio of sp^2 and sp^3 and not due to any external doping (Fig. 5).

This result has suggested that in carbonaceous materials, the meaning of n- and p-type needs to be addressed differently and should not perhaps be treated as we normally do with inorganic materials. Thus, naturally occurring p-type diamond need not be due to presence of dopant. It may be due to presence of larger concentration of sp^3 carbon atom. In other words, p-character is due to the absence of electron in π bond. Perhaps this may be the reason why it is difficult to either make or naturally obtain n-type diamond.

However, substitution with impurity atoms like nitrogen of some of the carbon atoms during the diamond film growth makes the film n-type. Nitrogen atoms in the diamond make bonds to both carbon and hydrogen. Therefore, the total bonding configuration changes by nitrogen addition. It forms a distorted substitutional site with one long bond forming a
Figure 4. (a) sp^2 carbon with π bond (shown in black square) exchanges with (b) sp^3 carbon, creating empty π bond (shown in empty square).
Figure 5. Variation in the sp^2 carbon content in the camphor pyrolyzed carbon films as a function of pyrolyzing time. Reprinted with permission from [16], M. Sharon et al., *Mater. Chem. Phys.* 56, 284 (1998). © 1998, Elsevier Science.

deep singly occupied donor level, 1.7 eV below the conduction band E_c, and also a doubly occupied state just above E_v due to quasi-N lone pair of this C—N bond [17]. The decrease of hydrogen bonded to carbon atoms can cause the increase of sp^2 bonding fraction, hence the decrease of the optical bandgap [18]. Doping diamond [19] with boron produces a shallow substitutional acceptor with a level at 0.38 eV above E_v. Phosphorus also acts like a substitutional donor, with a level about 0.46 eV below E_c. Replacement of one CH group by one phosphorus atom causes diamond to become n-type.

Typical Raman spectra for high-quality diamond and boron-doped diamond thin films feature one intense band at 1332 cm^{-1} with a line width of 5 to 8 cm^{-1}. The significantly broadened and shifted diamond line for the noncrystalline films results from decreasing grain size to the nanometer scale. To a first approximation, the linewidth is a measure of the phonon lifetime. The more defects (e.g., grain boundaries) and impurities (e.g., nitrogen) there are, the shorter the phonon lifetime and the broader the linewidth. Weak scattering intensity in the region of 1520 cm^{-1} is observed due to nondiamond sp^2 bonded carbon peak resulting from the π-bonded carbon atoms in the grain boundaries [20, 21] impurities in the film. Graphite, however, gives rise to a broader peak at 1580 cm^{-1}. The ratio of the intensities of these two peaks indicates how much of each phase is present. It is also dependent on the wavelength of excitation (normally excitation is done with 532 nm).

It can be seen that the ratio of the diamond to the non-diamond band intensities, I_{1339}/I_{1560}, is largest for the film deposited without any added N$_2$ and decreases for the film deposited with the gas. However, the ratio is independent of the N$_2$ level [22]. Raman spectra of boron-doped diamond films were studied by Ferreira et al. [15]. It is interesting to note that the intensity of the peak at 1332 cm^{-1} decreased as the concentration of boron was increased. Moreover, a new

peak started to appear at around 1200 cm^{-1}, whose intensity also increased with increase in doping concentration. This suggests that one may be able to establish a relationship between boron concentration and the intensity of either the 1332 cm^{-1} or the 1200 cm^{-1} peak.

Some of the CVD grown diamond film exhibits photoconductive signal if it contains absorption bands between 1.3 eV and 1.5 eV. This photoconductive response in the visible region can impair the performance of diamond detectors made for ultraviolet application [23]. Photoconductivity studies, therefore, are a useful technique to characterize diamond. It is interesting to note that Hall mobility in boron doped diamond decreases as the concentration of dopant is increased [24]. While at hole concentration of 5×10^{14} cm^{-3}, Hall mobility is in the vicinity of 1500 cm^2/Vs, for 5×10^{15} cm^{-3} hole concentration it falls down to 250 cm^2/Vs.

Three low-index morphologies are usually obtained during growth of diamond film: (100), (110), and (111), the latter being the most abundant. It is observed that while the morphology of the (111) and (110) surface is rough, (100) crystallites grow as platelets or tiles with partial overlap between neighboring ones. Most electrochemical studies are carried out with surfaces preponderant with (111) crystallites [25]. Robertson and co-workers [26] have suggested that chemical termination of (111) diamond surfaces shifts the electron affinity from +0.35 eV for clean surface to −1.3 eV for H terminated ones and about +2 eV for oxygen terminated ones. The shift occurs because the terminating groups are slightly polar and introduce a surface dipole layer. In the case of C—H groups, the H atoms are positive and the dipole reduces the electron affinity, while oxygen has a negative change and the C—O bond dipole makes the affinity more positive. As these effects are localized on the chemical bond, similar affinity changes may be expected on ta-C surfaces.

In Table 1, various properties of diamond are enumerated.

3.4. Electrochemical Properties of Diamond Film

In electrochemical work, there is a need to use an electrode which is inert and does not need larger additional potential (known as overpotential) than the equilibrium potential for carrying out electrochemical reactions. Moreover, one also needs a large potential difference between oxidation and reduction potential of water so that the electrode can be used safely for electrochemical reaction within the so-called window of the potential (i.e., within the range of potential in which water does not get electrolyzed) in aqueous solution. For this purpose, platinum or mercury has been used by electrochemists. Conducting diamond, being inert to alkali and acid, has been used as an electrode. Since doping of diamond has been possible, lately, boron-doped diamond films are getting more popularity in electrochemical studies than carbon electrodes (glassy carbon). Diamond thin-film electrode shows a very small background current and low double-layer capacitance. With 0.1M KCl solution between −1000 to +1000 mV, current is observed in the range of 50 mA/cm^2 and is highly stable. Sometimes a small oxidation peak is observed on the forward sweep at ~1200 mV just prior to the onset of chlorine evolution [31]. Boron-doped

diamond thin film shows a wide working potential window for solvent-electrolyte electrolysis in aqueous media. This means that diamond has large overpotentials for both hydrogen evolution and oxygen evolution. In 0.1M KCl as well as in 0.5M H_2SO_4, the working potential window is 3.5 V (i.e., from -1.25 to 2.3 V vs standard hydrogen electrode) as compared to 2.5 V for glassy carbon. These ranges greatly exceed the theoretical range of stability of water under ambient conditions (1.23 V). Diamond film is reported to show an increase in background current by less than 5% even after constant use for 15 hr, whereas in glassy carbon it increases to a value greater than 30.0%. Another application of diamond film is anodic stripping voltammetry of heavy-metal ions in aqueous media. It has been possible to electrodeposit Pt, Hg, and Pb on boron-doped diamond thin films [32]. Ferro et al. [33] have observed chlorine evolution at highly boron-doped diamond electrodes. They reported the chlorine evolution below 1 V versus SCE with NaCl solution. Since this electrode is stable in perchlorate solution, one can think of making a fuel cell operating with chlorine/hydrogen gas.

3.4.1. Electron Field Emission Effect

The field emission display (FED) is a new type of flat panel display which overcomes many limitations of liquid crystal display, because of its superior brightness, viewing angle, color rendition, response time, and operating temperature range. The activity in field emission display, sometimes called cold emission devices, is concentrated now mainly in vacuum microelectronic devices based on broad area multiple arrays, for example, flat panel displays, microwave devices, vacuum electron sources for electron guns for electron microscopes [34], etc.

For a perfectly flat metal surface with a typical work function of 5 eV, the electric field necessary to get measurable emission current is in the range of 2.5 V nm^{-1}, or in more appropriate units, 2500 V μm^{-1}. To generate such high electric fields, one has to use the effect of field enhancement at tip-like structures. For such purpose, silicon or metal microtips are generally used. Nevertheless, these materials suffer emission degradation due to sputter erosion and chemical contamination and therefore require a high vacuum environment for operation. On the other hand, carbon and especially diamond is found to emit at a very low electric field. The chemical inertness of carbon field emitters especially is one of the most important advantages over silicon or metal micro-tips.

Field emission from semiconductors in general can originate from the valence band or the conduction band, from an accumulation layer at the surface [35]. The great interest in electron emission from diamond was kindled by the work of Himpsel et al. [36], who reported high quantum yield for photon-electron emission from the (111) hydrogen terminated surface of diamond. Later it was determined [37] that the (111) hydrogen terminated diamond surface exhibits a negative electron affinity. The electron affinity of a semiconductor describes the energy barrier between the vacuum level outside the surface and the conduction band minimum inside the sample. Given this definition, the electron affinity of these prepared surfaces of diamond would exhibit a negative value, because the energy of electrons at the conduction

band minimum for diamond would be above the vacuum level, and this condition is termed negative electron affinity. The presence of a negative electron affinity means that electrons in the conduction band can be freely emitted into vacuum.

Field emission from high-quality diamond is actually quite difficult, largely because of its high resistivity. Field emission from polycrystalline diamond is easier and is found to vary inversely with the grain size. Development of conducting diamond thin films thus has led to new areas of cold electron emission from diamond. Recent results from diamond cold cathode demonstrate high emission current, good current stability, uniform emission, from an array of emitters, and emissivity even under poor vacuum conditions. Two approaches using ungated field emission cathodes with diamond coating have been proposed: (i) flat-film display, where patterned diamond film is used as addressable cathodes (lines) [38], and (ii) arrays of silicon tips with diamond coating, where addressing occurs by switching of p-n junctions formed in the Si substrate [39]. The turn-on fields of diamond films have been in the range of 1–30 V mm^{-1}; that is, the electric field needed to inject electrons from diamond film is in the range of 1–30 V mm^{-1}. A schematic of a test circuit of the field emission [40] is shown in Figure 6.

Sometimes, a series resistance of 5 $M\Omega$ is also connected to the sample to protect the equipment. The emitting area could be of the size 15 mm $\times$ 5 mm separated by a distance in the order of a few hundred micrometers. The system is kept in vacuum ($\sim 10^{-7}$ torr or sometimes even lower than this). When potential is applied across anode and cathode, current will appear after certain threshold voltage is applied. To show the nature of CV characteristics, a typical current density (A cm^{-2}) versus applied electric field obtained with kerosene-pyrolyzed carbon film deposited over alumina plate at 1000 °C is shown in Figure 7 [40].

It will be noticed that there is a threshold voltage of 2.20 V μm^{-1} before which no emission occurs. It is also necessary to confirm that this emission is not due to electric discharge of gas present in the system. In order to confirm, normally polarity of electrode is altered and current density (μA cm^{-2}) versus applied electric field (V μm^{-1}) is measured. If current characteristic as shown in Figure 7 were not obtained, this would suggest the absence of any current due

to electric discharge process. It has been reported that some fluctuation of field emission occurs. It is believed that the fluctuation of field emission current is caused by migration of absorbed gas molecules over the emitter surface, and ion bombardment to the emitter surface [41–43]. So the fluctuation can be increased as the impinging rates of the gas molecules and ions are increased. In order to reduce this effect, high vacuum is necessary. However, before a reliable emitter structure can be developed, the electron transport properties of the material must be well understood, especially regarding limitations on the current density and energy spread of the transmitted beam. Furthermore, an understanding of the emission process is necessary to accurately interpret emission [44]. There is ambiguity in explaining the actual phenomena which are responsible for the electron emission from diamond or materials like diamond. A simplified mechanism is discussed here so that this process can be qualitatively understood.

A basic process for injection of electrons into diamond is the tunneling of electrons from the cathode substrate through a potential barrier at the interface (i.e., a forbidden energy region) into the conduction band of diamond film [45]. It is expected that the cathode or metal over which diamond is deposited forms a metal/Schottky type of contact. An energy barrier is formed at the interface of the metal/diamond contact. When a negative bias is applied to the metal electrode (cathode), electrons are injected into the diamond film from the metal. The number of injected electrons depends on the barrier height and thickness. Therefore, the electron emission characteristics are improved by forming a low barrier height and by enhancing the electric field at the barrier of the diamond. In the case of the ideal Schottky junction, choosing the metal work function can change the barrier height. In order to enhance the electric field at the metal/diamond contact, on the other hand, it is desirable to use diamond films doped with shallow donor impurities because of the formation of a space charge layer due to ionized impurities. Incidentally, Geis et al. [46] have

found that phosphorus doping improves the emission in diamond. The process of electron emission can be summarized as follows:

1. Tunneling from the substrate (e.g., metal or semiconductor) into the conduction band (CB) of diamond. This is designated as electron injection process into the CB.
2. Transportation of the electrons to the diamond surface.
3. Escape of the electrons from the diamond surface to a vacuum.

The electrode of the behind diamond film, such as Si, Mo, etc. (i.e., substrate), forms a Schottky barrier. The electrons are injected from the electrode to the conduction band of the behind diamond film through the Schottky barrier by applying the electric field (step 1). The electrons at the diamond surface, on the other hand, can easily be emitted to a vacuum even by applying low electric field, because the diamond surface has negative electron affinity (step 3). However, it is difficult to transport electrons from the behind diamond film to the surface (step 2) because there is no effective means for n-type doping in the case of diamond. The emission current density strongly depends on the electron-transportation mechanism in the diamond film.

In addition to these, there is a possibility that the following process may also work to facilitate the electron injection [47].

1. Tunneling from the valence band (VB) of the semiconductor substrate into the CB of diamond. This is designated as hole injection from the diamond into the semiconductor substrate.
2. Zener tunneling, which is transition across the energy gap from the VB to the CB of a semiconductor or insulator under the internal applied field. This process is negligible for a wide-bandgap material such as diamond, except for extremely high fields ($\sim$10^4 V μm^{-1}).
3. Transition to the CB from the local impurity or imperfection level. This is field ionization process.

Druz et al. [48] have reported that reversibility of emission current versus applied potential (I-E cycles) depends upon the magnitude of emission current. It is also interesting to study whether electron field emission can be sustained by diamond films for a long period. In this context, they also have studied the time stability of the emission current of the DLC films. They observed the I-E curves to be reproducible after many measuring cycles, or after many hours without field applied; emission current was found to be constant at different fixed fields during at least one hour [49]. Sugino et al. [45] reported that emission property of polycrystalline diamond film depends upon the work function of the metal (e.g., Cu/diamond, Al/diamond, and Si/diamond) used for making the back contact with diamond. The reduction in the threshold voltage for these metals as compared to silicon is believed due to formation of a low energy barrier to electrons at the metal/diamond contact. On the contrary, Robertson and co-workers [50] have suggested that threshold field, instead of depending on the work function of substrate, depends upon the extent of nitrogen doping.

The field at which emission begins is also found to depend on sp³ content [45]. Sugino et al. [45] and Robertson and co-workers [50] have reported that variation in threshold energy depends upon the nitrogen content in the diamond film: as the concentration increases, the threshold field decreases to a minimum value at 0.4% N in the film, and thereafter it increases again with increase in nitrogen content in the film. It is concluded that the reduction in emission at higher N content suggests that bulk sp² bonding in diamond does not favor emission.

3.4.1.1. Fowler–Nordheim Theory

3.4.1.1. Fowler–Nordheim Theory Electron field emission for metal has been known for many years, and among the various theories put forward to explain this process, Fowler–Nordheim theory is used most for explaining the process in diamond or diamond-like carbon. It would be difficult to deal here in detail with this theory. However, Forbes [51] has given an extremely good review on the Fowler–Nordheim theory and its limitations. The theory of cold field emission of electrons from metal into vacuum is often called *Fowler–Nordheim (FN) theory*, after the first author to treat this effect as wave-mechanical tunneling through a triangular barrier. The standard physical assumptions of FN theory are that:

(i) the metal has a free-electron band structure;
(ii) electrons are in thermodynamic equilibrium and obey Fermi–Dirac statistics;
(iii) the surface is smooth and flat;
(iv) local work function is uniform across the emitting surface and is independent of external field;
(v) there is a uniform electric field above the emitting surface.

Considering these assumptions, the magnitude of emission current (J) may be written as

$$J = Aa\phi^{-1}E^2 \exp\{-b\phi^{3/2}/E\} \equiv Aa\phi^{-1}E^2 \exp\{-b\phi^{3/2}/E\}$$

Or

$$\mathrm{Ln}\,J/E^2 = \mathrm{Ln}(Aa\phi^{-1}) - b\phi^{3/2}/E$$

where $a \equiv e^3/8\pi h = 1.541434 \times 10^{-6}$ A eV V^{-2} (in SI unit), $b \equiv \{(4/3)(2m_e)^{1/2}\}/e\hbar = 6.830888 \times 10^9$ eV$^{-3/2}$ V m^{-1} (in SI Unit), $\phi =$ the local work function of the emitting surface, $E =$ external electric field (taken as a positive quantity), and $A =$ area of emission.

Thus a plot of $\mathrm{Ln}\,J/E^2$ versus $1/E$ would give a linear plot with a slope equal to $b\phi^{3/2}$. Since value of constant "b" is known, local work function of the emitting surface (ϕ) can be calculated from this analysis.

It has been also observed that when current-voltage characteristics of the electron emission are plotted in the Fowler–Nordheim coordinates of $\log(1/E^2)$ versus $1/E$, broken lines are observed, and near the break, plots have a more or less extended "shelf" segment where emission current is only weakly dependent on voltage. This behavior of getting broken line is in contrast to expected continuous line.

4. GRAPHITE-TYPE CARBON WITH PURE sp² CARBON CONFIGURED ATOMS

4.1. Structure of Graphite

Graphitic carbon is carbonaceous material with a layered structure but with a number of structural defects. Its density is 2.36 g cm^{-3}. It consists of layers in which each carbon atom is linked to three other carbon atoms by strong interplanar, covalent bonds which are stronger than those in diamond, with a C—C bond length of 1.42 Å (Fig. 8). However, a weak carbon-carbon bond exists between widely separated layers (interlayer distance of 3.354 Å). These widely separated layers account for the ease with which the layers glide over each other and cause the familiar softness of graphite.

Graphite, thus, has a structure in which trigonal planar carbon atoms are present in horizontal planes and each plane is separated by a distance of 3.354 Å. XRD of graphite is shown in Figure 9 [52]. For comparison, XRD of graphite, graphene sheet, hard-shell carbon, and multiwall carbon nanotubes are also shown. The most intense peak corresponds to (002).

From a crystallographic point of view, the term "graphite" is applicable only to carbon materials having a layered lattice structure with a perfect stacking order of graphene layers, either the more prevalent ABABAB . . . (hexagonal graphite) or the less common ABCABCABC . . . (rhombohedral graphite). Due to the small energy required for the transformation of an AB- into an ABC-stacking (and vice versa), perfectly stacked graphite crystals are practically not available. Therefore, the term "graphite" is commonly used regardless of the stacking order. In some carbons, the aggregates are large and relatively free of defects, for example, in highly oriented pyrolytic graphite (HOPG). For both forms of graphite, the in-plane C—C distance is 142 pm. This length is in between the bond length of C_{sp3}—C_{sp3} (i.e., 153 pm) and C_{sp2}=C_{sp2} (132 pm). There is a large difference between in-plane C—C distance, 142 pm, and the interlayer distance, 335.4 pm, in graphite (Fig. 8) that results from the different types of chemical bonding. Within planes
Figure 8. Schematic drawing of the crystal structure of hexagonal graphite showing AB-layer stacking sequence and unit cell.
Figure 9. XRD of graphene sheet, hard shell, purified MWNT, and graphite. Reprinted with permission from [52], X. Zhao et al., *J. Cryst. Growth* 198/199, 934 (1999). © 1999, Elsevier Science.

the C—C bonds are trigonal sp^2 hybrid σ bonds with delocalized π bonds. The large interlayer spacing suggests that the contribution to interlayer bonding from π-bond overlap is negligible.

When the turbostatically disordered structure becomes more distinct and dominates among the crystallites, the carbonaceous material is no longer graphitic and can be considered as a nongraphitic carbon. Nongraphitic carbonaceous materials consist of carbon atoms with most of them arranged in a planar hexagonal network but without the crystallographic order in the *c*-direction of the graphite structure. The ability for graphitization is higher (i) if the precursor material comprises highly condensed aromatic hydrocarbons, and (ii) if neighboring graphene layers or graphitic crystallites are suitably oriented to each other.

Unlike diamond, in which all the orbitals of the four valent electrons of carbon atom (one s and three p's) are hybridized (sp^3 hybridization) to make four equivalent, strong strictly directed bonds, in graphite only three of the four orbitals are combined (sp^2 hybridization), making three equivalent, strong, coplanar bonds with an angle of 60° between three σ bonds. The remaining fourth electron is quasi-free, that is, free to move within its layer, and it makes very weak bonds (π bonds) directed perpendicular to the

hexagon layers, thus bonding these layers to each other. The atoms within the layer are strongly bound and therefore the layers are compact and difficult to break. On the other hand, neighboring layers are hardly bound to each other, so that they can be easily moved with respect to each other, or even separated. Since it is very difficult to break the layers (i.e., by stretching them), graphite's strength is very large parallel to the layers, but since the layers can be easily separated from each other, strength is nearly zero across them. Along the layers, electrons can move easily and therefore graphite is a good conductor of electricity parallel to the layers, but an insulator across them.

Traditional graphite is made of a very large number of tiny crystals randomly oriented; that is, they point to different directions. Therefore, if one crystal is a good conductor in one direction, its neighbor may be an insulator in that direction, so that the net result is no bulk anisotropy at all. On the other hand, it is clear that if we could make all crystals to point in the same direction, we would have an anisotropic material. This is what we have in a pyrolytic carbon. Pyrolytic carbon is a monolithic polycrystalline graphitizable carbon material obtained by pyrolysis of a hydrocarbon vapor and deposition of carbon on a solid substrate heated to high temperature. The structure of pyrolyzed carbon is characterized by a strong preferred orientation of the constituent crystallites with their basal planes mostly parallel to the substrate surface. Properties of such carbon depend upon preparation conditions and are mostly determined by the deposition temperature.

Graphitization of carbon by metal is one of the processes to prepare graphite at lower temperature. It is observed that temperature at which graphitization occurs depends upon the initial state of the carbon. The lowest temperature of graphitization by Ni occurs for diamond or diamond-like carbon at 700 °C and 500 °C, respectively [53].

There has been considerable interest in the doping of graphite with elements such as boron, nitrogen, and silicon in order to modify the electronic, mechanical, and oxidative properties of this material. In recent years, a number of carbon-boron, carbon-nitrogen, and carbon-boron-nitrogen alloy structures have been proposed from the results of theoretical calculations, notably BC$_3$, C$_3$N$_4$, and BC$_2$N [54–57]. In terms of boron doping within the graphitic structure, it has been shown that the thermodynamic solubility of B in the C lattice [58] is around 2.35 at.%. Introduction of boron in graphite-like lattice induces the presence of disordered phases. These domains occur when boron content level is higher than a few percent. The exact nature of the boron sites in the higher-boron-content material still remains unclear.

The perfectly conjugated polyne (($-C\equiv C-$)$_n$), called "carbyne," is known as one of the carbon allotropes. Though many attempts have been made to synthesize it, synthesis is still under investigation [59, 60]. Carbyne has been considered to be a transition phase between graphite and diamond and a carbynoid material was experimentally observed to form diamond [61]. On the other hand, polyne was suggested to be a precursor for fullerene [62].

4.2. Application of Graphite

Graphite has been used for many industrial applications. It has been used as an electrode in electrochemical works, an inert crucible for high-temperature application, a solid lubricant, a precursor for synthesis of fullerenes, in carbon nanotubes, etc. It would be impossible to discuss applications of graphite in this chapter because of space limitations; also, they are well known and documented nicely at many places. However, recently graphite has found an application in an area related to environmental problems, for example, leakage of oil during transportation; its large absorbent capacity and easy manipulation are expected to avoid serious pollution problem. So far, some porous polymers, such as poly(propylene) and poly(ethylene terephthalate), have been used for the absorption of spilled oil, of which maximum absorption capacity is ∼10–20 g of heavy oil per 1 g of polymer [63]. Moreover, most of the polymers absorb water, as well as heavy oil. They do not have special selectivity for heavy oils. On the other hand, exfoliated graphite was found to absorb selectively a large amount of heavy oil. It is reported that about 80 g of heavy oil floating on water can be removed from 1 g of exfoliated graphite [64].

5. INTERMEDIATE FORMS OF CARBON CONTAINING MIXTURE OF sp^2 AND sp^3 CONFIGURED CARBON ATOMS

In previous discussions we dealt with carbon with 100% either sp^2 carbon (graphite) or sp^3 (diamond). Now we shall discuss carbon material possessing both forms of carbons. It will be noticed that the variation in the percentage composition of sp^3 and sp^2 carbon yields different forms of carbon. Therefore, a new method of classification has been suggested here, where the structure and properties of carbon materials are mainly governed by the ratio of these two forms of carbon. Under a suitable condition of preparation, it is possible to create different forms of carbon having different ratio of sp^3 and sp^2 carbon atoms. Diamond-like carbon and glassy carbon are two examples of such configurations, because they have different structures from graphite and possess both types of carbons (i.e., carbon with sp^3 and sp^2 configuration). We shall now try to discuss this class of carbon materials in brief.

5.1. Diamond-Like Carbon

5.1.1. Structural Aspects of DLC Film

Elemental carbon has six electrons, with configuration 1s^2 2s^2 2p^2. Thus when carbon atoms combine, there is flexibility in terms of allocation (hybridization) of the electrons in the 2s and 2p orbitals, giving rise to graphite (sp^2), diamond (sp^3), or a third allotrope of carbon, diamond-like carbon containing a mixture of sp^2 and sp^3 carbon atoms. When the diamond structure is incorporated with both tetrahedral (sp^3) and trigonal planar (sp^2) carbon-bonded atoms, the resulting film takes the form of diamond-like structure. In other words, in DLC, the clusters of three coordinated sp^2 carbon atoms are embedded in a sp^3 bonded matrix. The sp^2 regions of the DLC film are found to control electronic

properties such as bandgap, while the sp^3 regions control mechanical properties such as rigidity and hardness. Because of this, diamond-like structure shows almost all properties of diamond and the conductance properties of graphite. DLC films, depending upon the ratio of sp^2 and sp^3 carbon atoms, can also be stable, hard, and chemically inert like diamond.

Depending upon the ratio of sp^2 and sp^3 nature of carbon, various types of DLC films can be obtained [65]. Furthermore, there are two types of semiconducting amorphous carbon: (a) with hydrogen (a-C:H); and (b) pure carbon without hydrogen (a-C). In a-C:H, commonly obtained when a hydrogen gas is used as the plasma source, the rigidity of the amorphous network, and hence the "diamond-like" content, is influenced by the fraction of polymeric C—H bonds in different configurations. In a-C, it is the relative amounts of sp^2 and sp^3 C—C bonds in the network which determines the macroscopic electronic, optical, and mechanical properties of the materials. Thus, DLC covers a wide range of materials, from the a-C:H containing sp^3 content in the range of 20 to 50%, to the tetrahedral amorphous carbon (ta-C) containing essentially no hydrogen and sp^3 contents up to 70–85%.

A systematic classification of amorphous carbon films has been given by Biswas et al. [66]. According to them, classification of amorphous carbon films can be shown graphically in form of a triangle. The corners at the base of the triangle correspond to graphite (100% sp^2) and diamond (100% sp^3 carbon). The apex represents 100% H, but the upper limit for formation of solid films is defined by the tie line between the compositions of polyethene, —(CH$_2$)$_{n-}$, and polyethyne, —(CH)$_{n-}$. The majority of a-C films contain mainly sp^2 carbon, but the sp^3 carbon content can be varied over the range 5–55%; the hardness of the films increases with sp^3 content. The H content of a-C:H films can be varied over a wide range and the hardness of a-C:H film is inversely related to the hydrogen content. Films with very high sp^3 content (∼80–90%) and correspondingly high hardness have been called tetrahedrally bonded amorphous carbon films (ta-C films). Hard a-C:H films are called "diamond-like carbon" (DLC). Thus, in general, hardness increases with sp^3 carbon content, as the proportion of DLC increases. Conversely, the films become softer as the sp^2 carbon content and/or hydrogen content increases [67, 68].

5.1.2. Synthesis of DLC Films

There is a good review on the DLC films by Zhang et al. [69]. Generally, two basic ways have been used to synthesize a DLC film: one is through the vapor phase via hydrocarbon gases, and the other is by sputtering of a solid carbon source. The latter process usually gives nonhydrogenated or a-C films. In this process, classified as plasma vapor deposition (PVD), plasma of argon is allowed to hit the carbon target to sputter carbon, which in turn is deposited at the substrate to give a DLC film. In other processes, like chemical vapor deposition (CVD), hydrocarbon gas or mixture of hydrogen and a hydrocarbon such as methane (CH$_4$), n-butane (C$_4$H$_{10}$), acetylene (C$_2$H$_2$), camphor, etc., are used as the carbon source. These gases are activated by direct-current glow discharge, rf discharge, microwave discharge, ion beam, pyrolysis, etc. Sharon and co-workers [6] have

been able to get DLC film by pyrolysis of various naturally occurring precursor camphors.

5.1.3. Properties of DLC Films

5.1.3.1. Electrical Properties   In DLC, the clusters of three coordinated sp^2 carbon atoms are embedded in a sp^3-bonded matrix. Consequently, the bandgap of DLC film can be varied from 1 to nearly 4 eV according to the fraction of sp^3 bonding. Heat treatment of amorphous carbon films leads to the evolution of hydrogen and causes a structural change. Gradual release of hydrogen at the temperature range from 400 °C to 600 °C converts tetrahedral sp^3 into trigonal sp^2 structure. If this happens, then the bandgap of DLC film will decrease as ratio of sp^2/sp^3 increases. Sharon et al. [16] have shown that pyrolysis of camphor can give DLC films with various bandgaps depending upon the concentration of sp^2 present in the film. In addition to this, Sharon et al. [70] also studied the electrical conductivity of DLC film prepared by pyrolysis of camphor vapor and observed that if films are thermally heated below 600 °C, values of electrical conductivity are reproducible. This suggested that up to this temperature, there seems to be not much change in the ratio of sp^3 and sp^2 carbon and activation energy for conduction remains 1–1.3 eV. However, when the film is heated above this temperature, electrical value takes an altogether different reproducible path and the activation energy for conduction becomes much lower than 0.1 eV. This suggested that concentration of sp^2 carbon must have increased to make it highly conducting. These observations suggest that while ratio of sp^2/sp^3 controls the bandgap, pyrolyzing below 650 °C or sintering at temperature below 600 °C does not alter the ratio of sp^2/sp^3 carbon present in the DLC film. This property of DLC is useful if we wish to make semiconducting carbon of a specific bandgap and to know the temperature up to which the ratio of sp^2/sp^3 carbon present in the film does not alter.

It has been suggested that in a-C:H and a-C, it is the π bonding and π^* antibonding electronic states resulting from p-orbital bonding at sp^2 sites which determine the optical bandgap [71, 72]. The electronic properties of a-C are also determined by the π and π^* states as they in effect form the valence band and the conduction band edge states, respectively. In ta-C with very low sp^2 content, the π and π^* electronic states are highly localized within the much-wider-gap ($\sim$5 eV) σ-σ^* states arising mainly from the sp^3 hybridized diamond-like bonds. Does this mean that any carbon material with sp^3 configuration will always result in bandgap of $\sim$5 eV? This cannot be true. Earlier we discussed the reasons why natural diamond is p-type (Fig. 4), which has 100% sp^3 carbon, and why graphite with 100% sp^2 carbon is an electronic conductor. When carbon system contains both sp^3 and sp^2 carbon, a complex interaction of π bonding and π^* antibonding with σ bonding and σ^* antibonding should be considered in the formation of bandgap of a DLC film rather than only interaction of π bonding and π^* antibonding, because presence of σ bonding coming out of sp^3 carbon in DLC film neither can be neglected nor can be assumed to be $\sim$5 eV. It is therefore necessary to take a fresh look into the exact mechanism of the formation of bandgap in carbon films containing both sp^2 and sp^3 carbon. This is more

important because bandgap of DLC film can be varied from 1 to nearly 4 eV according to the fraction of sp^3 bonding.

In an amorphous network, however, the orientation of the π orbitals is randomized, so that two π bonds which are next to each other will not interact electronically if their orientations are orthogonal to each other. Therefore, in amorphous carbon even when there are a significant number of π-π^* states, conduction is through a hopping related process and consequently electronic properties such as mobility will remain very low compared to other amorphous semiconductors such as a-S:H [73].

Robertson and co-workers [74] have observed that ta-C changes its bandgap as per the doping level of nitrogen and so does the conductivity of the film. At nitrogen content above about 2%, the bandgap begins to close and bonding reverts towards sp^2. Like diamond, pure DLC films and those containing Cu exhibit p-type conduction, and those containing Ti and Si have n-type conduction [75]. However, they also reported that Cu concentration does not exceed 3.0 at.%. Incorporation of Cu into DLC films decreases the resistivity significantly.

Sharon et al. [76] have studied electrochemical properties of DLC film deposited on an alumina plate by pyrolysis of kerosene at 1000 °C in argon atmosphere. The electrochemical potential window of this film in contact with H$_2$SO$_4$ solution was investigated in potential range 2.5 V to -1.5 V vs SCE. The same experiment was repeated with platinum and glassy electrodes using a Pt electrode as a counterelectrode. The kerosene DLC film has the widest potential window (2.91 V) as compared to Pt (2.02 V) and glassy carbon (2.79 V). This result has suggested that kerosene-pyrolyzed carbon electrode can be used as an oxygen electrode more efficiently. They have suggested that DLC film prepared from kerosene is as good as platinum electrode.

5.1.3.2. Spectroscopic Properties   Since DLC film is a mixture of sp^3 and sp^2 carbon atoms, there is no crystallinity in the film. It is quite amorphous in nature and hence XRD cannot be taken as a confirmation for DLC film. Raman spectroscopy has been found very handy to characterize DLC film or to differentiate it from either graphite or diamond. If films contain amorphous sp^2-bonded (graphitic) carbon and sp^3-bonded (diamond-like) carbon (DLC), one gets broad ill-defined bands with high-frequency cut-off near 1332 cm^{-1} (in the range of 1350–1372 cm^{-1}, known as D-band or Raman active E$_{2g2}$ mode of graphite) for the sp^3-bonded carbon, and around 1580 cm^{-1} (usually in the range of 1519–1580 cm^{-1}, known as G-band, also referred to as the A$_{1g}$ mode frequency) for the sp^2-bonded carbon [77, 78]. Schwan et al. [79] have suggested that the G peak is not necessarily composed only of the E$_{2g2}$ mode of graphite, but also of sp^2 C=C stretch vibrations because single benzene rings exhibit a Raman peak at 1588 cm^{-1}. This feature is valid for all aromatic rings and condensed benzene rings. Therefore, it is suggested that possible contribution to the G peak may arise from the C=C sp^2 stretch vibrations of olefinic or conjugated carbon chains at about 1620 cm^{-1}. Thus, the existence of a G peak in the Raman spectrum does not necessarily prove that the a-C film consists only of graphite or fused benzene rings. The G peak might as well have its origin in olefinic chains in the carbon films. The existence of

a peak centered at about 1350 cm^{-1} proves the existence of aromatic or benzene clusters incorporated in the amorphous (hydrogenated) carbon films.

G-band is normally observed to be very broad. In principle, there may be four significant reasons for line-broadening feature in a-C:H films, namely, the cluster size, the cluster distribution, the influence of the stress in the films, and broadening due to chemical bonding. For graphite, Sakata et al. [80] found that the half-width of line-1580 cm^{-1} peaks increases linearly with increasing stress.

In hydrogenated DLC (a-C:H) films or unhydrogenated DLC (a-C) films, D-band is broad as compared to G-band. Nevertheless, intensity of D-band is greater with a-C type films as compared to a-C:H films [81]. The presence of the D-band and G-band peaks, therefore, can also indicate the co-existence of sp^2 bonds with sp^3 bonds. The shifting of the G-band resonance peak towards 1580 cm^{-1} infers the decrease in the sp^3 to sp^2 bond ratio. This is supported by the observations made by Cheng et al. [82]. They have shown that as the temperature of the substrate (gold coated silicon) over which DLC films was grown increases, the intensity of D-band (an indication of increase of sp^3 constituent of the film) increases.

It is reported that in a DLC film prepared below 400 °C, no Raman signal is observed unless it is annealed above 400 °C [83]. It is observed that with increase of the annealing temperature, the intensity ratio of I_D/I_G increased slightly. Shifting of G-line position from 1580 to about 1606 cm^{-1} and D-line position from 1380 to about 1345 cm^{-1}, and change in the intensity, are the most sensitive indications that the film is changing from one with bond-angle disorder to one containing three fold-cordinated crystallites, that is, the film is undergoing a graphitization process.

In principle, these reasons may also be true for the linewidth of D-band. It is possible to get some useful information about the cluster size in amorphous carbon from ratio of intensity of D-peak and G-peak (i.e., I_D/I_G) and the G linewidth [79]. In pure graphite, D peak is expected to be absent [84]. But if graphite is assumed to be disturbed by presence of sp^3 bonded carbon, the D peak will develop and rise in magnitude in the Raman spectrum. When material is composed entirely of sp^3 bonded carbon (and/or olefinic chains connected by sp^3 bonded carbon), the D peak should not be detected, because there exist no benzene clusters that give rise to disorder regions, which are responsible for the D peak. In other words, in a completely sp^3 network the I_D/I_G ratio will be zero. Schwan [79] thus suggested that the I_D/I_G ratio would go through a maximum if it is plotted versus G linewidth. Moreover, Tuinstra and Koenig [84] found that the Raman intensity of I_D/I_G is inversely proportional to the graphite crystallite size (L$_a$) as determined by XRD:

$$1/\mathrm{L_a} \propto I_{1355}/I_{1575} = I_D/I_G$$

It has been suggested that when G linewidth increases beyond 50 cm^{-1}, the resulting decrease in the I_D/I_G ratio would be indicative of a cluster size smaller than 10 Å. Raman spectra of graphite rod, graphene, sheet and multiwall nanotube are shown in Figure 10 to illustrate these behaviors.
Figure 10. Raman spectra in the frequency range 1200–2000 cm^{-1} for graphene sheets, outer shell, purified MWNTs, and graphite rod. Reprinted with permission from [85], Y. Ando et al., *J. Inorg. Mater.* 1, 77 (1999). © 1999, Elsevier Science.

Ager [86] has suggested that hydrogen incorporation into DLC films saturates double bonds, thus forming smaller sp^2 domains and helping sp^3 to cross-link; this increases both the optical gap to higher energy and the hardness of the film. Veerasamy et al. [87] have shown two prominent IR absorption peaks at 2920 cm^{-1} and 2840 cm^{-1}. They have assigned these peaks to stretching mode of C—H bond in sp^3 configuration in C—H$_3$ and C—H sites, respectively. Optical absorption coefficient [88] of a typical DLC film is reported to be 10^4 to 10^5 cm^{-1}. ^{13}C NMR spectrum of a-C:H film shows two peaks, one at around 30–40 ppm due to sp^3 bonding configuration and the other at about 150 ppm due to sp^2 configuration [89]. DLC can thus be amorphous carbon (a-C) or hydrogenated amorphous carbon (a-C:H) with a bandgap in the range of 1 to 4 eV according to the fraction of sp^3 bonding. Sharon et al. [16] have shown the dependence of bandgap with ratio of sp^2/sp^3 of DLC film (Fig. 11) prepared from pyrolysis of camphor.

5.1.3.3. Photovoltaic Effect Because DLC is known to possess a bandgap in the range of 1.0 to 4.1 eV, there have been some efforts to make a photovoltaic cell from semiconducting carbon like DLC. One of the constituents of most photovoltaic cells developed is inorganic semiconducting material such as Si, GaAs, etc. This has raised a question whether photocurrent obtained from such cell is due to inorganic semiconductor (e.g., due to Si or GaAs) or due to carbon as well. It is also questioned whether in these cells, carbon is acting as a metal, thus forming a metal-Schottky-type cell. In addition, none of these photovoltaic cells could be more economical than the silicon photovoltaic cell. Nevertheless, following are a few examples of
Figure 11. Variation of the bandgap of camphor pyrolyzed carbon as a function of the sp^2 carbon contents in the grown films. Reprinted with permission from [16], M. Sharon et al., *Mater. Chem. Phys.* 56, 284 (1998). © 1998, Elsevier Science.

the attempts made in developing a photovoltaic cell utilizing carbon as one of the constituents of the cell. A photovoltaic cell of configuration "C/n-Si" fabricated from the carbonaceous amorphous thin film prepared from the pyrolysis of 2,5-dimethyl-p-benzoquinone in argon atmosphere at 500 °C has been studied exhaustibly by Hong-an et al. [90]. They have also given the band diagram of the junction. Since the optical bandgap of carbon was observed to be 0.25 eV and the nature of carbon (n- or p-type) is not known, this photovoltaic cell may be considered as metal-Schottky-type cell, where carbon behaves like a metal. Recently, Romero et al. [91] have fabricated a carbon nanotube/BCHA-PPV. This shows a rectifying behavior as well as photocurrent. A semiconducting polymer, commercially available, soluble di-cholestanol derivative of poly(p-phenylenevinylene), poly(2,5-bis(cholestanoxy)-1,4-phenylenevinylene) (BCHA-PPV), was used as one component of the cell. The surface of a carbon nanotube was covered with a solution of BCHA-PPV in xylene under an overpressure of 2 atmospheres of argon in order to allow the polymer to penetrate the space between the tubes. A final layer of the polymer was subsequently spin cast onto the carbon nanotube. A second metallic contact of aluminum or gold thermally evaporated onto the polymer completed the device. Sharon et al. have developed a photoelectrochemical cell with DLC, carbon prepared from camphor [92]. They also developed a homojunction [93–94] carbon solar cell from semiconducting carbon obtained by pyrolysis of camphor of configuration p-C (100 nm)/n-C(100 nm)/n-Si(380 nm) giving an efficiency of 1.2%. Soga et al. [95] have fabricated homo- and heterojunction carbon solar cells of configuration "n-C/p-Si," "p-C/n-Si," and "n-C/p-C/p-Si" using amorphous carbon (a-C and a-C:H). The efficiency of these cells is about 2.1%. A p-n junction has been formed by bonding n-GaAs with p-diamond epitaxial layer [96]. A photoelectrochemical behavior of semiconducting boron-doped diamond

thin films has also been studied exhaustibly, principally by Pleskov and his co-workers [97–101] and by Fujishima and his co-workers [102]. Ago et al. [103] have made a photovoltaic cell of configuration "Al(transparent)/PPV(poly(p-phenylene vinylene)/MWNT/ITO (glass substrate)." They studied its current-voltage characteristics as well as its quantum efficiency (1.8%). A heterojunction carbon solar cell of configuration "Al/n-C$_{60}$/p-Si/Al" has been reported by Katz et al. [104]. Under natural sunlight conditions the short-circuit current density was found to be 42 μA cm^{-2} and the open-circuit voltage was 322 mV. A significant rectification property is obtained in the I-V characteristic of the junction.

In spite of this work, there is a need to make efforts to develop a homojunction carbon photovoltaic cell which is cheaper than the silicon photovoltaic cell, giving efficiency at least 10% so that it can be commercially viable.

5.1.3.4. Electron Field Emission Effect Details of theory and techniques to study electron field emission have been discussed in the diamond section. Here we shall discuss this behavior in relation to DLC films only.

Field emission from DLC is generally found more easily than from diamond. It is observed that the substrate over which diamond-like film is deposited has an essential impact upon the electron emission characteristics of the film. Either the electron properties of the interface itself or the growth morphology and structure of the film influence the electron field emission properties. When a diamond-like film is deposited on a flat substrate through a mask, the emission sites are most abundant at the edges of the film. It is likely that the most favorable conditions for emission will always be attained somewhere at the film edge [105]. Xu et al. [106] have proposed that, in the DLC films consisting of a mixture of sp^3 and sp^2 bonds, the sp^3 bonds in the clusters are the electron emission sites, whereas the sp^2 bonds in the clusters play the role of a transport path for supplying electrons. Cheng et al. [107] have studied the electron emission behavior of DLC film deposited over Cr/Si tip by laser ablation process (600 mJ laser energy). They reported that as the temperature of substrate increases, Raman shift at around 1550 cm^{-1} increases, which in turn increases, the current density of 340–436 μA cm^{-2}. This suggests that as the sp^2 content in film increases, emission current also increases. This observation also implies that emission current may increase with increase in sp^2 concentration up to some optimum concentration of sp^2; otherwise graphite should have given the maximum emission current. There has been considerable discussion about whether field emission from diamond and DLC is intrinsic or due to surface damage caused during its formation. There is a need to examine this behavior in detail. Sharon et al. [16] have suggested that carbon with 33.3% sp^2 behaves like an intrinsic material, and while higher concentration makes it n-type, lower concentration of sp^2 makes it p-type carbon. It would be interesting to study the electron field emission with carbon possessing different concentration of sp^2 carbon to establish any possible relationship with intrinsic character of carbon.

Threshold emission field for DLC is 20–40 V μm^{-1} which can be lowered to about 10 V μm^{-1} for optimized films, and to 5 V μm^{-1} for nitrogen-doped films [108, 109]. On the contrary, Kuo et al. [110] have observed that hydrogenated

DLC film grown in presence of NH_3 needs higher threshold voltage than film grown in presence of nitrogen for the electron field emission. They suggested that nitrogen doping is more effective with NH_3 than with nitrogen. It appears from the discussions that exact reasons for field emission with DLC films need more rigorous studies to arrive at some definite conclusion.

5.2. Fullerenes

5.2.1. Structural Aspect

The discovery of C_{60}, one of the family members of fullerene, was first reported in 1985 when Kroto et al. [3] measured a carbon cluster containing 60 atoms arising from their laser vaporization apparatus. The C_{60} molecules contain 12 pentagons and 20 hexagons. In the C_{60} molecules each carbon atom is bonded to three others by two longer bonds (length $\sim$145 pm) and one shorter bond (bond length $\sim$140 pm). This stable pure carbon molecule was found to have geodesic properties of a truncated icosahedral hollow cage and was named Buckminsterfullerene (C_{60}). An excellent and informative review on the growth of carbon nanostructure and fullerenes is given by Popov and co-workers [111]. Fullerene family are the most ordered structures among the known carbon clusters. They are said to be ordered structures because other forms of carbon are believed to be amorphous (e.g., carbon black, charcoal, active carbon, etc.). Crystals of C_{60} formed by vacuum sublimation have a face-centered cubic (fcc), crystal structure at room temperature $a_0 = 141.7$ pm. Those grown from solution have a variety of crystal structures depending upon the solvent used, for example, fcc, hexagonal close-packed (hcp), or orthorhombic structures. Since there are many good reviews, in-depth discussions on this material will not be made.

5.2.2. Properties

The discovery of Buckminsterfullerene has created a torrent of activity spanning the scientific disciplines. It has been speculated that the fullerenes should be excellent lubricants due to their low intermolecular shear strength and high volume compressibility. The optical and electrical properties and the electronic structure of C_{60} are still a matter of dispute. For example, the bandgap of C_{60} has been reported in the range of 1.5–2.15 eV by various authors [112]. Interestingly, Faiman et al. [113] have shown that the optical bandgap of C_{60} thin film can be shifted at will by controlling the deposition conditions leading to effective optical bandgap in the range of 1.5–2.5 eV. Kuzmany et al. [114] have shown a heterojunction photovoltaic solar cell (Al/C_{60}/p-Si/Al) giving a open-circuit voltage (under the sunlight illumination) of 322 mV. Licht et al. [115] fabricated a photoelectrochemical solar cell with C_{60} with various redox electrolytes (aqueous and nonaqueous) and have shown that such type of cell may be feasible with this material provided this material is cheaply available. Some of the properties of crystalline forms of carbon are shown in Table 2.

More information is becoming available about the biological properties of C_{60} and its derivatives. For example, C_{60} inhibits the replication of simian immunodeficiency virus

Table 2. Properties of diamond, graphite, and C_{60}.

Property	Diamond [116] (cubic)	Graphite [117] (hexagonal)	C_{60} [118] fcc
Bond length (pm)	154	142,335	146,144
Density (g cm^{-3})	3.52	2.26	1.72
Bulk modulus (Gpa)	442	286	6.8
Young's modulus (Gpa)	1054	102,036.3	16
Melting point (K)	4500	4450	1180
Thermal conductivity (W m^{-1} K^{-1})	15,000	2800	0.4

(SIV) *in vitro* and the activity of Moloney murine leukemia virus (M-MulV) reverse transcriptase [119]. A polyfullerenol has been found to suppress the levels of the microsomal enzymes *in vivo* and decrease the activities of P450-dependent monooxygenase and mitochondrial oxidative phosphorylation *in vitro* [120]. Water-soluble polythylene modified C_{60} accumulated at the site of tumors during testing, and after light irradiation the volume of the tumor was significantly reduced [121].

5.2.3. Synthesis

Much evidence suggests that fullerenes are a by-product of soot formation; on the other hand, there are observations pointing out that soot produced in fullerene processes is somewhat special compared to other soots. Small carbon clusters (less than 12 atoms) have been observed in sooting flames, in acetylene pyrolysis, and in carbon plasma produced by different methods. It is suggested that fullerenes and soot have the same precursors [122]. C_{60} has been produced from carbon materials other than graphite, such as coals, polymers, benzene soot, glassy carbons, kerosene, coorongite camphor [123, 124], etc. Unique fullerene-related materials to be synthesized include metallofullerenes and nanotubes and polyhedra. Many metals like cesium, potassium, barium, etc. have been successfully encapsulated into a fullerene cage. Laser vaporization [125] of graphite disk impregnated with lanthanum oxide gives a soot containing La_2C_{82}.

5.3. Carbon Nanomaterials

5.3.1. Structural Aspects

There are many mechanisms proposed to elucidate the formation of carbon nanotubes. One of the most accepted mechanisms is formation of carbon nanotube over a molten catalyst. A nucleation of metal and hydrocarbons takes place on the particle surface, it diffuses, and dissociates at the contact angle of the particle with the reactor wall. A carbon shell is produced which develops by lateral growth into a carbon nanotube.

A good description of nanotubes and various aspects related to carbon nanotubes are nicely dealt with in an article published by Kroto and co-workers [126]. Carbon nanotubes consist of graphene sheets wrapped to a cylinder. In other words, nanotubes consist of concentric hexagon-rich cylinders, made up of sp^2 hybridized carbons, as in graphite, and terminated by end-caps arising from the presence of

12 pentagons (six per end). It is possible to construct a cylinder by rolling up a hexagonal graphite sheet in different ways. There exist three forms of nanotubes (NTs): achiral NTs of the "armchair type," achiral "zigzag" NTs, and chiral or helical NTs (each pair of the hexagon sides is arranged at an angle other than 0° and 90° relative to the NT axis). First two of these are "nonhelical" in the sense that graphite lattices at the top and the bottom of the tube are parallel. In the armchair structure, two C—C bonds on opposite sides of each hexagon are perpendicular to the tube axis, whereas in the zigzag arrangement, these bonds are parallel to the tube axis. The structures of these NTs are usually described by means of two indices, n and m, which are related unambiguously to the NT diameter (d) and the chiral angle (θ, characterizing the deviation from the "zigzag" configuration and ranging from 0 to 30°):

$$d = a\sqrt{(3(n^2 + m^2 + mn))}/\pi$$
$$\theta = \arctan\{(-\sqrt{3}m)/(2n + m)\}$$

where a is the interatomic distance in the planar network. (n, m) nanotubes can be characterized by the chiral vector $\mathbf{C_h} = n\mathbf{a}_1 + m\mathbf{a}_2$ on the honeycomb lattice of a flat graphene sheet, where $\mathbf{a}_1$ and $\mathbf{a}_2$ denote the lattice vectors of graphite. The cylinders are formed by rolling up graphene sheet so that sites defined by lattice vector $\mathbf{R}$ fall on top of sites given by the lattice vector $\mathbf{R} + \mathbf{C_h}$. The chiral angle θ is given with respect to the $(\mathbf{a}_1 + \mathbf{a}_2)$ direction. Thus achiral NT of the "armchair" type are characterized by indices (n, m), those of the "zigzag" type have indices $(n, 0)$ and chiral ones are described by (n, m). Because of the sixfold symmetry of the honeycomb lattice, several different integer pairs (n, m) describe equivalent tubes. Dresselhaus and co-workers [127] observed that the intershell spacing (d_{002}) between the two graphene sheets of the nanotubes ranges from 0.34 to 0.39 nm and d_{002} increases as the tube diameter decreases. The empirical equation for the best fit to the data is found to be

$$d_{002} = 0.344 + 0.1\,e^{-D/2}\ (\text{nm}) \quad \text{for} \quad D \geq 0$$

where D is the inner tube diameter. The intershell spacing decreases exponentially and approaches 0.344 nm for tube of diameter greater than ~10 nm.

Apart from these classifications, two kinds of carbon nanotubes are now available: multiwalled nanotubes (MWNTs) and single-walled nanotubes (SWNTs). The diameter of MWNTs is typically in a range from 10 to 50 nm, and length is more than 10 μm. On the other hand, SWNTs are much thinner, being only 1.0 to 1.4 nm in diameter, while the length is on the order of 100 μm. The number of walls in MWNTs is theoretically unlimited but normally it does not exceed a few dozen. The distances between the neighboring shells are close to the interlayer spacing in graphite (0.34 nm); thus, the smallest diameter of carbon NT is ~0.7 nm. The diameter of the second and subsequent coaxial atomic layers is stipulated by the diameter for the innermost layer. In this connection, the structure of NT resembles that of onion fullerenes; if the inner shell is C_{60}, the second shell is C_{240}, the third one is C_{540}, etc. In most cases, the tips of NT are covered by hemispherical or conical caps, which contain not only hexagons but also pentagons, in which the configuration of the carbon atoms is less stable. These caps are somewhat more chemically reactive than the lateral surfaces.

Raman-scattering spectra [128] of single-walled nanotubes measured with incident laser wavelength from 488 to 783 nm shows two peaks, one at 1590.9 cm^{-1} and the other at 1567.5 cm^{-1}, with broad peak at 1549.2 cm^{-1} as compared to graphite peak at 1580 cm^{-1}. Their measurements suggest that as the diameter of the nanotubes increases, the resolution of Raman-scattering peaks, especially of 1567.5 cm^{-1} and 1549.2 cm^{-1}, diminishes and finally becomes one broad peak around 1580 cm^{-1}. When the diameter becomes about 5 nm, it is exhibited by multiwall nanotubes, polyhedral graphitic nanoparticles, or even graphitic layers.

The XRD patterns of graphene sheets, hard shell, purified MWNTs, and graphite rod are shown in Figure 9. In the XRD pattern of MWNTs, the (002) and (004) peaks shift to a lower angle as compared to those from raw graphite, indicating the wide d_{002} spacing of MWNTs.

One of the useful aspects of carbon nanometer tubes is their size-dependent physical and chemical properties. Theoretically, nanotubes are expected to be either an insulator or metal depending upon their diameter [129]. There have been some efforts to establish experimentally as well as theoretically a relationship between the diameter of the semiconducting carbon nanotubes and the bandgap. Smalley and others [130, 131] have reported a relationship between the bandgap and the diameter of the CNT which has been found to be in good agreement with the theoretical estimation [132].

Amaratunga et al. [133] have measured the activation energy (~0.6 eV for high-temperature range) for the electrical conductivity as well as the Hall mobilities (2.75 × 10^{-5} cm^2 V^{-1} s^{-1}) and optical bandgap (in the range of 1.5–2.0 eV) of carbon nanotube prepared under different conditions. It is interesting to note that Hall mobility is very low compared to diamond (1000–2200 cm^2 V^{-1} s^{-1}). Moreover, there seems to be a large difference between activation energy for electrical conduction and optical bandgap, suggesting that CNTs may possess many defect states promoting electrical conduction.

5.3.2. Preparation of Nanotubes

5.3.2.1. Carbon Arc Process Iijima and co-workers were the first to discover carbon nanotubes in the deposit on the cathode of carbon arc [134, 135]. Since then, there have been various approaches adopted to prepare carbon nanotubes. Rakov [136] has given a very exhaustive review on methods for preparation of carbon nanotubes. Nowadays, carbon nanotubes are produced by diverse techniques such as arc-discharge, pyrolysis of hydrocarbons over catalysts, laser evaporation of graphite, condensed phase electrolysis, for example, electrolysis of metal salts using graphite electrode, etc. All these techniques would be difficult to discuss in detail here. Hence, only a few of them are highlighted here.

The arc-discharge method is similar to that used for the synthesis of fullerenes. An inert gas atmosphere (preferably He) is flowed through a reaction vessel [137] at a controlled pressure. Two graphite rods constitute the electrodes,

between which a potential difference is applied. As the rods are brought closer, a discharge occurs resulting in formation of plasma. A deposit, which may contain carbon nanotubes under certain conditions, forms on the large negative electrode (cathode) while the smaller positive electrode (anode) is consumed. When a metal catalyst is to be used along with graphite, a hole is drilled in the carbon anode and it is filled with a mixture of metal and graphite powder. In this case, most nanotubes are found in the soot deposited on the arc-chamber wall. It has been found that vaporization of an anode containing Co, Co-Ni, Co-Y, Co-Fe, Ni, Ni-Y, Ni-Lu, and Ni-Fe gives deposits looking like a lace collar or a soft belt being formed around the cathode deposit. They contain SWNTs mixed with amorphous carbon and metal particles. Some catalysts (Cu, Cu with Ni, Pt, Y, or Fe; Ni, Ni with Y, Lu, or Fe) cause the formation of a "web." The addition of sulfur to Co catalysts also results in a greater amount of the web-like products. Higher yields of SWNTs with diameter ranging from 0.55 to 6 nm have been obtained with the positive graphite electrode mixed with different metals (Ni, Fe, Co, La) [138]. Since sulfur itself does not catalyze the formation of nanotube, its role seems to reduce to the stabilization of dangling bonds. The addition of Bi and Pb also causes increase in the NT diameter.

5.3.2.2. Catalytic-Assisted Pyrolysis (*Chemical Vapor Deposition*)

Pyrolysis of hydrocarbon (chemical vapor deposition) has also been extensively used for this purpose. Catalytic pyrolysis of hydrocarbons had been used to prepare carbon fibers even before the discovery of NT and fullerenes [139]. In this method, chemical precursor along with inert carrier gas is allowed to pass through a quartz tube maintained at some specific temperature. Organic precursor decomposes and the products are deposited on alumina plate. This method has given large quantity of nanotubes. Under this method one could use one furnace [140] and allow the vapor of precursor to enter the furnace for the pyrolysis. Alternatively, two furnaces could be used [141], one for pyrolysis and the other for vaporization of the precursor. Metal nanoparticles employed in the CVD synthesis of carbon nanotubes have been prepared by varieties of methods. Catalysts have also been used for this purpose. Catalyst powder of nanoparticles size could be kept in the furnace over which vapor of hydrocarbon is catalytically decomposed to form carbon nanotubes. Catalysts could also be mixed with precursor and vaporized to enter the furnace along with the vapor of precursor. Alternatively, catalysts could be in form of thin film deposited over some ceramic materials. One method is to use nanoporous or mesoporous substrates, such as zeolites [142], porous Si [143], and anodized Al_2O_3 [144], in which metal nanoparticles are confined through evaporation or impregnation. Another method is to etch a metal substrate or a metal-coated substrate by laser ablation [145] or plasma treatment [146]. The physical etching generates metallic nanoparticles, which play a role as catalysts for nanotubes growth. Many parameters, including the temperature and duration of the treatment, the gas composition and flow rate, and catalyst nature and size affect the nature of carbon species in the resulting materials [147]. For each type of precursor, one has to establish the best conditions to get the desired type

of carbon nanotubes. One of the best and easiest methods is to follow Taguchi Analysis [148].

It has been observed that nickel-catalyzed decomposition of CH_4 (99.99%) and H_2 (in 9:1) helps the growth of carbon nanotubes at 600 °C better than either 500 °C or 700 °C. In general, admixtures of Li, Cu, Ag, Zn, Cd, B, Al, In, Y, La, lanthanides, Si, Ge, Sn, Ti, Hf, Pb, Bi, S, Se, Cr, W, Mn, Ru, Pd, Pt, mixtures of two metals or of a metal with a nonmetal, and several carbides and oxides have been tested as catalyst for such purpose [149–153].

Huang et al. [154] have synthesized large-area highly oriented carbon nanotubes at temperature below 666 °C by plasma-enhanced hot-filament chemical vapor deposition. Acetylene gas is used to provide carbon and ammonia gas is used for dilution and catalyst. Pyrolytic methods have been used to generate helical nanotubes [155], hemitoroidal nanotube caps [156, 157], and bent nanotubes [158].

Pyrolysis of metallocene such as ferrocene, cobaltocene, and nickelocene yields carbon nanotubes and metal-filled onion-like structure [159, 160]. Decomposition of Fe and Co phthalocyanines is also accompanied by the formation of nanotube, whereas Cu phthalocyanine gives neither nanotube nor graphitized particles. Ferrocene has been used as the floating catalyst in the pyrolysis of thiophene giving relatively thick "ropes" and ribbons colored silvery black. The longest ropes were 3–4 cm long and have a diameter of 0.1 mm. Lee et al. [161] observed that nickel deposited over SiO_2 substrate dipped in dilute solution of HF for 100–200 s, or etched by NH_3, results in Ni particles acting as the nucleation seeds for the growth of carbon nanotubes. They could get vertically well-aligned CNTs of length 50 μm. Cao et al. [162] have been able to get bundles of aligned MWNTs by pyrolysis of xylene containing ferrocene. In a horizontal furnace maintained at 800 °C, mixture of hydrogen (150 sccm) and argon (900 sccm) has allowed to carry drop by drop a solution of ferrocene in xylene (0.12 g/ml) at an interval of 2 min. This arrangement gave bundles of MWNTs of average length 60 μm. Cheng et al. [163] have developed a high yield, low cost, and continuous nanotube growth process. Benzene or methane is transported to the furnace maintained at 1100–1200 °C with carrier gas hydrogen along with ferrocene as a catalyst. To enhance the growth of SWNTs a sulfur-containing additive (thiophene) was employed.

Helically coiled nanotubes [164] have been prepared by catalytic decomposition of benzene on Co/SiO_2 catalyst at 873 K. They have a 10 nm coil diameter, 50 nm coil pitch, and around 1 m length.

Carbon nanotubes have been synthesized by chemical vapor deposition at 700 °C and 800 °C using Ni-phthalocynanine as starting material. The tubes grew perpendicularly on the quartz surface. This precursor was preferred because Ni-phthalocyanine ($NiC_{32}N_8H_{16}$) can supply Ni, C, N, and H at the atomic ratio of 1:32:8:16 to preparation system [165].

Zhao et al. [166] have developed a simple technique to grow aligned MWNTs. Al sheet is electropolished in phosphoric/glycerol solution at 13–15 V for 10 min at 70–80 °C until a mirror finished is obtained. This Al sheet is anodized in 0.3 M oxalic acid solution for about 1 hr under 40 V at 25 °C. This sheet is immersed in 5% H_3PO_4 for some time

to remove partial alumina template, and then it is anodized again under the same condition. This gives a regular pore structure. Over this sheet cobalt metal was deposited in the pores by an ac current source of 50 Hz. Alumina membrane is removed from substrate by immersing in saturated HgCl$_2$ solution. By this process, a deposition of Co in the pores was achieved. This system was used for depositing carbon nanotubes by keeping it in a furnace at 650 °C and passing acetylene vapor. In this way, carbon nanotubes were deposited in the pores of the membrane. Advantage of this method is that carbon nanotubes are deposited as aligned nanotubes over metallic aluminum plate. Recently Maruyama et al. [167] have demonstrated a simple catalytic vapor deposition technique to synthesize high-purity SWNTs at low temperature (550 °C) by using methanol as the carbon source. It is suggested that the etching effect of decomposed OH radical attacking carbon atoms with a dangling bond, impurities such as amorphous carbon, MWNT, metal particles, and carbon nanoparticles are completely suppressed even at relatively low reaction temperature. Alcohol was sucked into the furnace rather than pushing through a carrier gas.

Sharon and his group [168] have been trying to synthesize carbon nanotubes by pyrolysis of natural precursors. Their group has been able to synthesize various forms of carbon nanotubes from natural precursor like turpentine and camphor (Fig. 12).

5.3.2.3. Laser Technique

Laser technique has been successfully used for the growth of carbon nanotubes. Single-walled carbon nanotube yield depends upon the power of laser beam (532 nm) used to ablate carbon target, irradiation time, the composition of the target, the pressure and flow rate of inert gas, and the target temperature. Kroto and co-workers [169, 170] pyrolyzed 2-amino-4,6-dichloro-s-triazine over cobalt thin films (deposited on an inverted silica substrate) and etched using laser technique. A bundle of aligned nanotubes of uniform length of around 100 mm and diameter of 30–50 nm grown perpendicularly over the substrate were observed. Guo et al. [171] have proposed an original method for the synthesis of SWNTs in which mixture of carbon and transition-metal are vaporized by a laser impinging on a metal-graphite composite target. They pointed out that in contrast to the arc method, direct vaporization allows far greater control over growth condition permitting continuous operation, and produces nanotubes in higher yield and better quality. Rinzler et al. [172] have been able to develop laser ablation technique to produce SWNTs yielding in the range of 60–90 vol.% of the carbonaceous soot material and at a production rate of about 1 g day^{-1}. There is a good review on the production of carbon nanotubes by Wolfgang et al. [173]. Some standard conditions for synthesis of nanotubes (SWNT and MWNT) using laser are given in Table 3. A self-explanatory schematic diagram of the laser evaporation technique is shown in Figures 13 and 14.

5.3.2.4. Electrochemical Method

Electrochemical method has lately been tried for the growth of carbon nanotubes. Matveev et al. [174] have been able to get MWNTs from acetylene at room temperature for the first time. Gaseous acetylene was purified by passing it through iron chloride solution. Gas was then dried by passing it through a layer of freshly melted KOH flakes. Purified acetylene was dissolved in liquid ammonia to get 15–20 mol% acetylene solution. This solution was electrolyzed at 233 K using n-Si (100) electrodes (separated by 4 cm) at 150 V for 5–10 h. Carbon curled nanotubes were found on the electrodes and exhibited a high aspect ratio (length/diameter) >1000. Liquid ammonia helps to dissolve hydrocarbon as well as to initiate chain radical reactions in the solution of hydrocarbon to facilitate growth of carbon nanotubes. Windle and co-workers [175] as well as Kroto and co-workers [176] have synthesized carbon nanotubes and nanoparticles electrolytically from normal graphite in molten alkali chlorides such as LiCl, NaCl, and KCl. Carbon nanotubes as well as nanoparticles and onion-like structures have been generated. The nature of products depends upon several factors including the electrolysis voltage and current, depth of electrode immersion in the electrolyte, the length of time the current is maintained, and the electrolyte. It is reported that carbon consumption for nanotube formation occurs at the graphite cathode where alkali metals form during the electrolysis. However, the major hurdle is the nonconducting nature of most organic precursors and insolubility of the organic materials in polar solvents or in solvents with high dielectric constant. Hence, though this technique is very suitable, these limitations have to be overcome before it can be used for large-scale synthesis of carbon nanostructures.

5.3.2.5. Effect of Particle Size of Catalyst

It has been observed that the particle size of the catalyst plays a role in the growth of MWNTs as well as SWNTs. For multi-walled nanotubes, the particle size needs to be larger than the nanotube diameter since catalytic process requires carbon species to diffuse through catalyst like Ni in order to grow multiwall nanotubes. For the growth of single-walled carbon nanotubes, the particle, which is attached to one end of the nanotubes, has to have the same size as the nanotube diameter where the carbon shell on the particles grows and transforms to a carbon nanotube. These relationships agree with the experiential evidences [177–179].

5.3.2.6. Opening and Insertion of Metal into Carbon Nanotubes

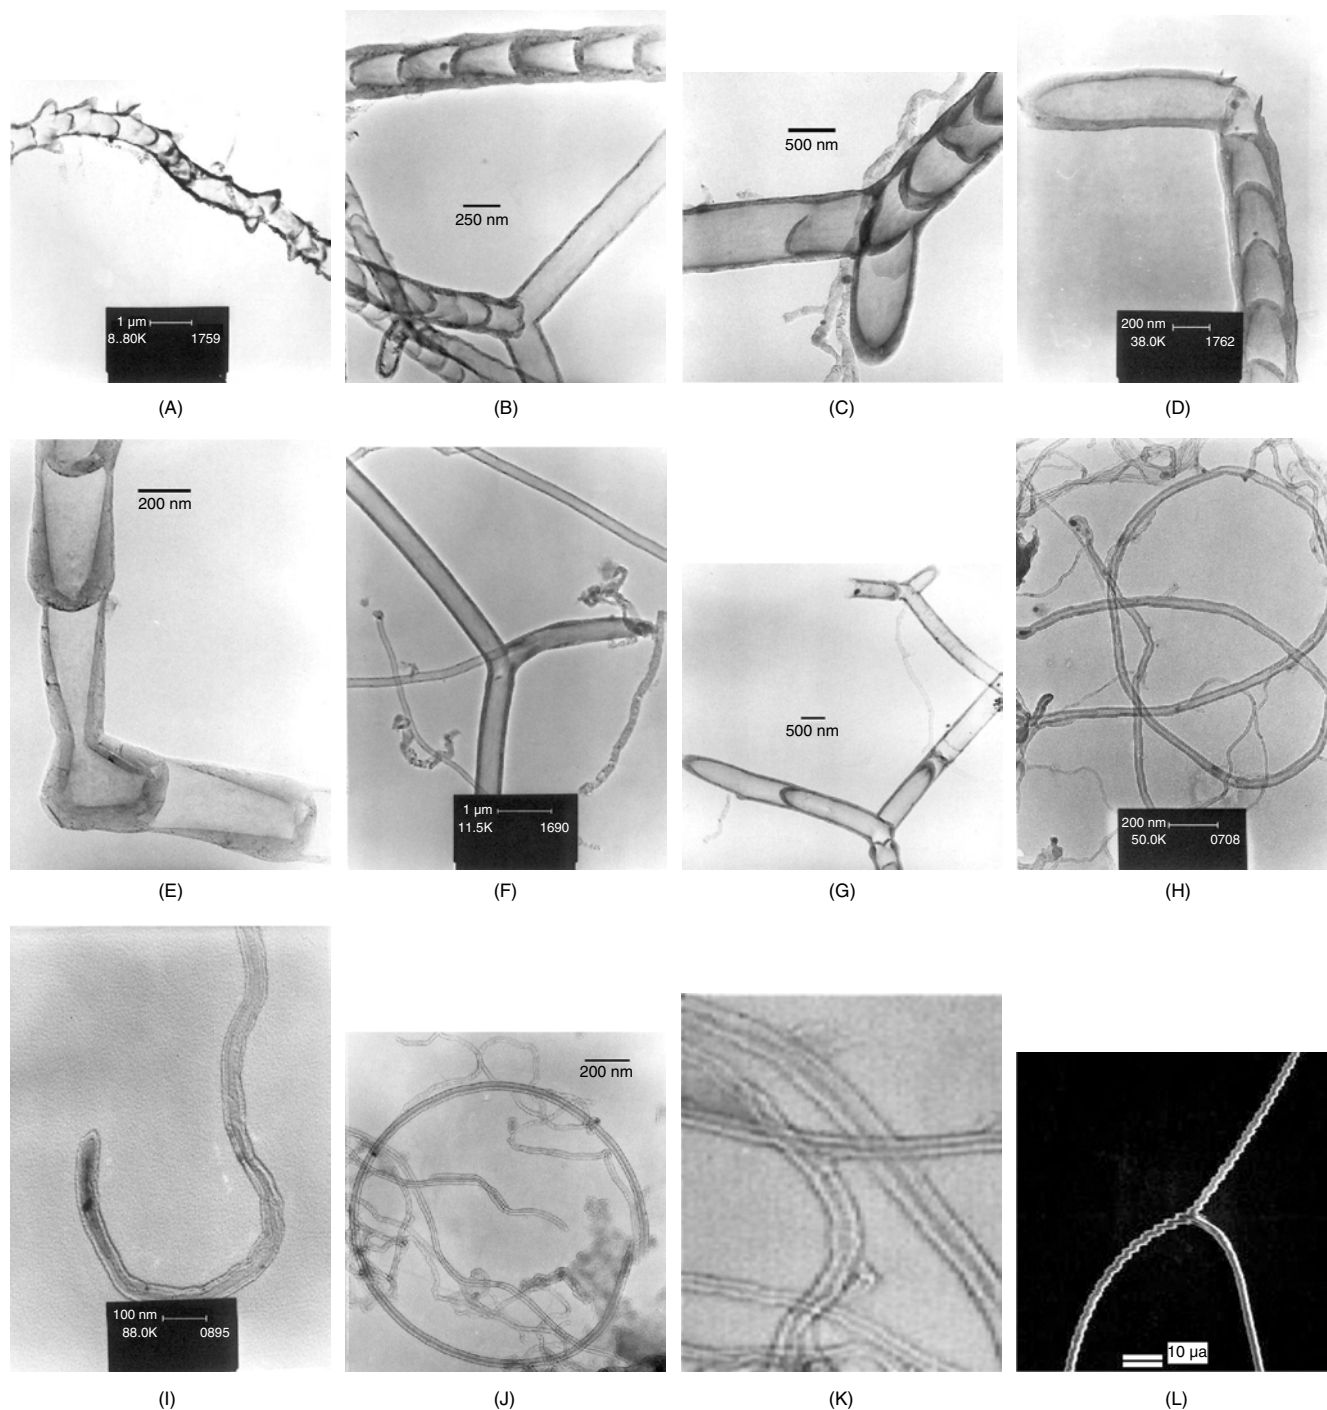
Carbon nanotubes prepared by any of these methods would be normally closed from one end of the tube. Hence, efforts have also been made to open one of the ends so that some chemistry could be done with these carbon nanotubes. One simple method is by a chemical route for opening multiwalled carbon nanotubes. This is achieved by boiling suspensions of nanotubes in aqueous nitric acid for several hours (~24 h) at 150 °C [180]. Several efforts have been made to encapsulate metallic particles like iron into carbon nanoparticles [181]. After opening the closed end of carbon nanotubes, filling in-situ with metal oxides such as NiO [182] or even metal like palladium has been achieved [183]. Ajayan and co-workers have been able to coat carbon nanotube with a single layer of metal oxide (V$_2$O$_5$) [184]. A novel electrolytic technique has been discovered by Kroto and co-workers [185] which yields fully filled metallic Sn nanowires. They also succeeded in coating carbon nanotubes with Sn nanowires by electrolyzing graphite electrode in molten mixture of LiCl and SnCl$_2$ under argon atmosphere.


Figure 12. Various types of carbon nanomaterials synthesized from turpentine and camphor. Bamboo-shaped branched CNT (A, B, C, F); Y-junction CNT (D, E); coiled double-walled CNT (G, I, J); enlarged portion of (G) to show double-walled CNT (H); formation of branching in CNT (K); Yofork type CNT (L) [168].

In this fashion many types of elements such as Pb, Bi, Cs, S, Se, etc. have been introduced into the carbon nanotubes easily. It has also been possible to dope potassium into single-walled nanotube. Due to donation of electron by potassium, its doping causes generation of electron carriers in the carbon nanotube. The Hall mobility for the electron is found to be 20–60 cm^2 V^{-1} s^{-1}, a value which is similar to hole effective mobility in nanotubes [186].

5.3.3. Purification of Carbon Nanotubes

When one measures the physical properties of MWNTs or SWNTs and plans their practical application, impurities like carbon nanoparticles are not desirable. There is a good review on the purification of SWNTs by Chiang et al. [187]. Many attempts have been made for purification of MWNTs [188]. Carbon single-walled nanotubes or multiwalled carbon

Table 3. Some favorable standard laser ablation conditions for synthesis of nanotubes.

Source	Source conditions	Target	Temperature	Gas	Results
Single pulsed Nd:YAG	λ 532 nm	Graphite (G)	Furnace 1200 °C	Argon	MWNTs
Double pulsed Nd:YAG	λ 1064 nm	G (98)/Ni (0.6)Co (0.6) at.%	Furnace 1200 °C	Argon	SWNTs 60–90 vol.%, 1 g/day
Cw-CO$_2$	λ 1064 nm	G (95)/Ni (4)/ Y (1) at.%	No furnace	Argon	SWNTs 80 vol.%, 130 mg/h
Solar light	Sunlight	G (96)/Ni (2) Co (2) at.%	No furnace	Argon	MWNTs and few SWNTs

nanotubes are typically accompanied by other carbonaceous materials when synthesized. A number of purification methods have been developed. They can be categorized into four major methods: (i) acid oxidation, (ii) gas oxidation, (iii) filtration, and (iv) chromatography. In the acid reflux procedure raw nanotubes are refluxed in nitric acid to oxidize the metals and impurity carbon. Sharon and co-workers [189] have purified carbon nanotube by refluxing it with concentrated HNO$_3$ for 24 h. TEM images of CNT films are shown in Figure 15. While Figure 15a shows the CNT before purification, Figure 15b shows CNT after purification. Globular particles at the end of the CNT (Fig. 15a) are the Co catalyst, which are absent in the purified material (Fig. 15b).

Unfortunately, acid-treated nanotubes are thought to have carboxylic acid groups at the tube ends, possibly, at defects on the sidewalls. Hence, acid-purified tubes must be checked before its application. Gas phase oxidation is used for the purification of MWNT [190]. This process suffers from the disadvantage of destroying SWNT. Combination of acid wash and gas oxidation process has also been applied for purification. Oxidation of acid-treated products at 550 °C for 30 min has given a good result to purify SWNT. TGA studies indicate that these purified tubes can withstand temperature up to 600 °C in air. Microfiltration and chromatography methods have also been found suitable, but are not so popular. Purification of multiwalled carbon nanotubes containing necessary carbon particles has been also achieved by heating the sample with infrared radiation in air [191, 192]. Unfortunately, more than 95% of the nanotubes are also destroyed in this process and the remaining nanotubes lose their protective end-caps. Recently, it has been suggested to

treat carbon nanomaterials (impure) with HCl and then with HNO$_3$.

5.3.4. Properties of Carbon Nanotubes

Before discussing various applications of carbon nanotubes, perhaps it would be appropriate to spend some time discussing the general properties of carbon nanotubes. Measurements of Young's modulus show that single nanotubes are stiffer than commercial carbon fibers. MWNTs can pass a very high current density of the order of 10^8 A cm^{-2} without adverse effect [193]. Properties of nanotubes depend on atomic arrangement (how the sheets of graphite are rolled), the diameter and length of the tubes, and the morphology or nanostructure. Work functions of MWNTs and graphite have been evaluated from the secondary electron in UPS HeI spectra by Ago et al. [194]. These values are given in Table 4. X-ray profile of purified and annealed SWNT has been given by Smalley and co-workers [196], showing well-defined reflections at 2θ corresponding to 6.3, 10.5, 16.5, and 22°.

An essential problem in understanding conduction in nanotubes is a crossover from metallic to nonmetallic behavior as the temperature is lowered [197]. Recent electrical transport measurements on bulk nanotubes, individual

multilayered tubes, and single-walled tubules have revealed that their conducting properties depend markedly on the degree of graphitization, helicity, and diameter. Carbon nanotubes are found to behave like metal, insulator, or semiconductor, depending upon the method of production—which controls the degree of graphitization, the helicity, and the diameter.

Collins et al. [198] have recently found that the thermopower of SWNT thin films changes from a large positive

Table 4. Work function of MWNTs.

Sample	Work function (eV)	
	Ago [194]	Shiraishi [195]
Purified MWNTs	4.3	4.95
Air-oxidized MWNTs	4.4	—
Plasma-oxidized MWNTs	4.8	—
Acid-oxidized MWNTs	5.1	—
Highly oriented pyrolytic graphite (HOPG)	4.4	4.80
Single-walled nanotube (SWNTs)	—	5.05
C_{60}	—	6.5

value to approximately 20 μV K^{-1} (at a temperature of 350 K) in air to negative values of approximately -12μV K^{-1} in vacuum, and so ascribed the positive thermopowers observed to the adsorption of oxygen. However, the negative thermopower magnitude seen in vacuum is still larger than typical metallic values instead of being close to zero. Grigorian et al. [199] found a negative thermopower for SWNT mats doped with Cs, again reaching a rather large magnitude of -15 μV K^{-1} near 150 K before decreasing in magnitude at higher temperature.

Carbon nanostructured materials are also considered for some electrochemical applications such as membrane support of catalyst for the electrocatalytic reduction of oxygen and the oxidation of methanol [200, 201], storage of lithium [202, 203], and supercapacitors [204, 205]. These properties are discussed later in detail.

5.3.5. Applications of Carbon Nanotubes

5.3.5.1. Biochemical Applications
SWNTs can be cut into smaller sections using sonication in a mixture of concentrated sulfuric acid and nitric acid. This process makes the tube opened. Once opened, tubes can be filled with a variety of materials, for example, enzymes, protein [206], and DNA [207]. The biomolecules appear to be encapsulated within an environment which offers some protection, and subsequent analysis of the catalytic activity of the immobilized enzymes showed that a significant amount of the enzyme retains its activity. Opening of tube tips has enabled the resultant OH and COOH groups to be functionalized using the standard chemical reaction conditions. For example, SWNTs have been functionalized at the opened tips by reaction with thionyl chloride and octadecylamine: the derivatized tubes are more soluble in organic solvents than their parent compounds and can subsequently be reacted further along the waists of the molecules [208]. This type of research is expected to help in drug delivery to infected human organs. A suitable drug can be inserted into the hollow space of the nanotubes and can be injected into body (with functionalized soluble carbon nanotubes). Drug will start operating slowly at the site, which is infected.

5.3.5.2. Hydrogen Storage by Carbon Nanotubes
Good reviews on hydrogen storage by adsorption in carbon nanotubes are given by Darkrim et al. [209] and Simonyan et al. [209, 210]. There are conflicting reports about the magnitude of hydrogen adsorbed by carbon nanotubes. However, soon we shall arrive at some results, which are reproducible. Dillon et al. [211] have reported that crystalline SWNTs have hydrogen capacity of 5–10 wt% at pressure less than 1 bar near room temperature. It has also been observed that some nanotubes can electrochemically store relatively large amount of (110 mA h g^{-1}) hydrogen, corresponding to a hydrogen storage capacity of 0.39 wt%. The reaction is reversible, indicating that the nanotubes can be used to produce electrodes for rechargeable batteries. Considering these properties, Rajalakshmi et al. [212] have made electrodes of purified and open single-walled carbon nanotubes and found them to behave like metal hydride electrodes in Ni-MH batteries, showing high electrochemical reversible charging capacity up to 800 mA h g^{-1} corresponding to hydrogen storage capacity of 2.9% compared

to known AB_5, AB_2 metal hydride electrodes. The charging and discharging potential was around -0.8 and -0.6 V versus SCE, respectively. In a separate attempt, Qin et al. [213] reported that MWNTs are promising candidates for hydrogen storage. The electrochemical capacity of MWNTs-Ni electrode can reach over 200 mA h g^{-1} at a current density of 200 mA g^{-1}. MWNT-Ni electrode showed a high rate of discharge capacity and long charge-discharge cycle life. The electrochemical reaction of MWNTs-Ni was controlled by the step of the hydrogen adsorption and the hydrogen oxidation, that is,

$$Ni + H_2O + e^- \rightarrow NiH_{ad} + OH^-$$

(this being the rate-determining step)

$$NiH_{ad} + MWNT \rightarrow MWNTH_{ad} + Ni$$
If this could be improved, then low-weight, high-power density Ni-carbon hydrogen battery could become a reality. Zuttel et al. [214] have tried to study the hydrogen storage capacity of carbon samples at room temperature by means of electrochemical galvanostatic measurement in a 6M KOH electrolyte. During the charge process, the water in the electrolyte dissociates at the working electrode (sample, negative electrode) into the adsorbed atomic hydrogen and OH$^-$ ions remaining in the electrolyte. The adsorbed atomic hydrogen may intercalate in the electrode or recombine at the surface to molecular hydrogen and diffuse into the electrode or form gas bubbles at the surface of the electrode. During discharge process, the hydrogen in the electrode recombines with OH$^-$ ions in the electrolyte to form water. This reaction is accompanied with a charge transfer and therefore, the amount of hydrogen desorbed from the electrode can be measured by measuring the electric charge, which is equal to the product of current and time in galvanostatic setup. In Zuttel's experiment, there is no evidence that discharged hydrogen has been completely adsorbed in the carbon. Hence, the experiment has to be designed such that one can be sure beyond any doubt discharge current is proportional to quantity of hydrogen gas adsorbed in the carbon matrix. This hydrogen storage is very attractive from the viewpoint of fuel cell technology, which requires a very high density of hydrogen molecules for clean combustion. The temperature programmed desorption (TPD) profiles of closed- and open-tip SWNTs with diameters of around 1.2 nm are compared with the results of activated carbon, which has micropores with diameter of around 3.0 nm. The peak at 133 K is seen to originate due to hydrogen molecules adsorbed inside the contamination amorphous carbon. This hydrogen is not useful because it cannot be used at room temperature. A peak at 288 K found only in the open-tip CNTs suggests that the hydrogen molecules are incorporated inside the hollow spaces of CNTs. The high-temperature desorption (288 K) of a large number of hydrogen molecules is a fascinating property for this application. The heat of adsorption for this site (19.6 kJ mol^{-1}) is larger than those for graphite ($\sim$4 kJ mol^{-1}) and activated carbons (12 kJ mol^{-1} for low coverage and 4 kJ mol^{-1} for high coverage). The well-aligned SWNTs with the diameter of 2.0 nm were predicted to be good candidates for use in vehicles, much better than metal hydrides [215]. It is reported that 4 wt% or higher of hydrogen can be stored in SWNT.

5.3.5.3. Lithium Secondary Battery   One of the biggest advantages of lithium battery is that one can get operating voltage in the range of 4.7–5.0 V. The theoretical capacity of lithium metal is considerably high 3862 mA h g^{-1}. Since lithium reacts vigorously with water, it is difficult to get this power in aqueous solution. Alternative method is to use nonaqueous solution and some device such that lithium could be transported into the solution. Herold [216] reported the first synthesis of Li-intercalated graphite. Later Besenhard [217, 218] observed electrochemical intercalation of alkali metal in graphite that is immersed in a nonaqueous electrolyte. Cyclic voltammetry of graphite in dimethylsulfoxide (DMSO), 1,2-dimethoxyethane (DME), or PC indicated reversible electrochemical reduction at potential more positive than that for Li deposition. This was attributed to an intercalation reaction involving lithium. General formula for intercalated lithium can be Li$_x$C$_y$; for $x = 1$, y is equal to 6 and for $x = 0.5$, y is equal to 12. For LiC$_6$, the electrochemical capacity is equivalent to 372 mA h g^{-1} C, and 186 mA h g^{-1} for LiC$_{12}$. In some special cases, it has been possible to get 1600 mA h g^{-1} capacity but soon after first cycle of operation, the capacity falls down to 460 mA h g^{-1}. Introducing defect by ball-milling is found to improve the capacity to 1000 mA h g^{-1}.

This observation attracted scientists to develop lithium battery using graphite as an electrode. The overall charge (Li intercalation in carbon, de-intercalation of metal oxide) reaction in a Li-ion battery that contains graphitic carbon and a lithiated metal oxide (MO$_2$, M = Co, Ni, or Mn) is

$$LiMO_2 + 6C \rightarrow Li_{1-x}MO_2 + Li_xC_6$$

The electrochemical synthesis of Li-intercalated graphite in a nonaqueous electrolyte containing a lithium salt can be represented by

$$x Li^+ + 6C + x e^- \rightarrow Li_xC_6$$
During charging, Li from the metal oxide is transferred to the carbon to form the negative electrode. Correspondingly, discharge (de-intercalation of Li from carbon) of Li-ion cell involves the reverse reaction. Lithiated carbon, in which the Li species are intercalated between the layer planes (i.e., in graphite) or associated with other sites (i.e., in disordered carbons), are produced by both chemical and electrochemical process. This transport of lithium back and forth during the charge and discharge process has led to the use of terminology such as "rocking chair," "shuttlecock," "SWING," etc., to describe Li-ion cell. After the discovery of carbon nanotube, this idea has been extended to carbon nanotubes.

The electrochemical intercalation of lithium in MWNT was achieved by placing lithium metal foil, a polypropylene porous separator soaked with the electrolyte solution, and a cathode prepared by mixing nanotubes with 5% of black carbon and 5% of polytetrafluoroethylene (PTFE) as a binder. Electrolytes are normally prepared with LiPF$_6$ (1M) in carbonate mixture (EC:PC:3DMC) [219]. Shinoda et al. [220], however, has suggested that lithium intercalation is possible with open SWNT.

Sharon and co-workers [221–223] have studied the application of carbon nanotubes and carbon nanobeads prepared

from pyrolyzed camphor and observed that capacity of battery is as good as that obtained with graphitic carbon. Slurry of camphoric carbon nanotubes was made with acetylene black and ethylene propylene diene monomer as a binder in a proportion of 86:10:4. This slurry was spread evenly onto a finally polished copper sheet. Lithium metal was used as counterelectrode. A Celgard 2500 microporous polypropylene, wetted with dimethyl carbonate, served as a separator. 1M LiPF$_6$ solution, prepared in 1:1 mixture of dimethyl carbonate and ethylene carbonate, was used as the electrolyte.

Typically, the potential of the carbon is >1 V before Li intercalation takes place. In the case of highly graphitized carbon, when current is applied to intercalate Li, the potential initially drops rapidly to near 0.8 V (vs Li/Li$^+$) where electrolyte decomposition and the formation of a surface film occur. When these reactions are taking place, the potential remains close to a constant value. Following electrolyte decomposition, the potential declines and the majority of Li intercalation occurs at <0.25 V. In the extreme case, electrolyte decomposition and gas evolution can occur with little or no lithium intercalation. In addition, the difference between the charge and discharge half cycles is attributed to the irreversible capacity loss, which represents the charge (coulomb) associated with electrolyte decomposition. Unfortunately, irreversible capacity is of the order of 120 mA h g^{-1}. Because the cell is manufactured in the discharged state, that is, no lithium present in the carbon structure, it is advantageous to minimize the irreversible capacity loss which reduces the amount of lithium that is available for the intercalation or insertion reactions.

Studies on various carbons indicate that the irreversible capacity loss increases with increase in the surface area. Nevertheless, some of the important properties that affect the electrochemical behavior of carbon in Li-ion cells are crystallinity, surface area, type and amount of surface groups, and particle size and shape. These parameters influence the capacity, cycle life, charge/discharge rate, and energy efficiency.

Recently, Fukutsuka et al. [224] have used sp^2 type carbonaceous thin film for insertion and extraction of lithium ion in a lithium secondary battery. However, the current density of only 26 mA g^{-1} could be obtained with such films.

In commercial cells, LiCoO$_2$ is the dominant lithiated metal oxide in the positive electrode (i.e., for the cathode). Spinel structure oxides [225, 226] like LiNi$_x$Mn$_{2-x}$O$_4$, LiNiVO$_4$ [227], LiCr$_x$Mn$_{2-x}$O$_4$ [228], LiCu$_x$Mn$_{2-x}$O$_4$ [229, 230], and less toxic spinel cathode Li$_2$FeMn$_3$O$_8$ [231] have also been used as cathode materials.

It is important to realize that though we can get the highest voltage with lithium battery, because lithium is scarcely available, in the long run, its cost can become very high for common man to use. On the other hand, other alkali metal like potassium, which is available in plenty, may prove to make a more cost-effective battery than lithium battery. Claye et al. [232] have been able to dope potassium into a SWNT. Since potassium is able to intercalate with SWNT, why not try to make a potassium battery?

5.3.5.4. Carbon Nanotubes as Supercapacitor
Supercapacitors are intermediate systems between electrochemical batteries, which can store high energy associated with

low power values, and dielectric capacitors, which can deliver very high power during few milliseconds. There is a good review on this topic by Burke [233]. Supercapacitors are also called electrochemical capacitors, electric double layer capacitors, or ultracapacitors. They are classified into three types: (i) electrostatic capacitor, (ii) electrolytic capacitor, and (iii) electrochemical capacitor. The electrostatic capacitor has a small capacitance. However, it can be charged/discharged at high voltage. Examples are ceramic capacitor, glass capacitor, mica capacitor, etc. The electrolytic capacitor has been used most generally up to now, because it has a large specific capacitance. The electrochemical capacitor is a new type of capacitor offering new features. The electrical energy storage system utilizing charge-discharge process of electric double layer on porous electrode is called "electric double layer capacitor (EDLC)." The specific capacitance of electrochemical capacitor is much larger (over 10–1000 times) than that of conventional capacitors. They have many advantages compared to the secondary battery; for instance, long cycle life (>100,000 cycles), simple principle and mode of construction, short charging time, safety, and high power density. The energy density of supercapacitors, however, is smaller than that of secondary batteries.

The most common applications of double layer capacitor are as button cell, memory backup for electronic equipment. They are also used as auxiliary power sources in small appliances like laptop computers, alarms, VCR, telephones, etc. They are well suited as a backup source because of their energy storage density, low cost, and maintenance-free long life operation. They have been used as a memory backup device because of their high cycle efficiency and the long cycle life. Moreover, recently EDLC is expected as the subpower source for hybrid electric vehicle (HEV) because EDLC can provide high power density (from 0.5 to 20 kW kg^{-1}) during few seconds or more, which leads to specific energy densities ranging from 0.5 to 10 Wh kg^{-1}. The electrochemical capacitor can use either nonaqueous electrolyte system or aqueous electrolyte system. Nonaqueous system can work at high working voltage, but internal resistance is high and needs hermetic seal to avoid moisture absorption. Absorption of moisture spoils the performance of the capacitor. On the other hand, aqueous solvent system has high ion mobility and high dielectric constant, making the internal resistance very small. However, this works at low voltage (around 1.3 V).

There are three different types of EDLC supercapacitors: (i) carbon/carbon, (ii) metal oxide, and (iii) electronically conducting polymers. In carbon supercapacitors, the electric charge is stored between a high surface area of carbon electrode/electrolyte interface. In these systems, the use of organic electrolytes allows the increase of the working voltage as compared to aqueous electrolyte. The electrode is composed of a current collector (e.g., nickel foam) in contact with an activated carbon. The current collector has to be electrochemically inactive in the potential window in which the system works. The active material is an activated carbon. Under a powder form, activated carbon (approximately 95%) is mixed with a binder (about 5% mixture of binder like carboxymethylcellulose and PTFE) and sometimes with an electronic conductor in order to reach good mechanical

and electronic properties to the electrode. After drying, the active material is laminated on each side of the current collector, to make about 600-μm-thick electrode. A basic typical design of the electrochemical capacitor of configuration $CNT|H_2SO_4||H_2SO_4|CNT$ sandwiched between two pieces of carbon paper assembled between Perspex plates is shown in Figure 16.

Pellet of CNT (B) is charged with external potential and when needed the same charge can be discharged externally to get the power. In order to increase the capacitance, carbon nanotube needs to be activated. Activated carbon used in supercapacitors must possess the following characteristics: (i) a high specific surface area to ensure high specific capacitance value, (ii) a low resistivity, and (iii) a microstructure well adapted in order to allow good electrolyte accessibility into inner surface of the electrode. The practical electrode material for EDLC is porous carbon such as activated carbons. The high capacitance (100–200 F g^{-1}) is due to high specific area (1000 m^2 g^{-1}) produced by many micropores (2 nm > pore width). In general, it is believed that there is a proportional relationship between the specific surface area and the electric double layer capacitance of the activated carbon. The electric double layer capacitance can be calculated by the amount of electricity passed during the charge or discharge process by using the following equation [234]:

$$c = it/w\Delta V$$

where c = electric double layer capacitance (F g^{-1}), i = current (A), t = charge or discharge time (s), w = weight of activated carbon in the electrode (g), and ΔV = potential change during charge or discharge process.

The surface area of activated carbons results from a complicated porous structure which involves pores of different size: macropores (>500 Å wide), mesopores (20–500 Å), and micropores (<20 Å). The smaller the pore size, the more difficult it is for the electrolyte to get in and, hence, the
A   Pt electrode
B   CNT pellets
C   Filter paper shocked with 0.1M Sulphuric Acid
D   0.1M Sulphuric Acid

Figure 16. Schematic diagram of a CNT based double layer capacitor. (A) Carbon paper, (B) CNT, (C) separator (filter paper soaked with electrolyte), (D) electrolyte. The assembly is held together by two Perspex plates.

capacitance of these materials depends not only on the surface area but also on the pore size distribution. At present, the best performing commercial activated carbons in organic electrolytes display capacitance values of about 120 F g^{-1}. These values are significantly lower than those in aqueous solutions.

Niju et al. [235] and Liu et al. [236] have suggested that carbon nanotubes can be used effectively as an electrode for supercapacitors. Barisci et al. [237] have found that electrode made out of nanotubes discharges faster in 1.0M NaCl solution at negative potential due to influence of dissolved oxygen. However, with 7.0M H$_2$SO$_4$ or 5.0M KOH, a different pattern is observed. A positive charge appeared to be better kept in acid while negative charge was more lasting in base, despite the influence of oxygen. Charges could be retained for more than 800 s.

Carbon aerogels, that is, a monolithic three-dimensional mesoporous network of carbon nanoparticles, are considered as promising materials for electrochemical capacitors [238]. The pyrolysis of organic aerogels based on resorcinol-formaldehyde (RF) or phenol-furfural (PF) precursors via a sol–gel process obtains carbon aerogels. The advantages of carbon aerogels for capacitor application are their high surface area, low density, good electrical conductivity, and the possibility of their usage without binding substances. The special porosity of aerogels is based on the interconnection with a specific surface area between 500 and 900 m^2 g^{-1} and a high pore volume (0.4–2.6 cm^3 g^{-1}). It has been proved that carbon aerogels with a diameter of pores in the range from 3 to 13 nm pointed out the best voltammetry characteristics and the highest capacitance values (70–150 F g^{-1}).

5.3.5.5. Electron Field Emission In this section, we shall devote our efforts to discuss the electron field emission studies made with carbon nanomaterials only. Detailed theory and other experimental details have been discussed in earlier section dealing with diamond. One of the striking properties of carbon nanotube films is that they are exceptionally good field emitters. Sometimes it has been assumed, wrongly, that nanotubes behave like metallic needle to describe the field emission properties. This is clearly an overly simplified picture of the situation, because we have to deal with a covalently bonded nanoscaled system. Thus, in contrast to the emission mechanism of DLC and CVD diamond films, where the emission mechanism is disputed, the field emission from nanotubes is clearly governed by their geometrical field enhancing properties. The electron field emission phenomenon with carbon nanotubes has been explained by tunneling of electrons from localized states at a tip with energies close to the Fermi energy, stimulated by the enhancement of the electric field from their structure [239].

Recently, Bonard et al. [240] developed a field emission diode in a cylindrical geometry with MWNTs deposited on the metallic cathode as the electron source. [Kanthal (Fe-Al-Cr) wire on which a liquid Fe catalyst is applied by dipping the rod in an ethanolic solution of 40 mM Fe(NO)$_3$ 9H$_2$O and dried.] This rod is heated to 720 °C and acetylene vapor is pyrolyzed to get a deposition of MWNTs over the rod. This coaxial rod coated with carbon nanotube is

found to give electron field emission. Most interesting part of this report is in observing electron emission even when anode and cathode are separated by a distance of 20 mm. They could show even illumination of tube by this method. A cylindrical assembly of luminescent tube containing carbon nanotube coated wire at its axis showed emission of light intensity like conventional mercury tube giving intensity to 10,000 cd cm^{-2}. It is suggested that this assembly may have applications in vacuum gauges of magnetic field sensors.

Bonard et al. [241] observed that maximum current that could be drawn from one MWNT was ~0.2 mA. The emission current was stable for few seconds before a catastrophic failure of the emission. Mostly large diameter tubes remained on the film after emission. It is very probable that the small diameter tubes were destroyed, through the ion bombardment (by gas phase electron ionization or by ion desorption from the anode or the isolator, both induced by the emitted electrons). On single nanotube tip, stable emission was observed for more than 100 hr at ~2 μA emission current (with 300 V).

Based on the Fowler–Nordheim model, it was calculated that electric field at the tip of SWNT is enhanced to about 1300 times what is observed with DLC, but there is some discussion on the validity of this model to SWNT. The model that electrons are emitted from single atomic wires protruding from the tip of CNTs is still hypothetical and has not been confirmed. It is very interesting to note that the opening of tips by oxidation with either oxygen-plasma treatment or by heating in oxygen gas makes the CNTs more highly emissive [242–244]. For this purpose, they produced aligned carbon nanotube films. An ethanol dispersion of the arc-produced carbon nanotubes is allowed to pass through an aluminum oxide micropore filter. In the filtration process, the nanotubes get stuck in the pores of the filter, causing them to stand perpendicular to the filter surface. The nanotubes-covered filter is placed face down on a teflon sheet and the nanotubes are printed onto the sheet under pressure, producing a layer of more or less vertically aligned nanotubes. This sheet is then covered with a perforated mica sheet of thickness 30 mm. A current was observed when a potential was applied between the carbon nanotubes (cathode) and the anode kept over the mica sheet. The I-V curve followed Fowler–Nordheim behavior. Carbon nanotubes/organic semiconducting polymer heterojunction has been found to show a rectifying behavior [245]. Over a teflon sheet, first carbon nanotubes are deposited, followed by deposition of a semiconductor polymer (commercially available di-cholestanol derivative of poly(p-phenylenevinylene), poly(2,5-bis(cholestanoxy)-1,4-phenylenevinylene), and then finally a thin film of aluminum or gold is deposited to give the ohmic contact. Threshold field for electron emission can be as low as 1 V μm^{-1}. It is argued that the emission results from sharp tips, as their work function is that of graphite, 4.7 eV.

5.4. Activated Carbon

Among the different forms of carbon materials, activated carbons are especially attractive as electrodes for capacitors from an economical point of view. In this case, a very developed surface area of the order of 2000 m^2 g^{-1}, with a controlled distribution of pores during the activation process, can be reached. Theoretically, the higher the specific surface area of an activated carbon, the higher the specific capacitance should be expected. The relationships between the BET surface area, the total pore volume, the average pore size, and the pore size distribution of activated carbon and its electrochemical performance as electrodes for supercapacitors have been discussed in detail by Shi and co-worker [246, 247].

Activated carbon has been extensively used as adsorbents, catalysts, and catalyst supports for the removal of pollutant species from gases or liquids and for purification or recovery of chemicals. Porosity of activated carbon is dependent not only on the starting materials (like coal, wood, coconut shell, etc), but also on the activation methods and processes. The processes for the preparation of activated carbons can be classified into two categories: physical and chemical activation. Physical activation involves carbonization of the raw materials followed by gasification of the resulting char in the presence of some oxidizing agents, such as steam or CO_2. The chemical activation is performed by the thermal decomposition of the precursor materials impregnated with chemical agents, such as KOH, $ZnCl_2$, and H_3PO_4. In the chemical activation, all chemicals act as dehydrating agents, promoting the formation of cross-link, resulting in the formation of rigid matrix. Surface functional group of activated carbon fibers can be improved by treatment with sulfuric acid, H_3PO_4, and HNO_3. Such activated carbon fibers are found to show increase in the absorption capacity of NH_3 [248] and chromium [249].

Other form of carbon, which has been known for ages, is carbon fiber. The basic structural unit of a carbon fiber is a planar network of connected benzene rings. These graphene planes are stacked on top of each other like the pages of a newspaper.

Hollow fibers are produced since carbon cannot reach the back of the particle. The growth will continue as long as the metal particle is covered by carbon and no clean surface is available. Therefore, from many points of view, nanotube can be considered as an extension of carbon fibers on a nanometer scale. Hollow coaxial tubes of graphitic sheets, ranging in number from 2 to 50, are typically observed in fullerene soot. The separation between concentric sheets is approximately 3.5 Å corresponding to (002) plane of graphite. The inner diameter varies between 1 and 3 nm.

6. NEED FOR PRECURSORS NOT DERIVED FROM FOSSIL FUELS

From these discussions, it is amply clear that though new forms of carbons like fullerenes, carbon nanotube, diamond films, and DLC films, are extremely useful forms of carbon and have many industrial applications, these materials have not been synthesized economically to be commercially attractive.

The sophistication needed by the conventional methods to get these materials in large quantity is the major reason for synthesis being uneconomical. This is primarily because most of the processes used for the synthesis of these materials include precursors containing either 100% sp^3 carbon

bonded materials or 100% sp² carbon bonded materials. The new carbon materials like nanomaterials belong to the intermediate class of carbon (as suggested in this chapter); their structures need the presence of a mixture of sp³ and sp² carbon bonded materials. Hence, it becomes essential to convert one of the pure forms of carbon, either sp³ to sp² carbon bonded materials or vice versa, as the case may be, so that the resulting material has the required proportion of sp³ and sp² carbon bonded atoms.

In addition, earlier discussions also revealed that all these nanomaterials need a combination of hexagonal and pentagonal structures. Most of the conventional precursors have only the hexagonal structures. For the formation of pentagonal structure, carbon of the precursor must break into elemental carbon to build the requisite number of pentagonal structures as and when needed during the synthesis. Therefore, there is a need to investigate some new type of precursor which meets above requirements as well as not being derived from fossil fuels like petroleum products. Sharon and his group have been exploring possible uses of precursors which are plant based, like camphor, turpentine oil, cashew nut oil, coconut shell oil, mustard oil, linseed oil, etc. With these precursors, their group has been able to synthesize almost all forms of carbon nanomaterials which are synthesized from petroleum based precursors like acetylene, benzene, etc. The advantage of plant based precursors is that when technology of carbon nanotechnology is established, it would have no fear of nonavailability of source materials, because one can cultivate them as and when needed, within few months period, whereas fossil fuels are destined to deplete one day and cannot be synthesized in such short span of time.

7. SUMMARY

Emphasis is made to classify carbon materials based on percentage of carbon atoms of sp³ type present in the samples rather than conventional classification. This type of classification opens a Pandoras box to prepare varieties of novel carbon materials. Various types of novel carbon materials, which have been synthesized by various techniques using various precursors, are discussed. Efforts have also been made to discuss the various newer applications of the novel carbon materials. Finally, a point has been brought to suggest that there is a need to discover nonconventional precursors which can be grown by cultivation and which are not related to fossil fuels.

GLOSSARY

Camphor A white crystalline substance, obtained from the tree *Cinnamonum camphora*, but the name has been given to various concrete odorous volatile products, found in different aromatic plants. The commercial Camphor comes only from *C. camphora* and *Dryobalanops camphora* (fam. *Dipterocarpacaea*). *C. camphora* is an evergreen tree; it grows to a great size. While the tree grows in China, etc., it can be cultivated successfully in sub-tropical countries, such as India and Ceylon, and it will thrive in Egypt, Formosa, Madagascar, Canary Islands and southern parts of Europe, California, Florida, and also in Argentina. The odor is peculiar, like sassafras and distinctly camphoraceous; this oil is said to be used in Japan for burning, making varnish, and for Chinese inks, as a diluent for artists' colors; it has a capacity for dissolving resins that oil of Turps has not. There is an erroneous idea that camphor acts as a preventive to infectious diseases. It is a well-known preventive of moths and other insects, such as worms in wood.

Chemical vapor deposition (CVD) One of the efficient ways of implementing vapor phase deposition in a manufacturing environment. Unlike physical deposition, CVD involves chemical reactions on the surface.

cw-CO₂ This laser is capable of continuously generating high power as much as 10 kW at a relatively ~40% efficiency. The active medium of the laser is a gas mixture of CO_2 and nitrogen with additive like He and water vapour.

Dangling bond At the interface of any solid material, for example, diamond, some of the bonds of carbon present at the interface is broken due to absence of carbon (i.e., at the interface), leaving carbon with an additional single unpaired electron. This unpaired electron can form bond with other material present at the interface. This type of bond is often referred as dangling bond to differentiate from normal covalent bond. Dangling bond is not of permanent type as covalent.

Electron affinity The energy difference between the energy state of a neutral atom and the energy state of a negative ion of the same atom is called electron affinity.

Fermi-Dirac statistics After the development of quantum mechanics, Sommerfeld modified the free electron theory by replacing the classical statistics of Boltzmann by the quantum statistics of Fermi and Dirac. The free electron theory suggests that all electron of the metal can have same energy so that, at the absolute zero of temperature, they all occupy the lowest available energy levels.

Fullerene A class of cage-like carbon compounds composed of fused, pentagonal and/or hexagonal sp² carbon rings. Fullerenes were first discovered in 1985 when the soccer ball shaped C_{60} (Buckminsterfullerene) was synthesized. The carbon atoms in C_{60} are arranged in a geometric shape consisting of 12 pentagons and 20 hexagons.

Hall Mobility The conductivity σ can be defined in terms of the number of conduction electrons (or holes) by $\sigma = n\,e\mu$, where μ is the mobility and is equal to the drift velocity per unit field. It has been shown by Hall that both the mobility and the mean free path of the electrons (or holes) can be determined experimentally. Thus conventionally mobility is also referred as Hall mobility.

Laser An acronym of light amplification by stimulated emission of radiation. They are monochramitic in nature and can be generated from various systems, like cw-CO₂ , Nd-YAG etc.

Nd-YAG The neodymium doped yettrium aluminium garnet laser is a solid-state laser.

Pyrolysis Formally defined as chemical decomposition induced in organic materials by heat in the absence of oxygen. In practice, it is not possible to achieve a completely oxygen-free atmosphere; actual pyrolytic systems are operated with less than stoichiometric quantities of oxygen.

Because some oxygen will be present in any pyrolytic system, nominal oxidation will occur. If volatile or semivolatile materials are present in the waste, thermal desorption will also occur.

Work function The work that must be done to remove an electron, which is inside the material at a distance far removed from the material, is called as the work function.

1. INTRODUCTION

Electron sources are used today in a wide range of applications such as microwave traveling wave tubes, e-beam evaporators, mass spectrometers, etc. Most applications rely on thermionic electron emitters operating in a temperature range of 950–2000 °C. Due to the high operating temperatures, the potential of miniaturization of thermionic emitters is strongly limited. Field electron emitters operating at room temperature, in contrast, hold great potential for miniaturization. The miniaturization of electron sources opens the field for new applications such as parallel e-beam lithography, flat panel displays, or data storage devices. However, the development of field emission electron sources has been hampered for half a century by the fact that tip-like field enhancing structures are needed to create locally high electric fields for field electron emission to take place. Today there is only one mature technology to produce field emitter arrays. This technology is the so-called Spindt type metal microtip process. The drawbacks of this technology are the expensive production, the critical lifetime in technical vacuum conditions, and the high operating voltage. Carbon nanostructures can be regarded as the potential second-generation technology to the Spindt type metal microtips. The advantages of carbon nanostructures are above all a potentially larger lifetime due to chemical inertness and lower operating voltage due to higher local field enhancement.

1.1. Electron Emission Sources in Vacuum Microelectronic Devices

In contrast to the well established solid state microelectronics, which relies on the scattering dominated drift of electrons (or holes) in the conduction band (valence band) of a semiconductor such as silicon, vacuum microelectronics makes use of the collision-free, ballistic motion of electrons in vacuum. The advantage of using a semiconductor as

transport medium for electrons resides in the fact that the energy required to promote an electron from the valence band into the conduction band is in the order of 1 eV and therefore much lower than the work function ϕ, the energy required to put an electron from solid into vacuum, which is usually in the order of 4–5 eV. Using doped semiconductors, the activation energy to produce carriers in the conduction band can be reduced further to a few meV, which makes it possible to have a saturated carrier concentration even at room temperature. Yet the motion of electrons in a solid has also some important disadvantages. Due to the collision dominated motion of the electrons in the conduction band, the drift velocities are considerably smaller than for ballistic motion in vacuum at comparable electric fields. Furthermore, power is dissipated due to the interaction of the electrons with the lattice. Especially for high power, high frequency applications, this power dissipation becomes a problem. It is this way in the field of high power radio frequency and microwave amplifiers that vacuum electronic devices such as electrontubes, magnetrons, or klystroms are still being used. In these devices the free electrons are usually generated by thermionic electron sources. Albeit rather inexpensive and delivering high current densities, thermionic electron sources have a number of significant drawbacks: The large heat dissipation causes rather large energy consumption, and most important of all, the thermionic electron sources cannot be made very small and cannot be turned on and off at high frequencies. The term "small" here refers to length scales in the order of micrometers. Field electron emission from solids may open the door for the miniaturization of electron sources. However, it was not until two decades ago that improvements in microfabrication techniques triggered much progress in manufacturing of devices with miniaturized electron sources. These devices are commonly called vacuum microelectronic devices and make use of a large number of micrometer-sized field emitting electron sources (Fig. 1).

A device design based on a large number of parallel operating micrometer-sized electron sources can offer interesting technological applications, such as high power radio frequency amplifiers, electron guns for klystroms or travel-ing wave tubes, parallel e-beam lithography, or data storage [2] where field emitted electron beams are used to read and write bits of data into a storing medium. However, the first large scale commercial application of microfield emission sources is likely to be for arrays of miniature, cold cathodes, which are required for thin matrix addressable cathodoluminescent display devices, called field emission flat panel displays (FED). It has become evident during the last decade that the fabrication process for Spindt type field emitter arrays using micrometer-sized metal tips (Fig. 1) is highly critical and cost intense. Therefore less expensive and less critical fabrication techniques of the electron emitting cathode must be sought.
An ideal electron source in a micrometer-sized device has to meet several important requirements [3]:

- The electron source must be capable of being fabricated to submicrometer tolerances so that the emitting area is precisely defined and geometrically and chemically stable during its operation lifetime.
- The emission current should be voltage controllable, preferably with drive voltages in a range obtained from "off the shelf" integrated circuits (<100 V).
- The source must be cable of emitting very high current densities so that the total current emitted from the small available area is sufficient for device operation. Even a current of one microampere from one square micrometer area requires a current density of 100 A cm^{-2}. Ten A cm^{-2} current density may be regarded as a lower limit for a source to reach wide applications in vacuum microelectronic devices.
- The energy spread of the emitted electrons should be comparable to conventional thermionic cathodes (i.e., <0.5 eV), or within tolerable limits for the particular device being considered.
- The emission characteristics should be reproducible from one source to another and should be stable over very long periods of time (ten thousands of hours) for acceptable device lifetimes.
- The cathode must be resistant to unwanted occurrences in the vacuum device environment, such as ion bombardment, reaction with the residual gases, temperature extremes, and arcing.
- Cathode manufacturing should be inexpensive, without highly critical processes, and adaptable to a wide variety of applications

With regard to these requirements field emission electron sources are regarded as a good choice, because they can satisfy many of the aforementioned requirements. They can deliver very high emission current densities in the order of several thousand A cm^{-2} with a very steep current–field characteristic. In order to generate the necessary electric field of >2500 V μm^{-1} to get sufficiently high field emission currents, classical field emission sources rely on field enhancing microtip structures. These microtips suffer from some inherent problems such as tip degradation due to sputtering effects, altering of the field emission properties due to tip contamination, and inhomogeneous emission properties in the tip array due to varying geometries. The development of new field emitters should focus on solving some of the aforementioned problems that microtips have. Namely, the

Figure 1. Field emitter array of evaporated metal tips, so-called Spindt tips [1].

emitter should be rather insensitive to sputter erosion and contamination, so that the emission properties remain stable over the entire lifetime of the device.

1.2. Electron Emission

Electron emission is defined as liberation of free electrons from the surface of a material caused by external energy in the form of light, heat, high electric fields, or collisions transferred to the electrons. The amount of energy required by the electron to emit from the solid surface is known as work function ϕ. According to the energy sources, the following four electron emission processes can be distinguished:

1. photoemission
2. thermionic emission
3. field emission
4. secondary emission

1.2.1. Photoemission

Photoemission is the emission of electrons from solids, liquids, or gases by the action of electromagnetic radiation. When radiation is absorbed by a solid, some of the electrons in the material gain sufficient energy to overcome the work function ϕ and escape into vacuum. The photoemission process could not be explained by classical physics until Einstein applied Planck's quantum theory to the photoelectric effect [4]. He postulated that light is absorbed by the solid in quantified manner so that the energy of an absorbed photon is completely transformed into the kinetic energy of an electron. The number of photoelectrons released is therefore proportional to the number of incident photons. The Einstein relation [See Eg. (1)] relates the kinetic energy E_{kin} of the photoemitted electron with its binding energy E_B in the solid and the energy of the incident photon $h\nu$

$$E_{kin} = h\upsilon - E_B - \phi \tag{1}$$

1.2.2. Secondary Emission

Secondary electron emission occurs from solid surfaces bombarded by high-speed electrons or other particles. When high-speed electrons suddenly strike a solid surface, they may give some or all of their kinetic energy to electrons in the solid. The secondary electron yield depends on many factors and is generally higher for high atomic number elements and at higher angles of incidence.

1.2.3. Thermionic Emission

Thermionic emission is the emission of electrons from hot solids. If an anode is placed near a heated solid (cathode) in vacuum, a current of electrons passes from the hot cathode to the anode. The current density depends only on the nature of the cathode material and the temperature of the cathode. The current is nearly independent of the electric field provided it is not too large, but still large enough to overcome the space charge limitation. The subject was first investigated by Richardson in 1902 quantitatively. He suggested empirically the following formula for the emission current density [5]

$$j = AT^{0.5} \exp\left(-\frac{b}{T}\right) \tag{2}$$

In 1914 Willson considered the thermionic emission to thermal evaporation of electrons and applied the Clausius–Clapeyron equation to the system. Richardson accordingly changed his original equation and suggested instead

$$j = AT^2 \exp\left(-\frac{\phi}{k_B T}\right) \tag{3}$$

Dushman in 1923 derived this formula theoretically using the Clausius–Clapeyron equation and assuming that the electrons obey Maxwell–Boltzmann statistics. The introduction of quantum mechanics and the recognition that electrons obey the Fermi–Dirac statistic led to a new treatment of the thermionic emission by Nordheim in 1928 who determined A to be 120 A cm^{-2} K^{-2} [6]. This value was twice as large as the one determined by Dushman due to the two spin states of the electrons.

1.2.4. Field Emission

The emission of electrons from the surface of a solid caused by a high electric field is called field emission. This phenomenon was first reported by Wood in 1897 and occurs at electric fields in the order of 5×10^9 V m^{-1} [7]. Such high fields are extremely difficult to realize on flat surfaces but can be generated by the field enhancing properties of tiplike structures.

Qualitatively, the field enhancement of a needle shaped tip with a spherical cap can be understood as follows. Let us assume a metallic sphere with radius r floating in a homogeneous electric field F_0 at a height h above a metal plate to which the sphere is electrically connected. For $h \gg r$ the electric potential of the sphere with respect to the surrounding space is $\phi = F_0 \cdot h$. The electric potential φ at the surface of the sphere can be written as

$$\varphi = \frac{1}{4\pi\varepsilon_0} \frac{Q}{r} = F_0 \cdot h \tag{4}$$

with Q being the charge on the sphere. The electric field F on the surface of the sphere is

$$F = \frac{1}{4\pi\varepsilon_0} \frac{Q}{r^2} \tag{5}$$

With the substitution of (4) into (5) we get for the local electric field F

$$F = \frac{\varphi}{r} = \frac{h}{r} F_0 \tag{6}$$

Equation (6) shows that the electric field at the surface of the sphere is enhanced by a factor equal to the ratio of the height h (above the metal plate) and the radius r of the sphere. This factor is called the field enhancement factor and is usually labeled by β, which is why it is sometimes called the beta factor.

In 1928 Fowler and Nordheim delivered the first generally accepted explanation of field emission in terms of the newly developed theory of quantum mechanics [8]. Fowler and Nordheim treated the conduction electrons in the metal as a gas of free particles obeying the Fermi–Dirac statistic. The electrons are confined to the metal by the surface

potential barrier, the shape of which is considered to be determined by the potential inside the metal (work function ϕ), the image charge potential, and the applied external potential.

In Figure 2 the situation of an electron with kinetic energy E near the Fermi energy E_F tunneling through the surface barrier is depicted. Assuming that inside the metal ($x < 0$) the electron experiences a constant potential ($V = 0$) and that at the surface ($x = 0$) there is a potential step to E_{vac} (vacuum energy), the electron potential $V(x)$ outside the metal ($x > 0$) and under the action of an electric field can be written by

$$V(x) = E_{\text{vac}} - eFx \tag{7}$$

Taking the influence of the image charge potential into account $V(x)$ is

$$V(x) = E_{\text{vac}} - eFx - \frac{1}{4\pi\varepsilon_0}\frac{e^2}{4x} \tag{8}$$

The transmission probability $D(E)$ for an electron with the energy E to tunnel a potential barrier $V(x)$ is given in the Wenzel, Kramers, Brillouin approximation [9] by

$$D(E) = \exp\left(-2\frac{\sqrt{2m_e}}{\hbar}\int_{x_1}^{x_2}\sqrt{V(x) - E_x}\,dx\right) \tag{9}$$

with $E_x = \hbar^2 k_x/2m_e$ the kinetic energy component perpendicular to the surface.

With the integration limits $V(x_1) = V(x_2) = E_x$ the transmission probability $D(E)$ for a given potential $V(x)$ only depends on E_x. For a triangular surface potential barrier (7) $x_1 = 0$ and $x_2 = (E_{\text{vac}} - E_x)/eF$. Substitution of (7) in (9) will lead to

$$D(E) = \exp\left(-2\frac{\sqrt{2m_e}}{\hbar}\int_0^{(E_{\text{vac}}-E_x)/eF}\sqrt{E_{\text{vac}} - eFx - E_x}\,dx\right) \tag{10}$$

By solving the elementary integral we find

$$D(E) = \exp\left(-\frac{4\sqrt{2m_e}}{3eF\hbar}(E_{\text{vac}} - E_x)^{1.5}\right) \tag{11}$$

The formula shows that the transmission probability $D(E)$ rapidly decreases with E_x so that only the highest occupied electron states near the Fermi energy E_F contribute
Figure 2. Schematic illustration of the surface potential barrier under the action of an external electric field.

to the emission current. With a first order development of $(E_{\text{vac}} - E_x)^{1.5}$ at E_F

$$(E_{\text{vac}} - E_x)^{1.5} \approx (E_{\text{vac}} - E_F)^{1.5} - \frac{3}{2}(E_{\text{vac}} - E_F)^{0.5}(E_x - E_F) \tag{12}$$

and the substitution of (12) into (11) and with $E_{\text{vac}} - E_F = \phi$, we find

$$D(E) = \exp\left(-\frac{4\sqrt{2m_e}}{3\hbar}\frac{\phi^{1.5}}{eF}\right)\exp\left(\frac{2\sqrt{2m_e}}{\hbar}\frac{\phi^{0.5}}{eF}(E_x - E_F)\right) \tag{13}$$

The emission current j density can be obtained by integrating the product of the occupation probability $f(E, E_F, T)$ (Fermi–Dirac statistic), the transmission probability $D(E)$, and the velocity component perpendicular to the surface v_x over all electron states in k-space:

$$j = 2e\int_k f(E, E_F, T)D(E)v_x\frac{d^3k}{(2\pi)^3} \tag{14}$$

For $T = 0$ K the Fermi–Dirac distribution is a step function and the integration has only to be carried out over states with $k < k_F$ with k_F being the Fermi wave vector. Therefore (14) transforms into

$$j = \frac{2e}{(2\pi)^3}\int_{k_x^2+k_y^2+k_z^2 < \frac{2m_eE_F}{\hbar^2}} D(E)\frac{\hbar k_x}{m_e}\,dk_x\,dk_y\,dk_z \tag{15}$$

By substituting (13) into (15) and solving the integral, we obtain the well known Fowler–Nordheim relation for the emission current density j,

$$j = \frac{e^3}{4(2\pi)^2\hbar\phi}F^2\exp\left(-\frac{4\sqrt{2m_e}}{3\hbar}\frac{\phi^{1.5}}{eF}\right) \tag{16}$$

where j is in A m^{-2}, F is the electric field in V m^{-1}, and ϕ is the work function in Joules. Usually the Fowler–Nordheim relation is expressed with numerical constants and with j in A cm^{-2}, F in V cm^{-1} and the work function ϕ in electronvolts:

$$j = 1.56 \times 10^{-6}\frac{F^2}{\phi}\exp\left(-6.83 \times 10^7\frac{\phi^{1.5}}{F}\right) \tag{17}$$

1.3. Work Function and Negative Electron Affinity

1.3.1. Work Function

As can be seen from the Fowler–Nordheim relation (16) the work function ϕ is the relevant physical parameter for the electron emission behavior of a conducting material. Therefore we will discuss here some important implications of the work function related to the field emission behavior of carbon thin films.

A possible definition of the work function ϕ is the amount of energy required to remove one electron at the Fermi energy from the solid and bring it to rest at an infinite distance from the solid. This definition leads to the situation that all metal surfaces electrically connected to each

other have the same work function. This is in contradiction to the observation. In order to get a sensible definition of the work function, the final state of the electron has to be chosen differently. A more precise definition of the work function is therefore: "The work function ϕ is the energy difference between two states of the whole crystal." In the initial state the neutral crystal containing N electrons is in the ground state with energy E_N. In the final state one electron is removed from the crystal to a region having only electrostatic energy denoted by ϕ_V. The crystal with the remaining $N-1$ electrons is assumed to be in its ground state with the energy E_{N-1}. This leads to

$$E_N + \phi = E_{N-1} + \phi_V \quad \Rightarrow \quad \phi = (E_{N-1} - E_N) + \phi_V \quad (18)$$

At nonzero temperatures, removal of an electron from the solid can be considered a thermodynamic change of states of the crystal. The energy difference $E_N - E_{N-1}$ can be replaced by the derivative of the Helmholtz free energy F with respect to the electron number with constant crystal volume and temperature

$$E_N - E_{N-1} \longrightarrow \left(\frac{\partial F}{\partial N}\right)_{T,V} = \mu \quad \Rightarrow \quad \phi = \phi_V - \mu \quad (19)$$

The chemical potential μ can be considered as the bulk part and the electrostatic potential ϕ_V as the surface depending part of the work function ϕ. The concept of surface and bulk depending part of the work function ϕ is depicted in Figure 3.

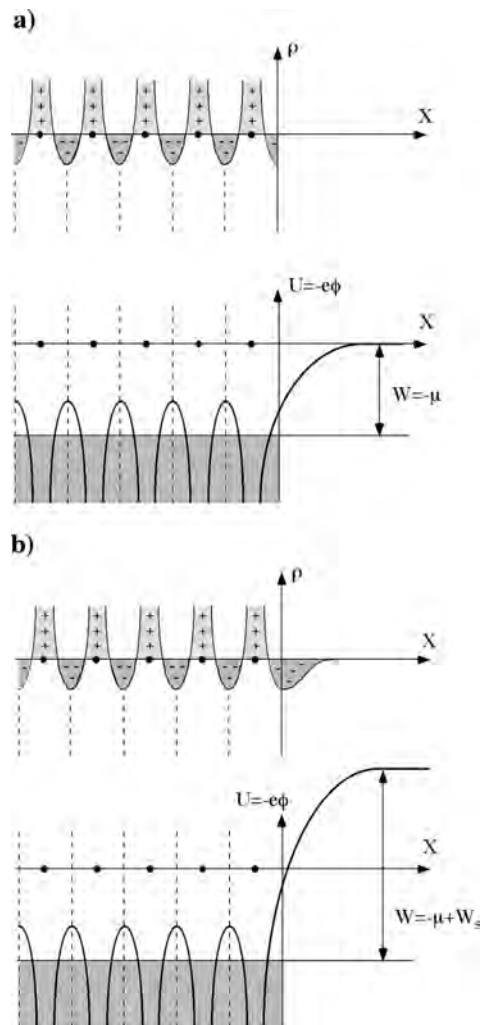
Figure 3a shows schematically the situation at the surface of a finite crystal without distortion of the charge density. The centers of gravity of the positive and negative charges in the Wigner–Seiz cell are the same (crystal with inversion symmetry) and therefore no electrostatic dipole moment occurs. The work function ϕ in this case depends on the chemical potential μ only. Yet this is not the real situation at a crystal surface as the electrons at the surface have the tendency to "spill" out into vacuum. Due to this the charge the Wigner–Seiz cell at the surface is different than inside the crystal. Also the position of the atoms at the surface can differ considerably due to relaxation and reconstruction effects as depicted in Figure 3b. The changed charge distribution results in a surface dipole moment. The direction of the surface dipole due to electron spill put is such that energy is needed to move the electron from inside the solid into vacuum. This energy has to be added to the chemical potential in order to obtain the work function. A further dipole due to spill-out of electrons occurs leading to a dipole moment which tends to decrease the work function. This contribution to the work function observed on rough (or highly stepped) surfaces is called the Smoluchowski effect. It explains also the tendency of body centered cubic crystal to show a decrease work function in the sequence of the $(100) \rightarrow (110) \rightarrow (111)$ planes and an increasing work function for face centered cubic crystals in the same sequence. A good parameter to characterize the work function ϕ of an element is the electronegativity χ. The electronegativity is defined as the arithmetic mean of the first ionization potential and the electron affinity of the neutral atom. The correlation between these two parameters


Figure 3. Schematic illustration of the electrostatic potential at the crystal surface. (a) Without distortion of the charge density (bulk density). (b) With modified charge density due to relaxation and reconstruction effects at the surface.

illustrates that the work function of an element still strongly reflects the property of the atom. The experimental data can be fitted to a straight line giving

$$\phi = 0.34 + 0.72\chi \quad [\text{eV}] \quad (20)$$

Another interesting relation between the work function and the cohesion energy can be established. Solids with large cohesive energy have high work functions. This can by qualitatively understood as work function and cohesive energy are coupled via the chemical potential μ. Using relation (20) we obtain for carbon with an electronegativity of $\chi_C = 6.2$ eV a work function $\phi_C = 4.8$ eV which is very close the 4.7 eV measured value on graphite [10]. With regard to the work function ϕ, carbon seems not to be the material of choice for cathodes of electron emitters. To give a comparison LaB_6 has a work function of 2.66 eV and YB_6 of 2.2 eV.

Adsorption or deposition of an element with a low electronegativity onto a solid with higher electronegativity will result in an electron transfer from the adsorbate to the solid

and therefore in the creation of a surface dipole moment. This dipole moment is opposed to the intrinsic surface dipole moment and thus reduces the work function. The work function lowering of thin layers of alkaline and earth alkaline metals has been known for a long time and is used in thermionic emitters [11, 12]. In order to lower the work function of thermionic emitters monolayer coverages of ThO, Sc_2O_3, or BaO are used. The world record of emission current density is currently held by a W/Re + Sc_2O_3 dispenser cathode with 400 A cm^{-2} at 965 °C [13]. The work function of this cathode was determined to be 1.16 eV. Here the combination of scandium and oxygen results in the drastic work function lowering due to electron transfer from scandium to oxygen. This creates a strong surface dipole moment reducing the work function of the W/Re of about 4.7 eV by 3.5 eV.

1.3.2. Work Function of Carbon Species and the Role of Hydrogen

On carbon materials hydrogen can take the role of the work function, lowering adsorbate. The influence of hydrogen and oxygen at the surface of tetrahedral amorphous carbon (ta-C) is illustrated in Figure 4. The samples produced by laser ablation of graphite are hydrogen free and with a high sp^3/sp^2 ratio, and we measured consistently work function values of 5.0 ± 0.2 eV. Between a sp^3/sp^2 ratio of 65% and 90% no significant variation of the work function value ϕ was observed. The termination of the surface with hydrogen or oxygen was performed by electron cyclotron resonance plasma treatment. The ultraviolet photoemission spectra (UPS) displayed in Figure 4 show the low energy region of the photoemission which is dominated by the emission of scattered electrons. The cutoff in these spectra denotes the minimum energy required for an electron to be emitted and therefore shows the energetic position of the vacuum level. For the hydrogen terminated ta-C surface (60 s H_2 plasma) the work function is reduced from

5 to 3.5 eV. Careful investigations of the corresponding X-ray photoemission spectrum reveal that hydrogen is incorporated into the first three monolayers (9 Å). The work function change induced by hydrogen has not only to be understood in terms of the surface dipole moment. In fact localization of electrons in the C–H bonds can also reduce the work function [14].

Exposing the same sample after hydrogen termination to an O_2 plasma increases the work function again to 6.6 ± 0.2 eV. The oxygen plasma strongly etches the superficial C–H groups forming C–O groups at the surface. Obviously oxygen, being a strong electron acceptor, leads to a surface dipole moment which increases the work function. As one can see the work function of the carbon surface can be varied between 3.5 and 6.6 eV depending on the surface termination.

1.3.3. Negative Electron Affinity

In the case of diamond the surface termination by hydrogen leads to a new aspect. Due to the wide bandgap and the lowering of the work function on a hydrogen terminated surface, the vacuum level can be lower than the conduction band minimum. This situation where the lowest unoccupied electron state (at the bottom of the conduction band) is higher than the lowest state in vacuum is called negative electron affinity (NEA). It means that an electron excited into the conduction band at the surface of a NEA diamond can be emitted into vacuum without any surface potential barrier. The NEA influences strongly the photoelectron as well as the secondary electron emission. Figure 5 displays schematically the photoemission process on a NEA diamond surface. On the left hand side a schematic band diagram is depicted and on the right side the UPS spectrum of a nanocrystalline chemical vapor deposition (CVD) diamond film after H_2 plasma treatment is depicted. The film was grown on Si(100) at 950 °C substrate temperature and with a 5% CH_4 in H_2 gas mixture at 40 mbar. Films grown under

these conditions exhibit good field emission properties (see Section 1.5.2). By irradiating the sample with ultraviolet (UV) (He: $h\nu = 21.2$ eV), electrons from the valence band are exited into the conduction band leaving a hole behind. Near the surface the surface (2 nm) the exited electrons have a good probability to escape the solid before losing energy due to inelastic scattering (light gray region in the spectrum of Fig. 5). At a larger distance from the surface the exited electrons lose energy due to inelastic scattering on their way to the surface. The typical scattering length is in the order of 1 nm for low energy electrons. Eventually the electrons will thermalize to the conduction band minimum (CBM), where the electrons can only lose further energy by recombination with holes in the valence band or by being trapped in defect states. As the lifetime (typically 1 ns) of an electron at the CBM is much larger than the scattering time during thermalization (typically 1 ps) there will be an accumulation of electrons at the CBM. In k-space the CBM is close to the X-point of the Brillouin zone and therefore the emission is preferred in the crystallographic (100) direction. This leads to a very intense and sharp peak in the UPS of (100) single crystalline diamond at the energetic position of the CBM [15, 16]. In the presented case of nanocrystalline diamond with crystallite size of a few nanometers, the peak is not as sharp; yet the low energy cutoff in the spectrum is at the position of the CBM indicating the NEA of this surface. By O_2 plasma treatment the work function of the diamond surface rises above the CBM and we have the situation of a positive electron affinity surface with measured work function values up to 6.3 ± 0.2 eV.

1.3.4. Local Aspect of Work Function Changes

As discussed in Section 1.3.1 the work function ϕ depends on the surface dipole moment, which can be influenced by adsorbates. In the case of carbon films hydrogen chemisorption at the surface can lead to a reduced work function. It has been suggested that the low threshold field for electron emission on carbon films is in fact connected with low local fields and that the emission takes place due to the extremely low work function in the range of 0.1 eV [17, 18]. Yet such low work functions are macroscopically not observed. Therefore it was proposed that the low work function regions are of atomic dimensions (e.g., due to the quantization of electron states in thin grain boundaries or due to electronically active defects) [19]. This model has some attractive properties as it would explain that the field emission is not homogenous but originates from some spots on the surface and that a high density of grain boundaries or defects (as in nanocrystalline CVD diamond) would lead to high density of emission spots.

Yet taking the small size of the low work function region into account one can observe that the relation between low work function and low field electron emission is not as straightforward as the Fowler–Nordheim relation might suggest. Changes in the work function on a surface have to be regarded as changes in the vacuum potential, with the occurrence of external electric fields. This situation is depicted in Figure 6a where the changed vacuum potential over a low work function (0.1 eV) spot of 2 nm diameter on a surface
Figure 6. Change in the vacuum potential over a low work function (0.1 eV) spot ($\phi = 2$ nm) on a high work function (5 eV) surface without external electric field applied. Reprinted with permission from [46], O. Gröning, Ph.D. Thesis No. 1258, University of Fribourg, Switzerland, 1999.

with 5 eV work function is shown. What the possible origins of such a very low work function could be we do not want to discuss here, but we want to focus on the effects on electron emission. As one can se from Figure 6a the low work function spot creates a kind of potential pocket over the surface, where the vacuum potential rises quickly to a value close to 5 V at some distance from the spot. In Figure 6b the shape of the vacuum potential perpendicular to the surface is depicted for four different lateral distances from the center of the spot. Here again one can observe that the work function is not effectively lowered. In case of thermionic emission the introduction of small low work function spots on the cathode surface would not affect the emission behavior unless their density becomes so important that they cover a non-neglecting part of the surface ($>10\%$). With regard to thermionic emission only the average work function $\langle\phi\rangle$ is given by

$$\langle\phi\rangle = \frac{1}{A_S} \int_{A_S} \phi(\vec{r})\, dA \tag{21}$$

where A_S is the surface area and $\phi(\vec{r})$ denotes the local work function.

The situation for field emission with an external electric field applied is depicted in Figure 7. The parameters for the calculation are the same as used before: low work function spot of 2 nm in diameter and 0.1 eV work function value on a surface with 5 eV work function. The applied external electric field is of 1000 V μm^{-1}. If we just apply the Fowler–Nordheim relation (16) we would expect for a work function of 0.1 eV detectable field emission currents in the pA range for electric fields around 5 V μm^{-1}. In Figure 7b we can see the tunneling barrier an electron would encounter for four different lateral distances from the center of the spot. The strongest effect of the low work function is of course at the center of the spot where the tunneling barrier is lowered considerably. Still in order to get a sufficient high transmission through the barrier the electric field has to be in the order of 1000 and not 5 V μm^{-1}. As can be seen the triangular barrier approximation (7) in this case is not valid anymore and therefore considerable deviation from Fowler–Nordheim behavior should be observed. The effect of a low work function spot on field emission is of course size dependent. One can make the estimation that in order to get

detectable field emission from a 0.1 eV work function spot at 5 V μm^{-1}, the spot size should have a diameter of about 1 μm and more. To our knowledge such a low work function area was never observed. Modifications of the work function cause changes in the vacuum potential; thus large electric fields can be generated at the border between two regions of different work functions. As the work function changes can be in the range of 1–2 eV and the distances over which these changes occur are in the order of nm, the fields associated with the work function change can be in the order of 1000 V μm^{-1}. Figure 8 depicts the situation occurring at a surface with 3 eV work function (e.g., H-terminated amorphous carbon) where a spot of 10 nm in diameter has a higher work function of 5 eV (e.g., amorphous carbon without H-termination).

Robertson [20, 21] suggested that the low threshold field electron emission of carbon films occurs due to high electric fields present at the transition zones from high to low work function regions. Figure 8a depicts the vacuum potential over the high work function spot. The inset in Figure 8a shows the equipotential lines and the electric field strength at the border of the low and high work function region. One

can see that the electric fields in this transition region can easily exceed 1000 V μm^{-1}. Figure 8b shows that the surface potential barrier even at a quite elevated electric field is not strongly affected by the transition from a high (4 nm) to low (6 nm) work function region. The external fields required to get detectable field emission currents are not lower in the transition region than in the low work function region. In order understand why the high local fields occurring from a change of work function do not influence significantly the field emission behavior we have to look at the conditions which lead to field emission at surfaces. This conditions can be expressed in a very simple manner: "There must be states available in the vacuum into which electrons from the Fermi energy or below can tunnel with sufficient high probability. This means that the vacuum potential has to be lowered below the Fermi energy within 2 nm from the surface (2 nm being roughly the tunneling distance for low energy electrons). This leads to a very simple relation between the work

function ϕ and the applied field F as $eF > \phi/2$ nm. In the model we are discussing the work function is always higher than or equal to 3 eV and therefore an external electric field at least of 1500 V μm^{-1} is needed in order to get the conditions for field emission.

1.4. Carbon and Its Allotropes

Carbon is a group IV element with the atomic number 6 and has the electronic configuration $1s^2\ 2s^2\ 2p^2$. Carbon materials span an enormous range of mechanical and electronic properties that is larger than that of any other element. The large range of physical properties for carbon materials is mainly due to the fact that the energies of the $2s$ and $2p$ states are very close in carbon, allowing different bonding configurations by rearranging its outer electrons. The reconfiguration of the $2s$ and $2p$ electrons is called hybridization.

1.4.1. Diamond

One possible hybridization consists of the linear combination of one s-state and three p-states resulting in a tetrahedral arrangement of the bonds, each at an angle of 109.5° to the other. The configuration is called sp^3 and results in a coordination number of four. Diamond is one example of the sp^3 configuration. The band structure of diamond is characterized by a large energy gap of 5.5 eV between the valence band maximum and the conduction band minimum. This makes it, in the undoped case, an insulator with a resistivity of $\sim 10^{20}$ Ω cm at room temperature. The large carrier mobility and the thermal properties make diamond an interesting material for electronic applications. The p-type doping has been realized with boron, resulting in an acceptor level at 0.37 eV above the valence band maximum [22]. However, n-type doping on the other hand has proven to be very difficult. Although substitutional doping can be achieved using the group V element nitrogen, the donor level at 1.7 eV below the conduction band minimum is far too low to be excited to the conduction band at room temperature [23]. Current investigations try to substitutionally dope diamond with phosphorus, another group V element, and with lithium and sodium, two group I elements, which are expected to be incorporated on interstitial lattice positions.

1.4.2. Graphite

Another possible configuration for the bonding electrons occurs for carbon atoms that are arranged in a honeycomb network. In this geometry, bonding orbitals composed of one s and two p orbitals (sp^2) are formed 120° to each other in one plane. These form the strong covalent bonds between the carbon atoms in graphene layers of graphite called σ-bonds. The resulting atom lattice consists of a hexagonal atom arrangement with a nearest-neighbor distance of 1.421 Å, which is about 7% shorter than in the diamond lattice. The one remaining orbital is delocalized and has a p_z configuration, called the π-orbital. Near the Fermi level, the density of states (DOS) consists exclusively of the delocalized π-electrons. These states are directly related to the presence of sp^2-bonded carbon and their spectral weight

in a photoemission spectrum allows, for example, the determination of the fraction of sp^2-bonded carbon in amorphous carbon [24]. The two-dimensional dispersion relation for the π-electron system can be calculated within the tight-binding approximation [25] and is displayed in Figure 9. If the interaction between the graphene sheets is neglected the DOS at the Fermi level E_F drops to zero. This is due to the fact that the occupied π-bands and the unoccupied π^*-bands just touch at the corners of the first Brillouin zone, called K points, making graphene a zero bandgap semiconductor. The Fermi surface consists in this case the six K points. The occupied and the unoccupied π-bands are symmetric with respect to the Fermi energy E_F. The displayed hexagon shows the two-dimensional Brillouin zone and defines the plane with $E = E_F$. The bottom of the occupied band is related to the nearest neighbor C–C overlap integral γ_0 and is, for the honeycomb structure, equal $3\gamma_0$. For graphite, γ_0 can be estimated to be 2.8 ± 0.2 eV [26]. The overlap of the π-orbitals on adjacent atoms of the same layer is the reason for the delocalization of the π-states and is responsible for the high charge carrier mobility in graphite. The description of graphene, however, is not sufficient to understand the properties of three-dimensional graphite, in particular regarding the π-states near the Fermi level. The weak interlayer bonding of graphite, which is often incorrectly referred to as van der Waals bonding, originates from the small overlap of the π-orbitals between the atoms of adjacent layers. This creates two types of atoms, since in the ABA stacked graphite, only one-half of the atoms, called α-atoms, are positioned above an atom of the adjacent layer. The consequence on the electronic structure is that the degeneracy of the π-bands is lifted. See Figure 10.

1.4.3. Fullerenes and Nanotubes

Fullerenes can be viewed as closed networks of sp^2-bonded carbon. The local curvature needed for the closure is induced by the incorporation of pentagons in the atomic arrangement. The experimental discovery of fullerenes occurred in the investigation of unusual infrared emission from large carbon clusters streaming out of red giant carbon stars [27] and the development of a laser vaporization cluster technique to produce such kinds of carbon clusters [28].

Figure 10. Band dispersion of the occupied and unoccupied π-bands in the first Brillouin zone of graphene. The gray scales indicate the energy relative to the Fermi level E_F: Black corresponds to -8.4 eV and white to $+8.4$ eV. The white lines show the two-dimensional Brillouin zone. Reprinted with permission from [129], P. Ruffieux, Ph.D. Thesis No. 1387, University of Fribourg, Switzerland, 2002.

According to Euler's theorem, 12 pentagons are required to close a structure. The most stable molecule is C_{60}, where all 60 carbon atoms have identical positions located at the corners of a truncated icosahedron. See Figure 11.

Another class of carbon nanostructures related to fullerenes was discovered in 1991 by Iijima [29] and consists of rolled-up graphene sheets, so-called carbon nanotubes (CNT). Depending on the number of shells present in the tube, one refers to single-walled nanotubes (SWNT) or multiwalled nanotubes (MWNT). Typical dimensions of the tubes are one to several nanometers in diameter with lengths of several micrometers.

The band structure of SWNTs can basically be explained by the dispersion relation calculated for graphene (Fig. 12b). However, one important restriction on the allowed states originates from the periodic boundary conditions in the circumferential direction of the tube. This reduces drastically the number of allowed wave vectors in this direction and leads to the one-dimensionality of the bands, which expresses itself in the appearance of van Hove singularities in the density of states. Figure 12b shows the band dispersion of graphene as a gray-level plot and the allowed states for a (5, 5) SWNT (black lines). This representation
Figure 11. Buckminster (C_{60}) fullerene.

Academic Press, San Diego, 1996. © 1996, Academic Press.

of the allowed states shows that the electronic properties of a SWNT are directly related to the chirality of the tube. The tubes are metallic if the allowed wave vectors cross the K point of the Brillouin zone or are otherwise semiconducting. Using the description with the wrapping vector (n, m), the tubes are metallic if $n - m = 3i$, i being an integer, or are semiconducting if $n - m \neq 3i$. The energy bandgap E_g of semiconducting tubes decreases with increasing tube diameter according to $E_g = (\gamma_0 \cdot a_{C-C})/d_T$ [30]. Here, a_{C-C} denotes nearest-neighbor distance and d_T denotes the tube diameter which is given by $d_T = \sqrt{3}a_{C-C}\sqrt{m^2 + mn + n^2}/\pi$. This leads to a bandgap of 0. 34 eV for a typical tube diameter of 1.2 nm.

1.5. Carbon Thin Films

As mentioned, due to its three possible hybridization sates (sp, sp^2, sp^3), carbon can exist in various stable allotropic forms. The thermodynamically stable form of carbon at normal conditions is graphite. The free energy difference between the different allotropic phases is relatively small, for instance 0.03 eV/atom between diamond and graphite, which is slightly higher than $k_B T$ at room temperature (0.025 eV). However, there is always a large energy barrier between the different allotropic phases, which makes them all very stable at normal conditions. Therefore all stable allotropic as well as amorphous carbon phases can be synthesized or deposited as thin films by plasma processes or pyrolysis.

1.5.1. Diamond Films

In 1971 Deryagin and Fedoseev reported successful continuous growth of diamond at low pressures by methods which they later described [31]. The outstanding properties of diamond, including its hardness, chemical inertness, good optical transparency, and high thermal conductivity, triggered enormous research activity in diamond thin film deposition during the past 15 years. The book *Low-Pressure Synthetic Diamond* edited by Dischler and Wild [32] gives a nice and complete overview on the manufacturing and applications of diamond thin films.

Diamond thin films can be deposited by various low-pressure techniques such as hot-filament, MW plasma, dc plasma, or plasma jet methods [33]. The low-pressure diamond deposition process is fundamentally different from those of diamondlike carbon (DLC). Characteristic for the DLC deposition process is the physical effect of the impinging energetic ions with the hydrocarbons physisorbed on the surface of the growing film. In opposition to that the diamond deposition process is the result of various chemical reactions on the surface of the growing film. The difference between the DLC and the diamond deposition processes clearly finds expression by the precursor gas needed. While for diamond deposition the hydrocarbon precursor must be strongly diluted with hydrogen (typically $CH_4/H_2 = 1/99$), the DLC deposition process does not need hydrogen. The hydrogen chemistry is essential for diamond growth at low pressures. The ternary C, H, O Bachmann diagram (Fig. 13) shows with which gas composition CVD diamond can be grown. The growth surface of diamond can be represented schematically by a layer of carbon atoms terminated with atomic hydrogen. Individual hydrogen atoms are removed and provide a chemically active site for addition of carbon. Hydrogen abstraction has been estimated to occur every 70 μs on average, with each such site being refilled after 15 μs [35, 36]. Growth occurs when a hydrocarbon radical is attached at an active site of the lattice and loses its hydrogen atoms through hydrogen abstraction. Among the different radicals (acetylene, acetyl [37], methane and methyl [38]), methyl radicals are usually accepted as the main growth species, especially for the (100) surface [38]. Harris [39] proposed a five-step methyl based growth model as shown in Figure 14. First, the abstraction of a surface hydrogen atom by atomic hydrogen of the plasma produces a H_2 molecule and a radical site on the growing surface (Fig. 14b). This site can receive a hydrogen atom (Fig. 14a) or a methyl radical (Fig. 14c). The next step is the abstraction by atomic hydrogen from the plasma of a hydrogen atom of the methyl group or of another surface hydrogen atom (Fig. 14d). Finally, another hydrogen atom is abstracted to leave two adjacent radical carbon atoms. They react to form a carbon–carbon
Figure 14. Methyl based diamond growth according Harris [39].

bond (Fig. 14e). The so-formed molecule is called adamantane. In parallel, a methyl group can be added to the CH_2 radical site to form an ethyl group (C_2H_5), diversifying the growth mechanisms [39]. Frenklach and Spear [40] proposed a growth mechanism based on addition of acetylene to radial site. Characteristic for CVD diamond deposition is the need for nucleation centers on the substrate surface. On commercial silicon wafer without any treatment the CVD diamond process leads to the deposition of individual nanocrystallites with a very low density, lower than 10^5 nuclei per cm^2. The main reason for this extremely low nucleation density is the high surface energy of diamond. Surface nucleation enhancement is necessary in order to get continuous polycrystalline films. Three main mechanisms are known for diamond nucleation:

- nucleation on dislocation ledges, kinks, or intentional scratches
- diffusion barrier enhanced nucleation
- nucleation on a molecular precursor

The corresponding techniques are:

- Scratching the substrate with diamond or ceramic powders creates defects which act as nucleation centers [41]. The nucleation density is between 10^5 and 10^{10} cm^{-2}.
- Enhanced nucleation on a precursor such as thin metal films, graphite fibers, C_{60}, or others [41, 42] can also be used. The nucleation density is between 10^6 and 10^{10} cm^{-2} depending on the precursor.
- A further technique is the bias enhanced nucleation by applying a dc or radio frequency potential during the first few minutes of the deposition [43–45]. The nucleation density obtained with this technique is between 10^8 and 10^{11} cm^{-2}. This technique is the only one which allows oriented growth relative to the substrate as shown in Figure 15.

The quality of the diamond films depends strongly on the deposition conditions and can be indicated by the full width at half maximum (FWHM) of the Raman line at 1332 cm^{-1}. Films with high crystalline quality are typically grown at $T = 850$ °C and carbon precursor concentration of about 1%

Figure 13. Ternary diagram for CVD diamond film growth according to Bachmann et al. [34].
Figure 15. SEM pictures of (100)-oriented polycrystalline diamond film grown by PACVD on silicon (100): (a) top view, (b) side view. Reprinted with permission from [130], E. Maillard-Schaller, Ph.D. Thesis No. 1145, University of Fribourg, Switzerland, 1996.

(e.g., CH_4) in hydrogen. These films exhibit a strong and sharp Raman line 1332 cm^{-1} (Fig. 16a). For higher substrate temperatures $T > 950\,°C$, and higher carbon precursor concentration the diamond films become nanocrystalline or ballas t like as shown in Figure 16b. Zhu et al. [47] were the first to point out a relation between the quality of the diamond films measured by the FWHM of the Raman 1332 cm^{-1} line and the field emission properties. By decreasing the crystalline quality, monitoring it with the FWHM of the 1332 cm^{-1} Raman line, the threshold field to get an emission current of 1 nA decreases. The film they have investigated showed threshold fields above 20 V μm^{-1}. Today CVD diamond films exhibiting threshold fields below 5 V μm^{-1} can be grown with reasonably good reproducibility.

1.5.2. Amorphous and Diamondlike Carbon Films

Apart from crystalline graphite and diamond, carbon films consisting of a disordered network of sp^2 and sp^3 bonded carbon can be deposited. Due to their disordered nature these films are referred to as being amorphous carbon. Amorphous carbon thin films may be broadly classified as:

- Amorphous carbon (a-C), usually deposited by physical vapor deposition processes.
- Hydrogenated carbon, (a-C:H), usually deposited by plasma-assisted chemical vapor deposition (PACVD) [48–51].

In general amorphous carbon films are well characterized by two parameters, the ratio of sp^3 to sp^2 bonded carbon and the amount of hydrogen in the films. According to that, the classification of amorphous carbon can be represented in a ternary phase diagram as shown in Figure 17. The corners at the base of the triangle correspond to diamond (100% sp^3) and graphite (100% sp^2). The upper limit for formation of solid films is defined by the tie line between the compositions of polyethylene –(CH$_2$)$_n$– and polyethyne –(CH)$_n$–.

The tetrahedral amorphous carbon (ta-C) and the hydrogenated tetrahedral amorphous carbon (ta-C:H) are often called diamondlike carbon as they can exhibit hardnesses close to that of diamond. DLC films can be synthesized at room temperature by PACVD or other ion assisted processes. Any hydrocarbon precursor with sufficient vapor pressure can in principle be used for PACVD of DLC films. Commonly used process gases are acetylene (C_2H_2) and methane (CH_4). The DLC deposition is a nonequilibrium

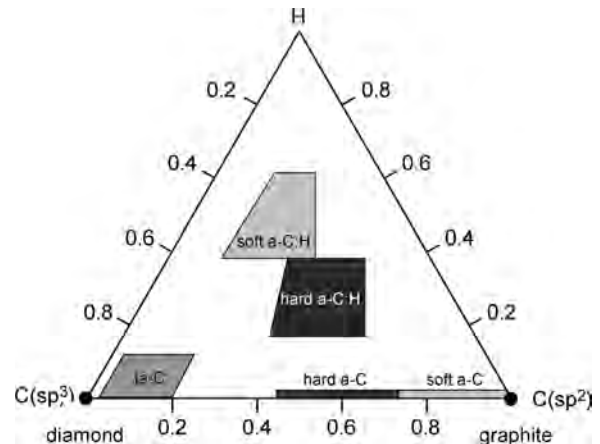

Figure 17. Phase diagram for amorphous carbon thin films according to Bachmann [52].

process characterized by the interaction of energetic ions with the surface of the growing film. The deposition of DLC by PACVD has to be done on negatively biased substrates to actuate reactions like thermal and pressure spikes at the growth surface by energetic ions. Tsai and Bogy [53] calculated for 100 eV ions thermal spikes of 3300 K and pressures of 1.3×10^{10} Pa for a period of 10^{-10} seconds. The lifetime of these spikes is much longer than the vibrational period ($\sim 10^{-14}$ s) for diamond and thus well beyond what is required to allow bonding. The DLC process forms a metastable amorphous material whose structure is conserved due to extremely high quenching rates of the thermal spikes. The hardness of the DLC film can be varied adjusting the substrate bias [54]. An excellent overview on the growth, physical properties, and applications of amorphous carbon thin films has been given by Silva et al. [55].

With regard to the electronic properties the ratio of the π and σ states plays an important role. Where the π states originate from sp^2 and sp^1 bonded carbon, σ states are contributed from all carbon atoms. As a consequence the σ states always form two extended bands as illustrated in Figure 18a. Depending on the amount of sp^2 and sp^1 bonded carbon, π bands of a more or less extended character are formed at the edges of the σ bands [56]. Therefore it is clear that the amount of the π states in the amorphous carbon will strongly influence the bandgap of the material. Due to the disordered nature of the material the band edges are not sharp but there are tail states extending into the gap. The semiconducting properties of amorphous carbon arise from the differences in the carrier mobility of extended and localized states and lead to the formation of a mobility gap as shown in Figure 18b. Due to the presence of localized states around the Fermi level and the band tails, electronic transport properties are associated with four different regions of the DOS [47].

(a) transport by carrier excitation beyond the mobility edges into extended states at E_C and E_V

$$\sigma = \sigma_0 \exp\left(-\frac{E_C - E_V}{k_B T}\right) \qquad (22)$$
where $\sigma_0 = \mu_{\mathrm{ext}} \cdot e \cdot N(E_C) \cdot k_B T$, μ_{ext} is the extended state mobility, and $N(E_C)$ is the density of states at the conduction band edge

(b) transport by carrier excitation to localized states at the band edges and hopping at the band tail

$$\sigma = \sigma_1 \exp\left(-\frac{E_C^* - E_F + \omega_1}{k_B T}\right) \qquad (23)$$

where $\sigma_1 \ll \sigma_0$, ω_1 is the hopping activation energy, and E_C^* is the tail states energy of the conduction band

(c) transport by hopping of carriers in the tail states around the Fermi energy E_F

$$\sigma = \sigma_2 \exp\left(-\frac{\omega_2}{k_B T}\right) \qquad (24)$$

where ω_2 is the hopping activation energy

(d) variable-range hopping, dominant for most material at lower temperatures

$$\sigma = \sigma_2' \exp(-BT^{-1/4}) \qquad (25)$$

where $B = 2(\alpha^3/k_B N(E_F))^{1/4} = $ const, α is a measure of the decay of the wave function on a single potential well, $\sigma_2' = v_{\mathrm{ph}} e^2 N(E_F) \langle R \rangle^2$, $\langle R \rangle$ is the average hopping distance, and v_{ph} depends on the phonon frequency

Hydrogen being monovalent can saturate dangling bonds in the amorphous carbon and therefore reduce the defect states in the gap as in the case of amorphous silicon [58].

1.5.3. Nanotube Films

Carbon nanotubes are ultrathin carbon fibers with nanometer-size diameter and micrometer-size length and were discovered by Iijima in 1991 [29] in the carbon cathode used for arc-discharge processing of fullerenes (C_{60}). The structure of CNTs may be viewed as enrolled cylindrical graphene sheets and closed by fullerenoid end caps. There exist SWNTs and MWNTs, consisting of several nested coaxial single wall tubules. Typical dimensions of MWNTs are: outer diameter 2–30 nm, inner diameter 1–3 nm, length 1–100 μm. The intertubular distance in MWNTs is 0.340 nm, slightly larger than the interplanar distance in graphite, which is equal to half of the unit-cell parameter c ($0.5c = 0.3455$ nm). SWNTs tend to agglomerate and form bundles of several tens of nanotubes. The SWNTs in bundles are in two dimensions and closed-packed, and the intertube distance is 0.334 nm [59].

Several methods have been developed to synthesize CNTs. All of them, arc evaporation [60], laser ablation [61], CVD [62], and plasma enhanced chemical vapor deposition (PECVD) [63], work at elevated temperatures (>600 °C) and metal particles (e.g., Fe, Co, Ni) are involved in the reaction. The CNT growth by CVD or PECVD requires a metallic catalyst. The catalytic methods for CNT growth have their origin in the corresponding works on carbon fibers [64, 65]. Baker and Harris [65] proposed a model for the catalytic carbon filament growth in which the hydrocarbon precursor is decomposed on the surface of the catalytic

Figure 18. (a) Sketch of the DOS and (b) the mobility gap of *a*-C as a function of energy.

metal particle, producing hydrogen and carbon, which then dissolves into the metal. Then the dissolved carbon diffuses through the particle, to be precipitated on the trailing face, forming the filament. This model seems also be applicable for the general CNT growth (Fig. 19). Figure 20 shows scanning electron microscope (SEM) pictures of a CNT brush grown perpendicularly on the substrate. The backscattered electron image (Fig. 20b) reveals small metal clusters (white spots) on top of the CNT brush. This picture supports that the catalytic growth model for carbon fibers proposed by Baker and Harris [65] is also valid for CNTs. Figure 21b shows a transmission electron microscope (TEM) picture of a nanotube with the encapsulated metal catalyst. However the growth mechanisms responsible for the structure type of the growing CNT (SWNT, MWNT, chirality) are still unknown.

Using the CVD process dense CNT films with preferential orientation normal to the substrate surface can be grown [66–68]. The orientation of the individual nanotubes in the film is forced by the tube density. Above a critical density the direction of the growing nanotube is confined by the surrounding growing tubes resulting in a growth orientation normal to the surface. Remarkable for the growth of dense CNT films by CVD is that all individual nanotubes have exactly the same height. The SEM picture in Figure 21a reveals that the CNT film consists straight as well as twisted CNTs suggesting that the individual CNTs have different growth rates. The straight nanotubes in the film may have the lowest growth rate and may limit the growth rate of the entire film by anchoring the "cap" of the film. We observed that the "cap," the top of the CNT film, is a thin layer composed of clusters from the metal catalyst and amorphous carbon. It seems that the individual nanotubes cannot pass through this thin film. Nanotubes with higher growth rates are therefore confined within in the growing film and are forced to twist which may explain the film structure shown in Figure 21. Because the CNT growth is a catalytic process it is relatively easy to prepare patterned films. For this two strategies can be followed, one by patterning the catalyst material, from solutions or by evaporation onto the substrate using classical lithography techniques [69, 70]. We, for example, used microcontact printing to pattern the catalyst onto the substrate [71]. For this a polydimethylsiloxane stamp was first hydrophilized to considerably increase the affinity between stamp and the metal catalyst–ethanol
Figure 20. SEM pictures of a CNT brush produced by CVD: (a) secondary electron image, (b) backscattered electron image.

solution. The stamp was subsequently inked and after drying the catalyst was printed on a silicon wafer. Wei et al. [72] showed another route to produce patterned CNT films. Instead of patterning the catalyst onto to the substrate they stimulated CVD growth of a CNT by exposing SiO_2 patterned Si- wafers to a xylene/ferrocene $[C_8H_{10}/Fe(C_5H_5)_2]$ vapor mixture. They used substrate consisting of Si(100) wafers capped with 100 nm thick thermal oxide. Pattering of Si/SiO_2 was generated by photolithography followed by a combination of wet and/or dry etching (i.e., standard microfabrication technology). The precursor mixture used gives rise to selective growth of MWNTs of diameters 20–30 nm on silica surfaces [73]. There is no CNT growth on Si, but the aligned CNTs grow readily on SiO_2 in a direction normal to the substrate surface.

Recently several research groups have shown that well-aligned CNTs with controlled site density can be grown by PECVD [74–77]. Bower et al. [78] used microwave CH_4/H_2 plasma to show that PECVD enables a vertically oriented growth of MWNTs. In elegant experiments, the growth was first started with the plasma on and after a certain period, the plasma was turned off and the growth was continued with the same deposition parameters. While the nanotubes in the first period under PECVD conditions exhibited a high degree of alignment, the continued growth under CVD conditions showed randomly oriented curly tubes. The authors claimed that the electric self-bias imposed on the substrate surface appears to be the primary mechanism responsible for the conformal alignment. The advantage of the PECVD process compared to the CVD process is that the alignment

Figure 21. SEM picture from the side view of the CNT brush shown in Figure 20.

of the CNT can be achieved by the influence of the electric field and not by steric repulsion, which allows the growth of aligned CNTs with controlled site densities as shown in Figure 22.

1.6. Hope for the Flat Thin Film Electron Emitter

In the early 1990s several publications [80–82] were given showing highly efficient electron emission at low electric fields from carbon based materials like diamond and DLC thin films. These cathode films are referred to as flat thin film electron emitters and were thought to provide the solution to several of the technological difficulties associated with the cathode design in FEDs. The reason for this stems from the fact that a surface which emits electrons more or less homogeneously at fields as low as some few volts per micrometer due to a low work function ϕ or NEA requires less expensive patterning processes, much simpler device design, and much cheaper driving electronic circuitry. Probably the most influential paper was that of Geis et al. [82]. They built an array of diodes (Fig. 23), known as a hot-electron device, described in 1966 [83]. These diodes apparently work by adiabatic heating the electrons by passage across a p–n junction and hot electrons escape from the lateral surfaces. It is suggested that electron emission efficiency be improved by having low electron affinity emitting surface. Geis and his co-workers suggested for their diamond devices that the NEA of certain crystal planes is responsible for the electron emission, which leads peoples to dream about a flat electron emitter. In contrast to the micrometer-sized design of field emitter array (FEA) tips, the ideal flat electron emitter could be homogeneously deposited by, for example, chemical vapor deposition over rather large areas

Figure 23. Drawing of the cathode design used by Geis et al. [82].

with much lower spatial tolerance and hence lower cost. Instead of defining hundreds of FEA microtips as electron sources for one pixel of an FED, the whole FEA subelement could be replaced by an electron emitting flat thin film as illustrated in Figure 24, where, however, the gate not has been sketched around the flat thin film emitter.

2. CHARACTERIZATION OF THE FIELD EMISSION BEHAVIOR

In the 1990s carbon thin films received great interest as electron emitting cathodes. In 1991 the Russian scientists Djubua andChubun [80] investigated the electron field emission from different materials in Spindt tip geometry and found DLC emitters show the lowest turn-on voltages. In the same year Wang and co-workers [81] presented electron field emission measurements on polycrystalline CVD diamond films. They suggested that emission comes from areas between crystallites and not from sharp pointed crystallites as might be expected. They speculated that graphite inclusions or NEA might be responsible for the low turn-on voltages. Afterward, for a wide range of different carbon

based materials unusual field emission properties have been demonstrated [85–91]. Certain DLC and CVD diamond films show emission currents in the mA range at applied electric fields as low as 2 V μm^{-1}. Despite the promising experimental results little was known about the mechanism which accounts for the observed currents. Several theoretical approaches have been forwarded suggesting emission from energy bands in the gap [92]. However, all models fail when explaining the outstanding role of carbon material for field emission. Investigations on CVD diamond film have shown that emission does not occur homogeneously over the surface but is rather concentrated in μm and sub-μm sized spots [93].

2.1. Emission Models and Energy Distribution of the Emitted Electrons

As mentioned, many models to explain the field emission from CVD diamond and also from single crystalline diamond have been presented. Figure 25 schematically shows different emission models. Since the measurement of the field emitted electron energy distribution (FEED) will be important within the context in this chapter, implications of the different models on the peak shape and position of the electron distribution are discussed here. The models presented cannot give a complete overview of all proposed models for the origin of the low field electron emission from diamond and related materials. An excellent overview on hypotheses about emission mechanism from carbon films has been given by Forbes [94].

2.1.1. Classical Fowler–Nordheim Model

In Figure 25a the classical situation of field emission from metals is depicted. On the left hand side the density of occupied electron states of the emitter near the Fermi energy is assumed to be the Fermi–Dirac distribution for $T = 300$ K. An electric field of 2700 V μm^{-1} and an emitter work function of 5.3 eV are assumed. Under the action of the intense field the surface potential step, confining the electrons to the solid, becomes a triangular barrier. If the width of the barrier at the Fermi energy decreases below about 2 nm the tunneling probability for the electrons is not neglectable anymore and an emission current can be observed. On the right hand side of Figure 25a the resulting FEED is shown. The energy distribution shows a peak centered at the Fermi energy E_F of the emitter. The low energy side of the peak shows the exponentially decreasing tunneling probability with decreasing energy due to the increasing width of the tunneling barrier. The position of the FEED peak in energy is located at the potential of the emitting surface. Usually the reference energy is the Fermi level position of the back contact to the emitter. This means that if there is a potential difference between the emitter surface and the contact, the position of the FEED peak will shift to lower energies. Such potential drops always occur due to the electron emission which charges the emitter surface positively. The amount of emitter charging is such that it brings emission current and supply current through the emitter in equilibrium. The current-field characteristic of the emission is described by the Fowler–Nordheim relation (16).

2.1.2. Conduction Band Emission Model

Figure 25b displays the emission model proposed by Geis et al. [95] to explain the low field electron emission from nitrogen containing single crystalline diamond and polycrystalline CVD diamond having NEA. The EA of a solid is defined as the energy difference between the lowest unoccupied electron state in the solid and the energy of an electron at rest outside the solid (vacuum level). In case of metals the work function ϕ and the electron affinity χ are equivalent, since there is no energy difference between the highest occupied and the lowest unoccupied states ($T = 0$ K). In case of semiconductors and insulators the situation is different due to separation of the occupied and unoccupied states by the energy gap. Semiconductors and insulators show NEA, if the

vacuum level is below the conduction band minimum. This means that electron in the conduction band will experience no surface potential barrier for the emission. In case of diamond surfaces it was demonstrated that hydrogen termination of the (111) and (100) of p-type diamond surfaces leads to NEA [96, 97]. It is obvious that NEA related electron emission will crucially depend on an efficient mechanism to populate the empty conduction band with electrons. In the case of boron doped single crystalline diamond such population of the conduction band during field emission seems not to occur and it was found that the field emission originates from the valence band at local fields above 2000 V μm^{-1} [98]. Substitutional nitrogen in diamond is known to produce a deep donor state 1.7 eV below the conduction band [99]. But the activation energy of 1.7 eV is too large to give an efficient thermal excitation of electrons into the conduction band at room temperature. Nevertheless, Geis proposed the ionization of this donor state can lead to a space charge layer at the metal diamond interface, causing downward band bending in the diamond. In the case of an ionized donor density of more than 2×10^{19} cm^{-3}, the depletion region is thinner than 20 nm, which allows electrons to be injected from the metal contact into the conduction band of the diamond, when a relatively low potential drop of a few volts over the depletion layer is present. The injected electrons will thermalize quickly (typically in 10^{-12} s) to the conduction band minimum, where they are transported in a diffusion dominated process, with typical lifetimes of 10^{-9} s [100], to the surface and are emitted into vacuum due to NEA. In the case of nitrogen containing diamond a CsO monolayer seems to be necessary to create a sufficiently large dipole moment to produce the NEA.

Diederich et al. [16] have shown by UPS that hydrogen termination can generate an efficient NEA surface for the B-doped diamond (100) surface but not for the N-doped diamond (100) surface due to the high upward band bending. In the NEA model the field emission current will be limited by the tunneling of electrons through the interfacial potential barrier and not by the surface potential barrier. The FEED will reflect the energy distribution of the indicating position of the conduction band minimum. In the ideal case of flat band conditions at the surface the width of the FEED peak should be of the order of $k_B T$ although strong band bending at the surface can lead to a significantly larger width of the FEED peak. Furthermore, the position of the FEED peak should be shifted to lower energies, reflecting the potential drop between the diamond surface and the metal contact, which is necessary for electron injection.

2.1.3. Defect Band Emission

Figure 25c displays the emission model proposed first proposed by Zhu et al. [47]. This model accounts for the experimental observation that the field emission properties of CVD diamond films correlate with the film quality measured by the FWHM of the Raman 1332 cm^{-1} line, indicating a decreasing threshold field with increasing linewidth. In order to explain this behavior Zhu et al. proposed the presence of defects bands in the energy gap of the diamond. The formation of these defects bands is supposed to raise the Fermi level close to the vacuum level and is

therefore responsible for a strong reduction of the work function of the defective diamond film. This could only occur if no Fermi level pinning at the surface states is assumed. Furthermore, the defects bands would provide a steady current flow to the surface and sustain a continuous current. The reduced work function will then give rise to the observed field emission. A threshold field of 20 V μm^{-1} for 1 nA emission current corresponds to a work function $\phi \cong 0.2$ eV and a threshold field of 3 V μm^{-1} would correspond to $\phi \cong 0.05$ eV (assuming Fowler–Nordheim-like emission with no field enhancement). These work function values are extremely low and highly questionable. Yet, if a moderate local field enhancement, which could also explain the spotty local emission characteristic of diamond films, of 10–30 is taken into account, the work function values would increase to a more reasonable range around 1 eV. There are materials showing work function values around 1.2 eV, like ScO [101]. In this model the electrons are emitted due to the tunneling through the surface potential barrier, like the classical Fowler–Nordheim tunneling (Fig. 25a). Yet due to the reduced work function the local fields involved in the emission process can be considerably low. The resulting FEED would be characterized by very narrow peaks due to the low local field at the emission site. The width of the surface potential barrier would rapidly increase with decreasing energy, leading to a narrow energy range, where the tunneling probability is large enough to give measurable electron emission.

2.2. Measurement of the Field Emission Properties

2.2.1. Current–Voltage Measurements

Usually current–voltage (I–V) measurements are used to characterize the electron emission behavior according to the Fowler–Nordheimrelation (16). From these measurements technologically important parameters such as threshold field F_{th} or the current density j can be determined, but not the work function ϕ as the physically relevant parameter. The reason for this is that experimentally one does not measure current–field characteristics but current–voltage characteristics, where one relates the applied voltage to some applied field for example by dividing the applied voltage with the anode cathode distance. The problem is that this applied field may not correspond to the local field present at the emission site due to some field enhancement effects. Assuming that F_0 ($F = F_0 \beta$) denotes the applied electric field in a field emission measurement, the Fowler–Nordheim relation (16) will change to

$$j = \frac{e^3}{4(2\pi)^2 \hbar \phi} F_0^2 \beta^2 \exp\left(-\frac{4\sqrt{2m_e}}{3\hbar} \frac{\phi^{1.5}}{eF_0\beta}\right) \quad (26)$$

with

$$B_v = \frac{e^3}{4(2\pi)^2 \hbar \phi} \quad \text{and} \quad A_v = \frac{4\sqrt{2m_e}}{3\hbar e}$$

The Fowler–Nordheim relation can be written by

$$j = B_v F_0^2 \beta^2 \exp\left(-A_v \frac{\phi^{1.5}}{F_0\beta}\right) \quad (27)$$

By replacing the local field F at the emission site by the applied field F_0, the electron emission will yield a straight line in the Fowler–Nordheim (FN) plot [$\ln(j/F_0^2)$ vs $1/F_0$], as can be seen from the Fowler–Nordheim relation (27). The slope of this straight line will be equal to

$$\text{FN}_{\text{Slope}} = -A_v \frac{\phi^{1.5}}{\beta} \qquad (28)$$

F_0 is a function of the applied voltage, whereas β generally is unknown. In the case of well defined emitter geometry (e.g., a tip with aspect ratio $h/r = \beta$), the work function ϕ can be calculated within a certain accuracy. In the case of thin film emitters this is generally not possible. This means that the work function ϕ of the emitter cannot be determined from the measurement of the I–F_0 (resp. I–V) characteristics alone.

2.2.2. Field Emission Spectroscopy

The situation is different when one has additional information such as the energy distribution of the field-emitted electrons [46]. Figure 26 shows schematically the situation at a metal surface under field emission conditions ($\phi = 5.3$ eV and $F = 2700$ V/μm), and the resulting energy distribution of the emitted electrons.

In section 1.2.4, Eg. (13), it was shown that the transmission probability for an electron with energy $E(k_x, k_y, k_z)$ close to the Fermi energy E_F can be expressed by

$$D(E) = \exp\left(-\frac{4\sqrt{2m_e}}{3\hbar} \frac{\phi^{1.5}}{eF}\right) \exp\left(\frac{2\sqrt{2m_e}}{\hbar} \frac{\phi^{0.5}}{eF}(E_x - E_F)\right)$$

with $E_x = \hbar^2 k_x / 2m_e$ (the kinetic energy component perpendicular to the emitter surface).

The total energy distribution $P(E)$ of the field emitted electrons can be derived from (13) by

$$P(E) = \frac{2e}{(2\pi)^3} f(E, E_F, T) \int_{k_x^2 + k_y^2 + k_z^2 = E} D(E) \frac{\hbar k_x}{m_e} \, dk_x \, dk_y \, dk_z \qquad (29)$$
Figure 26. Schematic illustration of the situation at a surface under field emission conditions and the resulting energy distribution of the field emitted electrons (calculated for $F = 2700$ V/mm and $\phi = 5.3$ eV).

Substituting of (13) into (29) and solving the integral, one finds

$$P(E) = f(E, E_F, T) \frac{\sqrt{2m_e}}{2(2\pi)^2 \hbar^2} \frac{eF}{\phi^{0.5}} \exp\left(-\frac{4\sqrt{2m_e}}{3\hbar} \frac{\phi^{1.5}}{eF}\right)$$
$$\times \exp\left(2\frac{\sqrt{2m_e}}{\hbar} \frac{\phi^{0.5}}{eF}(E - E_F)\right) \qquad (30)$$

This relation for the total energy distribution of the emitted electrons can be divided in an energy dependent and a field dependent intensity term, denoted as $B(F, \phi)$. The relation (30) can then simplified to

$$P(E) = f(E, E_F, T) \cdot B(F, \phi) \exp\left(2\frac{2\sqrt{2m_e}}{\hbar} \frac{\phi^{0.5}}{eF}(E - E_F)\right) \qquad (31)$$

Stratton [102] modified relations (30), (31) in order to describe the total field emitted energy distribution of electrons originating from the valence band and obtained

$$P_V(E) = f(E, E_F, T) \cdot B(F, \phi)$$
$$\times \exp\left(\frac{2\sqrt{2m_e}}{\hbar} \frac{(\chi + E_G)}{eF}(E - E_V)\right)$$
$$\times \left(1 - \exp\left(\frac{2r\sqrt{2m_e}}{\hbar} \frac{(\chi + E_G)}{eF}(E - E_V)\right)\right) \quad (32)$$

where χ is the electron affinity of the semiconductor, E_G is the energy gap, E_V is the energy of the valence band maximum, and $r = m_e/m^*$ is the ration of the electron mass and the band electron mass. To fit the field emission spectra (FES) of carbon materials the relation (32) with $E_V = E_F$, $E_G = 0$, $\chi = 0$, and $r = 1$ can be used due to the zero bandgap semiconductor character of graphite. It has to stressed that relation (31) assuming emission from a free electron gas and relation (32) assuming emission from the valence band edge are extreme cases for carbon materials; the true character can be somewhere in between.

With

$$C_v := 2\frac{\sqrt{2m_e}}{e\hbar} \qquad (33)$$

one can easily see from relations (26) and (31) that

$$\frac{A_v}{C_v} = \frac{2}{3}\phi U_0 \qquad \Rightarrow \qquad \phi = \frac{3}{2U_0}\frac{A_v}{C_v} \qquad (34)$$

where A_v is the slope of the Fowler–Nordheim plot (28) with respect to the applied voltage U_0 and C_v is the exponential factor of the low energy part of the field emission energy distribution measured at the applied voltage. By determining A_v and C_v the work function ϕ at the emission site can be determined without the need to know the field enhancement factor β. Knowing the work function the local field present at the emission site can be determined from

$$F = 2\frac{\sqrt{2m_e}}{e\hbar} \frac{\phi^{0.5}}{C_v} \qquad (35)$$

In these considerations and derivations a triangular emission barrier as described by relation (7) is assumed.

A significant improvement of the emission model results from the influence of the image charge potential on the derivation of the Fowler–Nordheim law and the total energy distribution. The Fowler–Nordheim relation (16) becomes

$$j = \frac{e^3}{4(2\pi)^2\hbar\phi}\frac{1}{t^2(y)}F^2\exp\left(-\frac{4\sqrt{2m_e}}{3\hbar}\frac{\phi^{1.5}}{eF}v(y)\right) \quad (36)$$

with

$$y = \frac{\Delta\phi(F)}{\phi} = \frac{\sqrt{\frac{e^3F}{4\pi\varepsilon_0}}}{\phi} \quad (37)$$

where $t(y)$ and $v(y)$ are the so-called elliptical functions which are tabulated [103]. The parameter y is the ratio if the field dependent work function lowering $\Delta\phi(F)$, due to the influence of the image charge potential (Schottky effect) and the work function ϕ of the emitter. The total energy distribution transforms into

$$P(E) = f(E, E_F, T)\frac{\sqrt{2m_e}}{2(2\pi)^2\hbar^2}\frac{eF}{\phi^{0.5}}\frac{1}{t(y)}$$

$$\times\exp\left(-\frac{4\sqrt{2m_e}}{3\hbar}\frac{\phi^{1.5}}{eF}v(y)\right)$$

$$\times\exp\left(\frac{2\sqrt{2m_e}}{\hbar}\frac{\phi^{0.5}}{eF}t(y)(E-E_F)\right) \quad (38)$$

Figure 27 displays the values of the elliptical functions $t(y)$ and $v(y)$. In the field and work function range for carbon field emitters the parameter y varies between 0.3 and 0.4. In this regime the following approximations for $t(y)$ and $v(y)$ can be made:

$$t(y) \approx 1.02 \quad (39)$$

$$v(y) \approx 0.98{-}1.1y^2 \quad (40)$$
Figure 27. Plot of the elliptical functions $t(y)$ and $v(y)$. The markers represent the tabulated values [103] and the solid lines are approximations to $t(y)$ and $v(y)$.

Substituting (39) and (40) into (37) the Fowler–Nordheim relation becomes

$$j = \frac{1}{1.04}\frac{e^3}{4(2\pi)^2\hbar}\frac{F^2}{\phi}\exp\left(\frac{e^2\sqrt{2m_e}}{3\pi\hbar\varepsilon_0\phi^{0.5}}\right)$$

$$\times\exp\left(-0.98\frac{4\sqrt{2m_e}}{3\hbar}\frac{\phi^{1.5}}{eF}\right) \quad (41)$$

From relations (41) and (38) one can see that the estimation of the work function ϕ taking into account the image charge potential, using the slope of the Fowler–Nordheim plot A_v and the exponential factor C_v, will lead to

$$\phi = \frac{1.02}{0.98}\frac{3}{2}\frac{A_v}{C_vU_0} = 1.04\frac{3}{2U_0}\frac{A_v}{C_v} \quad (42)$$

This is about 4% larger than without taking the image charge potential into account (34).

2.2.3. Example: Determination of the Work Function ϕ of MWNT

Experimental Setup The energy resolved field emission measurements were carried out in an OMICRON surface analysis system (base pressure $p < 10^{-10}$ mbar) equipped with a VSW EA 125 HR electron energy analyzer. The measurements were carried out in the constant analyzer energy mode with pass energy of 5 eV which corresponds to an energy resolution of 40 meV between 100 and 1000 eV kinetic energy. The high voltage was set to the sample by a Keithly 237 instrument with a ripple voltage less than 5 mV. The field emission spectra were measured between 1 pA and 1 nA total emission current, with count rates of 100 to 10^6 cps. Figure 28 shows the cut through the sample holder used for the measurements. Details of the experiment can be found in [104].

Results Figure 29 displays a series of FES measured from a sample of MWNTs recorded at room temperature at different applied voltages and therefore different electric fields. The applied voltage U_0 was subtracted from the kinetic energy scale of all spectra giving the energy relative to the
Figure 28. Schematic cross-sectional view of the sample holder used for the FES measurements.
Figure 29. Series of FES of a MWNT field emitter recorded at different applied voltages. The inset shoes the FN plot derived from the FE spectra. A_v is the slope of the FN plot. Reprinted with permission from [46], O. Gröning, Ph.D. Thesis No. 1258, University of Fribourg, Switzerland, 1999.

Fermi energy E_F. The solid lines are fits to the data using relation (32) assuming $T = 0$ K and taking the spectrometer resolution into account. By integrating the spectra over the energy we obtain a value which is proportional to the emission current density. Therefore we obtain a current–voltage characteristic that can be displayed in a FN plot (inset Fig. 29).

The FES in Figure 29 show a very narrow, asymmetric shaped energy distribution (FWHM = 375 meV) of the emitted electrons located at the Fermi energy E_F. As discussed in Section 2.1 such an energy distribution is characteristic for Fowler–Nordheim tunneling (Fig. 25a). The straight line in the FN plot (inset Fig. 29) over five orders of magnitude in the emission current proves the Fowler–Nordheim emission for the MWNT field emitter.

As the slope of the FN plot with respect to the field F at the emission site depends on the work function alone by $\phi^{1.5}$, the work function ϕ of the emitter can be determined. Yet we have to realize that in a field emission experiment current–voltage characteristics are measured. In the case of two parallel plates acting as anode and cathode separated by a distance d, the applied field is given by $F_0 = U_0/d$. The local field F at the emission site is then $F = F_0 \cdot \beta$. As discussed β is generally not known and the FN plot is plotted with coordinates $\ln(j/F_0)$ vs F_0^{-1}. Hence the slope of the FN plot is proportional to $\phi^{1.5}\beta^{-1}$. The FN plot depicted in the inset of Figure 29 is given with respect to the applied voltage and the slope $\text{FN}_{\text{slope}} = -A_v\phi^{1.5}\beta^{-1}$ (28) equals 20,152 V. The local field F at the emission site can be expressed by $F = U_0 \cdot \beta$, where β is the field enhancement factor, this time not with respect to the applied field F_0 but to the applied voltage U_0. Therefore β has in this case the dimension $[\text{m}^{-1}]$.

Figure 30 shows the field emission spectrum from the series in Figure 29 recorded at an applied voltage of $U_0 = 680$ V. The dashed line is a Gaussian curve fitted to the high energy side of the peak, whereas the solid line is a fit according to relation (32). One can see the asymmetric shape of the field emission distribution, where the low energy side of the peak shows the exponential decrease with decreasing energy as expected. Using the definition (33) for C_v the relation for the total energy distribution $P(E)$ (31) can be simplified to

$$P(E) = f(E, E_F, T)B(F, \phi) \exp\left(C_v \frac{\phi^{0.5}}{F}(E - E_F)\right) \quad (43)$$

Using this relation the low energy side of the FES can be fitted and we can obtain a value of

$$C_v\phi^{0.5}F^{-1} = C_v\phi^{0.5}U_0^{-1}\beta^{-1} = 9.09 \ [\text{eV}]^{-1}$$

With this value, the value for FN_{slope}, and relation (34) the work function ϕ at the emission site can be determined:

$$\frac{A_v\phi^{1.5}\beta^{-1}}{C_v\phi^{0.5}U_0^{-1}\beta^{-1}} = \frac{A_v}{C_v}\phi U_0 = \frac{2}{3}\phi U_0$$

$$\Rightarrow \quad \phi = \frac{3}{2U_0}\frac{A_v\phi^{1.5}\beta^{-1}}{C_v\phi^{0.5}U_0^{-1}\beta^{-1}}$$

$$\phi = \frac{3}{2 \cdot 680 \ [\text{V}]} \cdot \frac{20156 \ [\text{V}]^{-1}}{9.09 \ [\text{eV}]} = 4.89 \text{ eV}$$

As can be seen the unknown field enhancement factor β is cancelled out in this calculation. The obtained work function value $\phi = 4.89 \pm 0.3$ eV is a bit higher than for highly oriented pyrolythic graphite with a work function of 4.55 ± 0.1 eV but is in very good agreement with the work function of sputtered graphite (highly disordered) of 4.9 ± 0.2 eV.
Figure 30. FES spectrum recorded at an applied voltage $U_0 = 680$ V from the FES series depicted in Figure 29. Reprinted with permission from [46], O. Gröning, Ph.D. Thesis No. 1258, University of Fribourg, Switzerland, 1999.

This example shows that the work function ϕ at the emission site can be determined accurately by measuring the I–V characteristic and the energy distribution of the emitted electrons. Knowing the emitter work function ϕ, the local electric field F present at the emission site can be determined from definition (33) using

$$C_v \phi^{0.5} F^{-1} = 9.09 \; [\text{eV}]^{-1} = 5.68 \times 10^{19} \; [\text{J}^{-1}]$$

$$\Rightarrow \quad F = C_v \frac{\phi}{5.68 \times 10^{19} \; [\text{J}^{-1}]}$$

$$= 2 \frac{\sqrt{2m_e}}{e\hbar} \cdot \frac{8.93 \times 10^{-10} \; [\text{J}^{0.5}]}{5.68 \times 10^{19} \; [\text{J}^{-1}]}$$

$$= 2.5 \times 10^9 \; [\text{Vm}^{-1}]$$

This value for the electric field at the emission site corresponds very well to the electric field of 2700 V/μm predicted by the Fowler–Nordheim relation (16).

3. CARBON BASED ELECTRON EMITTERS

Since the first observation and investigations of the low field electron emission properties of natural and chemical vapor deposited diamond in the early 1990s [20, 21], the interest in this field has steadily increased until the present day. This interest is not of a scientific nature only (over 150 patents [105] were issued on the subject of diamond field emitters alone) although the physical nature of the low field electron emission from diamond is still under dispute.

Our works on carbon thin films show clearly that one has to distinguish strictly between the applied electric field (defined as the applied voltage devised by the anode–cathode distance) and the local field present at the emission site. From the technological point of view the applied field is the relevant parameter to characterize the field emission, as it determines what voltage has to be applied for a given anode–cathode distance. Yet, with regard to the physical nature of the emission, only the local field present at the emission site is relevant. In a field emission experiment in general only the applied electric field can be determined directly and it is very difficult to estimate the local fields on a real cathode surface. The combined measurement of the current–field characteristic and the field emitted electron energy distribution of an emitter allows one to determine independently the local field F and the work function ϕ of the emitter. In all cases we have investigated (CVD diamond, DLC films, and CNTs) we found that the local fields present at the emission site are always in the order of 2500 V μm^{-1} and higher, although the applied field ranges between 1 and 50 V μm^{-1}. The emission process is in all cases ordinary Fowler–Nordheim tunneling with emitter work functions around 5 eV.

3.1. CVD Diamond Thin Film Emitter

On CVD diamond films exhibiting a good crystalline quality, with a low defect density and large (>1 mm) crystallites (Fig. 16a), we found in most cases that the field emission showed very distinct, nonreversible activation characteristics

[106–109]. Figure 31 shows a typical current–field characteristic of the activation of boron doped good crystalline CVD diamond film. In the first voltage sweep from zero upward, the measured current remained below 1 pA up to a critical field E_C. At this field, a sudden and persistent increase of the current occurs. The value of E_C can vary significantly with the film under investigation because the occurrence of vacuum discharge depends on many parameters such as residual gas pressure, surface roughness, surface contamination, and anode–cathode geometry [110]. In our setup, typical values for E_C ranged between 100 and 400 V μm^{-1}. When the voltage is lowered, a reversible field emission characteristic can be observed at a turn-on field E_{on}. The values for E_{on} can range between 2 and 50 V μm^{-1}.

Typically the arc formed a small crater in the diamond film. By means of atomic force microscopy and Raman spectroscopy a graphitization of the diamond film around the crater can be observed. This results in an increased local conductivity and an increased roughness in the submicrometer range in this zone. Field emission spectroscopy showed that after the activation process the field emitted electrons originated from the states at the Fermi energy E_F indicating the metallic nature of the emission site. The local field F at the emission sites is in the order of 3000 V μm^{-1} and the work function ϕ of the emitter is around 5 eV.

CVD diamond films exhibiting bad crystalline quality, nanocrystalline films (Fig. 16b), do not require an activation step. Usually these films are characterized by a Raman spectrum showing a very weak or even absent 1332 cm^{-1} diamond line but strong features of sp^2 bonded carbon. These films exhibit turn-on fields below 5 V μm^{-1} [111, 112]. The current–field characteristics of these films are Fowler–Nordheim-like in the low current regime. In the high current regime deviations from the Fowler–Nordheim law can be observed depending on the resistivity of the deposited
Figure 31. Typical current–field characteristic of the activation of a weakly emitting CVD diamond film. At a critical field E_C the discharge activation takes place and leads to a drastically and persistently increased current (1–2). If the field is subsequently lowered (4–5), a reversible field emission characteristic around E_{on} can be observed (5–4–3). (The constant current observed for higher fields is due to the current limitation of the voltage source.) Reprinted with permission from [107], O. Gröning et al., *J. Vac. Sci. Technol. B* 17, 1064 (1999). © 1999, American Institute of Physics.

film. From FES an average work function ϕ of 5.7 eV for nanocrystalline diamond can be determined. The local field F present at emission sites is around 2500 V μm^{-1}, whereas the applied fields range between 2 and 10 V μm^{-1}. This implies that strong field enhancement effects are the basis for the low field emission property of this material. Internal field emission and injection of electrons into the conduction band of the diamond and subsequent emission due to negative electron affinity could be ruled out as a possible emission model. This is due to the absence of internal electric fields in the diamond film under field emission conditions. The strong field enhancement effect is most probably due to the surface morphology of the films with a large peak to peak roughness of up to several micrometers and sharp local features on the nanometer scale.

3.2. Diamondlike Carbon Thin Film Emitter

Diamondlike carbon films show field emission properties very similar to those of CVD diamond films. On smooth, structureless (with regard to the surface morphology) DLC films, we only could observe discharge activated field emission [113]. This activation can be observed on polymer films as well as on carbon films with high sp^3 content. This shows that in the activation step the film acts mainly as a carbon source whereas the chemical nature of the carbon film we start is not of major importance.

Nonactivated low field electron emission from DLC films with applied field range of 10–30 V μm^{-1} can be observed when graphitic clusters are present in or on the film. Compared to the smooth parts of the DLC films these clusters show an enhanced conductivity. As in the case of the nanocrystalline CVD diamond the current–field characteristic of the emission is Fowler–Nordheim-like in the low current regime and the FES exhibit the typical shape of Fowler–Nordheim tunneling. Local fields F of 2500–3000 V μm^{-1} and emitter work functions ϕ around 5 eV have been determined. The investigation of the graphitic clusters on the DLC films by high resolution scanning electron microscopy revealed nanotubelike structures, with diameters down to 7 nm and lengths up to several hundred nanometers (Fig. 32). Laser ablation and filtered cathodic arc deposition seem to be the methods of choice to deposit good emitting DLC films. Both methods are used in the production of nanotubes as well.

3.3. Carbon Nanotube Field Emitter

3.3.1. Work Function of Carbon Nanotubes

The investigations on the field emission properties of CVD diamond and DLC emitters show clearly that the electron emission of carbon based materials is ordinary Fowler–Nordheim tunneling and field enhancement structures on the surface are required for low field electron emission. Nanotubes (CNTs) have the ideal shape to act as field enhancing structures and they can be produced relatively simply in large quantities.

We have investigated the field emission properties of MWNTs and SWNTs. On thin films we measured emission site densities of 10,000 cm^{-2} at applied fields below
Figure 32. SEM pictures of graphitic structures present on good emitting DLC films.

5 V μm^{-1} [104, 114, 115]. Simultaneous field and photoemission electron spectroscopy (XPS) allowed us to compare the work function at the emission site with the average work function of the CNT films. In the case of the MWNTs we determined an emitter work function $\phi = 4.9 \pm 0.3$ eV by FES. By XPS we measured an average function of 4.8 ± 0.1 eV. In the case of SWNTs we determined a lower work function of 3.7 ± 0.3 eV by FES.

The reduced work function for SWNTs can be attributed to an electrostatic effect, due to the small radius of curvature of the SWNTs at their ends. One of the constituents to the work function is the work an electron has to perform against the image force. In the case of nanostructures, it is important to notice that the image potential for a plane and a small sphere (radius <10 nm) differs considerably. In the planar and the spherical case the image potential can be written as [116]

$$\varphi_{\text{plane}}(x) = -\frac{1}{4\pi\varepsilon_0}\frac{e^2}{4x} \tag{44}$$

$$\varphi_{\text{sphere}}(r) = -\frac{1}{4\pi\varepsilon_0}\frac{e^2 R^3}{2r^2(r^2 - R^2)} \qquad (r > R) \tag{45}$$

where R is the radius of the sphere. It can be easily seen that for $r/R = 1 + d$ $(d \ll 1)$ φ_{sphere} coincides with φ_{plane}

with $x = R \cdot d$. The difference in work function between the planar and the spherical case equals [117]

$$\phi_{\text{sphere}} = \phi_{\text{plane}} - \frac{5}{8R^{-1}} \frac{e^2}{4\pi\varepsilon_0} \qquad (46)$$

This effect was demonstrated by the observation that the ionization potential of small clusters depends on their size. An increase of the ionization potential with decreasing size was observed [118, 119]. According to (46) in SWNTs with diameter around 1.4 nm the work function is reduced by 1.3 eV. Compared to MWNTs with work function values around 5 eV SWNTs with 1.4 nm diameter would have work function values of 3.7 eV which corresponds well with the values we determined by FES.

3.3.2. Environmental Stability

The term environmental stability is used to describe the interaction of electron emitters with the gaseous environment in which they are operated. Such interactions typically lead to emission current fluctuations on a time scale of seconds to minutes. If the current fluctuations are large they may negatively affect the device performance. In addition the device long-term stability is dependent on the emitter interactions with its environment, wherefore investigations on environmental stability are important. Such investigations have been done in the past on etched metal tips using field emission microscopy. The field emission microscope (FEM) invented by Müller [120] in 1937 has for a long time been the state of the art to investigate adsorption and diffusion phenomena at surfaces with almost atomic resolution.

Figure 33 shows FEM patterns commonly observed from SWNTs and MWNTs. These emission patterns are not stable in time but show switching from one configuration to another. The switching frequency increases with increasing currents and is in the order of 1 Hz. Associated with this instability of the emission spot are fluctuations in the emission current as indicated by the different intensities of the emission patterns in Figure 33b. Each emission pattern has
a well defined emission current for a given applied voltage. Therefore the emission current fluctuates between different current levels associated to the different emission patterns. The difference between the highest and lowest current level can be up to a factor of 10. Such kind of random telegraphic noise was observed by different groups [46, 121, 122]. It is recognized that the FEM patterns on the screen reflect the electronic structure, the anisotropy of the work function, local variation of the microscopic field, and electron transmission probability of a CNT cap. This means that atomically sized areas on the CNT cap, where the work function is lower or the local electric field is higher than the surrounding regions, are reproduced with higher intensity on the phosphor screen. Therefore the different emission patterns of CNTs can be understood in terms of switching between differents states with relatively small energy differences in levels close to the Fermi energy. In order to illustrate how these states are formed and what they may look like one can take the π-states of a benzene molecule (C_6H_6) as an example (Fig. 34).

In analogy to the C_6H_6 molecule the π-states of CNT cap can be thought as linear combinations of p_x orbitals which protrude out perpendicular to the carbon lattice on the tube apex. The limited variety in shape, style, and energy of such π-states can only partly explain the large number of emission patterns observed by the FEM. It therefore seems plausible to think that the energy levels of the CNT at the apex are modified through adsorbed molecules coming from the gas phase during field emission. Sometimes the sticking is very firm and may result in a resonant tunneling state which can lead to increased tunneling probability and anisotropy in the field emission current [123]. We observed that the field emission fluctuations are not sensitive to H_2 and H_2O, the two the main components of residual gases in vacuum systems, up to 10^{-4} mbar gas pressure. Increased partial pressure of O_2 causes degradation of the field emission due to

reactive ion etching. The suggestion of Rinzler et al. [122] that the emission fluctuations are due to individual desorption processes induced by ion bombardment seems very convincing.

4. MICROSCOPIC CHARACTERIZATION OF THIN FILM EMITTERS

The development of field emission electron sources has been hampered for half a century by the fact that tiplike field enhancing structures are needed to create locally high fields for field electron emission to take place. Usually the higher the field enhancement, the smaller the effective emission area of the tips gets, as the radius of curvature gets increasingly small. Although the field emission current density can easily exceed 1000 A cm^{-2}, the total emission current per single tip remains small as the emitting surface, being the apex of the field enhancing tip, is small. The total current per single tip in field emission rarely surpasses 0.1 mA. In contrast, thermionic emitters can deliver electron emission currents of up to 400 A cm^{-2}. This situation resulted in the fact that field emitters are only used where high brightness rather than high currents are requested, for example, in the case of high resolution electron microscopy (SEM, TEM). The key to reaching planar field emitters of high current density approaching 1 A cm^{-2} resides in the integration of a large number of field enhancing tips on a surface.

4.1. Field Enhancement Distribution Function

Whereas a single field electron emitter can be said to be completely characterized in terms of its work function ϕ at the emission site, the field enhancement factor β, and the resistance R, the description of the overall emission behavior from a thin film emitter with a large number of emission sites requires a statistical approach [121]. The number of degrees of freedom with regard to geometrical alignment, orientation, length, diameter, and interemitter distances within the thin film emitter ensemble is much larger than for a single emitter. It can also be expected that ϕ and R exhibit some variation. Electrostatic screening has to be taken into account for thin film emitters, since the presence of a large number of emitters may affect the local electric field F at the emission sites. The emission properties can therefore vary considerably from one position to another within the thin film emitter.

An example of a thin film emitter with a large scatter in the spatial emission current $I(x, y)$ is shown in Figure 35a, where parts of the surface show no emission at all. The spatial scatter in the electron emission $I(x, y)$ is highly undesirable, because the device performance with regard to brightness homogeneity is largely reduced. In order to understand and improve the electron emission homogeneity of thin film emitters with a large number emitter sites a quantitative description of the $I(x, y)$ map in terms of field enhancement factor β, work function ϕ, emission area A, and resistance R is needed.

Thin film electron emitters are often characterized in terms of a "threshold" field F_{thr} required to obtain a given
Figure 35. (a) Variation of the emission current $I(x, y)$ under a constant applied voltage $U_0 = 320$ V (tip–cathode distance $d \sim 7$ μm). (b) Corresponding local variation of the field enhancement factor $\beta(x, y)$. Reprinted with permission from [121], L. O. Nilsson, Ph.D. Thesis No. 1337, University of Fribourg, Switzerland, 2001.

field emission current density in a typical large anode diode type field emission experiment. Such characterization can be misleading since a cathode with a spatial extension in the mm^2 range may contain a small number (sometimes only one) of strong emitters and thus can have a low threshold field F_{thr} which obviously will not guarantee a high emission current density, because the emitter ensemble shows a certain distribution of the field enhancement factor β and therefore in the emission current density. In this picture the field emission properties of a thin film must be represented by a function $f(\beta)$, where the number of emitters dN on a surface area A with field enhancement factors in the interval $[\beta, \beta + d\beta]$ is given by

$$dN(\beta) = A \cdot f(\beta) \cdot d\beta \tag{47}$$

The field enhancement distribution function $f(\beta)$ is then defined as

$$f(\beta) = \frac{1}{A} \frac{dN}{d\beta} \qquad [\text{emitter/cm}^2] \tag{48}$$

According to the definition, $f(\beta)$ is proportional to the probability of the field enhancing structures in the interval $[\beta, \beta + d\beta]$ per unit area. Consequently one may view $f(\beta)$ as a probability distribution. Assuming the same relation for the emission current as a function of the local field F at the emission site for all emitters of the thin film, the field emission properties are completely determined by the field emission distribution function $f(\beta)$.

In terms of the Fowler–Nordheim relation (16) the assumption of a general relation for the current–field dependence of the electron emission means that all emitters have the same emitting area and the same work function ϕ. The assumption that the work function ϕ is constant for all emitters can partially be justified by the fact that the emitters consist of the same material. Actually, we have found in FES that the work function at the emission site of carbon based materials is always in the range of 4.7–5.1 eV. The argument that the emission area should be constant can for CNTs is partially justified by the fact that all the emitters are of the same dimensions.

In order to describe the emission current as a function of the local field F the simplified Fowler–Nordheim relation

as proposed by Brodie and Spindt [3], where the elliptic functions are approximated, can be used

$$I = A \cdot \frac{1.5 \times 10^{-6}}{\phi} \cdot F^2 \exp\left(\frac{10.4}{\phi^{0.5}}\right) \exp\left(-6.44 \times 10^7 \frac{\phi^{1.5}}{F}\right) \tag{49}$$

I is the emission current in amperes per single emitter, A is the emission area of the emitter in cm^2, ϕ is the work function in eV, and F is the local electric field [V/cm] present at the emission site.

In a field emission device, the external electric field F_0 is generated by a voltage U_0 applied between the cathode with the emitting structures and an anode. In configurations where anode and cathode are represented by two parallel plates separated by a vacuum gap d the applied field is $F_0 = U_0/d$. The local field at the emission site is then defined as $F = F_0 \cdot \beta$. Relation (49) becomes

$$I = A \cdot \frac{1.5 \times 10^{-6}}{\phi} \cdot F_0^2 \cdot \beta^2 \exp\left(\frac{10.4}{\phi^{0.5}}\right)$$
$$\times \exp\left(-6.44 \times 10^7 \frac{\phi^{1.5}}{F_0 \cdot \beta}\right) \tag{50}$$

This is now the relation for the emission current I of a single emitter for a given applied field F_0 which depends only on the field enhancement factor β. The field emission behavior of an ensemble of field emitters is therefore completely determined by the field enhancement distribution function $f(\beta)$. Important parameters such as the threshold field F_{thr} and the emission site density can be immediately derived from the field enhancement distribution function $f(\beta)$. Using relation (50) for the emission current the threshold field F_{thr} can be determined from the following relation

$$I_{\text{thr}} = A \int_0^\infty f(\beta) \cdot I(\beta, F_{\text{thr}}) \, d\beta$$
$$= A \cdot \frac{1.5 \times 10^{-6}}{\phi} \exp\left(\frac{10.4}{\phi^{0.5}}\right) \cdot \int_0^\infty d\beta \cdot f(\beta) \cdot F_{\text{thr}}^2 \cdot \beta^2$$
$$\times \exp\left(-6.44 \cdot 10^7 \frac{\phi^{1.5}}{F_{\text{thr}} \cdot \beta}\right) \tag{51}$$

Here A denotes the surface of the cathode under investigation. It is worth noting that the threshold field F_{thr} will depend on the cathode area which is measured, so that it is only sensible to define the threshold field F_{thr} with regard to a given emission current density j_{thr}. In other words, the measured threshold field F_{thr} decreases with increasing surface area measured. The characterization of the emission properties of a thin film emitter just by stating the threshold field F_{thr} is therefore very questionable.

4.2. Emission Site Density

The emission site density (ESD), which gives the number of active emitters per unit area at a given applied field or voltage, is one of the key parameters in characterizing the field emission performance or quality of a planar field emission cathode. An active emitter is an emitter giving an emission

current larger than some threshold current (e.g., 10 nA). Therefore the ESD as function of the applied field F_0 can be calculated from $f(\beta)$ by

$$\text{ESD}(F_0) = \int_{\beta_{\min} = F_{\min}/F_0}^\infty f(\beta) \, d\beta \qquad [\text{cm}^{-2}] \tag{52}$$

$F_{\min}$ is the local field at the emission site required to produce a minimum detectable emission current $I_{\min}$. In an experimental setup using a phosphorous screen $I_{\min}$ corresponds to the minimum emission site current, required to observe the emission spot by eye.

The emission current density is calculated in a similar manner

$$j(F_0) = \int_0^\infty f(\beta) \cdot j(\beta, F_0) \, d\beta \qquad [\text{A cm}^{-2}] \tag{53}$$

Unfortunately in many publications the performance of planar field emission cathodes is still characterized by I–V measurements alone. Figure 36 displays the field emission spots on a phosphorous screen of two carbon thin film emitters at the same applied field and emitting roughly the same emission current density of about 0.1 mA cm^{-2}, so that from the I–V characteristic both thin film emitters would yield a comparable behavior and one would judge them to have the same field emission performance. It is, however, obvious that the ESD is considerably higher for sample B. Whereas on sample B the emission current originates from a relative high density of emission sites the emission current of sample A is delivered from only a few but quite strong emitters. Therefore the emission performance of sample B should be judged considerably higher than for sample A because emitter degradation will more easily occur on sample A at higher fields.

In conclusion, any standards of characterization of thin film electron emitters must include the field enhancement distribution function $f(\beta)$ and knowledge of the spatial emitting properties $\beta(x, y)$. With these two parameters the collective emitting behavior of thin film electron emitters is completely characterized.
Figure 36. Optical micrographs of field emission spots collected on a phosphorous screen of two different diamond thin film emitters at the same applied electric field of 4.5 V μm^{-1}.

4.3. Characterization by Scanning Anode Field Emission Microscopy

The scanning anode field emission microscope (SAFEM) allows the investigation of the field emission properties of thin film emitters with lateral resolution in the submicrometer range [124]. The SAFEM is based on a micrometer-sized tip which serves as an anode. By recording the emission as a function of the spatial position of the tip above the thin film emitter, field emission maps with submicrometer resolution can be obtained. Such maps can be extended up to $5000 \times 5000 \ \mu m^2$. The SAFEM can operate in two different modes. In the first mode the emission current is recorded for a constant applied voltage U_0. This mode is called the constant voltage mode (CVM). The $I(x, y)$ map obtained in the CVM is the analog to the electron emission on a phosphor screen, albeit with higher resolution. In the second mode of operation the emission current is maintained on a constant level for every tip position along the field emission scan and the voltage applied to the tip must therefore be adjusted according to the individual emitter efficiency. Since the spatially recorded emission voltage $V(x, y)$ is determined for a constant emission current this mode is called the constant current mode (CCM).

As shown in the previous section, the knowledge of the field enhancement distribution function $f(\beta)$ gives an almost complete characterization of field emission behavior of thin film emitters. Therefore the experimental characterization of thin film emitters should include the determination of $f(\beta)$. The field enhancement distribution function $f(\beta)$ can be obtained from the spatial distribution of field enhancement factors β, the so-called field enhancement map $\beta(x, y)$. In theory $\beta(x, y)$ can be calculated from the topography of the surface $h(x, y)$, for example, by solving the Poission equation at the surface. However, in general the Poission equation cannot be solved because it is extremely difficult to measure $h(x, y)$ with nanometer resolution. Therefore another method is used to derive $\beta(x, y)$. Through relation (50), the emission current I is directly related to field enhancement factor β; therefore the local emission current $I(x, y)$ on thin film emitter is given by

$$I(x, y) = A \cdot \frac{1.5 \times 10^{-6}}{\phi} \cdot F_0^2 \cdot (\beta(x, y))^2 \exp\left(\frac{10.4}{\phi^{0.5}}\right)$$
$$\times \exp\left(-6.44 \times 10^7 \frac{\phi^{1.5}}{F_0 \cdot \beta(x, y)}\right) \quad (54)$$

Hence, the measurement of $I(x, y)$ could theoretically be used to calculate $\beta(x, y)$.

Scanning anode field emission measurements operating in the CVM can be principally used to obtain spatially resolved emission current $I(x, y)$. Since the anode is located very close to the emitting surface, the surface topography and the local field enhancement cause the applied electric field to fluctuate several times from one site to another. Such variation in the applied electric field causes emission current fluctuations of many orders of magnitude into the regime of resistor limited emission and emitter degradation [125]. Since expression (54) is describes pure Fowler–Nordheim emission, field emission measurements (CVM) which may

go into the resistor limited emission regime cannot be used as the basis to calculate $\beta(x, y)$.

In order to derive $\beta(x, y)$ and avoid current saturation effects, not to say emitter destruction, the scanned electron emission measurement has to performed in the CCM. In the CCM the voltage applied to the anode varies as a function of the anode position over the thin film emitter, in order to maintain the same emission current for every point. If the current is reasonably low ($\sim$50 nA), one will obtain a spatially resolved field emission image of the extraction voltage $V(x, y)$, without current saturation effects or emitter destruction. This is both experimentally and conceptually beautiful since $V(x, y)$ is actually an inverted image of the field enhancement landscape $\beta(x, y)$ according to

$$\beta(x, y) = \frac{d \cdot F}{V(x, y)} \quad (55)$$

where d is the tip–sample distance and F is the local field at the emission site required for a fixed emission current I predicted by the Fowler–Nordheim relation (54) (see Fig. 37).

4.4. Carbon Nanotube Thin Film Emitters

As discussed, the key for reaching planar field emitters of high current density approaching 1 A cm^{-2} resides in the integration of a large number of field enhancing tips on a surface. Depending on the required emission current density, the density of the emitting tips has to be in the range of 10^6–10^8 cm^{-2}. This limits their size to micrometer or even submicrometer dimensions. CNTs have proven to be ideally suited to serve as field enhancing structures for field emission applications due to their exceptionally high aspect ration with lengths in the micrometer range and diameters ultimately down to one nanometer. Furthermore, they can be readily produced in large numbers by relatively simple and cost effective techniques. One has to acknowledge that when it comes down to creating free electrons in vacuum the method most widely employed to produce these electrons is thermionic emission. The advantage of thermionic electron
Figure 37. SAFEM measurement from a CNT thin film in the CCM. Extraction voltage map $V(x, y)$ for 10 nA emission recorded with an tip–cathode distance of 7 μm.

sources is their simple operation. However, thermionic electron sources have some major drawbacks. They are power controlled, via the temperature, and therefore direct modulation of the emission is rather slow. Further, due to operation at high temperatures (~2000 K) the realization of micrometer sized emitters is practically impossible due to insufficient heat dissipation. Micro- and nanosized field electron emitters hold the possibility of miniaturizing vacuum electronic devices. In this context CNT thin film emitters offer an attractive possibility to produce the key component of an electron source, namely the field emitting tip, in large numbers using inexpensive processes.

In CNT thin films as they are produced by CVD over supported catalysts the growth yields to nanotubes with rather ill defined diameter, length, orientation, and spatial distribution. All these properties, however, influence the field enhancement and therefore the field emission properties. The field enhancement of a metallic needle shaped structure perpendicular in a homogeneous electric field is in first approximation h/r. From this it is clear that the length, diameter, and orientation of the CNT with respect to the electric field will immediately influence the field enhancement. In addition, the tube density will influence the field enhancement due to electrostatic shielding [126]. As discussed in the previous section, the ensemble of field emitters represented by a CNT thin film is therefore difficult to be characterized a single parameter such as threshold electric field F_{thr} to obtain a given field emission current density. Because the CNT emitter ensemble shows a certain distribution in the field enhancement the emission properties have to be described statistically by the field enhancement function $f(\beta)$ according definition (48). It was shown that under the assumption that all emitters have the same work function ϕ, the local emission current $I(x, y)$ on thin film emitter can be written as

$$I(x, y) = A \cdot \frac{1.5 \times 10^{-6}}{\phi} \cdot F_0^2 \cdot (\beta(x, y))^2 \exp\left(\frac{10.4}{\phi^{0.5}}\right)$$
$$\times \exp\left(-6.44 \times 10^7 \frac{\phi^{1.5}}{F_0 \cdot \beta(x, y)}\right)$$

In order to account for experimental observed emission currents and field emission spectra of MWNTs, $A = 10^{-9}$ cm^2 is a reasonable value for the emission area of a MWNT. This value might seem too large for a MWNT with a typical diameter of 30 nm. Yet one has to consider that though the pre-exponential factor A_v [see (27)] has the dimension of a surface, it not only takes account of the emitting area but also depends on the band structure of the emitter. Assuming a mean value of 4.9 eV for the work function and using the emission area A mentioned previously the emission current I for a MWNT is given by

$$I(x, y) = 3.36 \times 10^{-14} \cdot F_0^2 \cdot (\beta(x, y))^2 \exp\left(-\frac{6.99 \times 10^8}{F_0 \cdot \beta(x, y)}\right) \tag{56}$$

and the threshold field F_{thr} for a MWNT thin film emitter can be determined from the following relation according to

relation (51)

$$I_{thr} = A \int_0^\infty f(\beta) \cdot I(\beta, F_{thr}) \, d\beta$$
$$= A \int_0^\infty d\beta \cdot f(\beta) \cdot 3.36$$
$$\times 10^{-14} \cdot F_{thr}^2 \cdot \beta^2 \exp\left(-\frac{6.99 \times 10^8}{F_{thr} \cdot \beta}\right) \tag{57}$$

A calculated $\beta(x, y)$ landscape compiled from a extraction voltage map $V(x, y)$ is presented in Figure 38a. By counting the field enhancement values ΔN in the interval $[\beta, \beta + d\beta]$ one can get a histogram with the distribution of the field enhancement factors β, as shown in Figure 38b. It is worth noting that the amplitude of the histogram is, however, dependent on the choice of the bin with $d\beta$. The normalized distribution $dN/d\beta$ equals the scanned area A times a functional dependence $f(\beta)$. At first glance the shape of the normalized distribution $dN/d\beta \propto f(\beta)$ appears to be asymmetric with a maximum located at the β value of 50. This apparent asymmetric behavior is, however, due to a measurement artifact. β values below 50 are "screened" due to neighboring field emitters with large β values. The probability to detect field emitters is thus a monotonic increasing function of β according to

$$A_E \propto \left(1 - A_0 \int_\beta^\infty f(\beta) \, d\beta\right) \to 1 \qquad \text{when } \beta \to \infty \tag{58}$$

The integral can be understood as the area A_E occupied by emitters with field enhancement factors larger than β. The effective β distribution $\phi(\beta) = A_E(\beta)f(\beta)$, as calculated from the true β distribution $f(\beta)$, can be fitted to the experimental values as shown in Figure 38b. It can be shown that $f(\beta)$ can be fitted to experimental data over five orders of magnitudes using scanning and integral (screen) field emission measuring techniques according to

$$f(\beta) = k_1 \exp(-k_2 \beta) \tag{59}$$

where k_1 is the measured macroscopic emission site density and k_2 is connected with the structural order/disorder of the field enhancing structures. By changing k_1, k_2 the field emission properties of any surface can thus be tuned. Engineering technological relevant field emission cathodes is
Figure 38. (a) Field enhancement $\beta(x, y)$ landscape calculated from an extraction voltage map $V(x, y)$ which is an analog of the one presented in Figure 37. (b) Histogram of the field enhancement factors β in (a).

thus the story of how to change/manipulate the fundamental relation (59).

The question as to what a technologically relevant and useful ESD for a CNT thin film emitter will be has to be answered in view of the application the emitter should be used in and of course in view of the competing technologies. Comparison with silicon or metal microtip arrays indicates that an ESD of the order of 10^6 up to 10^8 cm^{-2} at applied electric fields below 50 V μm^{-1} should be aimed at. The characterization of EDSs above 10^4 cm^{-2} using a phosphorous screen setup is challenging due to the overlap of the emission spots. As in the phosphorous screen the anode–cathode distance gives the resolution of the SAFEM. Figure 39 displays three field enhancement maps of the same region of a randomly oriented MWNT thin film at different tip–sample distances evidencing the increasing resolution with decreasing tip–sample distance. As can be seen in Figure 39c a resolution is given in first approximation as twice the tip–sample distance. This means that in order to resolve 10^7 emitters per cm^2 the tip–sample distance should be of the order of 2–3 μm. Such a tip–sample distance is of the same order as the typical height of the CNTs and therefore is about the limit of what can be achieved.

Figure 40 displays a high resolution field enhancement map derived from a SAFEM voltage map $V(x, y)$ recorded at a tip–sample distance of 2–3 μm on a randomly oriented CNT thin film. The black diamond dots indicate the position of emission sites with field enhancement factors larger than 130. On the investigated area of 2.4×10^{-5} cm^{-2} 164 such emitters could be detected resulting in an ESD of 6.8×10^6 cm^{-2}. The field enhancement was determined under the assumption that the local field present at the CNT apex is 3800 V μm^{-1} in order to emit 11 nA, which is the current at which the SAFEM $V(x, y)$ map was recorded. A field enhancement factor larger than 130 therefore means that the applied field is lower than 30 V μm^{-1}. This measure-
Figure 40. High resolution SAFEM field enhancement map $\beta(x, y)$ of a randomly oriented CNT thin film recorded at 11 nA emission current and a tip–sample distance of $\sim$3 μm.

ment demonstrates that relatively crude, as-deposited CNT thin films exhibit already the potential to achieve technologically relevant ESDs at moderate applied fields. However, it is important to point out that the high ESD indicated of a few million per cm^{-2} is to a certain extent academic as it cannot be exploited on large cathode surfaces. The reason for this is the large spread in the field enhancement factor β the individual emitters exhibit. For the randomly oriented CNT thin films we discuss here the field enhancement distribution $f(\beta)$ follows an exponential law as described in (57). This kind of field enhancement results in the situation that on a large cathode area (e.g., 1 cm^{-2}) there are a few very strong emitters of very high field enhancement ($\sim$1500) resulting in a threshold field of 1–2 V μm^{-1}. However the ESD is very low, only 1–10 cm^{-2}. Upon an increase in the applied field the ESD increases rapidly, but at the same time the emission current from the first few emitters increases exponentially. With further increase of the applied field the point is reached where the emission current of the first strong emitters is so large that they get destroyed. From this point the ESD hardly increases anymore as a situation is reached where the appearance of a new emitter is balanced by the disappearance of old strong emitters upon increase of the applied field. For as-deposited MWNT thin film emitters this point is reached typically at about 10 V μm^{-1} with an ESD of $\sim$10,000 cm^{-2} and an emission current density of $\sim$10 mA cm^{-2} over the whole thin film emitter. It is clear that under such circumstances the cathode suffers irreversible degradation and that the operation of a cathode in such conditions is highly critical from the point of view of stability and lifetime. The values for the field, the ESD, and the emission current density given are not of a general nature as they depend on numerous parameters. However, it is important to notice that the emitter degradation at low applied fields is the limiting factor for the performance of such cathodes. In order to enhance the field emission performance of such cathodes a detailed understanding of the degradation of the degradation mechanism and subsequently the improvement of the degradation behavior is required.

Figure 41 shows the SAFEM field enhancement map $\beta(x, y)$ of a randomly oriented MWNT thin film emitter, with regions which have suffered high emission current degradation previously. The region from $x = 0$ μm to $x = 55$ μm has been strained with 1.5 μA and the region from

Figure 39. SAFEM field enhancement maps recorded at 11 nA emission current of the same region of a randomly oriented CNT thin film emitter with different tip–sample distances ($d = 33, 13, 7$ μm).
Figure 41. SAFEM field enhancement map $\beta(x, y)$ of a randomly oriented MWNT thin film with two high emission current strained regions on the left hand side. Region I ($0 < x < 55$ μm) has been strained previously with 1.5 μA and region II ($55 < x < 110$ μm) with 2 μA.

$x = 55$ μm to $x = 110$ μm has been strained with 2 μA emission current by the SAFEM. The region $x > 110$ μm has not been current strained. After current straining a field enhancement map $\beta(x, y)$ was recorded at 11 nA and a tip–sample distance of 4–5 μm. One can observe that in the current strained regions the emitters with a high field enhancement factor β have been removed, whereas they are still present in the unstrained region. The values at which the current degradation occurs can vary from 500 nA up to a few μA, which is more than 100 times lower than for a single CNT welded on a metal tip. I–V measurements on two point contacted CNTs have shown that straight and probably defect-free CNTs, repeatably can conduct currents up to 3 mA ballistically without heat dissipation [127, 128].

The emitters which are then left over with a lower field enhancement factor β are typically very stable and robust, which means that they can sustain emission currents well above 1 μA even up to 100 μA for short periods of time. A closer inspection of the regions strained by 1.5 and 2 μA shows that the average field enhancement is higher in the region strained with the lower current. This behavior indicates that the high current degradation is linked to the enhancement, where the critical current for degradation decreases with increasing field enhancement and therefore increasing aspect ratio.

Figure 42 illustrates the degradation of a single emitter as opposed to the collective current degradation behavior displayed in Figure 41. Figure 42a and b shows field enhancement maps $\beta(x, y)$ (@ 11 nA emission current) before and after the central emitter has been subjected to high current degradation. The I–V characteristic displayed in Figure 42c shows that the irreversible degradation occurs abruptly at an applied voltage of 290 V, which corresponds to an applied electric field of 14.5 V μm^{-1}, and at a current level of 2.2 μA. The degradation manifests itself by a current drop of almost three orders of magnitude. As can be evaluated from the field enhancement maps the value of the field enhancement at this position has decreased from 630 to 250. It has to be pointed out that most probably the
Figure 42. Single emitter high current degradation measured on a MWNT cathode. The field enhancement maps (a) and (b) show the reduction in the field enhancement factor for the emitter indicated by the arrow (a) before and (b) after the degradation event. In the maps white corresponds to high and black to low field enhancement. Diagram (c) displays the I–V characteristic of the degradation where the crosses indicate the experimental data, the black solid line the theoretical Fowler–Nordheim behavior, and the gray solid line the resistor limited I–V behavior. The schematic drawings (d) and (e) represent emitter degradation due to large power dissipation due to either high intratube resistance or high contact resistance.

emission after degradation does not originate from the same CNT as before but from a tube nearby, which was concealed by the original emitter.

The black curve in Figure 42c indicates the theoretical Fowler–Nordheim emission behavior. One can observe that in the low current regime the measured I–V characteristic is well described by the Fowler–Nordheim law. However, above 100 nA emission current a pronounced deviation from the Fowler–Nordheim behavior can be observed. This current saturation continues to a voltage of about 290 V and an emission current of 2.2 μA, where a sudden and irreversible decrease of the emission current to a value of 7 nA occurs. The emission behavior in the non-Fowler–Nordheim regime can be modeled using a resistor limitation approach, where it is assumed that there is a voltage drop between the emission site (being the CNT apex) and the electron reservoir (being the electrical contact of the CNT on the substrate). This results in the situation that the full applied voltage does not generate the extraction field F for the electron emission, but this voltage is reduced by the product of the emission current and the resistance in the current path. Assuming an ohmic resistor the high voltage behavior in Figure 42c can

be modeled reasonably well with the following relation:

$$I = C_1 \cdot (V - \Delta V)^2 \exp\left(-\frac{C_2}{V - \Delta V}\right)$$

$$= C_1 \cdot (V - R \cdot I)^2 \exp\left(-\frac{C_2}{V - R \cdot I}\right) \qquad (60)$$

C_1 and C_2 are positive constants in Eq. (60) which is equivalent to the Fowler–Nordheim relation (16) taking into account the proportionality between the voltage and the field. Relation (60) is of course recursive and has to be evaluated numerically. From the emission current and the voltage drop one can estimate the amount of power dissipated in the resistor. In principle the voltage drop could be determined from the model; it has to be stressed, however, that in order to do so the influence of the voltage drop on the local field at the apex of the tube should be known. This in turn requires information on the exact location of the voltage drop in the current path and the amount of electrostatic shielding the emitter experiences. Both are generally unknown. The draws in Figure 42d and e illustrate the possible origins of the voltage drop due to either a high internal resistance in the CNT (e.g., due to defects) or a high contact resistance. It can be estimated that the voltage drop in the saturation regime has to be of the order of 10 V at 2 μA emission current which gives a power of 20 μW dissipated. Taking into account the very small volume of the contact $V_c \cong (d_{tube})^3 \approx 5 \times 10^{-17}$ cm^{-3} one estimates a power density in the range of 10^{12} W/cm^3 dissipated in the contact. This can easily explain the emission degradation and the observed local substrate melting due to high emission currents [125].

From this consideration it becomes obvious that the operating the emitter in the current saturation regime is always risky as the current saturation is a sign of power dissipation and therefore of possible degradation. From the I–V curve in Figure 42c it becomes apparent that the voltage window where the emitter can be operated usefully with an emission current between 10 nA and 2 μA is rather small. This finding can be related generally to CNT emitters by realizing that the window of operation for an emitter corresponds to about twice the threshold field. Together with the large spread in the field enhancement distribution function $f(\beta)$, this leads to the limitation in the emission performance of randomly oriented CNT thin film emitters. The threshold field of macroscopic CNT thin film emitters of 1 cm^2 area is generally around 2 V μm^{-1}. SAFEM investigations, however, show that an interesting ESD of the order of 10^6 cm^{-2} is reached only for applied fields higher than 25 V μm^{-1}. According to the previous consideration emitter degradation has to be expected for applied fields around 5 V μm^{-1}. It is therefore not possible to reach that required for the high ESD without very severe emitter degradation.

4.5. Optimal Structure for Carbon Nanotube Based Electron Field Emitters

As shown in the previous sections the field emission properties of a thin film emitter can be fully characterized by the field enhancement distribution function $f(\beta)$, which depends on the geometry of the emitting structure and the

electrostatic shielding between the emitting structures. To quantify the negative influence of electrostatic shielding on the emission properties we have carried out computer simulations, calculating the field emission current density for CNT arrays of tube different densities. Figure 43 illustrates the effect of the electrostatic shielding in CNT films with different tube densities. A quantitative analysis of the computer simulation shows that optimum field emission properties for a CNT film can be expected, if the mean distance between the tubes is about twice their height. The simulations show further that the field enhancement factor β of the tubes in a film shows a wide distribution, as it is influenced by the orientation of the tube with respect to the applied electric field and by the degree of electrostatic shielding a tube receives from its neighboring tubes. In real CNT films the differences of length and diameter of the individual tubes will further contribute to the distribution of the field enhancement factor β among the CNTs. This distribution gives rise to inhomogeneous field emission properties of CNT thin film emitters. The simulations shown demonstrate clearly why a homogenous emitting CNT film must be formed by identically ordered CNTs. The ideal case of such a CNT film is displayed in Figure 44, where all tubes have the same length, diameter, orientation, and distance from each other. As shown in Section 1.5.3, it is possible to grow films with well-oriented CNTs. The problem of all these films for field emission is that the spacing between the individual tubes is not large enough to prevent electrostatic shielding. It is a big challenge for the nanotechnology to develop processes required for the deposition of CNT films, optimal for field emission. In the case of a flat panel display a CNT based field emission technology will ultimately need to fulfill the following requirements to be competitive with the current metal tip technology:

- growth of individual CNTs at well-defined positions, tolerance ~100 nm
- growth of individual CNTs with well-defined orientation
- growth of individual CNTs with a well-defined aspect ration ($\beta = h/r$), tolerance $d\beta/\beta \sim 5\%$
Figure 43. Two-dimensional simulation of the electrostatic potential in films with random distributed and oriented CNTs and different tube densities. (All tubes have the same length and diameter.)
Figure 44. Two-dimensional simulation of the electrostatic potential in an ordered CNT array.

- massively parallel processing (10^8 tubes per cm^2)
- large area deposition ($\sim$m^2)
- low cost processes

5. CONCLUSIONS

Significant progress in the understanding of the electron emission has been achieved since the first reports on the low threshold field electron emission from carbon thin film emitters in the early 1990s. It seems certain that the low threshold field electron emission from carbon thin film electron emitters can be accurately described by Fowler–Nordheim tunneling. Fowler–Nordheim tunneling requires high electric fields in the order of 3000 V/μm generated by field enhancing structures.

Contrary to a single emitter, the emission properties of a thin film emitter require a statistical treatment, since the field enhancing structures exhibit a distribution with regard to the filed enhancement β. Therefore the electron emission properties of thin film emitter with an ensemble of field enhancement structures have be characterized in terms of the spatial field enhancement, the field enhancement map $\beta(x, y)$. The variation in β for different field enhancement structures leads to a β distribution, the field enhancement distribution function $f(\beta)$, which can be seen as a probability function of the field enhancing structures. The field enhancement distribution function $f(\beta)$ can be said to give an almost complete characterization of the field emission properties, contrary to the threshold field F_{th}, of thin film emitters. The field enhancement distribution function $f(\beta)$ has been shown to be exponential for randomly oriented CNT thin films. In order to obtain a field emission device with uniform brightness and high emission site density from thin films, stringent requirements must be placed on the permitted spatial variation of the emitting sites and therefore the variation of the field enhancement β. Homogeneous electron emission from an ensemble of field emitting structures, defined as $dI/I < 50$, requires a relative variation of the field enhancement $d\beta/\beta$ smaller than 4%. Therefore it is desirable to optimize the density of sites close to the highest field enhancement of the ensemble to the limit of electrostatic screening effect. The example of CNT based field electron emission technology demonstrates clearly the difficult path from *nanoscience* to *nanotechnology*. The development of devices based on nanostructures needs, in addition to the process technology, characterization methods and knowledge which cover all aspects, from the fundamental physical phenomena of the individual nanostructure up to the integral behavior of the large number of nanostructures forming the macroscopic device.

GLOSSARY

Carbon nanotube (CNT) A carbon allotrope consisting of rolled-up graphene sheets.

Emission site density (ESD) The number of emitters per unit area, which delivers for a given applied electric field an emission current larger than a given threshold current.

Field emission spectroscopy (FES) Measurement of the energy distribution of the field emitted electrons.

Scanning anode field emission microscope (SAFEM) A scanning probe microscope working with a micrometer-sized tip scanned at constant distance over the cathode surface and with applied fields high enough for field electron emission.

Carbon Nanotube Growth by Chemical Vapor Deposition

M. Meyyappan

NASA Ames Research Center, Moffett Field, California, USA

CONTENTS

1. INTRODUCTION

The interest in carbon nanotubes (CNTs) and the level of research activities across the world have been extraordinary in the last decade. CNTs were first discovered by Sumio Iijima of the NEC Corporation in 1991 [1] in the soot of an arc-discharge apparatus. These are elongated fullerenes with diameters as small as 0.7 nm and lengths of up to several microns. Single-walled carbon nanotubes (SWNTs) exhibit unique electronic properties in that they can be metallic or semiconducting, depending on their helicity. This allows the formation of semiconductor–semiconductor and semiconductor–metal junctions useful in device fabrication. SWNTs also possess extraordinary mechanical properties. The Young's modulus of individual SWNTs has been estimated to be around 1 TPa, and the yield strength can be as large as 120 GPa [2].

The interesting combination of electronic and mechanical properties of CNTs has led to wide-ranging investigations of their potential in future electronics and computing, field-emitter devices, sensors, electrodes, high-strength composites, and storage of hydrogen, lithium, and other metals. For a detailed discussion on the properties and applications, the reader is referred to several volumes edited by Saito et al. [2], Meyyappan and Srivastava [3], and other review articles [4]. This chapter focuses on CNT growth and large-scale production by chemical vapor deposition (CVD) and related techniques such as plasma-enhanced CVD (PECVD). The early processes used for CNT production were laser ablation and an arc-discharge approach. Both are able to produce single- and multiwalled nanotubes, and continue to be popular among researchers. Details on these processes can be found in [4–6]. CVD is amenable for nanotube growth on patterned surfaces, suitable for the fabrication of electronic devices, sensors, field emitters, and other applications where controlled growth over masked areas is needed for further processing.

A variety of different CNT structures is possible by CVD and related techniques. A SWNT is a rolled-up tubular shell of graphene sheet which is composed of benzene-type hexagonal rings of carbon atoms. A multiwalled carbon nanotube (MWNT) is a rolled-up stack of graphene sheets into concentric cylinders. The walls of each layer of the MWNT or the graphite basal planes are parallel to the central axis ($\theta = 0$). In contrast, a stacked-cone arrangement (also known as a Chevron structure, ice-cream-cone structure, or piled-cone structure) is also seen, where the angle between the graphite basal planes and the tube axis is nonzero [7]. Nolan et al. [7] suggest that hydrogen satisfies the valences at cone edges in such structures. (An MWNT has no graphite edges, and therefore there is no need for valence-satisfying species such as hydrogen.) Since the stacked-cone structures exhibit only small θ values, and are not solid cylinders but are mostly hollow, they can be called multiwalled carbon nanofibers (MWNFs) [8]. Note that the terminologies graphitic carbon fibers (GCFs) and vapor-grown carbon fibers (VGCFs) have long been used to denote solid cylinders.

The CNT growth literature has grown rapidly in recent years. A reasonably complete (but not exhaustive) list of references in areas discussed in this chapter is given below:

- early works on carbon fibers/filaments [9–15]
- thermal CVD of SWNTs [16–27, 59]
- thermal CVD of MWNTs [7, 28–55]
- CNT growth on atomic force microscope (AFM) cantilevers [56–59]
- electric-field assistance in thermal CVD [60–62]
- floating catalyst CVD of SWNTs [63–69] and MWNTs [70, 71]

- PECVD of MWNTs and MWNFs [8, 59, 72–92]
    - — dc plasma [83–85, 87–91]
    - — plasma-assisted hot filament [72, 73, 75]
    - — microwave plasma [74, 76–82]
    - — RF capacitive and inductive [8, 59, 86, 92]
- theoretical analysis of CNT growth [93–95]
- computational model and simulation of CNT growth [96–98].

This chapter is organized as follows: Section 2 presents an overview of the growth apparatus used in thermal CVD and PECVD; catalyst preparation techniques are outlined in Section 3; growth results from thermal CVD of SWNTs and MWNTs, the effect of the electric field on alignment, and plasma-grown nanotubes are presented in Section 4. Growth mechanism is the subject of Section 5, and a brief overview of applications for the thermal CVD- and PECVD-grown material is presented in Section 6.

2. GROWTH APPARATUS

As markets for CNTs are not developed, there is no commercial equipment industry now, unlike the case with the semiconductor equipment industry. So, the equipment is mostly homemade, low-throughput batch reactors. When the market changes to large-scale product-oriented (devices, sensors, nanoelectromechanical systems, etc.) from the current academic-research-dominated scenerio, the worldwide equipment vendors (currently catering to the semiconductor and MEMs market) will undoubtedly move in to meet the demands since the growth hardware is very much similar, as will be seen below.

2.1. Thermal CVD

The thermal CVD apparatus for CNT growth is very simple [18, 24, 59]. It consists of a quartz tube (diameter of 1–2 in) inserted into a tubular furnace capable of maintaining $\pm 1\,°C$ over a 25 cm zone. Thus, it is a hot-wall system, and primarily atmospheric pressure CVD. Cold-wall reactors, common in the semiconductor industry, where the substrate holder is directly heated from below (resistance, inductance, or other heaters), have not been reported in the literature. Since the growth is catalyst promoted at temperatures of 500–1000 °C and does not depend on precursor dissociation at these temperatures, either a hot- or a cold-wall system could be designed to be effective for CNT growth. The substrate, typically about or smaller than 1 in now, is placed inside the quartz tube. In thermal CVD, either CO or some hydrocarbon such as methane, ethane, ethylene, acetylene, or other higher hydrocarbons is used without any dilution. The feedstock is metered through a mass flow controller. A typical growth run would involve purging the reactor first with argon or some other inert gas until the reactor reaches the desired growth temperature. Then the gas flow is switched to the feedstock for the specified growth period. At the end, the gas flow is switched back to the inert gas while the reactor cools down to 300 °C or lower before exposing the nanotubes to air. Exposure to air at elevated temperatures can cause damage to the CNTs.

Typical growth rates range from a few nm/min to 2–5 μm/min. CNT growth is largely empirical at present, and

diagnostics and modeling studies are rare. For example, the effects of reactor length and diameter, flow rate, and so on, on growth characteristics are completely unknown. One study using a mass spectrometer [99] and another involving a computational fluid dynamics modeling [98] confirm that the precursor dissociation (in the case of methane at 900 °C) indeed is very small, and the growth proceeds due to the catalytic activity of methane on particle surfaces.

For growth on substrates, the catalyst mixture needs to be applied to the substrate (see Section 3) prior to loading it inside the reactor. This is the so-called supported catalyst approach. In contrast, CVD can also be used to grow large quantities of nanotubes using a "floating-catalyst" approach [63–71]. In this case, a nozzle system [64, 65] may be used to inject the vaporized catalyst precursor into the flowing CO or hydrocarbon. A second furnace may be required to heat up the catalyst precursor system to its dissociation temperature [63, 70]. The floating-catalyst approach is amenable to scale up for large-scale production to meet the "commodity market" demands of nanotubes in a variety of structural applications.

2.2. PECVD

The plasma enhancement in CVD first emerged in microelectronics because certain processes cannot tolerate the high wafer temperatures of the thermal CVD. For example, charring of photoresists on patterned wafers could be a problem. The plasma CVD allowed an alternative at substantially lower wafer temperatures (room temperature to 100 °C), and hence, has become a key step in integrated-circuit manufacturing. The low-temperature operation is possible since the precursor dissociation (necessary for the deposition of all common semiconductor, metallic, and insulating films) is enabled by the high-energy electrons in an otherwise cold plasma. In contrast to this familiar scenerio, CNT growth does not need precursor dissociation, and as such, the well-known efficiency of a plasma to tear apart the precursor gas for reactive radical generation should not be a factor. What is known to date about the catalytic activity of the transition metal particles for CNT growth tells us that growth does not occur below 550 °C. Hence, the cold wafer scenario is out of the question, at least for now, until new knowledge emerges. It is not clear, then, what the true role of the plasma in CNT growth is, despite a large number of articles in this field [8, 59, 72–92]. However, there is enough empirical evidence that the cold plasma enables more vertically aligned CNTs than thermal CVD [59, 75, 81, 85, 92]. Whereas any marginal alignment seen in thermal CVD samples is due to a crowding effect (nanotubes supporting each other by van der Waals attraction), individual, free-standing, and vertically oriented CNTs are possible with PECVD, as will be seen in Section 4.

As in the case of earlier technology waves such as microelectronics materials and diamond deposition, researchers have attempted dc [83–85, 87–91], RF [86], hot-filament aided with dc [72, 73, 75], microwave [74, 76–82], electron cyclotron resonance, and inductively coupled plasma reactors [8, 59, 92]. An overview of plasma fundamentals and plasma equipment can be found in [100, 101]. A dc plasma reactor consists of a pair of electrodes in a grounded chamber, with one electrode grounded and the second connected

to a power supply. The negative dc bias applied to the cathode leads to a breakdown of the feedgas. The wafer with the catalyst layer may be placed either on the anode or cathode for CNT deposition. The electrode holding the wafer may need an independent heating source to raise the wafer temperature to the desired growth temperature. Instead of a resistive heater underneath the electrode, a tungsten wire suspended in the plasma stream may serve as the heating source. This is the so-called hot-filament system with plasma assistance. These two systems have successfully yielded MWNTs and MWNFs, as evidenced from [72, 73, 75, 83–85, 87–91]. However, the bias on the wafer in these systems appears to be very high (>300 V). It is well known that ions gain substantial energy in the sheath from high electric fields, and the high-energy ion bombardment of the wafer often leads to damage, which is well known from silicon and III–V semiconductor literature. It is for this reason and the poor efficiency of the dc systems that the semiconductor industry abandoned these sources a few decades ago.

Since the plasma can dissociate the hydrocarbon, creating many reactive radicals, pure hydrocarbon feedstock in plasma reactors may lead to substantial amorphous carbon deposition. Therefore, it is desirable to dilute the hydrocarbon with argon [8], hydrogen [8, 59], or ammonia [75, 81]. The pressure in the reactor typically ranges from 1–20 torr, with a hydrocarbon fraction of up to 20%. Atmospheric pressure operation of plasma systems is uncommon due to power coupling problems. Low-pressure operation in the tens of millitorrs would result in very slow growth rates. So, PECVD reactors are typically operated at 1–20 torr pressure levels for CNT growth. At these pressure levels, inductive coupling to hydrocarbon/H_2 systems appears to be difficult; the coupling appears to have a large capacitive component [8, 92]. The capacitive component decreases with an increasing fraction of argon. Microwave sources are very popular at these pressures and power levels of up to 2 KW, and have been widely used for diamond deposition. Following this success, CNT literature also consists of several successful demonstrations of MWNT growth using microwave sources [79–82].

In addition to the source, matching network, and other power-coupling components, the equipment consists of mass flow controllers and one or more vacuum pumps. The growth chamber itself is grounded. All plasma reactors are cold-wall systems, with the substrate directly heated using some form of heat source from below the substrate holder. First, the wafer is loaded in the reactor, and the system is pumped down to 10^{-5} torr or below to minimize impurities and water vapor. The substrate holder is heated to the desired temperature. Then the feedstock is admitted, and the flow rate and chamber pressure can be set to desired levels independent of each other with the aid of a throttle valve. Next, the power from the power source is coupled to the plasma. At the end of the run, the heater, power source, and gas flow are turned off, and the system is purged with argon flow. The wafer is removed after the reactor cools down below 300 °C.

3. CATALYST PREPARATION

Although there have been some studies reporting CNT growth without catalysts in arc discharge processes, it is widely acknowledged that transition metal catalysts are needed for SWNT, MWNT, and MWNF growth by CVD. It is also believed that the catalyst on the substrate must be in the form of particles instead of smooth, continuous films. There have been several studies indeed correlating the catalyst particle size and the diameter of the resulting nanotubes [26, 41, 53, 55, 79, 86, 88, 102]. The metals used to date as catalysts include Fe, Ni, Co, and Mo. It is possible to apply these onto the substrate from solutions containing them or they can be directly deposited using some physical techniques. These two approaches are different in terms of needed resources, time and cost, and the nature of the resulting products. A brief overview is provided on the two routes to supported-catalyst preparation, and also the floating-catalyst approach for large-scale production.

3.1. Solution-Based Catalyst Preparation

The literature contains numerous recipes for preparing catalysts from solutions, and one such recipe is given below [44]. First, 0.5 g (0.09 mmol) of Pluronic P-123 triblock copolymer is dissolved in 15 cm³ of a 2:1 mixture of ethanol and methanol. Next, $SiCl_4$ (0.85 cm³, 7.5 mmol) is slowly added using a syringe into the triblock copolymer/alcohol solution, and stirred for 30 min at room temperature. Stock solutions of $AlCl_3 \cdot 6H_2O$, $CoCl_2 \cdot 6H_2O$, and $Fe(NO_3)_3 \cdot 6H_2O$ are prepared at the concentration of the structure directing agent (SDA) and inorganic salts. The catalyst solutions are filtered through 0.45 μm polytetrafluoroethylene membranes before applying onto the substrate. The substrate with the catalyst formulation is loaded into a furnace, and heated at 700 °C for 4 h in air to render the catalyst active by the decomposition of the inorganic salts and removal of the SDA. Admission of hydrocarbon feedstock into the reactor at this point would initiate nanotube growth.

It is noted that a mixture of transition-metal-containing compounds along with structure-directing agents is used in the above recipe. It is difficult to find optimum concentrations of each constituent in a trial-and-error approach as the number of trials is large. Cassell and coauthors pioneered a combinatorial optimization process for catalyst discovery for the growth of SWNTs [25] and MWNTs [44]. This rapid throughput approach, coupled with characterization techniques, allows the development of catalyst libraries with a minimal number of growth experiments.

In general, even with the right formulation known *a priori*, solution-based approaches are time consuming. A typical preparation includes such steps as dissolution, stirring, precipitation, refluxing, separation, cooling, gel formation, reduction, drying/annealing/calcinations, and so on. The overall process is cumbersome and time consuming; some recipes even call for overnight annealing. Another problem is the difficulty in confining the catalyst within small patterns.

3.2. Physical Techniques for Catalyst Preparation

Physical techniques, such as electron gun evaporation [83–85, 102], thermal evaporation [88], pulsed laser deposition [46], ion beam sputtering [8, 24, 55, 59, 92], and magnetron sputtering [75, 78, 79, 86, 91], have been successfully used in catalyst preparation. These techniques are quick, easy, and amenable to produce small patterns, in contrast to the solution-based approaches discussed in the previous section. Typically, a thin catalyst film (<20 nm) is applied by these techniques. The eventual particle size and the resultant nanotube diameter seem to correlate to film thickness. Thinner films in general lead to smaller particles and tube diameters [88, 102]. While a small grain size is not guaranteed in as-prepared films, further insurance steps appear to help in breaking the films into desired particles. For example, in PECVD techniques, an inert gas plasma or hydrogen plasma is run first prior to admitting the feedgas and initiating growth [76, 80]. The plasma ion bombardment will create particles. In thermal CVD, the substrate with the catalyst often first faces a "preparation step," where an inert gas at the growth temperature flows through the reactor for about 10 min, prior to admitting the feedgas. This influences the size of the particles. In some cases, particularly with Ni films, a pretreatment with NH_3 has been used, where Ni is etched into small particles [75, 83, 91]. Delzeit et al. [24, 55] have shown that the introduction of a metal underlayer (such as Al) can be used instead of any chemical pretreatment steps. Thermodynamics and kinetic studies [7] indicate that alloying a catalyst with a noncatalystic metal increases the number of reactive sites through surface clusters. In addition, an underlayer such as Al allows tuning of the final conductivity of the substrate plus CNTs. The metal underlayer may also play the role of a barrier layer between an incompatible catalyst metal and substrate, which is the case with Fe and a highly oriented pyrolytic graphite substrate.

3.3. Floating-Catalyst Approach

If a stream of catalyst particles can be injected into the flowing feedstock, it is possible to produce nanotubes in the gas phase. This approach is amenable for scale up to large-scale production. Sen et al. [70] first reported such a possibility when they used ferrocene or nickolecene as a source of the transition metal and benzene as carbon source. Nikolaev et al. [64] used CO disproportionation aided by Fe clusters created from $Fe(CO)_5$. The transition metal sources vaporize at temperatures much lower than that for the gas phase pyrolysis of the carbon sources. In using ferrocene or $Fe(CO)_5$, the iron particles condense together and form clusters. An iron cluster of 40–50 atoms (~0.7 nm diameter) is about the size of the smallest SWNT. Smaller clusters tend to evaporate, and are unstable. Very large clusters are also not ideal for nanotube growth as they favor graphitic overcoating. Declustering or break up of large clusters also happens in the reactor. It is the competition between various processes (clustering, evaporation) that creates favorable-size clusters [96]. Tuning of various parameters such as temperature, flow rates of various gases, injection velocity of the $Fe(CO)_5$, residence time, and so on is done to obtain

reasonable quantities of nanotubes. The kinetics of cluster formation and nanotube growth reactions is not well understood, and a preliminary model is presented by Dateo et al. [96]. The availability of reliable kinetics data would lead to reactor and process design simulations, based on traditional chemically reacting flow models, as attempted by Gokcen et al. [97].

4. GROWTH RESULTS

This section presents sample results from the literature to give an indication of the current possibilities. In Section 3.1, a solution-based catalyst recipe was discussed, along with optimization procedures using a combinatorial approach. Figure 1 shows results from such an optimization run. The top image shows a 5×5 array, with each spot having different compositions of Si, Fe, Co, and Al-containing compounds. The wafer with 25 different formulations was loaded in a CVD reactor, and the growth was carried out at 850 °C for 20 min. Scanning electron microscopy (SEM) and confocal Raman spectroscopy were used to characterize SWNTs from each spot to identify the most active catalyst compositions. An SEM image of SWNTs from one such location is given in Figure 1.
Figure 1. SWNT growth by thermal CVD. Top panel shows a low-magnification SEM image of a discovery library of candidate SWNT catalysts. The most active region is outlined in white. A representative high-magnification image of a composition within the active region shows (bottom panel) a predominance of SWNTs. (Image courtesy of A. M. Cassell.)

Figure 2 shows results for SWNT growth by thermal CVD on a 400 mesh TEM grid used as a substrate. First, an underlayer of Al (10 nm thick) and an active catalyst layer of Fe (1 nm) were deposited inside the open areas of the grid using ion beam sputtering [24]. The results are for 1000 sccm of methane flow at 900 °C for a period of 10 min in a thermal CVD reactor. SWNTs are seen in each of the open areas; a larger magnitude SEM image in Figure 2b clearly indicates a mat of nanotubes. Figure 3 provides a TEM image of this sample indicating SWNTs.

Raman spectroscopy is a valuable tool to characterize CNTs, identify if they are semiconductor or metallic, and determine impurities present. Figure 4 shows an example of Raman spectra obtained with 514 and 633 nm excitation lasers. The laser power is 2 mW focused on a 1 μm spot. The sample shows the characteristic narrow G band at 1590 cm^{-1}. A signature band at 1730 cm^{-1} for SWNTs is also seen. From the radial breathing mode, the sample is estimated to have a broad SWNT diameter distribution from 1.14 to 2.0 nm.

Ion-beam-sputtered catalyst layers such as Fe or Ni along with the Al underlayer can also be used to grow MWNTs. MWNT growth is facilitated by using ethylene at 700 °C (lower than for SWNTs), as seen in Figure 5. A theoretical
Figure 3. TEM image of the sample in Figure 2.
(a)
(b)

Figure 2. SWNT growth on a 400 mesh TEM grid. Prior to growth, 10 nm Al and 1 nm Fe are deposited into open areas. Growth conditions: 1000 sccm methane at 900 °C for 10 min. (a) Low-magnification image of SWNTs. (b) High-resolution SEM of one of the squares. (Image courtesy of L. Delzeit.)
Figure 4. Raman spectra results for SWNT samples from Figure 2.
Figure 5. MWNT tower grown by thermal CVD. (Image courtesy of L. Delzeit.)

analysis by Karzow and Ding [93] indicates that production of MWNTs is favored over SWNTs when the growth temperature is kept below 900 °C and the carbon supply at the catalyst particle surface is relatively high (note that this does not imply carbon supply from gas phase pyrolysis, which leads to unwanted amorphous carbon). The MWNT tower seen in Figure 5 can be obtained on a variety of substrates such as silicon, quartz, mica, and highly oriented pyrolytic graphite.

Most SWNT and MWNT growth on substrates tends to result in either a mat of nanotubes (as in Fig. 1b or Fig. 2b) or towers as in Figure 5. However, in some applications, such as in transistor fabrication, it is desirable to have a single nanotube (preferably SWNT) bridging two electrodes. While one can always transplant a nanotube from bulk samples, *in-situ* growth is preferable. This can be accomplished by using an electric field to direct the growth [61, 62]. The electric-field effect in thermal CVD has been demonstrated by Delzeit et al. [62], in which directed growth of an SWNT spans across two electrodes 25 μm apart.

Figure 6 shows vertically aligned, individual, freestanding MWNFs grown in a high-density plasma reactor. The reactor consists of an inductive coil, as well as a separate RF capacitive power supply at the bottom electrode supporting the wafer. The nominal pressure in the reactor is 3 torr. At this pressure, the power coupling to the plasma is not entirely inductive, but there is a capacitive component. The gas flow consists of 100 sccm of a 20:80 methane/H_2 mixture. Vertical MWNFs as in Figure 6 are suitable for the development of electrodes needed in biosensors and other applications [103, 104]. The MWNFs contain the catalyst particles at the tip, as shown in the TEM image in Figure 7. The metal particles can be easily removed using a two-step procedure of thermal oxidation in air (200–400°), followed by a dilute acid (12% HCl) treatment [105]. The production of MWNFs seems to correlate with the high percentage of H_2 in the feedgas mixture and high RF powers to the substrate; this correlation was verified using atomic hydrogen emission lines in an emission spectroscopy analysis of the plasma [8]. In contrast, when the hydrogen dilution is low, for example, by adding a large fraction of argon or at low substrate power levels, MWNTs result instead of MWNFs. A TEM image of these MWNTs is shown in Figure 8.
Figure 7. TEM image of one of the fibers in Figure 5 showing an Fe particle at the tip.

It was mentioned in Section 2.2 that a variety of plasma sources is used by the nanotube community. Figure 9 shows well-aligned, individual, freestanding MWNFs using a dc plasma-assisted hot-filament CVD. The SEM image shows that catalyst particles remain at the top of the MWNFs. In this case, the silicon substrate contains a 100 nm Cr barrier layer and a 20 nm nickel catalyst layer. The catalyst layer is pretreated with 80 sccm of NH_3 at 4 torr for about 10 min with filament heating. For MWNF deposition, 35 sccm of C_2H_2 is used. The dc bias on the substrate is 550 V. The height of MWNFs in Figure 9 is about 10 μm for a growth time of 20 min. In order to obtain the type of vertical structures shown in Figures 6 and 9 with thermal CVD, one needs to use porous templates to hold the catalysts. For example, Li et al. [36] grew vertical MWNTs by using a porous alumina template in which the pore spacing can be controlled.

5. GROWTH MECHANISMS

Nanotube growth on catalyst particles has similarities to traditional gas–solid interaction processes such as thin-film deposition on substrates. The process proceeds according to the following sequence of steps, and one or more of these steps may be rate controlling, which varies from case to case and requires careful experimental analysis:

1. diffusion of precursor(s) through a thin boundary layer to the substrate
2. adsorption of species onto the surface
3. surface reactions
4. desorption of product species
5. diffusion of species through the boundary layer into the bulk stream.

In low-temperature plasmas, the bombardment of positive ions on the substrate may provide the energy needed in step 3 or aid in the desorption in step 4.

Figure 8. TEM image of an MWNT.
Figure 9. MWNFs grown by dc plasma-assisted hot-filament CVD. (Image courtesy of A. M. Cassell.)

In common processes in microelectronics such as the deposition of silicon, aluminum, silicon nitride, and so on, extensive studies have been performed to identify rate-controlling steps and to understand surface processes. The diamond literature also features numerous such studies. Unfortunately, in CNT growth, there have been no careful experimental investigations to date on this subject. However, earlier studies on carbon filaments in the 1970s discussed the process sequence described above [9–11]. A hydrocarbon such as methane adsorbed onto the catalytic particle surface releases carbon upon decomposition, which dissolves and diffuses into the particle. When a supersaturated state is reached, carbon precipitates in a crystalline tubular form. At this juncture, two different scenarios are envisioned. If the particle adherence to the surface is strong, then carbon precipitates from the top surface of the particle, and the filament continues to grow with the particle anchored to the substrate. This is called the base growth model. In cases where the particle attachment to the surface is weak, then carbon precipitation occurs at the bottom surface of the particle, and the filament lifts the particle as it grows. In this case, the top end of the filament is decorated with the catalyst particle. This scenerio is aptly called the tip growth model.

Baker and coworkers [9–11] arrived at the above mechanisms for carbon filament growth based on temperature-dependent growth rates, activation energy for various steps, and electron microscopy observations. It is commonly believed in the CNT community now that the mechanisms for the filament growth apply, by extension, to nanotube growth as well [18, 95]. The most common reason is the visual observation of catalyst particles on the top or bottom ends, as was the case with filament studies.

In CNT literature, the term "vertical alignment" is the most misused. In most cases, any alignment seen is due to the crowding effect, and in SEM images with large-scale bars, crowded CNTs about 0.5 μm and above in height would look well aligned. But individual CNTs within the ensemble grow almost like vines, although the ensemble looks nicely aligned. This is the case with both thermal and plasma CVD. However, individual, free-standing, vertical carbon nanostructures are also enabled by PECVD [8, 75, 84, 85, 88, 89]. Invariably, these are MWNFs, and coinciden-

tally, they all follow the tip growth mechanism. In plasma CVD, it is entirely likely that ion bombardment not only creates particles from thin catalyst films, but also makes their attachment to the surface weak. Hence, the observed tip growth mechanism is not surprising. Merkulov et al. [85] assert that the presence of the catalyst particle at the tip is essential for the vertical alignment of MWNFs. Combining the effects of electric field and the compressive or tensile stress at the particle interface, they argue that the particle at the tip provides a stable negative feedback mechanism assuring vertically aligned growth.

The development of reliable, reproducible, large-scale processes requires an understanding of growth mechanisms, the effect of process parameters on growth characteristics, and gas phase and surface kinetics. Such knowledge is possible only with careful diagnostics and modeling studies. While the CNT literature is full of recipes, growth results, and early application demonstrations, diagnostics and modeling articles are almost nonexistent. A fundamental question in CNT growth relates to the identification of precursor species responsible for growth. In thermal CVD, it is almost unambiguous that the feedstock hydrocarbon reacts at particle surfaces to produce carbon for diffusion into the particles; the temperatures are kept at a level to minimize gas phase pyrolysis of the hydrocarbons [98, 99]. In contrast, the cold plasma in PECVD dissociates the feedstock hydrocarbon, and produces other stable hydrocarbons and very active (high sticking coefficient) radicals in the bulk phase [8, 98]. All of these species, not just the feedstock from the supply tank, reach the catalyst particle surface. This will make the PECVD results different from thermal CVD CNT structures. The situation in PECVD is more complex, and not well understood.

6. APPLICATIONS FOR CVD/PECVD GROWN NANOTUBES

A SWNT grown directly on an AFM cantilever has been shown to be a robust, high-resolution tip for atomic scale imaging [57]. Whereas conventional silicon probes either wear out quickly or even break, SWNT tips wear only slowly. Imaging of metallic, semiconductor, and dielectric surfaces [57], DNAs [59], and proteins with atomic scale resolution has been demonstrated. The use of MWNT tips has allowed us to perform profilometry [58] in integrated-circuit manufacturing, where the need exists to map the depth and shape of holes and trenches. These demonstrations have led to the active development of scale-up techniques to produce hundreds of CNT tip cantilevers on a wafer compared to the current one-at-a-time production.

The ability to grow nanotubes on patterned substrates has potential applications in field emitters, which are being considered for flat panel displays for TV and computer screens and large outdoor displays. CNT-based nanoelectronics is not a near-term technology. Although CNT-based diodes and transistors have been demonstrated, it is not clear what the eventual device, circuit, or architecture will look like, but CVD and related techniques are expected to play a significant role.

Vertically aligned multiwalled nanotubes and fibers, which are free standing, appear to be suitable as electrodes. An

array of such MWNFs reinforced with SiO_2 (in the space between individual tubes) for isolation and mechanical stability has been demonstrated [103]; such gap-filled arrays can be used in biosensor development, where DNA is attached to individual fiber ends [104]. This type of array has also been considered for the development of infrared detectors [106]. When scale-up efforts become successful and the price goes down, SWNTs are expected to play a significant role in structural applications through high-strength, low-weight composites. The field of CNTs is still very young, and it will take another decade or so to see matured technologies and successful commercial applications.

GLOSSARY

Carbon nanotube   A cylinderical form of carbon, configurationally equivalent to a two-dimensional graphene sheet rolled into a tube.

Chemical vapor deposition   Thin-film preparation technique which relies on source gases or vapor of chemicals which react on a substrate to produce the desirable product film.

Plasma-enhanced chemical vapor deposition   Similar to CVD, where gas dissociation is by energetic electrons instead of by thermal heating.

Carbon Nanotube Sensors

Jun Li, Hou Tee Ng

NASA Ames Research Center, Moffett Field, California, USA

CONTENTS

1. INTRODUCTION

Carbon nanotubes (CNTs) belong to a family of materials consisting of seamless graphitic cylinders with extremely high aspect ratios [1–4]. The typical diameters vary from about one to hundreds of nm and the length spreads from tens of nanometers to hundreds of micrometer or even centimeters. The cylindrical structure of CNTs was originally discovered by scientists at NEC in 1993 [5]. Due to their intriguing nanometer scale structures and unique properties, CNTs have quickly attracted intensive attention in the past few years in many fields such as nanoelectronic devices [6–13], composite materials [14], field-emission devices [15, 16], atomic force microscope probes [17–20], and hydrogen/lithium ion storage [21, 22]. Many studies have also reported ultrahigh sensitivity of CNT-based sensors [13, 23–25]. The extremely high surface-to-volume ratio of a carbon nanotube is naturally ideal for efficient gas/chemical adsorption. The one-dimensional quantum wire nature makes their electronic properties very sensitive to gas or chemical adsorption. Both of these factors are essential for achieving high sensitivity of the sensors. In the past few years, CNT sensors have been demonstrated in many applications involving gas molecules, liquid phase chemicals, and biomolecules. CNTs have shown improved performance compared to conventional sensors utilizing materials such as semiconducting metal oxides [26], silicon [27], organic/polymeric materials [28], and carbon black–polymer composites [29]. In this chapter, we intend to summarize the most recent progress in CNT sensors and discuss the common materials properties and sensing mechanisms behind the different applications.

2. FABRICATION OF CARBON NANOTUBE SENSING DEVICES

2.1. Growth of Carbon Nanotubes

The methods to grow CNTs with desired quantities and qualities for sensor applications were only established in the past few years. A host of experimental approaches have been explored, improved, and modified to successfully synthesize CNTs, both single- and multi-walled, for sensor applications. Commonly used techniques include electrical arc-discharge, laser ablation, and chemical vapor deposition. In most growth processes, a catalyst which is either a metal or a mixed alloy is used.

The growth of single-walled CNTs (SWCNTs), though in small quantities, was first demonstrated by Iijima and Ichihashi [30] and Bethune et al. [31] using the electrical arc-discharge techniques. The SWCNTs were typically accompanied by a substantial amount of amorphous carbon, carbon nanoparticles, and other carbon-based materials. By using the laser ablation method, Smalley et al. [32] have further improved the purity and synthesized amount of SWCNTs on the grams level. The as-synthesized SWCNTs are presented mostly in the form of ropes with individual nanotubes aggregating into hexagonal crystals due to the van der Waals interaction. An example of a SWCNT rope is shown in Figure 1. Subsequent studies by other groups have improved on either the designs or experimental formulations to obtain better quality and larger quantity products. For example, Kajiura et al. [33] have used a newly designed chamber which was equipped with a filtering zone to produce high content of SWCNT ropes under controlled gas flow conditions. Journet et al. [34] have optimized the SWCNT growth by incorporating yttrium and nickel into a carbon anode. Both techniques as mentioned above have also been successfully used to synthesize multiwalled CNTs (MWCNTs).

Recently, chemical vapor deposition (CVD) has gained popularity in synthesizing both SWCNTs and MWCNTs with good yields. A typical growth process involves passing a
Figure 1. Transmission electron microscopy images of the cross-section of the end of a SWCNT rope made of hundreds of SWCNTs. The scale bar is about 1 nm. Reprinted with permission from [43], A. G. Rinzler et al., *Appl. Phys. A* 67, 29 (1998). © 2002, Springer-Verlag.

hydrocarbon gas over a heated catalyst at high temperature for a period of time. Dai et al. [35] have demonstrated using the techniques to synthesize SWCNTs with high quality by passing methane over alumina supported catalyst in the temperature range of 850–1000 °C. By optimizing the catalyst preparation and growth conditions, the quality and yields of the nanotubes could be further improved as demonstrated, for instance, by the work of Liu et al. [36], Colomer et al. [37], Rao et al. [38], and Smalley et al. [39]. More recently, Smalley et al. [40] have demonstrated large-scale production (10 g/day) of high purity SWCNTs using a gas phase CVD process, termed the HiPco process. By using iron catalytic clusters, formed *in-situ* from $Fe(CO)_5$, with a high pressure (30–50 atm) and a high temperature (900–1000 °C) process, they have reported that SWCNT material of up to 97 mol% purity could be produced at a rate of 450 mg/h.

With continual effort in the development of growth techniques and methodology, it is expected that CNTs with the desired properties, qualities, and quantities could be obtained in the near future.

2.2. Preparation of Carbon Nanotube Films

The active component of a carbon nanotube sensor (see Section 3) is presented either in the form of a thin film or a single nanotube configuration. In the former, it is usually fabricated separately and integrated subsequently in the device fabrication route, unlike the latter. The fabrication of the thin film CNTs usually starts from the raw CNT materials. Because of the use of catalytic materials, for example, transition metals and metallic species, in the synthesis of nanotubes, the as-synthesized CNTs usually contain certain amounts of these metallic nanoparticles, coexisting with various forms of carbon. In order for the CNTs to be useful in various sensor applications, it is important that they should be free of the impurities and made into the right geometrical configurations. Indeed, various efforts have been demonstrated by researchers to purify CNTs.

Bandow et al. [41] have demonstrated a purification procedure for SWCNTs, which were prepared by pulse laser ablation, that separates coexisting carbon nanospheres (CNS), metallic nanoparticles (MN), polyaromatic carbon, and fullerenes from the SWCNT fraction. According to the reported procedure whereby no oxidation treatment was used, the process involved first the suspension of CNS, MN, and SWCNTs in nonaqueous solution using a cationic surfactant and then subsequent trapping of SWCNTs on a membrane filter. Approximately 84 and 6 wt% of purified SWCNTs and CNS can be separated respectively from the as-prepared samples. Using an alternative method which incorporates hydrothermal treatment along with Soxhlet extraction of fullerenes, oxidation, and strong acid dissolution of metallic particles, Tohji et al. [42] have shown a purification approach to obtain arc-discharge SWCNTs with purity $\sim$ 95 wt% . For large-scale purification of CNTs, Rinzler et al. [43] have demonstrated a readily scalable process capable of handling SWCNTs in large batches. The typical purification process begins with refluxing the as-synthesized samples in strong nitric acid, followed by repetitive washing/centrifugation and filtration cycles. The finished product could then be readily peeled off the filter membrane to produce a freestanding mat, the so-called "bucky paper." Another treatment approach, which involved air oxidation at elevated temperature as the first step and subsequent microfiltration, was reported by Shi et al. [44] to obtain more than 90% purity SWCNTs. Cinke et al. recently reported SWCNTs with purity up to 99.6% after a two-step purification process [45].

To quantify the effectiveness of the purification process, microscopic techniques such as scanning (Fig. 2) or transmission electron microscopy have been used to investigate the microstructures of the treated samples. Alternatively, spectroscopic techniques including Raman spectroscopy and analytical techniques such as thermogravimetric analysis have been used to determine the quality of the treated samples.

2.3. Fabrication of Sensing Devices

Depending on the sensing applications, different device architectures and fabrication routes are required to successfully achieve their desired functions. Common to all, carbon nanotubes as the critical components of the sensing devices are integrated either directly or indirectly during the fabrication routes. A variety of different methods, ranging from advanced micro- or nano-lithographic techniques to hand-made processes, have been demonstrated by various researchers to build functional devices.

In the arena of gas sensing devices, both single and thin film CNTs have been utilized. To fabricate single SWCNT field-effect gas sensors, Soh et al. [46] and Kong et al. [13] have combined a synthesis method and microfabrication techniques to obtain CNT-based electrical circuits on a silicon substrate with controllable positions and length (ranging from 300 nm to 10 μm). The electrical circuits could then be connected to macroscopic electrodes leading to external monitoring devices. In a typical fabrication process, three steps of electron beam lithography using polymethylmethacrylate as the resist were involved. As depicted
Figure 2. Scanning electron microscopy images of purified SWCNTs prepared by (a) dc arc-discharge and (b) laser pulse ablation. (a) Reprinted with permission from [42], K. Tohji et al., *J. Phys. Chem. B* 101, 1974 (1997). (b) Reprinted with permission from [41], S. Bandow et al., *J. Phys. Chem. B* 101, 8839 (1997). © 1997, American Chemical Society.

in Figure 3, the first step involves patterning of the Ti/Au alignment marks on the Si substrate. In the second step, regular windows (5 μm $\times$ 5 μm) were formed in the resist followed by deposition of the catalyst. Next, the resist was removed, leaving behind the patterned catalyst islands. Carbon nanotubes were then synthesized via methane CVD to bridge between the islands. A final step involving patterning of the electrical contact pads over the catalyst islands was performed to complete the devices. The as-described approach has been reported to allow a large number of integrated CNT sensors to be built in an array although various issues including the interface between the nanotube and catalyst metal as well as metal contact electrodes remain to be investigated.

A simpler fabrication route which involved deposition of dichloroethane-dispersed SWCNT thin film onto silicon dioxide substrates with prepatterned gold electrodes was adopted by Collins et al. [23] to realize gas sensing. The approach was adapted by Sumanasekera et al. [24], without the underlying gold electrodes, to fabricate gas sensors for detection of hydrocarbons. Using a different fabrication route, Ng et al. [25] have used freestanding MWCNT thin films grown from soft-lithography-mediated selective CVD approach to successfully integrate a flexible polydimethylsiloxane (PDMS) framework into microsensing devices. As shown in Figure 4A, a PDMS substrate with integrated ultrasharp polymeric probes was first fabricated by a micromolding technique [21]. This was then followed by an imprint
Figure 3. Schematic of processing steps to fabricate SWCNT FET sensors. Reprinted with permission from [46], H. T. Soh et al., *Appl. Phys. Lett.* 75, 627 (1999). © 1999, American Institute of Physics.

process and Au evaporation to lay down the contact pads. The MWCNT membrane was then anchored by spreading onto the polymeric probes' region, which simultaneously overlaid onto the Au contact pads (Fig. 4C). Another PDMS slab with an opening was then bonded permanently onto the framework. Using a different platform, Chopra et al. [47] have demonstrated that either SWCNTs or MWCNTs could be casted as a thin film on an etched copper conductor circuit sitting on a Duroid board to achieve resonator based remote gas sensing.

The aforementioned gas sensors are typically solid-state devices. However, with simple adaptation and modification, liquid-phase chemical sensors could be fabricated as well. As demonstrated by Nugent et al. [48], a MWCNT microbundle was picked out from a boule produced by electrical arc-discharge and physically attached to the end of a copper wire electrode using a conductive silver paint. The electrode assembly was then placed in a typical electrochemical setup such that only the nanotube bundle came into contact with the solution. Alternatively, it has been shown by Britto et al. [49] and Li et al. [50] that random CNTs (mixed thoroughly with bromoform) and bulky paper strips respectively could be packed inside a glass tube to serve as a working electrode for the detection of electrochemical active species.

While using a bottom-up integrated approach, Li et al. [51] have demonstrated uniquely the fabrication of vertical arrays of CNTs on a silicon substrate which could serve as a chemical and biosensor upon attachment of biomolecular or chemically active species as show n in Figure 5. The vertically aligned MWCNTs were first grown using dc biased hot-filament plasma CVD on a metal film covered silicon substrate. They were then subjected to tetraethyloxysilicate (TEOS) CVD for gap-filling of SiO_2. SiO_2 dielectrics was found conformally filled in the gap between individual
Figure 4. Schematic of processing steps to fabricate a MWCNT film sensor.

MWCNTs and hence reinforced the MWCNT array. The excess SiO_2 was subsequently removed and allowed the exposure of MWCNT tips via a mechanical polishing step. The fabrication route is reported to be suitable for fabricating various nanoelectronic devices besides sensor applications.

3. APPLICATIONS AND MECHANISMS OF CARBON NANOTUBE SENSORS

3.1. Gas Sensors

As we mentioned earlier, CNTs have a common property in their large surface-to-volume ratio. This makes them potentially very useful adsorbent materials. In particular, extensive work has been focused on their potential as ultrahigh H_2 storage medium [21, 52–54]. Rich literature including both theoretical and experimental efforts can be found on the gas adsorption phenomena on various CNTs prepared and treated with different methods. For the interests of applications in gas sensors, we address only the work relevant to electronic properties of CNTs, the change of which, upon
Figure 5. Schematic of processing steps to fabricate vertical carbon nanotube nanoelectrode arrays by a bottom-up method. Reprinted with permission from [51], J. Li et al., *Appl. Phys. Lett.* 81, 910 (2002). © American Institute of Physics.

gas adsorption, can be readily transduced into measurable sensing signals. By far, most reported CNT gas sensors are based on these transduction mechanisms.

3.1.1. Adsorption of Gas Molecules on Carbon Nanotubes

In the last section, we described the structures of SWCNTs, MWCNTs, SWCNT bundles/ropes, and SWCNT/MWCNT films. Obviously, each type of CNT has quite different absorbing properties for different gases. Even in the simplest case of a single SWCNT, the gas adsorption and its effects on CNT properties depend strongly on the chirality of the CNT, which is generally assumed to be randomly distributed with two-thirds of it semiconducting and the remaining one-third of it metallic. On the other hand, most of the transport studies of CNTs were carried out under ambient conditions, which are inevitably affected by the oxygen adsorption [55]. It is important to understand the fundamental issues of gas adsorption on CNTs.

The dependence of electronic properties on chemical environment was first reported by Kong et al. [13] based on the study of a single SWCNT field-effect transistor (FET). Collins et al. [23] and Sumannasekera et al. [24] later reported that both electrical resistance R and thermoelectric power (TEP) S of SWNT bundles and thin films are sensitive to gas adsorption. Upon exposure to O_2, NO_2, or NH_3 gases, the conductance of semiconducting tubes is changed dramatically, presumably due to the charge transfer from

the adsorbates [13, 23]. The TEP of SWNT bundles was also found to be sensitive to inert gases such as N_2 and He due to the collision with CNT walls [24]. Theoretically, it has been shown that O_2 adsorption has a significant effect on the electronic properties of small semiconducting nanotubes [55]. Zhao et al. studied the electronic properties of three types of SWCNTs, that is, semiconducting zigzag $(10, 0)$ and $(17, 0)$ tubes and metallic armchair $(5, 5)$ tubes upon the adsorption of O_2, NO_2, NH_3, CO_2, CO, H_2O, N_2, H_2, and He with first principles methods [56]. It was found that O_2 and NO_2 are electron acceptors (-0.06 to -0.14 electron per molecule) with relatively larger adsorption energy (~ 0.30 to 1.0 eV) while all other gas molecules are electron donors with negligible charge transfer (~ 0.01 to 0.035 electron per molecule) and weak binding (<0.15 eV). Generally, all the gas molecules studied are weakly physisorbed on CNT surfaces. Charge fluctuation of even the weakly bonded molecules was found to have a pronounced effect on the transport properties of metallic SWCNT, consistent with previous experimental studies [24].

Most as-prepared SWCNTs, particularly those by high temperature techniques such as arc-discharge and laser ablation methods, are long and capped (i.e., sealed at the ends). Only the exterior surfaces are considered accessible by gas molecules. However, the long SWCNTs can be uncapped or cut into short open tubes by acid treatment [45, 57, 58]. The open tubes expose the internal channels to gas molecules resulting in a much larger adsorption. A study using CH_4 adsorbate shows a large hysteresis loop after nitric acid treatment, indicating the capillary condensation inside the nanotube [59]. The diameter of a carbon nanotube is expected to be important in defining the adsorption of gases inside the internal pores of CNTs. A grand canonical Monte Carlo simulation work found that the preferential adsorption of gas molecules with different size in a binary mixture can be switched by controlling the internal diameter of the tube and the temperature [60].

Commonly, SWCNTs pack together into bundles (or ropes) due to van der Waals interaction as revealed by Thess et al. [32]. As a result, there are at least four distinct sites in which gas molecules can adsorb (see Fig. 6) [61]. The interior *pore* of an individual tube, as we mentioned earlier, is only one of them. The other three sites are all related to the exterior surfaces of individual tubes, including: (1) the external bundle *surface*, (2) the *groove* formed at the contact between adjacent tubes on the bundle outer surface, and (3) inside an interstitial *channel* at the contact of three tubes in the bundle interior [60]. Depending on the size and wettability, some of these sites might be excluded for specific gas molecules. For hydrogen adsorption, it has reported that the binding energy (E_B) at these sites following the order $E_B(\text{channels}) > E_B(\text{grooves}) > E_B(\text{pores}) > E_B(\text{surface})$ [61, 62]. Williams et al. calculated the binding energy and specific surface area contributions (σ) of these sites to be (1) channels: $E_B = 0.119$ eV, $\sigma = 45$ m^2/g, (2) grooves: $E_B = 0.089$ eV, $\sigma = 22$ m^2/g, (3) pores: $E_B = 0.062$ eV, $\sigma = 783$ m^2/g, and (4) surfaces: $E_B = 0.049$ eV, $\sigma = 483$ m^2/g [61, 62]. Clearly, the channels and grooves have much larger binding energy but less available surface area. The outer surface has only weak adsorption consistent with the
Figure 6. Schematic structure of a SWCNT bundle showing different sites for gas adsorption. Reprinted with permission from [65], C. K. W. Adu et al., *Chem. Phys. Lett.* 337, 31 (2001). © 2001, Elsevier Science.

study of a single SWCNT surface [56]. These studies provide a good fundamental understanding of the gas adsorption on SWCNTs. For individual MWCNTs and MWCNT films, much less work has been done due to the complexity in tube structure. However, both the external and internal surfaces are expected to contribute to the gas adsorption. The defects, in particular, could play a more important role in changing the electrical properties of MWCNTs upon gas adsorption.

3.1.2. Gas Sensors Based on Single Carbon Nanotube FETs

The Si-based field-effect transistors are sensitive to the electron transfer induced by gas adsorption and therefore could be used as gas sensors for certain applications [27]. SWCNTs are known to be semiconducting if their chirality (m, n) satisfies $m - n \neq 3 \times$ integer. It was demonstrated that a semiconducting SWCNT (S-SWCNT) connected to two metal electrodes exhibits *p*-type transistor characteristics with the conductance tunable over several orders of magnitude by changing the gate voltage applied on the Si substrate [13]. Such a phenomenon was attributed to the adsorption of O_2 as electron acceptor in ambient environment. The theoretical work mentioned above predicts about 0.1 electron transfer per O_2 molecule [56]. With the typical diameter (~ 2 nm) and length (~ 3 μm) of the S-SWCNT in the FET device (see Fig. 3), the adsorption/desorption of even a single O_2 molecule can produce about a 1×10^{16} e/mm^3 charge density in the SWCNT if simply calculated from the volume. This is about the level of the charge density in a moderately doped Si device. In reality, the quantum wire nature of SWCNT makes the conductance of the tube even more sensitive to any local charge along the one-dimensional

wire. Therefore, the sensitivity of single molecule adsorption/desorption could, in principle, be achieved with such miniaturized S-SWCNT FETs.

Kong et al. [13] demonstrated that the conductance of a single S-SWCNT sample decreased by about 100-fold after exposure to NH_3 (0.1 to 1% in Ar or air) for about 10 minutes. On the other hand, exposure to NO_2 molecules [2 to 200 parts per million (ppm) in Ar] increased the conductance of the S-SWCNT sample by about 1000 times when it was initially depleted by a back-gate voltage (Vg) of $+4$ V. The sensitivity, that is, the ratio between the resistance after and before gas exposure (R_{after}/R_{before}), was found to be significantly better than other room-temperature operated gas sensors based on conventional materials. Since the SWCNT is a hole-doped semiconductor, the adsorption of electron donating NH_3 molecules causes the hole depletion and reduced conductance while NO_2 exposure results in enriched hole carriers and enhanced conductance. The chemical nature of the gas molecules is indicated in the I–Vg curve which is characteristically shifted by -4 V after exposure to NH_3 and shifted by $+4$ V after exposure to NO_2. It is possible to fabricate arrays of such miniaturized sensing devices with ultrahigh sensitivity as well as chemical characteristics. A significant drawback is the slow recovery time ($\sim$12 hr) after exposure to NO_2, which is likely due to the slow desorption of strong adsorbates. The influence of O_2 in the ambient environment to the initial sample is also worth further investigation. Much more systematic study is still needed to develop this system for practical applications.

3.1.3. Electrical Resistance Based Gas Sensors

Molecular interactions were found not only to affect the conductance of a single S-SWCNT but also to change that of bulk samples consisting of SWCNT bundles/ropes. Br and I intercalations were reported to enhance the conductance of bulk film consisting of SWCNT ropes [62, 63]. Kong et al. demonstrated that the resistance of a SWNT mat decreased to about a half of the original value after exposure to a 200 ppm NO_2 flow for $\sim$10 min while it increased to about 1.5 times of the original value in a 1% NH_3 flow [13]. Apparently, both metallic and semiconducting SWCNTs in the bulk sample are affected by the gas adsorption. The effect of different gas molecules such as NH_3 and NO_2 on the bulk sample is very consistent with that of the single S-SWCNT transistors.

Collins et al. also found that the electrical resistance R measured with a thin film of SWCNT bundles is particularly sensitive to O_2 in the environment [23]. An experiment measuring the electrical resistance switched by 10 to 15% as the chamber was alternately flooded with air or evacuated to $\sim$10^{-6} Torr. Measurable changes in R were found at oxygen partial pressure as low as 10^{-10} Torr. However, other major gas constituents of air such as N_2, CO_2, H_2O, etc. and inert gas molecules such as Ar and He have little effect on the electrical properties of the SWCNT film. Further transport experiments indicate that once SWCNTs have been exposed to oxygen, it is not possible to fully deoxygenate them at room temperature even under high-vacuum conditions. This irreversibility is similar to that of

NO_2 adsorption on a S-SWCN transistor gas sensor, which limits the application of CNTs in gas sensors.

Apparently, electron acceptors such as O_2 and NO_2 have dramatic effects on the electrical properties of SWCNTs. Many previously reported electronic properties of CNTs are dominated by preadsorbed O_2 from ambient environment. The slow recovery time or irreversibility is likely due to the strong adsorption or capillary effects, particularly when using open-ended SWCNT bundles. MWCNTs with much larger tube diameter, on the other hand, can change from microporous (such as SWCNT bundles) to mesoporous or even macroporous materials. MWCNTs could potentially have much less interaction with the gas molecules. The sensitivity of electrical resistance R to the gas environment may drop but the reversibility could be improved.

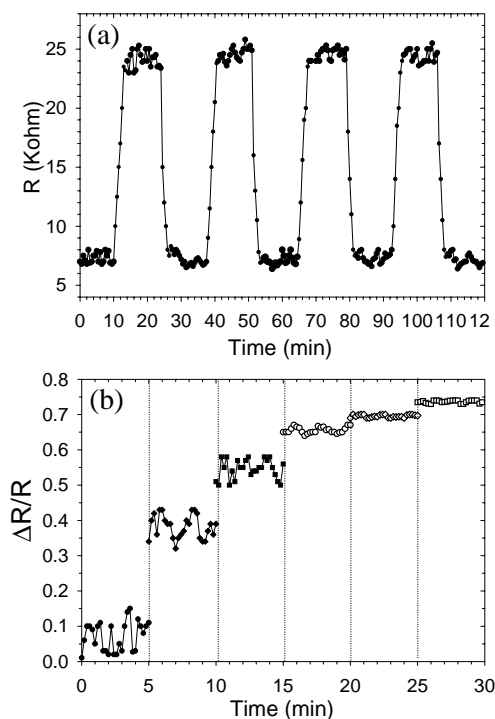
Ng et al. reported a study of gas sensing using a 1.5 mm $\times$ 1.5 mm $\times$ 25μm freestanding MWCNT membrane grown on a polymer template by thermal CVD (as shown in Fig. 4) [25]. Due to the decomposition and shrinkage of the polymer material, the MWCNT–catalyst composite membrane peeled off from the substrate while still maintaining the desired pattern from the substrate. Thus formed membrane contains loosely entangled MWCNTs mixed with catalyst and carbon particles. As shown in Figure 7, simple electrical resistance measurements following cycling the chamber pressure between ambient atmosphere and high vacuum


Figure 7. Variations in the electrical resistance (R) of the MWCNT membrane with the surrounding medium, (a) spontaneous changes in R while cycling the environment between vacuum and ambient atmosphere, and (b) the ratio of the electrical resistance drop from the value at the base pressure vs different oxygen dosing pressure: $\bullet$, 6.4×10^{-7} Torr; $\blacklozenge$, 3.1×10^{-4} Torr; $\blacksquare$, 9.0×10^{-4} Torr; $\bigcirc$, 1.4×10^{-3} Torr; $\diamond$, 2.1×10^{-3} Torr, and $\square$, 2.7×10^{-3} Torr. Reprinted with permission from [25], H. Ng et al., *J. Nanosci. Nanotech.* 1, 375 (2001). © 2001, American Scientific Publishers.

show a very reversible response. R drops by a factor of three (from about 24 to about 7 kOhm) when venting the vacuum with air. Similar to Collins et al. [23], Ar or N_2 did not show any effect. The recovery time is about 2 to 3 minutes which is likely limited by the pumping and venting speed. Stepwise increase of the oxygen base pressure indicates that R is most sensitive to O_2 in the range from 10^{-6} to 10^{-3} Torr. About 80% of the changes in R occurred at oxygen base pressure less than 10^{-3} Torr. Over about 3×10^{-3} Torr, the change in R is saturated likely because all the surface sites have already been occupied.

It is worth noting that most studies [13, 23, 25] were carried out at room temperature, at which oxygen is difficult to remove once they adsorbed onto the CNTs. As a result, the measured electrical resistance R was dominated by the preadsorbed O_2 molecules and little change was observed when exposing the sample to inert gases such as N_2 and Ar. However, Sumanasekera et al. found that the four-probe electrical resistance $R(T)$ of a mat of SWNT bundles showed easily measurable change even upon exposure to 1 atm of N_2 or He after being degassed in high vacuum at elevated temperature ($\sim$500 K) [24]. The change in R is small ($\sim$2–3% increase from vacuum to 1 atm N_2 and $\sim$10% increase from vacuum to 1 atm He). The recovery time is slow (>2 hr) but quite reversible. The increase in R upon exposure to inert gas was attributed to the gas collisions with the nanotube wall.

3.1.4. Thermoelectric "Nanonoses"

The thermoelectric power (TEP) S, defined as

$$S = \Delta V / \Delta T \tag{1}$$

where ΔV and ΔT are voltage difference and temperature difference between two spots in the sample, is another parameter strongly correlated with the electronic properties of the materials. Collins et al. studied the change in TEP upon cycling the environment between vacuum and pure atmospheric pressure oxygen [23]. The response was found to be in good consistency with the change of R. The oxygen exposed SWCNT film has a positive TEP of about $+20$ μV/K. The value quickly decreases and reaches about -10 μV/K a few minutes after oxygen was removed from the chamber. This phenomenon was attributed to the change in the carrier (hole) density upon the adsorption/desorption of O_2 as electron acceptors.

Eklund et al. did a series of careful work at elevated temperature ($\sim$500 K) at which the adsorption/desorption of both strong adsorbates and inert gas molecules is completely reversible [24, 65, 66]. They attributed the strongly negative TEP after degassing to the change of metallic tubes to n-type semiconductors. As we mentioned earlier, at 500 K, easily measurable electrical resistance change was obtained even upon exposure to inert gases. Both TEP and the SWNT bundle resistivity ρ can be measured at different wt% of gas adsorption. Eklund et al. [65] attributed the total bundle resistivity to two things: (1) the scattering mechanisms preexisting in the bundle before gas adsorption (ρ_0), for example, from phonons and wall defects, and (2) the extra impurity scattering due to the adsorbed gas (ρ_a) with

$$\rho = \rho_0 + \rho_a \tag{2}$$

Approximately, the TEP and resistivity have the Nordheim–Gorter (NG) relation as

$$S = S_0 + (\rho_a/\rho_0)(S_a - S_0) \tag{3}$$

where S_0 and S_a are the contributions to the thermoelectric power from the host resistivity ρ_0 and additional impurity resistivity ρ_a from the adsorbed gas, respectively. If the gas molecules are physisorbed on the tube walls by van der Waals interaction, E_F will be unaffected and $(S_a - S_0)$ is a constant, resulting in linear NG curves as shown in Figure 8 for N_2, He, and H_2. On the other hand, strong chemisorption has a much more profound effect on the host band structure and E_F. Thus, $(S_a - S_0)$ must depend on the gas coverage, resulting in nonlinear NG plots as shown in Figure 8 for O_2 and NH_3. It is noteworthy that the NG plots for even inert gases such as N_2, He, and H_2 are significantly distinct from each other. Potentially, the NG plots at elevated temperature can differentiate different molecules and find applications in thermoelectric "nanonose" as proposed by Eklund et al. [65].

3.1.5. Remote Gas Sensors

The above-mentioned gas sensors based on single CNT FET, electrical resistance, and TEP all rely on direct electrical connections to the sensing elements exposed in the sampling environments. For some applications such as detection of corrosive gases and samples in sealed environments, remote or non-direct-contact sensors are required. Recently, Chopra et al. reported a carbon-nanotube-based resonant-circuit sensor for ammonia [47]. Similar to the electrical resistance and TEP sensors, tens of micrometer thick CNT film was used as the adsorbent material due to the large uptake capability defined by its huge surface area. Both
Figure 8. NG plots (S vs ρ) showing the effect of gas adsorption on the electrical properties of the SWCNT mat. Reprinted with permission from [65], C. K. W. Adu et al., *Chem. Phys. Lett.* 337, 31 (2001). © 2001, Elsevier Science.

SWCNTs and MWCNTs were used. The CNT films were simply deposited on a disk shaped Cu resonator on a Duroid board. A radio frequency transmitter sends a microwave signal to the interrogation region of the Cu resonator, producing a strong signal at its resonant frequency ($\sim$4 GHz). The resonant frequency was found shift downward by a few MHz after exposure to NH_3 gas over $\sim$100 ppm. The response and recovery time were found to be about 10 min, a reasonable short time. The resonant frequency shift was attributed to the change in the effective dielectric constant of the CNT film upon exposure to NH_3. In principle, other strong adsorbates may affect the downshift of the resonant frequency differently and the chemical nature of the gas may be derived. Even though the sensitivity is low, the remote sensor may find applications in certain corrosive or toxic environments as well as those that require nondestructive testing.

3.2. Liquid-Phase Chemical Sensors

From the structural point of view, the main body of CNTs, particularly MWNTs, can be considered as graphitic layers rolled into cylinders. The sidewall of CNTs is expected to present similar physical and electronic properties to the graphite basal plane. The studies discussed in previous sections on the gas adsorption on the sidewall of CNTs is, in many aspects, consistent with previous studies on graphite surfaces [67–69] except for the difference in the surface area. Along the tube axis, it is expected to present high conductivity similar to graphite in-plane properties. For SWCNTs, the large curvature and small tube dimension are likely to cause interesting quantum effects to deviate from graphite properties. The electronic properties of SWCNTs are also easily affected by adsorbates since almost every carbon atom is exposed at the surface. MWCNTs, on the other hand, have essentially only the outmost and innermost shells exposed to other molecules and thus are less sensitive to the perturbation from adsorbates. Their larger size also makes them more similar to graphite cylinders. In liquid solutions, the sidewall of MWCNTs is expected to present an anomalously small effective capacitance and a slow electron transfer rate similar to graphite basal plane electrodes. However, the open end is a very active electrode similar to the graphite edge plane. Electron transfer along the tube axis is expected to be fast similar to that within a graphite plane. These properties made CNTs, particularly MWCNTs, very interesting electrode materials. Electrons could be caught at the active end and transported along the tube to the other end without much interference from the solution. For this purpose, the interest is in the nanostructure of CNTs which improves the performance over conventional materials rather than the influence of their electronic properties by other molecules. In this section, we summarize some of the studies using CNTs as electrodes, which may potentially lead to dramatic improvements in the performance of current chemical and biological sensors by incorporating unique properties of CNTs.

Nugent et al. demonstrated an ideal Nerstain behavior of the $K_4Fe(CN)_6$ reaction using an open end WCNT bundle produced by electric arc-discharge [70]. The fast electron transfer rate from the tube ends along the tube axis agrees well with the cylindrical graphite model. Ideal reversible

cyclic voltammetries were also obtained in measuring the oxidation of neurotransmitter dopamine [48] and redox proteins such as cytochrome c and a "blue" copper protein azurin [71]. Efficient electrocatalytic reduction of dissolved O_2 was also demonstrated [72]. However, all these studies use compact CNT paste or big bundles in which CNTs mixed with each other as well as organic binders in an uncontrolled way. Even though the specific capacitance of the graphitic sidewall is relatively small, they still contribute a huge capacitive background due to the enormous surface area [49, 73, 74]. For chemical sensor applications, the exposed surface area needs to be minimized. It was demonstrated that a loosely packed MWCNT membrane is able to detect neurotransmitter catechols at concentrations down to a few μMs [25]. A series of CNTs with different densities was carefully studied by Li et al. to explore these issues [50].

Much work is desired to develop well-defined CNT electrodes from both the fundamental and application points of view. Campbell et al. demonstrated that single MWCNTs $\sim$80–200 nm in diameter and 15–50 μm in length show reversible characteristic steady-state radial diffusion behavior consistent with fast electron transfer [75]. The sidewall of the CNT can be insulated with polymer and only the very end of the tube is exposed. This can find unique applications in the analysis of redox biospecies such as neurotransmitters and proteins in a live single cell [76].

Another effort in the development of well-defined CNT electrodes was demonstrated by NASA scientists using vertically aligned MWCNTs [50]. Li et al. used vertically aligned CNTs with an average diameter of $\sim$50–100 nm and nearest-neighbor distance of $\sim$200–500 nm on metal coated Si substrates. SiO_2 was deposited by TEOS CVD to insulate both CNTs and subtrate metal layers. A mechanical polishing process followed to planarize the sample to remove excess materials which results in an array of nanoelectrodes with only the open ends of MWCNTs exposed. This method provides a unique bottom-up scheme to fabricate nanoelectrode ensembles (NEEs) similar to those demonstrated by Menon and Martin [77] by filling metals into the one-dimensional pores in the filtration membranes. The sensitivity is expected to be improved by orders of magnitude for measuring small redox species using such NEEs compared to conventional electrodes. Ordered nanoelectrode arrays with precisely controlled size and density could be achieved by employing appropriate lithographic techniques. The nanoelectrode array approach is very promising since it takes full advantage of CNTs via miniaturization to achieve ultimate sensitivity and may be incorporated into microfluidic devices, microelectromechanical systems (MEMS) chromatography instruments, and biomedical/environmental monitoring devices.

3.3. Biosensors

As we described in the discussion of S-SWCNT FET gas sensors [13], even small electron transfer between S-SWCNT and adsorbates can cause a significant change in the conductance of the device. Biomolecules such as DNA, RNA, and proteins are all heavily charged molecules in most conditions. The adsorption of such molecules onto the CNT

surface is expected to change its electronic properties similar to gas molecules. Therefore, the FET devices could be employed as biosensors. Particularly, recognition of specific biomolecules could be realized through the specific interaction with preimmobilized molecules. For this purpose, the functionalization of biomolecules such as DNA and proteins was intensively pursued in the past few years.

Dai et al. have reported a series of work for sidewall functionalization of single SWCNTs for protein immobilization [78, 79]. The SWNT is intended to be used as the sensing element based on its electronic properties. As a result, the graphitic sp^2 sidewall structure has to be preserved. Noncovalent bonding of some precursor molecules on the CNT sidewall was demonstrated for this purpose, either by the π-stacking of the conjugate pyrenyl group of 1-pyrenebutanoic, succinimidyl ester, or coating with a surfactant (Triton) mixed with amine-terminated poly(ethylene glycol). Both methods efficiently modified the CNT surface and incorporated functional groups so that further covalent bonding of protein molecules such as biotin can be followed. The functionalized CNTs were then demonstrated with specific recognition of ferritin and streptavidin. These methods can be extended to the recognition of other biomolecules based on specific interactions of antibody–antigen and complimentary DNA strands. However, the response in electrical conductance has not been reported so far.

The very end of the CNT, particularly the open end, is chemically much more active due to the dangling sp^2 bonds similar to the graphite edge plane. The chemistry to functionalize these sites is more mature. Wong et al. demonstrated that the open end of the CNT is rich in —COOH group and thus can be used for selective covalent bonding of primary amine molecules by carbodiimide chemistry [18, 80]. NASA scientists further demonstrated that DNA oligoprobes can be covalently functionalized, by the same chemistry, to an array of vertically aligned MWNTs embedded in SiO_2 matrix with only the open ends exposed [81]. Similar to other DNA microarrays, the covalently bonded DNA probes can sustain more stringent control such as washing at elevated temperatures so that only specifically binded target DNA molecules can be hybridized with the probes. A NASA–NCI joint work has demonstrated an electrochemical DNA sensor based on an array of DNA functionalized nanotube electrodes [51, 81, 82]. The nano- bioelectronics platform is expected to provide unsurpassed electrochemical sensitivity, a high degree of miniaturization, great ease, and low cost operation.

4. DISCUSSIONS AND FUTURE DEVELOPMENTS

In summary, CNTs are attractive materials for various sensor applications. Their small dimension and large surface-to-volume ratio make them very sensitive to adsorbates from the environment. The electronic properties such as resistance/conductance, thermoelectric power, and dielectric constant can directly indicate the adsorption of target species. For applications which do not involve direct measurements of the inherent electrical properties of CNTs, the finite size and unique graphitic properties of CNTs can

still dramatically improve the performance, as demonstrated in electrochemical applications. It has been reported that CNTs can be used in sensing gases, liquid-phase chemicals, and biomolecules. The work summarized here only covers the CNT which is only one of the doors leading us to the nanotechnology world. Other nanomaterials such as semiconducting or metallic nanowires [83], nanoparticles [84, 85], quantum dots [86–88], and dendrimers [89] have all shown great potential in sensor applications. These nanomaterials allow bridging of the gap between microdevices and biomolecules to achieve an integrated micro-nano-bio heterogeneous system. We should expect great progress in this field in the near future.

A few papers reported the most recent progress on gas adsorption on CNTs during the period in which manuscript was written. A Ricca et al. [90] studied the physisorption and chemisorption of O_2 on the inner and outer walls of a $(9, 0)$ CNT using ONIOM method and the MP2 correlation treatment which includes long-range dispersion interactions. In contrast to previous theoretical work using density functional theory [55, 56], only physisorption of triplet O_2 occurs both inside and outside the tube with very weak binding energy and little charge transfer. Chemisorption likely occurs with singlet O_2 which has a very high barrier and is not popular under normal conditions. The CNT FETs were also proposed to operate as unconventional "Schottky barrier transistors", in which transistor action occurs primarily by varying the contact resistance rather than channel conductance [91]. Therefore, the mechanism of the CNT FET sensor for gas adsorption needs further investigation.

GLOSSARY

Carbon nanotube Seamless graphitic cylindrical fibers made of carbon atoms. It could be single walled if there is only one graphitic sheet in the cylindrical structure or multi-walled if there is more than one sheets rolled into the tube.

Chemical mechanical polishing (CMP) A process typically used in the semiconductor industries to planarize the surfaces of a water to achieve optically flat topography. A slurry which consists of small spherical particulates and additives is used during the polishing process. The compositions of the slurry could be tailored to selectively polish the material of interest.

Chemical vapor deposition (CVD) A process which involves deposition of a thin film using a selected choice of chemical precursors at elevated temperature.

Deoxyribonucleic acid (DNA) A macromolecule consisting of one or two strands of linked deoxyribonucleotides.

DNA hybridization Formation of a duplex structure by two complementary single strands of DNA.

Polydimethylsiloxane (PDMS) A network of polymer chains with Si–O backbones and methyl (CH3) side group.

Single-walled carbon nanotube ropes/bundles Multiple single-walled carbon nanotubes aggregated into hexagonally packed ropes/bundles side by side due to the strong van der Waals interactions between them.

Soft lithography A lithographic technique which involves non-optical components to achieve patterning of features with dimensions ranging from the millimeter to nanometer length scale.

Carbon Nanotubes: Synthesis by Arc Discharge Technique

Yoshinori Ando

Meijo University, Tenpaku-ku, Nagoya, Japan

CONTENTS

1. INTRODUCTION

Carbon nanotubes were serendipitously discovered by Iijima [1] in 1991 in a specimen of the present author [2]. Arc discharge between two graphite rods was carried out to make fullerenes [3], and the nanotubes were observed in the residual of the cathode deposit. The method was similar to Krätschmer's ac contact arc [4], with the difference that the two graphite rods were 1–2 mm apart and a dc arc was used. It was done by replacing the silicon block of one electrode by a graphite rod in the apparatus used for making ultrafine powder of SiC [5]. On the other hand, Iijima had been interested in observing various kinds of carbon [6, 7] by using high-resolution transmission electron microscopy (HRTEM), since before the discovery of fullerenes [8]. The observation of a fullerene byproduct, the cathode deposit of the dc arc discharge, was also one of them. As a result, he found one-dimensional fibers having quite a new morphology of carbon [1]. They are made of rolled graphene sheets classified into two categories depending on the number of concentric shells: single-walled carbon nanotubes (SWNTs) or multiwalled carbon nanotubes (MWNTs). After the discovery of MWNTs in the cathode deposit of the carbon arc [1], two years later SWNTs were found [9, 10] in sootlike deposits formed in the carbon arc chamber.

It should be noticed that both MWNTs and SWNTs were first prepared by dc arc discharge of graphite, though there is a difference in the catalyst requirement [9, 10]. Later on, in order to prepare MWNTs, the chemical vapor deposition (CVD) method for large-scale synthesis [11] and thermal decomposition of SiC for aligned MWNT synthesis [12] were applied. However, highly crystallized MWNTs could be produced only by the arc method, because of the high power density under the growth condition. A high yield of SWNTs could be produced by laser ablation [13], whereas the arc discharge [14] and CVD [15] methods were found suitable for their large-scale production. This review focuses only on the arc-discharge method for producing MWNTs and SWNTs.

In the case of the arc method, apart from dc/ac, arc current, gas pressure, and so on, the nature of the ambient gas also plays an important role [16, 17]. Especially, the crystallinity of the MWNTs is highly elaborated when evaporating in pure hydrogen gas [18]. The characteristic features of H_2 arc MWNTs are high crystallinity and a very thin innermost tube. The physical properties and Raman spectra of H_2 arc MWNTs are extremely intrinsic [19–23], and H_2 arc MWNTs really resemble quantum fibers. Electrical and mechanical applications of these H_2 arc MWNTs are expected.

2. PREPARATION OF MULTIWALLED CARBON NANOTUBES BY CARBON ARC

2.1. The Method

To prepare MWNTs, dc arc discharge between two pure graphite rods has been carried out [2, 16, 24, 25] using a vacuum chamber, as shown in Figure 1. Of course, the alignment of the two graphite rods can be vertical [16, 24, 25] or horizontal [17, 26]. After the chamber is evacuated to a vacuum higher than 10^{-5} torr by using an oil diffusion pump, an inert gas (or appropriate active gas) is introduced into the chamber. Then a dc arc voltage of approximately 25 V is applied between the two graphite rods which are 1–2 mm apart. Within a few minutes, the anode is consumed and carbon soot is formed in the chamber. When an inert gas is used as the ambient gas, fullerenes are included in the soot [3].

Another part of the evaporated carbon is deposited on the top of the cathode. In the cathode deposit [2, 24] and on the top of the cathode deposit [27], MWNTs and coexisting carbon nanoparticles are observed by using scanning electron microscopy (SEM).

HRTEM observation of the cathode deposit dispersed on a TEM microgrid has been carried out. There is a concentric Russian doll structure of rolled graphene sheets with some helical arrangement [1], as shown in Figure 2. The distance between each layer is the same as the {002} lattice spacing of graphite, namely, 0.34 nm. A schematic atomic model of a four-wall MWNT is shown in Figure 3, which has a helical arrangement and the edge is zigzag type [28]. When the cathode deposit is observed by using SEM, the MWNTs are seen as fibers, as shown in Figure 4. Usually, not only fibrous MWNTs but also a number of coexisting carbon nanoparticles are observed [2, 27], as shown in Figure 4. The evaporation of graphite rods has been carried out in He ambient gas, and fibrous MWNTs are observed in the cathode deposit and on the top surface of the cathode deposit as well [27].

2.2. Effect of Ambient Gas

The first specimen of MWNTs was prepared by dc arc discharge evaporation in the ambient gas of He [3], although Iijima erroneously wrote Ar in his first report [1]. Since then, not only inert gas such as He or Ar but also active CH_4 gas has been tried as the ambient gas of arc discharge [2, 16, 17, 24]. As a result, MWNTs are formed in all gases of He,
Figure 2. HRTEM micrographs of MWNTs: (a) five-wall, diameter 6.7 nm; (b) two-wall, diameter 5.5 nm; (c) seven-wall, diameter 6.5 nm and the smallest hollow diameter 2.2 nm. Reprinted with permission from [1], S. Iijima, *Nature* 354, 56 (1991). © 1991, Macmillan Magazines Ltd.

Ar, and CH_4 within a pressure range of 20–200 torr. At an intermediate pressure of 100 torr, the quantity of prepared MWNTs is found as follows: Ar < He < CH_4 [24]. It is known that fullerenes such as C_{60} cannot be produced in an ambient gas containing hydrogen atoms. On the contrary, thin and long MWNTs with few coexisting nanoparticles can be prepared in CH_4 gas more than in an inert gas; as an example, see the SEM micrograph [16] shown in Figure 5. From the mass spectra of the chamber gas before and after evaporation [17], it was confirmed that methane undergoes a thermal decomposition as follows:

$$2CH_4 = C_2H_2 + 3H_2$$
Figure 3. Atomic model of four-walled carbon nanotube.
Figure 4. SEM micrograph of MWNTs prepared at dc arc current of 70 A in He 200 torr.

In this reaction, the calculated mole ratio of the gas before and after evaporation was 1 : 2. This led to the necessity to carry out the arc evaporation of the graphite rod in pure C_2H_2 or pure H_2 ambient gas. In the case of pure C_2H_2 gas, a similar result as in CH_4 gas is obtained. On the contrary, arc discharge in pure H_2 gas shows quite remarkable improvement [18].

A typical optical photograph of the top of the cathode [18, 29] after H_2 arc evaporation is shown in Figure 6, which is obtained after 3 min evaporation by a dc arc current of 50 A in H_2 gas at 60 torr. The top surface is composed of three regions: a central black region A, a surrounding silver-gray region B, and a very thin outer region C. When the outer region C is observed using SEM, "carbon roses" are seen [18, 29, 30], as shown in Figure 7. Each petal of a carbon rose is made of very thin graphene sheets [30], that is, nanopetals. In fact, they are composed of several lay-

Figure 6. Top-view photograph of the deposited cathode after H_2 arc discharge. Reprinted with permission from [29], X. Zhao et al., *J. Cryst. Growth* 198/199, 934 (1999). © 1999, Elsevier Science.

ers of parallel graphene sheets, the thinnest one consisting of only two graphene sheets. The region B is a hard, thick deposit which is observed to be a graphitic layered structure. MWNTs are observed in the central thick black deposit A, as shown in Figure 8a. There are fewer nanoparticles coexisting with the pristine MWNTs in H_2 (Fig. 8a) than in He or Ar gas. Therefore, purification is very easily achieved by infrared radiation in air at 500 °C for 30 min [20, 31], as shown in Figure 8b. Such purified MWNTs look like a sponge (Fig. 9) [31], which is easy to manipulate with tweezers for various measurements. The size of the sponge is 10 mm^2 area $\times$ 0.1 mm thickness, and the mass is about 1 mg.

2.3. Structure of H_2 Arc MWNTs

The structural features of MWNTs produced by H_2 arc discharge can be elucidated by HRTEM [18, 21]. As shown in Figure 10a, as-grown MWNTs are highly crystallized with perfect coaxial tube layers [21]. The diameter of the innermost tube A is about 1.2 nm and the outer diameter of

the MWNT is 13 nm. There are 16 graphene sheets on both sides with a regular spacing of 0.34 nm. The arrow *B* points out amorphous carbon seen in pristine MWNTs. A cross-sectional view of an MWNT (but not of the same one as in Fig. 10a) is shown in Figure 10b. Concentric circles are seen, but with half-fringe discrepancy at each arrowed position.

Based on HRTEM observation, the innermost diameter distribution can be obtained [22]. The mean value of the innermost tube is 1.0 nm, whereas that for He arc MWNTs is usually more than 3 nm. The innermost tube observed in H_2 arc MWNTs is 0.4 nm (Fig. 11) [32]. The innermost tube is supposed to possess an armchair $(3,3)$ structure.

3. PREPARATION OF SINGLE-WALLED CARBON NANOTUBES BY CARBON ARC

3.1. Lab-Scale Production

Two years after the discovery of MWNTs, SWNTs were found by Iijima and Ichihashi [9] and by Bethune et al. [10], independently. An HRTEM micrograph of the single-shell tube with diameter 1.37 nm [9] is shown in Figure 12.
Figure 9. SEM micrograph of purified MWNTs sponge. Reprinted with permission from [31], Y. Ando et al., *Jpn. J. Appl. Phys.* 37, L61 (1998). © 1998, Institute of Pure and Applied Physics, Japan.

SWNTs were found in the specimen produced by arc discharge using a graphite rod including a metal catalyst (Fe), not in the cathode deposit but in the carbon soot. Incorporation of the metal catalyst is essential to produce SWNTs. In Iijima's case, a mixture of methane (10 torr) and argon (40 torr) was used as the ambient gas [9]. Bethune et al. prepared SWNTs under slightly different conditions using a Co catalyst in helium gas [10]. However, in both cases, the yield of SWNTs was very small.

3.2. Mass-Scale Production

High-yield SWNTs were first obtained by laser ablation [13], in which unwanted nanoparticles were negligible as compared to SWNTs. However, the overall quantity of SWNTs
Figure 11. HRTEM micrograph of a 4-Å tubule. Reprinted with permission from [32], L.-C. Qin et al., *Nature* 408, 50 (2000). © 2000, Macmillan Magazines Ltd.
Figure 12. HRTEM micrograph of SWNT. Reprinted with permission from [9], S. Iijima and T. Ichihashi, *Nature* 363, 603 (1993). © 1993, Macmillan Magazines Ltd.

obtained was still very small. Later on, Journet et al. succeeded in obtaining a large quantity of SWNTs by the arc discharge method [14]. They used a bimetallic catalyst; the best results were obtained with 1 at% Y and 4.2 at% Ni. An SEM micrograph of SWNTs as high density of entangled carbon filaments is shown in Figure 13, which is formed as a collar around the cathode deposit and is not the cathode deposit itself. Such SWNTs are also obtained in other places, that is, rubbery soot condensed on the chamber walls, web-like structures between the cathode and the reactor walls, and a cylindrical deposit at the cathode end.

3.3. Arc Plasma Jet Method

Unlike the case of MWNTs, the cathode deposit of arc discharge using a metal-doped anode does not include SWNTs [14]. Hence, an attempt was made to reduce the cathode deposit and increase the quantity of soot generated that contains SWNTs [33]. A pure graphite cathode and metal-doped anode were set at an angle of 30°, and discharge was carried out with the arc flame occurring along the inclined cathode. This new method to produce SWNTs is known as the arc plasma jet (APJ) method [33].

The evaporation rate of the anode and the production rates of the carbon soot and cathode deposit measured in SWNT production experiments under He gas at 500 torr [33] are shown in Figure 14a and b. In the case of APJ, more than 80% of the evaporated anode yields cotton-like soot containing SWNTs and less than 20% appears as cathode deposit. On the contrary, the quantity of deposit in the conventional arc method is larger than the soot at a dc

Figure 14. Evaporation rate of the anode, production rate of carbon soot, and production rate of deposit measured in SWNT production experiments under He gas of 500 torr: (a) APJ method, (b) conventional arc method. Reprinted with permission from [33], Y. Ando et al., *Chem. Phys. Lett.* 323, 580 (2000). © 2000, Elsevier Science.

arc current higher than 70 A. Figure 15 shows a characteristic SEM micrograph of cotton-like carbon soot produced by the APJ method [33]. A large number of entangled SWNT bundles and nanoparticles of Ni are seen. The catalyst metal particles are usually covered by thick amorphous carbon, which is hard to remove. Nevertheless efforts to purify as-grown SWNTs are in progress.

4. PROPERTIES OF SWNTs AND MWNTs

4.1. Structures

The helical structures of MWNTs and SWNTs are elucidated from their electron diffraction patterns observed by TEM [1, 9]. The atomic structure of individual SWNTs can be determined by scanning tunneling microscopy (STM) [34, 35]. All three types of possible structures predicted theoretically—chiral, zigzag, and armchair—were confirmed experimentally by STM images [34–36].

X-ray diffraction (XRD) measurement of H_2 arc MWNTs is performed using a synchrotron radiation source [37]. The

Figure 13. SEM micrograph of large-scale production of SWNTs by arc discharge. Reprinted with permission from [14], C. Journet et al., *Nature* 388, 756 (1997). © 1997, Macmillan Magazines Ltd.
Figure 15. SEM micrograph of carbon soot containing SWNTs which were prepared by the APJ method. Reprinted with permission from [33], Y. Ando et al., *Chem. Phys. Lett.* 323, 580 (2000). © 2000, Elsevier Science.

powder XRD patterns (wavelength 0.9942 Å) are collected using a powder X-ray diffractometer equipped with an imaging plate. H_2 arc MWNT samples are sealed in a quartz capillary and the temperature is controlled in a range from room temperature (RT) to 900 K. XRD profiles are taken as a function of temperature. The XRD profiles of the (002) peak at RT and 873 K are analyzed by Gaussian line shape as shown in Figure 16. Thus, each peak is decomposed into three kinds of peaks: *A*, *B*, and *C*. The first two peaks, *A* and *B*, are due to defective MWNTs, while peak *C* is most probably due to a perfect Russian-doll-type structure.

4.2. Electric Properties

Not only the helical structure of SWNTs but also the electronic density of states can be measured by STM [34, 35]. It has been confirmed that SWNTs are metallic or semiconducting depending on the wrapping angle and the tube diameter. The electrical transport measurements of individual SWNTs [38] also coincide with the theoretical predictions [39].

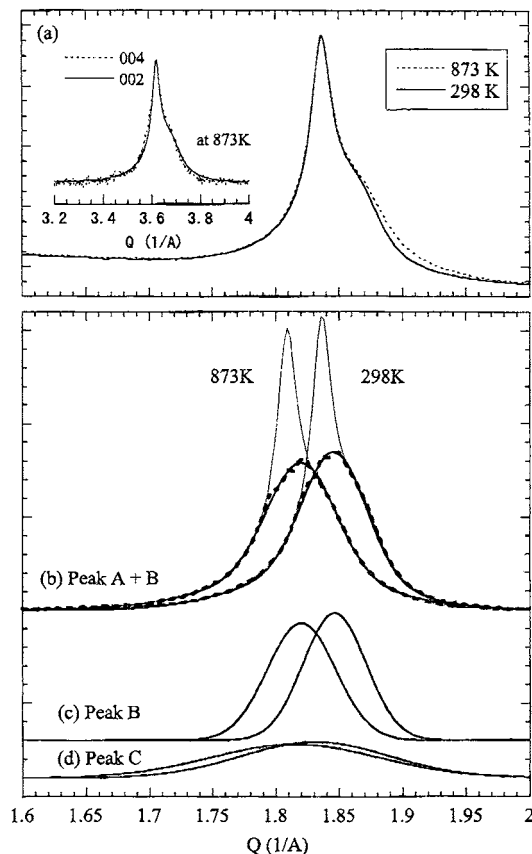
On the other hand, the electric resistance of individual MWNTs has been measured by a micro-manipulator system [40]. Individual H_2 arc MWNTs can conduct high electric current [19], 1.0×10^7 A/cm². The temperature dependence of their electric resistance in curve *a* (Fig. 17) shows that the resistance decreases with increasing temperature. This


Figure 17. Temperature dependence of electric resistance of MWNT. Curve *a* is obtained from a single MWNT and curve *b* is obtained from a bundle of MWNTs. The arrows show the direction of the temperature change. Curve *a* is semiconducting and curve *b* is metallic. Reprinted with permission from [19], Y. Ando et al., *Diamond Relat. Mater.* 9, 847 (2000). © 2000, Elsevier Science.

temperature dependence corresponds to the semiconducting character of MWNTs. In curve *b*, the resistance increases with increasing temperature, namely, metallic character.

Field emission measurements of the spongy bulk of H_2 arc MWNTs have also been carried out [19]. A practically desirable field emission current density of 1 mA/cm² is achieved only at an anode voltage of 580 V. The value of the applied voltage is reduced to a field (applied voltage/gap distance) of 1.2 V/μm. A light source device, which emits primary color of super-high luminance and fast switching, has been developed by using the spongy bulk of the H_2 arc MWNTs [41]. High current density is obtained and enough electron emission is maintained for a long time. A super-high green luminance of 1.0×10^6 cd/m² is achieved by the light source device.

4.3. Raman Spectra

The Raman spectra of SWNTs show their characteristic features [42, 43]. In the low-frequency region, radial breathing modes (RBMs) are observed at frequency values inversely proportional to the diameter of the SWNTs [42, 43]. The observation of RBM peaks is necessary to confirm the presence of SWNTs. In the high-frequency region, the splitting of G-band modes and its splitting due to the cylindrical structure of SWNTs are observed.

In the past decade, extensive Raman experiments have been performed on MWNTs synthesized by arc discharge evaporation in helium gas and by CVD. However, the reported Raman spectra closely resemble that of graphite, and no RBMs have yet been found [44–46] except by Jantoljak et al. [47]. On the other hand, many Raman-active modes [22, 48] are observed for H_2 arc MWNTs in the low-frequency region. The resonance effect of each mode [49] is similar to that of the RBM in an SWNT. It is known that RBMs are expected to have an A_{1g} symmetry, and the wave number of the RBM is proportional to the inverse of the diameter of the SWNT [42, 43].

Figure 18 shows the micro-Raman spectra [22] in the low-frequency region (100–600 cm⁻¹) for three specimens of

Figure 16. X-ray diffraction profile of H_2 arc MWNTs. Reprinted with permission from [37], Y. Maniwa et al., *Phys. Rev. B* 64, 073105 (2001). © 2001, American Institute of Physics.
Figure 18. Raman spectra of MWNT mat in low-frequency region. Reprinted with permission from [22], X. Zhao et al., *Chem. Phys. Lett.* 361, 169 (2002). © 2002, Elsevier Science.

H_2 arc MWNT mats, (*A*)–(*C*). For comparison, the Raman spectra of SWNTs produced by the APJ method [33] and highly oriented pyrolytic graphite (HOPG) are also displayed in Figure 18. In contrast to HOPG, many sharp Raman-active peaks are observed in the Raman spectra of the MWNT mats. The highest frequency peak is observed at 570(3) cm^{-1} in MWNTs (*A*), where the full width at half-maximum (FWHM) is given in parentheses. By observing the polarized Raman spectra from single straight bundles of MWNTs, each Raman-active peak in Figure 18 is assigned an RBM [22]. In the case of MWNTs, the RBM comes from the thin innermost diameter. From the RBM frequency the diameter of the innermost tube can be determined. Thus, the highest frequency peak 570 cm^{-1} is due to the smallest innermost tube of 0.4 nm [32].

The characteristic features of the Raman spectra are also observed in the high-frequency region for individual H_2 arc MWNTs dispersed onto a silver substrate [23]. Surface-enhanced Raman scattering (SERS) spectra are taken from a single H_2 arc MWNT. Three examples of Raman spectra are shown in Figure 19a and b for the low- (100–600 cm^{-1}) and high- (1450–1650 cm^{-1}) frequency regions, respectively. In Figure 19a, single RBM peaks of different frequencies with sharp FWHM can be seen for each H_2 arc MWNT, *A*, *B*, and *C*. The RBM frequencies of 216, 403, and 192 cm^{-1}
correspond to the innermost diameters of H_2 arc MWNTs: 1.09, 0.58 and 1.23 nm, respectively. SERS spectra *A*, *B*, and *C* in Figure 19b show multiple splitting of the G-band modes in H_2 arc MWNTs. These peaks are analyzed by Lorentz fit [23] and decomposed into a broad graphite-like line at approximately 1580(20) cm^{-1} and sharp lines with FWHM of about 4 cm^{-1}. The latter originate from the thin innermost tubes of H_2 arc MWNTs [23].

4.4. Nanocomposite Structure

By removing the cap of the MWNT or SWNT, other materials such as some metals or fullerenes can be inserted into the tube [50–52]. Nanotubes act as molds for the fabrication of metallic wires, some of which are less than 2 nm in diameter [50]. From these viewpoints, new composite materials have been made. As an interesting phenomenon, heat treatment of SWNTs filled with C_{60} [52] leads to the formation of double-wall carbon nanotubes (DWNTs) [53]. This is a new method for making DWNTs.

5. APPLICATIONS OF MWNTs AND SWNTs

Potential applications of carbon nanotubes are predicted for electrical, electronic, mechanical, and chemical applications, such as field emission [54], flat-panel display source, quantum wires [38], X-ray source [54], contact needle of atomic force microscopy, hydrogen storage, gas sensors, capillarity-induced filling of metal [50], and fullerene peapods [52]. Highly crystallized MWNTs and SWNTs produced by arc discharge should have more potential for electronic and mechanical applications. Application-based research of SWNTs and MWNTs is continuously increasing worldwide.

GLOSSARY

Arc discharge Evaporation method of graphite electrode using arc discharge. Usually carried out in inert gas.

Arc plasma jet (APJ) Method to prepare SWNTs by a special kind of arc discharge.

Carbon nanoparticles Nanometer-sized particles made of carbon, which usually has onion-type layered structure.

Carbon nanotube Tube composed of carbon atoms only, having a diameter on the order of nanometers. Each tube is made of a rolled graphene sheet.

Carbon roses Petal-like carbon made of graphene sheets, which resemble a rose.

Chemical vapor deposition (CVD) An alternative method to make fibers or carbon nanotubes.

Field emission Electron emission from metal just by applying electric field without heating the metal.

Fullerenes Represented by C_{60}, which is a macromolecule having a cage structure consisting of hexagonal and pentagonal carbon rings.

G band Typical Raman peak of graphite observed at 1582 cm^{-1}, which has E_2 symmetry.

Figure 19. Surface-enhanced Raman spectra from individual MWNT: (a) low-frequency region, (b) high-frequency region. Reprinted with permission from [23], X. Zhao et al., *Appl. Phys. Lett.* 81, 2550 (2002). © 2002, American Institute of Physics.

H$_2$ arc MWNTs MWNTs prepared by dc arc discharge in H$_2$ gas.

Multiwalled carbon nanotubes (MWNTs) Consisting of many rolled graphene sheets.

Radial breathing mode (RBM) Observed in low-frequency region of Raman spectra of thin tube. The frequency is proportional to the inverse of the tube diameter.

Raman spectra Spectra of Raman shift measured by laser acquisition.

Single-walled carbon nanotubes (SWNTs) Consisting of only one rolled graphene sheet.

X-ray diffraction (XRD) Pattern to clarify crystal structures.

1. INTRODUCTION

The source of the most commonly used cathode ray tube (CRT) is an electron, which is thermally ejected from a hot cathode surface. To facilitate the electron ejection, a material with low work function such as a barium oxide compound has been used [1]. The ejected electrons are accelerated through the electric field for rastering and exciting the phosphor screen to display images. The electron emission and acceleration process lead the CRT to consume a lot of power, to operate at high voltage, and to be very bulky. Even though there are some advantages to conventional CRTs such as wide viewing angle, fast response time, unlimited colors, and low price, these CRTs are losing the competition in the display market these days. One major reason is that, in nature, the large dimension and high operational voltage do not allow the CRT to be portable. Portability, however,

is one of the essential features that a display must satisfy in the information age to permit accessibility to the intellectual resources at any time and any place. Therefore, the demand for a flat-panel display, which is slim, light, and operating at low voltage and at low power consumption, has become even stronger.

The annual revenue of the fast-growing global market of flat-panel displays (FPDs) is supposed to reach 80 billion dollars in 2010 [2]. Such tremendous growth of the FPD market has been empowered by the wide distribution of the laptop computer and technical developments in the area of FPDs. In the FPD market, there are several types of displays: liquid crystal display (LCD), plasma display panel (PDP), organic electroluminescence display (OELD), and field emission display (FED). At present, the LCD, dominating about 80% of the market, is very light and slim and operates at low voltage, but contains problems such as limited colors, narrow viewing angle, narrow operation voltage, and high power consumption. LCDs should overcome these problems in order to maintain their position in the market. At the same time, other types of FPDs have to show technical superiority to survive in the market. For instance, PDPs can be readily scaled up to over 60 in., but consume heavy power for plasma generation and still do not show the wide color range that CRTs can display. The OELD, which is flexible and can be fit into almost any shape, operates successfully only for a few hundred hours and degrades fast and furthermore shows low thermal stability.

Among these displays, the FED has captured only a small portion of the market. The CRT and FED have many internal structural features in common, except for the electron

ejection gun. In FEDs, the electrons are ejected by the strong local electric field from many sharp tips. The electric field can be switched on and off swiftly, contributing to the fast response time. FEDs can also provide unlimited colors, a wide viewing angle, and a wide operating temperature, but with low power consumption and low applied voltage. In addition to the above advantages, there are millions of tips in a pixel. Therefore, if one of the emitters stops functioning, another emitter contributes to the field emission. All theses properties of the FED make it an almost perfect display. However, many technical issues have yet to be resolved to meet the requirements for commercialization.

The field emission phenomenon was not clearly understood until the adoption of quantum mechanics, because field emission is different from thermionic emission, where sufficient kinetic energy should be given to the electrons in order to surmount the potential barrier at the interface between the vacuum and the surface of the emitter [3–5]. Field emission is a tunneling phenomenon, which cannot be described by classical mechanics. In the presence of a strong electric field, electrons can tunnel through the potential barrier since the barrier becomes dramatically narrow under such a strong field, as shown in Figure 1. Therefore, the field emission is expected to vary with the strength of the applied field and the work function of the emitter materials. Some efforts neglecting this tunneling effect were made in the 20th century, but turned out to be unsuccessful for characterizing the relationship among the above parameters [6], until Fowler and Nordheim formulated the relationship based on quantum mechanics. In their formula, the emission currents can be described as follows:

$$J = A(\beta V)^2 \exp(-B\phi^{3/2}/\beta V) \qquad (1)$$

where ϕ is the work function of the tip, A and B are constants, and β is a field enhancement factor depending on the geometrical structure [7].

Metal tips were used to study the field emission in the early days. The metal tips are prepared by electrochemical etching [8, 9] and lead to an intensification of the electric field. Among various metals, refractory metals, such as tungsten, and molybdenum are utilized for field emitters because of their high melting temperature and mechanical robustness to high electrical stress [10, 11]. An emitter coated with a thin film of low work function, such as Cs, can render lower operation voltage, but the chemically reactive Cs becomes easily oxidized, decreasing the current density [12]. However, the high work function and low field enhancement factor of metal emitters of about 10 require an ultrahigh vacuum environment and appreciable emission voltage in the range of $3–7 \times 10^9$ V/m, which would eventually result in the ionization of the residual gases, physical sputtering of the emitter tip, and fluctuation of the emission currents. For these reasons, coating the emitter tips with wide bandgap materials (WBGMs) exhibiting negative electron affinity (NEA) such as diamond, SiC, c-BN, LiF, and CaF have been attempted [13–16]. Even though the high mechanical hardness and chemical inertness of the WBGM are very beneficial for field emitters, concurrently a wide bandgap becomes a prime obstacle that hinders large electron emission and lowers electrical conductivity unless the coating thickness is controlled with high precision.

Another attempt to circumvent the high turn-on voltage of the metal emitters is miniaturization of the device by microfabrication techniques from the semiconductor industry. The pioneering achievement was first made by Spindt in 1968 [17]. He fabricated a gate-structured cathode consisting of a cathode and a gate electrode. For the cathode, thermal evaporation of molybdenum was conducted through the microcavity, which had been preformed on a layered structure of gate/insulator/cathode. The gap between the gate and the conical-shaped emitter is only about 0.5 μm and the cathode is a matrix-addressed Mo emitter array. The proximity of the gate electrode and the high population of emitters, 2.5×10^7 emitters/cm^2, contribute to the large available emission current of 1000 A/cm^2 at a bias voltage of 100 V [18]. Despite the fact that such prominent advancements enable us to operate FEDs at low voltage with large emission current, the operation voltage is still too high to be met by the current integrated circuit (IC) chip driving circuit and furthermore thin-film deposition for making the emitter array is not an effective approach for lowering the manufacturing cost and scale-up of the display.

2. ADVANTAGES OF CARBON NANOTUBES

As briefly mentioned in the previous section, field emitters should be robust in order to sustain a high electric field and large emission current. Therefore, the emitter material should have a high melting point, high thermal and electrical conductivity, and high physical stiffness. In addition, low work function is one of the important factors in making a field emission device operable at low voltage. High mechanical stiffness would help emitters to minimize the geometric deformation from ion bombardments; chemical inertness must be a significant advantage making emitters immune to the residual gases. However, it is not easy to find a material satisfying all these requirements. Nonetheless, carbon nanotubes (CNTs) are a potential material for field emitters in many aspects. The CNT first reported by Iijima et al. is a seamless tubular structure formed by rolling
Figure 1. Schematic diagram of potential barrier (a) on the emitter surface, (b) under an applied electric field, and (c) with the effect of image potential. ϕ and ϕ_{eff} are the work functions on the emitter surface without and with the combination of the applied field and image charge, respectively.

up and matching a graphene sheet [19]. The cylindrical CNT is composed of single layers or concentric multilayers of the graphene sheet. The geometric structure of the CNTs makes them very effective field emitters when they are placed inside the electric field due to the large aspect ratio coming from a small diameter ranging from one to several nanometers for single-walled CNTs (SWCNTs) and a few tens of nanometers for multiwalled CNTs (MWCNTs) and a length of several micrometers. CNTs, sp^2-bonded carbon networks, are supposed to have a high Young's modulus with low mass density. However, the technical difficulties involved in the manipulation of the nanotubes mainly come from the small diameter and the tendency of the CNTs to form bundles, which makes direct measurement of the mechanical properties a challenging subject. As a consequence, only a few measurements on the Young's modulus have been reported. The studies have been carried out under or inside a microscope. One approach is to correlate it with the amplitude of a standalone oscillating CNT whose bottom is fixed at the substrate [20, 21]. The detailed characteristics of the CNT motions observed inside a transmission electron microscope (TEM) are analytically studied after printing the micrographs. Measurements made on many SWCNTs reveal that the Young's modulus is 1.25 TPa, which is greater than the modulus along the basal plane of the graphite. Another approach is to use atomic force microscopy (AFM) to bend an SWCNT bridging a pore of an ultrafiltration alumina membrane using an AFM tip [22, 23]. But, regardless of the experimental methods, the Young's modulus of the SWCNT is about 1 TPa. Also, in the case of the multiwalled CNT with a diameter larger than 2 nm, the Young's modulus is on the same order as that of the graphite. This suggests that a large diameter does not induce stiffening [22].

CNTs, quasi-one-dimensional structures with the unique electronic structure of a graphene sheet [24], exhibit very high electric and thermal conductivity [25]. The electronic properties are highly responsible for the geometric structures [26]. Although graphite is a semimetal, the CNT can be a metal or a semiconductor, depending on the diameter and chirality of the tube, with various energy bandgaps usually below 1 eV [26–29]. The influence of these versatile electronic properties on the geometrical structures originates from the unique mirror-image band structure of the graphene sheet and the quantization of wave vectors along the circumferential direction. The periodic boundary condition along the circumference allows only a certain set of k states of the planar graphite sheet to be available, depending on the tube diameter and chiral angle. In general, the chiral angle of each single-walled CNT can be designated by an integer pair (n, m), where n and m are indices of two basis vectors of the graphene sheet. Any choice of (n, m) classifies CNTs into two categories, depending on the metallicity. All (n, n) tubes have a band degeneracy, which is induced by crossing π and π^* states at $k = 2/3(\pi/a_0)$. Therefore, these tubes should be metallic. The (n, m) tubes satisfying $n - m = 3i$, where i is a nonzero integer, should also be metallic. All others are large-gap semiconductors. For semiconducting tubes, the bandgap decreases inversely proportional to the diameter. The above band-folding scheme is valid for tubes with a large diameter. However, for the

$(n, 0)$ tube with a small diameter, this scheme is not adequate because the strain energy dramatically increases as the degree of curvature becomes larger. This curvature effect or strain opens up the small bandgap, whereas the tube is practically metallic at room temperature due to the small bandgap. The curvature effects become more prominent, at which point the tube is under mechanical stress because of an enhanced mixing of the σ and π states [30].

To construct the closure of the graphene sheet, the incorporation of topological defects, pentagons, is essential. It results that, many different structures can exist at the cap. The variety in cap structures stems from the variable number of pentagons involved and their relative positions with respect to the hexagons [31]. Due to this property, it is possible that there exist several different cap structures at the same tube diameter and the consequence is remarkable differences in the electronic structures at the cap.

The electronic structures in correlation with the chirality and the diameter of the tube have been examined by scanning tunneling spectroscopy (STS) [32–34]. Raman spectroscopy has proved to be an easily accessible, reliable, and nondestructive method to probe the chirality and diameter of the individual tube [35]. However, these approaches are not applicable for the investigation of the cap geometry. The structure of the cap has been investigated using field emission microscopy (FEM) [36–38]. A pentagon ring of carbon is clearly seen. In addition, since the pentagon is a defect, the electronic structure at the cap should be different from that on the wall. As mentioned previously, the diversity in structure results in various local electronic structures at the cap [39]. Understanding the local density of states (LDOS) originating from these defects has huge significance for discovering the field emission properties since, in some topological configurations, the localized states can emerge very near the Fermi level at which the field emission take places [40]. At pentagonal sites, the field emission is observed to be stronger and gas adsorption is more active than at other hexagonal areas [36]. Dean et al. have proposed that the nonmetallic behavior observed at the high voltage region might be related to the defect states [41]. Unfortunately, complete comprehension of the emission behavior correlated with the cap geometry is not well established. This will require systematic studies in the near future.

When the carbon nanotube was first discovered in 1991, it was a soot synthesized by arc discharge [19]. Usually, this growth method together with laser ablation is known to produce highly crystalline single-walled and multiwalled nanotubes [42]. The generated CNTs are entangled in bundles, with amorphous carbon, graphitic particles, and other forms of carbons as by-products [43, 44].

The entanglement of the CNTs with amorphous carbon layer and catalyst particles along the tube leads to the laborious purification process consisting of sonication, air oxidation, and acid treatments [44]. After the purification process, only a small amount of CNT with high quality is obtained. However, in the two growth methods, since the synthesis takes places over a very local area at extremely high temperature, the scale-up of the growth system is practically impossible. Also, without the removal of amorphous carbon, metal particles, and graphitic particles, the application of pristine

CNTs as field emitters causes the emission properties to be uncontrollable. However, if we understand the growth mechanism, where catalytic decomposition of hydrocarbon is involved, the control of diameter, length, directional growth, and scale-up of growth system, which are impossible in arc discharge and laser ablation, would be achieved in a chemical vapor deposition (CVD) system.

In CVD, all the growth parameters from arc discharge and laser ablation are precisely controlled and slowed down over a prolonged growth period. First, in CVD, the heating of catalyst metals is carried out after the CVD chamber is filled with carrier gases and hydrocarbon sources up to a certain pressure. Usually, catalyst metals such as Fe, Ni, and Co are deposited on a Si substrate or porous support such as alumina and zeolite to hold the nanoparticles inside the channels [45–47]. During the temperature elevation, the control of diffusion and agglomeration of metal particles due to thermal energy is very critical to monitor the tube diameter and density [48]. The growth temperature varies with the gas species and catalyst metals, but ranges between 600 and 1000 °C. As carbon sources, C_2H_2, CH_4, CO, ethylene, and even alcohol are used [48–51]. Recently, the growth of CNTs aligned in the perpendicular direction to the substrates has successfully been accomplished by many groups [52–55]. CVD tubes grown for 20–30 min are, on average, about 10–50 μm long and 50 nm wide. The huge progress in CNT growth using the CVD method has led to a reduction in the purification steps and resulted in vertically aligned tubes. Still, the growth of CNTs below 550 °C over a large area in an economic way requires further investigation for their practical application.

3. FIELD EMISSION PROPERTIES OF CARBON NANOTUBES

Before de Heer and his group studied the field emission using highly oriented CNTs [56], the growth of the CNTs using the CVD method had been demonstrated [57, 58]. Although CVD growth promises several advantages for applications as field emitters compared to arc discharge and laser ablation synthesis, the realization of the field emitter was postponed due to poor alignment of the CVD-grown tubes. However, later, more adaptable CNTs with better orientation were grown on mesoporous media by the CVD method by Li et al. [59]. The above pioneering research has ignited worldwide research on CNTs as field emitters. MWCNTs can be grown in a preferential direction using catalyst particles deposited on Si substrates using a magnetron sputter. However, the complexity of the growth parameters such as temperature, flow rate, catalyst metal, gas species, pressure, and grain size of catalyst metal results in wide diversities in tube structure, diameter, density, length, and crystal quality.

Characterizations of electron field emission from CNTs, which are placed inside a strong electric field, have been carried out in many different ways. We know from (1) that the emission currents are a function of work function and field enhancement factor. However, the work function, in particular, at the emitting site, is not the same as that at the bulk and is very sensitive to local electronic structures. Many groups have demonstrated from FEM studies

that field emission occurred through the cap, and the cap structures observed on the phosphor screen are different from tube to tube. This implies that emission currents might change dramatically depending on the cap geometry, but systematic studies have not been carried out due to the various geometries. Some theoretical calculations on the effects of cap structures have been conducted only on certain types of tubes [39, 60]. Kim et al. proposed that the localized states of the pentagon defect contribute to the field emission only at strong electric field and the degree of charge accumulation at the cap shows stronger dependence on the tip sharpness rather than the local atomic geometry [61].

From the aspect of electronic structures, CNTs are different from previous metal emitters. Nevertheless, the Fowler–Nordheim (F–N) characteristic curve obtained from CNTs resembles that of metal emitters. Due to the advantage of the tip geometry, the CNT has a lower turn-on voltage, between 1 and 2 V/μm. The SWCNT has a lower turn-on voltage than the MWCNT. The evaluated field enhancement factor from the F–N plot based on a work function of 5.0 eV is about 1000–3000 and 2500–10,000 for MWCNTs and SWCNTs, respectively [62]. The higher field enhancement factor for SWCNTs is attributed to the smaller diameter. Bonard et al. have also tested the emission stability of both tubes for long-term operation. The emission currents from the SWCNTs degrade about 10 times faster than those from the MWCNTs. This degradation could be explained possibly by the structural weakness of the SWCNT edge to the ion bombardment of residual gases [62]. The higher stability of the MWCNTs could also be explained by the tube edge interactions, where the tube edges are stabilized by lip–lip interactions via spot-welded adatoms [63].

The directional dependence of the emission properties was also studied. The field emission has been examined as a function of the angle of CNTs with respect to the substrate [64]. Contrary to the general belief that the low turn-on voltage of CNTs is attributed to the high aspect ratio, where the aspect ratio is presumed to be even greater with the CNTs aligned in parallel with the electric field, the CNTs parallel to the substrate eject electrons at a lower turn-on voltage. It has been proposed that numerous defect sites along the tube wall contribute to easier electron emission. Another possible explanation is the catalyst existing at the end of the tube, which degrades the field emission currents.

With regard to the fabrication of flat-panel displays based on the CNTs, depositing the emitters with an optimum number of CNTs per unit area is crucial, since the poor emission properties observed from the CNT films grown by CVD are speculated to originate from high tube density due to the shielding effect of the electric fields. Several approaches have been attempted to regulate the CNT emitter density on the substrates. One approach is to regulate the grain size and density of the catalytic particles during thin-film deposition using typically RF (radio frequency) magnetron sputter, which enables one to control the grain size and density by the plasma power, substrate temperature, and deposition time [65].

Another way to deposit catalyst particles is to print using a stamp. This is called micro-contact printing (μCP), which uses a patterned elastomeric stamp to transfer a self-assembling material (SAM)–forming ink. The stamp is

made by casting a polydimethylsiloxane (PDMS) elastomer on a master with a designed pattern prepared by MEMS (microelelctromechanic system) techniques. A catalyst-containing solution is used for the ink. [66–68]. The transfer of catalyst particles is made by compressing a stamp against the substrate after dipping the stamp into the ink or placing a droplet on the stamp. The primary advantages of μCP are its simplicity and scalability. One can readily change the concentration of the catalyst ink and generate reproducibly the same pattern over a large area. Bonard et al. have examined the correlation of concentration of catalyst ink to CNT growth. In their study, up to a certain concentration, the alignment of CVD-grown CNT becomes better along the vertical direction and then CNTs do not grow above the optimum concentration [69].

Another way to control the emitter density is to use a template, which arranges the metal particles along geometric channels. The template is composed of arrays of pores, whose diameter and pore–pore distance are well defined through the anodizing process [70]. During the anodization of high-purity aluminum, we can change the pore diameter, pore–pore distance, and pore depth by varying the voltage, temperature, reaction time, and proper choice of chemicals. Using an anodized aluminum oxide (AAO) template, monodispersed pores with a high regularity over a large area have been obtained by several groups [71–74]. One of the benefits of using the AAO template is that we can precisely control the ratio of height to diameter, which is an essential factor for regulating field emission and minimizing screening effects, as shown in Figure 2a and b. The detailed significance of screening effects due to the neighboring tubes is well documented in the literature [75]. The most efficient ratio of tube height to tube–tube distance is known to be

Figure 2. SEM images of CVD-grown CNTs using AAO template. The average tube diameter and tube–tube distance are (a) 38 and 104 nm and (b) 19 and 65 nm, respectively. The variation of field enhancement factors in the function of tube height. The intertube distance is (a) 104 nm and (b) 65 nm. Reprinted with permission from [75], J. S. Suh et al., *Appl. Phys. Lett.* 80, 2392 (2002). © 2002, American Institute of Physics.

about unity. The field enhancement factor at this configuration ranges from 2500 to 3500, as shown in Figure 2c and d.

All the approaches mentioned above manage the as-grown tube density by arranging catalyst particles before the tube growth. The following screen-printing method is used to handle the ready-grown nanotubes. In the screen-printing approach, the as-grown or purified SWCNTs are dispersed in isopropyl alcohol and mixed with an organic binder such as nitrocellulose and ethylcellulose. The mixture with homogeneously dispersed CNTs is pasted on the prepatterned cathode electrodes [76, 77]. However, the number of emitters per unit area is also very sensitive to the pasting techniques.

Another parameter as significant as the tube density in achieving emission uniformity is the film roughness. Initially, the emission pattern of the CVD-grown tube is very poor. The reason is that tubes protruding out from their neighborhood dominate the emission currents. Improvement in the uniformity of the emission pattern requires removal of those protruded tubes. The removal process is known as high-voltage annealing, since the tube is gradually burned away by resistive heating at large emission currents. While the duration of the annealing process is strongly dependent on the applied voltage and emission currents, it usually lasts longer than 24 h.

The field emission characteristics of CNTs at room temperature exhibit current suppression at a high-field region, that is, a decrease in the slope of the F–N curve, which is different from those of the typical metal tips [18, 78]. The turn-on voltage of the CNTs is as low as a few volts per micrometer, lower than that of the typical metal tips by a factor of 100 [79]. Several mechanisms such as space charge, screening effects, metal particles at the cap, and gas adsorbates have been proposed in order to explain the current suppression at high field.

Lim et al. have checked various possible causes and have concluded from a slope change during only rise sweep, not fall sweep, in their I–V curves that the release of gas adsorbates at large emission currents are the origin of current suppression [80]. Several groups have observed thermal motions of the gas adsorbates at the cap using FEM [36, 37, 81, 82]. The cause of thermal fluctuation in FEM images is local heating for large emission currents. At the stage that gas adsorbates initially reside on the surface of cap, the emission currents are stable and the FEM image is motionless. As the increasing emission currents start to heat up the cap resistively, local heating, the emission currents fluctuate as do the FEM images. At even higher bias voltage, a complete desorption of gas adsorbates on the cap is observed with a significant current decrease. At desorption, the temperature is reported to be around 1000 K [41, 82]. The cyclic repetition of voltage sweep generates consistent I–V characteristics and FEM micrographs. As a consequence, local resonant states present on the surface of the cap temporarily disappear and reappear in parallel with an increase and decrease in the emission currents. Field emission enhanced through the resonant states becomes suppressed in the absence of adsorbates.

For the purpose of clarifying the effects of each gas species, Dean et al. intentionally exposed CNTs to different gases and studied the variation of the emission properties.

Saito et al. have investigated the variation of the emission properties upon adsorption and desorption of gas adsorbates [36]. They observed the migration of gas adsorbates on the cap of the CNT and found that the pentagon site is favorable for electron emission because of not only geometrical protrusion but also the presence of strongly localized states. It is also found that the gas adsorbates preferred to reside on the pentagon sites. To remove the gas adsorbates, heating to about 1300 K is required. This temperature is somewhat higher than the desorption temperature witnessed by Dean et al. After heating, the stepwise decrease in emission currents was observed as the gas adsorbates came off the cap, as shown in Figure 3.

Among the species introduced into a vacuum system, water vapor is the only species enhancing emission currents. Water molecules are removed from the surface of the CNT at about 900 K and degrade the emission. Lim et al. studied the effects of different gases on the field emission properties as a function of exposure times. In their experiment, oxygen gas reduces the emission currents significantly through the oxidative etching process. The erosive etching of oxygen gases destroys the sp^2 network and depletes the 2p–π electron states, which contribute to the field emission currents [83, 84]. The destruction of tube structure and reduction in electronic states near the Fermi level result in high turn-on voltage and low emission currents. After oxidation, the contents of the sp^3-bonded structures increase. The reverse transition from sp^3 to sp^2 is partially achieved as the MWCNTs were annealed above 750 °C.

Theoretical calculations on the electronic structures in the presence of gas adsorbates and an adsorption mechanism have provided a clearer understanding of the effects of field emission upon gas species [85–87]. The influence of water molecules on field emission has been studied. Water molecules, whether they maintain the molecular structure or break into ions on the cap, always increase the emission currents. Maiti and his colleagues have assessed the influence
Figure 3. FEM images showing progressive desorption of gas adsorbates with the change of emission currents. The first pattern was taken 60 s after the beginning of heating. The following patterns were taken (b) 90 s, (c) 120 s, and (d) 130 s after heating, respectively. (e) Heating was turned off. Reprinted with permission from [36], K. Hata et al., *Surf. of water molecules that exist on the cap. In their study, they chose a closed tube and water molecules to be physisorbed on the cap. Polar water molecules construct complexes stable up to several hundred degrees, with a corresponding decrease in the ionization potential and stability of the highest occupied molecular orbital (HOMO). The resulting electronic structure becomes more favorable to field emission. The preservation of the molecular structure of water neglects the possibility that water molecules can break into H and OH ions. The residence of water fragments such as H and OH ions on the open edge of armchair and zigzag tubes is theoretically well simulated by Hwang and Lee [88]. The resulting electronic states with the Fermi level shifted toward the conduction band by 0.14–0.17 eV enhance the field emission for both armchair and zigzag tubes, where the effect is more pronounced in the zigzag tube edge because of the introduction of additional states near the Fermi level.

Kim et al. have explored the adsorption of hydrogen, nitrogen, and oxygen molecules at the open edge of CNTs. The shift of the Fermi level upon each gas is presented in Table 1. In their study, oxygen gases with stronger electronegativity suppress the emission currents by creating a dipole layer toward the inner tube at the edge of the tip. In the case of hydrogen gases, the weaker electronegativity in the hydrogen atom than in the carbon atom is supposed to promote the emission currents. However, experimental results show that the hydrogen gases do not affect the field emission appreciably. Such a result may be attributed to the absence of resonant states, even though adsorption of hydrogen gases shifts the Fermi level toward the conduction band. Nitrogen gases are supposed to be less effective than other gases, since the binding state to the edge is relatively weak and the dipole strength is weak due to a negligible charge transfer [85].

As CNTs are exposed to oxygen gases, the situation becomes more complicated due to the progressive change in the cap geometry. The etching process must be more active around the cap area than the wall due to the pentagonal defect sites. Park et al. have pointed out that at the stage of molecular adsorption emission currents are enhanced by the electronic structures and local field intensification at the adsorption sites. In the case of atomic adsorption, the latter effect is more dominating, whereas molecular oxygen generates more currents from the new energy states. However, for prolonged exposure, the cap structure becomes open and the edge can be terminated with atomic oxygen, resulting in a decline in the emission currents [87].

Strengthening of the electric field due to sharp geometry occurs at the cap. The amplified field narrows the potential barrier so that electrons tunnel more easily into a vacuum. Therefore, the field emission electron strongly reflects the

local density of states (DOS) at the emitting site. As mentioned earlier, the integration of pentagon rings into the hexagon network creates significant modification in the local DOS. In addition, it is shown by scanning tunneling spectroscopy (STS) that the number of pentagon rings and their relative positions to the hexagon generates a wide variation in electronic structures [39]. The theoretical evaluation of a $(5, 5)$ metallic nanotube, whose cap is a hemisphere of C_{60}, reveals the existence of localized states about 0.8 eV above the Fermi level. Therefore, this means that the local DOSs at the cap strongly influence the field emission behavior. The energy distribution of electrons emitted from the MWCNT was measured by Fransen et al. [37]. A distinguishable difference between the metal tip and the MWCNT tip is the shift in the peak position upon extraction voltage. This opens up two possibilities. One is that the nanotube is semiconducting and the other is that the insulation layer between the W tip and the nanotube induces a voltage drop. It is not clear yet which mechanism dominates.

The reason that we have studied various emitter materials and examined the environmental stabilities is to securely preserve the tip from degradation. The degradation process either breaks out abruptly or progressively develops over a long period. The degradation of the tips can be divided into two types: chemical contamination and physical destruction of the tip geometry. Since current suppression, triggered by the chemical adsorption of gas molecules, was addressed previously, here, the cause of the geometrical damage due to large emission currents and ion bombardments will be discussed. Usually, in metal emitters, vacuum breakdown results from the abrupt increase in pressure between the electrodes, which is responsible for the introduction of materials from the cathode and anode. When the tip is involved in the vacuum breakdown, the sudden increase in pressure between the two electrodes is attributed to large emission currents, which melt and evaporate the tips. This catastrophic vacuum breakdown forms a conducting path between the electrodes, leaving the devices malfunctional. Another deformation of the tip is triggered by the bombardment of ionized residual gases. The gases existing between the gap become ionized by the emitted electrons and the ionized gas molecules are accelerated toward the tip. The sputtering process continues progressively during the operation of the FED and can end up with a vacuum breakdown in the long run. Although CNTs show exceptional conductivity and physical stiffness, they develop slow variations in their structures unless the driving voltage is less than the sputtering threshold. The circumstance in which CNTs are exposed to energetic ion particles has been well simulated inside a field ion microscope (FIM) by Hata et al., who found that CNTs are damaged at an electric field above 10 V/nm [89]. The study also reports that the field evaporation of MWCNTs and SWCNTs produces carbon clusters. The major product constituting the cluster is C_{20}, which is the smallest cage structure composed of hexagons and pentagons. For the field-induced unraveling process, it was shown by Lee et al. from theoretical simulation that the zigzag tube is more favorable for the unraveling of carbon atoms and the field strength is similar to the result from the previous experiment [90]. Dean et al. also witnessed a slow disintegration of carbons from the tip [91]. In their field

emission microscopy (FEM) studies, an individual SWCNT is able to withstand emission currents up to 1–2 μA, corresponding to 10^9 A/cm^2. Above this current level, CNTs begin to show local heating evidenced by blurred ring images spinning continuously, as shown in Figure 4. The rotating ring on an FEM image is evidence that the CNT is being eroded away from thermal evaporation at about 1600 K.

To enhance environmental stability and durability to ion bombardment, chemical contamination, and local heating, various materials have been used as coatings at the apex of the metal tip [92–94]. However, in the case of CNTs, only a couple of studies have been carried out. The criteria for the choice of coating material include chemical inertness, mechanical hardness, and thermal conductivity. Diamond-like carbons (DLCs), which consist of sp^2 and sp^3 carbon, are good electric and thermal conductors and are physically hard as well due to the tetrahedral sp^3 bond. It is reported that deposition of 20-nm-thick DLC reduces the turn-on voltage from 2.6 to 1.5 V/μm [95]. However, such advantageous effects disappear as the coating thickness increases to 50 nm. Another material studied is MgO deposited on CVD-grown vertically aligned MWCNTs. The role of the MgO layer is to lower the turn-on voltage by resonantly enhancing tunneling inside the MgO layer [96].

Doping is another way to enhance the field emission properties by altering the electronic structure. The most commonly used doping materials are boron and nitrogen. Several studies report remarkable changes in the structure and growth behavior. However, the correlation of those changes with field emission effects has not been reported. Only one group has reported that Cs-doped SWCNT film shows a remarkable decrease in work function and turn-on voltage, which is similar to the metal tip [97]. Although the encouraging reduction in work function of the CNT has been achieved, Cs deposition is not applicable to the usual vacuum environment of FED due to degradation [98].

4. APPLICATIONS

Several applications such as FED, electron multiplier, and X-ray gun have been demonstrated. Among these applications, the FED will have the largest impact on our society by revolutionizing the display. The fast-growing FPD market and the superior properties of FED have led companies such as Motorola and Candescent to invest in research and development of microtip FEDs. In spite of well-established fabrication technologies, the high production expense, tip degradation, and difficulty in scale-up make Mo tip-based FED uncompetitive with other types of FPDs in the market. The array of the microtip, called the Spindt cathode, was made by evaporating an emitter material through the gate holes. As the size of the cathode becomes larger, the nonuniformity and production cost go up rapidly.

To overcome the problems arising from scalability and fabrication cost, several concepts for low-cost and scalable cathodes were proposed by different industries such as Canon, Matsushita, Hitachi, Samsung, and ISE Electronics. Among these enterprises, Samsung and ISE Electronics are using CNTs as field emitters.

The first FED taking advantage of CNTs, demonstrated by Wang et al., has a different form of cathode array [99]. For this cathode construction, a composite of nanotube and epoxy is squeezed into microchannels on a glass substrate since selectively CVD-grown CNT emitters are not accessible to a large area and sodalime glass substrate. The growth temperature inside the CVD chamber is between 650 and 1000 °C. The emitter density of the as-prepared cathode in the FED is about two tubes/μm^2. A panel, 1×1 cm^2 in diode structure, successfully operates inside a vacuum system at an applied voltage of 300 V.

A fully sealed FED, 4.5 in. in diagonal, with a high brightness of 1800 cd/cm^2 has been demonstrated by Choi et al. [76]. To achieve an operable pressure, a nonevaporable getter was used. In the display, purified SWCNT was mixed with an organic binder. This composite was squeezed into a premade substrate through the metal mesh. In this method, the uniform dispersion and vertical alignment of the CNTs must be satisfied in order to meet the practical performance requirements. To meet the requirements, after pasting the composite, a pretreatment such as rubbing and electric field conditioning was carried out to align the embedded CNTs in the vertical direction, followed by burning of the organic binder [100]. This fully sealed diode-type display (200-μm glass spacer) turns on at less than 1 V/μm and emits 1.5 mA at 3 V/μm.

The matrix-addressed CNT-FED proves that the cathode array produced by mechanical printing of the mixture of the CNT and epoxy/organic binder on the electrode-patterned sodalime glass is scalable, enabling one to enlarge the panel without limitation in size and with low production cost.

The above two prototype FEDs are configured in a diode structure, consisting of a cathode and anode. Under this configuration, the ejection of electrons from the emitter surface is achieved at high voltage since the vacuum gap is about 200 μm. The diode structure is not able to tune the colors and brightness once the electrons leave the surface of the emitter. Imposing an additional gate electrode at a typical distance of about 1 μm above the emitter makes for low-voltage operation and a full range of colors. A few gate structures and fabrication processes have been suggested [99, 101–103]. The common aim of all these different structures is to efficiently tune the emission currents, simplify the fabrication process, and collimate the electron beam to the corresponding phosphor cells with a finer color tuning.

The most common triode structure is a normal gate. The gate electrode is placed between the emitter and the anode. Samsung developed a fully sealed normal-gated FED with an active area of 5 in. [101]. The CNT emitters inside the microcavity are electrically isolated from the gate electrode and sit on a resistive amorphous Si layer. The gate hole and the emitter diameter are 30 μm and 20 μm, respectively. The applied voltage over the 1.5-μm insulator gap between the gate and the cathode turns on the display panel at 65–70 V. The emitted electrons are accelerated through a 1.1-mm vacuum gap at 1.0–1.5 kV. Researchers at Samsung observed that at a higher anode voltage the anode current increased, since the transmittance of the ejected electrons became higher. The device renders 256 gray scales. Since Samsung prepared the emitter array using the printing method, the whole process can be carried out below 400 °C.

The organic binder degrades the vacuum inside the FED, even after combustion of the organic binder. Therefore, depositing CNT emitters in the microcavity using the thermal/MPE-CVD method might be effective to avoid the current fluctuation due to outgassing [104, 105]. Current fluctuation due to outgassing is observed to be larger than 7% in a fully sealed FED [76]. In the CVD approach, the critical issue is how to control the tube number and vertical alignment inside the microcavity. Precise control of these parameters requires monitoring the grain shape, the size of the Ni particles, and the morphology of the TiN sublayer. Pribat et al. implanted a single CNT in each cavity with a diameter of 200 nm by controlling the size of the catalyst particles.

The normal-gated FED fabricated by Samsung has displayed promising picture quality. However, one of the problems observed with the normal-gated FED is crosstalk. The circular shape of the cathode in the microcavity enhances the electric field at the edge of the cathode, leading to a strong widening of the electron trajectory [106]. Therefore, the emission pattern is brighter at the edge rather than at the center due to crosstalk with neighboring pixels. Another disadvantage of the normal-gate structure arises from the cathode fabrication. Since the gate electrode is formed at the final fabrication step, the contamination of the CNT with gate materials is unavoidable.

In the under-gate structure, the gate electrode is located below or at the same height as the cathode so that the trajectory of electrons is tilted with respect to the normal direction. The schematic view of an under-gate structure is shown in Figure 5a. The CNT film is pasted at the edge of the cathode electrode. This geometry, which concentrates the electric field at the edge, contributes to a narrowing of the electron trajectory, resulting in a uniform emission pattern and better color separation. A benefit of the under-gate configuration in terms of fabrication is that the manufacturing process becomes greatly simplified. A prototype monochromatic FED, 15 in. in diagonal, designed with the under-gate structure is shown in Figure 5b.
Figure 5. (a) Schematic view of an under-gate structure. (b) Monochromatic 15-in. FED fabricated with an under-gate structure.

ISE Electronics also demonstrated a CNT-based FED, which is shown in Figure 6a. This FED has many different features compared to the FED made by Samsung. In the display from ISE Electronics, the emitters are prepared using the thermal CVD method. The benefit of the CVD-grown tubes is good uniformity in the emission pattern, resulting from the smooth surface and round edges of the CNT electrodes [107]. However, the problems found during operation of the display are thermal distortion and vibration of the gate electrode. Deformation of the gate electrode is not a result of the growth temperature. The gate electrode is made of metal and is formed like a long metal wire [108]. The gate electrode shows local thermal expansion by emission currents. The inhomogeneous emission pattern contributed by the thermal distortion was circumvented by introducing a gate–insulator composite between the ribs of the anode
Figure 6. (a) Schematic of a triode structure with gate–insulator composite having through holes. (b) CNT-FED panel in 40 in. diagonal. Reprinted with permission from [110], S. Uemura et al., "SID'02 Digest," 2002, p. 1132. © 2002, Society of Information Display.

and cathode electrodes. The composite is compressed by an atmospheric pressure during the evacuation process, which enables the gate–insulator composite to compensate for the thermal distortion. In addition, the combination of metal and insulator is also advantageous in preventing thermal vibration due to the insulator. All these new features in the display enhance the emission pattern tremendously by maintaining the exact distance between the gate and the cathode electrodes over the whole area. ISE Electronics demonstrated a 40-in. CNT-FED panel with the benefits of all the above features, as shown in Figure 6b. The pixel size of the panel is 2.54 mm × 7.62 mm [3 (RGB) × 2.54 mm] [109, 110].

The application of a CNT as an electron multiplier does not seem to be attractive because of the metallic characteristics of the sp^2 bond. Therefore, the secondary electron emission (SEE) is not expected to be high. Usually, a large amount of SEE has been observed on the surface of an insulator such as MgO, SiO_2, and diamond. The common property among these materials is that they are insulators with sparse free electrons. Therefore, once the valence electrons are released by energetic incident electrons, the valence electrons do not lose energy by an inelastic collision with conduction electrons. Consequently, those electrons arriving at the surface can escape into the vacuum as long as their kinetic energy is larger than the work function. From all these aspects, the electronic structures of the CNT are not good for the SEE. Nevertheless, what makes the nanotube attractive as an electron multiplier is its geometric structure. The possible application of CNTs to electron multipliers was demonstrated for the first time by Yi et al. [111]. In their experiment, catalytically CVD-grown MWCNTs on a silica glass were coated with a MgO layer, which is one of the SEE materials. As they bombarded the surface of the MgO, a huge electron emission was detected with this geometry. The SEE yield in this case is measured to be 22,000 and is very sensitive to the backbias, a voltage applied to the MWCNTs [112]. This value is promisingly large compared to the MgO by itself, whose SEE yield is about 800. Kim et al. proposed that Townsend avalanche effects due to field amplification at the tip of the MWCNT is responsible for the generation of the huge number of secondary electrons in the MgO film. The large field enhancement factor of CNTs, however, highly exaggerates the electric field at the tip and triggers the secondary electron emission. The field enhancement factor of the MWCNTs is about 1000–2000. The thickness of the MgO layer is also one of the critical parameters determining the SEE yield. The amplification phenomenon is most prominent in a MgO layer with a nominal thickness of about 500–2000 Å.

Luminescent lighting elements equipped with carbon nanotube emitters have been successfully exhibited [113, 114]. The lighting elements shown so far are, in principle, working on field emission. In particular, the flashlight designed by Saito et al. is similar to a gated-structured FED. The technical advancements accomplished by CNTs, compared to conventional thermionic filaments, include superior environmental and emission stability together with low power consumption. This device can operate in a high vacuum range

and sustain stable emission currents over 4000 h. In addition, the intensity of luminance is twice that of conventional devices [115, 116].

Another application of the lighting element was accomplished by Bonard and his colleagues [114]. A luminescent tube was constructed in a cylindrical shape to take advantage of the stronger electric field than diode structure at the same gap distance. Inside the tube, tungsten wire, which was coated with catalyst particles, was used for the growth of MWCNTs and placed at the center of the tube for electron emission. The I–V characteristics of the tube show a good agreement with the Fowler–Nordheim equation. The brightness obtained from a tube 50 mm long and 21 mm wide is reported to be 10,000 cd/cm^2.

Most X-ray tubes currently on the market produce electrons by resistively heating a tungsten filament above 2000 °C. Some of the problems naturally inherent in thermionic electron emission have been mentioned before. In addition, the thermionic cathode intrinsically has low response time and the chemical reaction with residual gases shortens the lifetime, which leads to failure of the cathode as well. To liberate the current X-ray tube from the above-mentioned problems, the hot cathode has been replaced by a CNT-based cold cathode [117]. In this setup, tungsten wire, on which MWCNTs were grown after deposition of cobalt as a catalyst, was used as the electron source. The MWCNT-covered W cathode contributes to a better X-ray image compared to the thermionic cathode due to the narrower energy distribution of the emitted electrons. It also shows a high operating vacuum pressure of 10^{-7} torr. However, low emission currents and short lifetime at this pressure prove that the tube is still far from the marketable stage. Yue et al. resolved the problems of coating SWCNTs on a flat metal disk by electrophoresis [118]. In this case, the solid attachment of the CNT to a metal disk is very crucial, particularly under a strong electric field. To enhance the adhesion between the tube and the metal disk, an iron interlayer was evaporated onto the substrate. The as-prepared cathode easily yields a current density of 30 mA/cm^2 with negligible fluctuation during operation for 18 h. The above results show that CNT-based X-ray tubes seem to overcome the technical difficulties in present X-ray tubes such as lifetime, environmental stability, and portability.

5. CONCLUSIONS

The availability of CNT-based vacuum microelectronics on the market is dependent on technical advancements and a profound understanding of the fundamental field emission mechanism. All the studies carried out on individual or multiple tubes have shown that the field emission properties are well explained by the Fowler–Nordheim formula. Nevertheless, there exist many scientific issues that are not clearly answered. For instance, the effects of defect states existing at the cap, at which field emission actively takes places, have not been studied well. In addition to this defect effect, comprehension of the difference between an open and a closed tube under intensive electric field is also important. The deposition of CNTs over a large area and at a temperature below 500 °C is another issue to be solved. The cause of field penetration observed from FEM studies is still ambiguous whether it is due to the existence of a semiconducting tube or an insulating layer between the CNT emitter and the metal support.

The effective work function at the cap of the clean CNT is one of the intrinsic parameters to be clarified. Several groups have measured the work function of the CNT and reached the conclusion that the work function is slightly less than that of graphite. However, field emission preferentially takes place at the pentagon defects, in which strong localized states are observed near the Fermi level. Therefore, the work function at the emitting site is expected to be different from the previously known values. Comprehension of the work function at the emitting sites can elucidate the real field enhancement factor appearing in the F–N plots, since these two parameters are strongly correlated.

There are unique properties originating from low dimensionality. The ballistic movement and Luttinger liquid behavior of conduction electrons have been observed. The details of these properties are well described in the literature [119, 120]. How these low-dimensional properties influence the field emission currents are to be explored in the future.

Regardless of the lack of understanding of the intrinsic field emission properties of CNTs, various realizations of CNT-based applications have shown that the CNT is very efficient for field emitters. However, these applications are just prototypes. To meet commercializable performance, the existing technical obstacles should be resolved.

One of the key parameters that significantly influences the performance of the FED is phosphor. Even though phosphor has a long history of use, the FED has demanded a new phosphor suitable for low voltage operation. In the cathode ray tube, the electrons are sufficiently accelerated to excite the phosphor screen, which is protected by a thin metal film. The phosphor used in CRTs can generate a full range of colors with acceptable efficiency. In addition, conventional high-voltage phosphors are well characterized, commercially acceptable, and widely used. The most widely used phosphors for color display are P22 red, green, and blue triplets. Among these, green has the most significant effect on brightness.

The use of high-voltage phosphor for FED turned out to be unsuitable due to the degradation in lifetime and luminescence efficiency. Large emission currents can be supplied to compensate for the low brightness, but this leads to shorter lifetime due to significant chemical degradation. In addition, the larger emission currents will end up increasing the manufacturing cost for high-power circuits.

Numerous materials have been tried and their luminescence properties have been examined. Following are most the promising luminescent materials for low-voltage full-color FED applications: for red, $SrTiO_3 : Pr$, $Y_2O_3 : Eu$, $Y_2O_2S : Eu$; for blue, $ZnGa_2O_4$, $Y_2SiO_5 : Ce$, $ZnS : Ag, Cl$; for green, $Zn(Ga, Al)_2O_4 : Mn$, $Y_3(Al, Ga)_5O_{12} : Tb$, $Y_2SiO_5 : Tb$, $ZnS : Cu, Al$ [121]. Among the above phosphors, only the $ZnO : Zn$ phosphor shows a lifetime longer than 10,000 h and stable emission and is comparable in performance to monochromatic FEDs [122]. To improve the current phosphor, various modifications have been made and the modifications can be classified into three categories: formation of conducting films, improvement

of chemical and radiation stability, and increase in the luminance efficiency [123]. Modification of the luminescent materials has consisted of the formation of the corresponding salt and solution with subsequent annealing in air. The reduction process results in an insulating layer such as SiO_2, MgO, TiO_2, and SnO_2. These layers are resistant to electron bombardment, are chemically stable, and are known to increase the luminescence efficiency and conductivity as well. With all the above properties, new low-voltage phosphor is supposed to have a fast decay time, thermal stability during the panel manufacturing process, no evaporable substances contaminating the emitters, and acceptable grain size for precise coating [124].

The cathode arrays can be prepared using thermal evaporation through a gate hole. This approach, however, is not easy for scale-up and the production cost may be high. Screen printing is a new approach to overcome the scalability problem with an easy manufacturing process. Regarding the size of the cathode, this approach has no limitations. Printing the mixture of CNT and organic binder requires a firing step to burn out the organic binder at about 350 °C. After removing the binder, the solid attachment of the CNT to the electrode is very important. Therefore, an appropriate choice of electrode material can reduce the firing temperature [125].

The width of the pasted CNTs is about 120 μm on the 390-μm-wide cathode electrodes [106]. The large space between the cathode electrodes fabricated by the screen-printing method provides only 240×576 lines in a 9-in. FED. The smallest pixel size that one can obtain from the current screen-printing method is about 70 μm. Therefore, the finer pitch pattern could define pictures more precisely. A new patterning process permitting a higher resolution FED with finer pitches such as the liftoff method and photolithography has been shown [77, 125]. Using the photolithography approach, the pixel was downsized to 30 μm.

The solid insulation between the cathode and the anode should be obtained for field emission. To insulate between two electrodes, a thin insulating layer, called a spacer, is used. The choice of spacer materials brings many important issues into consideration. For instance, the spacer must be thin, mechanically strong, vacuum compatible, exhibiting low leakage current, and withstanding a strong electric field [126]. Since the spacer is supporting the voltage difference between the cathode and the anode and being exposed to emitted electrons, the resistance of the spacer should be high enough to prevent leakage current and, simultaneously, low enough to dissipate accumulated charges. Electron bombardment can charge the spacer negatively or positively, depending on the energy of the emitted electrons. Induced charges on the surface of the spacer will significantly change the trajectory of the electrons, resulting in image distortion. Choi et al. have simulated the trajectory of electrons in the presence of the charged spacer. Their results show that the image of the dot arrays near the charged spacer appears less luminescent and the dot size looks smaller than one near the uncharged spacer [127].

In certain cases generation of the secondary electron emission along the spacer surface can lead to disastrous failure of the device. This voltage breakdown along the spacer, called surface flashover, is initiated in the triple-junction region, where spacer, vacuum, and electrode join [128]. Although the detailed mechanism of how the electron ejection at the triple-junction area develops into surface flashover is not clearly understood, the most widely accepted mechanism is secondary electron emission avalanche (SEEA), which is initiated at the triple junction.

Since the surface flashover is ignited by electrons emitted from the triple junction, the introduction of a void at the junction area lowers the electric field. In addition to the void, the insertion of metal strips into the spacer can be advantageous in two ways. First, the metal strips reduce the flashover since it is strongly correlated with charging of the spacer. Second, the image distortion due to charge accumulation on the spacer could be minimized by the conducting strips. However, besides the above two parameters, other parameters also have significant effects on the surface flashover. For instance, the length of the spacer, the spacer surface roughness, the sharpness of the electrodes at the edge, the surface condition of the spacer, and the spacer material itself can all trigger a catastrophic vacuum breakdown.

Physical sputtering of the CNT emitters shortens the lifetime of the FED rapidly. The prototype CNT-FEDs introduced in the literature degrade significantly in a few hours. While an effort to extend the lifetime has been made using double-wall nanotubes (DWNTs), the FED cannot survive long enough to meet the commercial requirement, about 20,000 h.

In this review, we have discussed many important aspects of carbon nanotube–based field emitters that are still under intensive research and development. Because of their short history, some of the phenomena observed during field emission are not well identified. Nevertheless, it has been proven that CNTs are a great applicant for field emitters and tremendous progress has been made. Also, various types of applications have been exhibited. Bringing the prototype devices to the point of acceptable performance and marketable manufacturing cost requires overcoming many of the challenging problems described previously.

GLOSSARY

Adsorbate A substance that adheres on the surface of the material under investigation.

Anodization Method of plating metal for corrosion resistance, electrical insulation, thermal control, abrasion resistance, sealing, improving paint adhesion, and decorative finishing. Anodizing consists of electrically depositing an oxide film from an aqueous solution onto the surface of a metal, often aluminum, which serves as the anode in an electrolytic cell. Plate properties such as porosity, abrasion resistance, color, and flexibility depend on the type, concentration, and temperature of the electrolyte, the strength of the electrical current and the processing time, and the type of metal being plated.

Electronegativity In chemistry, the tendency of an atom to attract an electron pair shared with another atom in a chemical bond.

Electrophoresis The electrostatic attractive movement of charged particles in a colloidal solution that is under the influence of an electric field.

Fermi level A measure of the energy of the least tightly bound electrons within a solid. The value of the Fermi level at absolute zero is called the Fermi energy and is a constant for each solid. The Fermi level changes as the temperature increases and as electrons are added to or withdrawn from the solid. According to quantum mechanics, each energy level can accommodate only two electrons. The Fermi level is the energy level having the probability that it is exactly half filled with electrons. Levels of lower energy than the Fermi level tend to be entirely filled with electrons, whereas energy levels higher than the Fermi level are unoccupied.

Field enhancement Amplification of the applied electric field at the edge of the emitter.

Getter A material with a high sticking coefficient. Therefore, residual gases physically colliding with the surface of getter materials are permanently removed from a vacuum system. After the saturation of the getter surface, the getter is reactivated and adsorbed gas molecules sink into the bulk of the getter. Th, V, Ti, and Zr are used for pumping a vacuum system.

Microcavity A cavity is about 1 μm deep and a few micrometers wide in Spindt structure. This cavity is fabricated by MEMS techniques to form metal emitters through the thermal evaporator.

Shielding effect Weakening of the applied electric field at the tip of the emitters due to the high density of the emitters.

Thermionic emission Emission of electrons that has high enough energy to overcome the surface potential from thermal excitation.

Work function Required energy for electrons to overcome the surface potential barrier.

Carbon Nanotube-Based Supercapacitors

Young Hee Lee, Kay Hyeok An, Ji Young Lee, Seong Chu Lim

Sungkyunkwan University, Suwon, Korea

CONTENTS

1. INTRODUCTION

Recently, there have been considerable attempts to use carbon nanotubes (CNTs) for the electrodes of electrochemical energy storage systems, such as Li-ion secondary batteries [1–6], electrochemical hydrogen storage [7–9], fuel cells [10, 11], and supercapacitors [12–21]. Carbon nanotubes are attractive materials for the electrodes of electrochemical energy storage devices due to their superb characteristics of chemical stability, low mass density, low resistivity, and large surface area. Recent developments in massive synthesis of carbon nanotubes [22–24] have accelerated new applications of these materials to the area of electrical energy storage systems.

In particular, applications of CNTs as the electrode materials for supercapacitors have ignited significant worldwide investigations on their microscopic and macroscopic porous structures and electrochemical behaviors [12–14, 20–21, 25–30]. The CNT electrodes exhibit a unique pore structure and high usage efficiency of specific surface areas [12, 15, 17, 19–21]. The CNT electrodes for the electric double-layer type of supercapacitor have excellent absorption characteristics due to the accessible mesopores formed by the entangled individual CNTs [12, 13, 19–21].

Supercapacitors [31–36] (also called electrochemical capacitors, electric double-layer capacitors, or ultracapacitors) have several advantages compared to the secondary battery, for instance, long cycle life (>100,000 cycles), simple principle and mode of construction, short charging time, safety, and high power density. Among them, the power density of supercapacitors is the most remarkable property. The power density of supercapacitors is larger than that of the secondary battery by about 10 times [31, 35, 36], although the energy density of supercapacitors is smaller than that of the secondary battery, which is a serious drawback to be applied for practical devices. Supercapacitors have been used as small-scale energy storage devices in electronic stationary, such as memory backup devices and solar batteries with semipermanent charge–discharge cycle life. Now the capability of supercapacitors with high power density extends its application to various other novel devices of load leveling, hybrid capacitor–battery system, cold-starting assistance, and catalytic converter preheating [31]. To apply the supercapacitors to various practical devices—even to electric vehicles—the development of supercapacitors with both high power density and high energy density is prerequisite.

The principle of electric energy storage by an electric double layer in a charged capacitor has been known since 1745. The idea of utilizing this principle to store the electrochemical energy for practical purposes of battery cells had been first proposed in the patent granted to Becker in 1957 [37]. The patent proposed electrical energy storage by means of the charges held at the interfacial double layer of a porous carbon material in aqueous electrolytes. After Becker, the SOHIO Corporation in Cleveland commercialized the electric double-layer capacitor (EDLC) with high surface area of carbon materials in a nonaqueous solvent (organic solvent) containing a dissolved tetraalkylammonium salt electrolyte [38]. Such organic electrolyte systems provided higher operating voltages (2.3–3.0 V) owing to the higher decomposition voltages of organic electrolytes than those of aqueous ones. Therefore, they can accommodate higher charge densities and provide larger specific energy storage increase by the square of the operating voltage attainable on charge.

A different principle of the capacitor using metal oxide electrodes, originating from the redox reaction as in a battery, was developed between 1975 and 1981 by the Conway group [39–42]. Although these systems have some problems

for commercial applications in that the electrode materials are expensive and have a limiting nominal voltage of 1 V, useful military applications have been developed [31].

After the discovery of conducting polymers in the 1980s, the possibility of employing electroactive conducting polymers, such as polypyrrole or polyaniline, for electrochemical pseudocapacitor materials was suggested by the Gottesfeld group [43–45]. These conducting polymer systems offer opportunities for storing electrochemical energy through the redox capacitance, the so called pseudocapacitance.

The large capacitance compared to conventional capacitors (on the order of several or more farads per gram) that can be developed with metal oxides and conducting polymer–pseudocapacitor systems and also with carbon double-layer capacitors led to the terms "supercapacitor" and "ultracapacitors" for these two types of high-specific-capacitance devices [31, 35]. Recently, it has been suggested that the more general term "electrochemical capacitors" be used to refer to these systems [31, 35]. The operating principles of electric double-layer capacitors and electrochemical pseudocapacitors, the differences between these two types of capacitors, the different types of electrode materials, and the differences between a supercapacitor and a battery are discussed in Sections 2–4.

2. PRINCIPLES OF OPERATION

In a conventional capacitor (condenser), the charge accumulation is achieved electrostatically by positive and negative charges residing on two interfaces separated by a vacuum or a molecular dielectric (a film of mica, a space of air, or an oxide film). Supercapacitors store the electric energy in an electrochemical double layer formed at the interfaces between the polarizable electrodes and the electrolyte solution. Positive and negative ionic charges within the electrolyte accumulate at the surface of the polarizable electrodes and compensate for the electronic charges at the electrode surface, as shown in Figure 1. This charge distribution layer is called the electric double layer (or electrochemical double layer). Figure 1 presents the principle of an electrochemical capacitor. The thickness of the double layer depends on the concentration of the electrolyte and on the size of the ionic clusters and is typically on the order of 5–10 Å for concentrated electrolytes [46]. The capacitance, C, accumulated in the electric double layer formed at the interface between the polarizable electrodes and the electrolyte solution is defined by

$$C = \varepsilon/4\pi\delta \int dS \qquad (1)$$

where ε is the dielectric constant of the electrolyte, δ is the distance from the electrode interface to the center of the ion, and S is the surface area of the electrode interface. The corresponding electric field in the electrochemical double layer is very high and assumed to be up to 10^6 V/cm easily [31, 35]. Compared to conventional capacitors where a total capacitance is typically on the order of picofarads and microfarads, the capacitance and the energy density stored in the supercapacitor by the electrochemical double layer is much higher. To achieve a higher capacitance, the surface area of the electrode is additionally enlarged by using porous electrodes, where an extremely large internal surface area is expected.

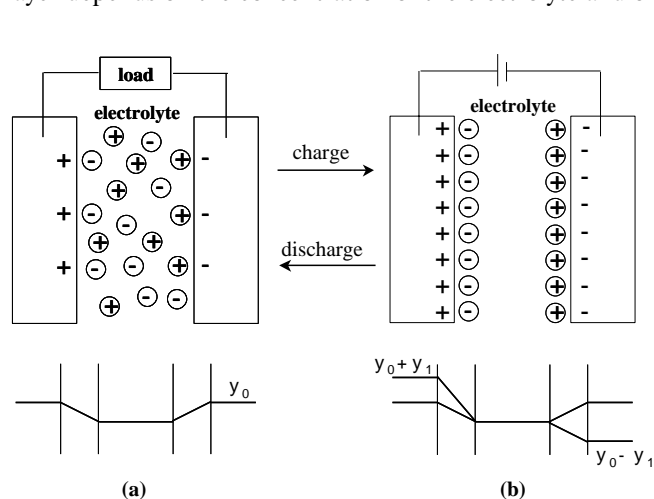
There are several techniques for determining the specific capacitance, such as a unit-cell test (two-electrode system), a half-cell test (three-electrode system), and an impedance test. The unit-cell and half-cell tests are mainly used to determine the specific capacitance of the supercapacitor. The specific capacitances reported in the literature are not consistent, mainly due to the experimental methods used to determine them. For the sake of consistency, it is worth specifying the electrochemical technique for intercalculating the specific capacitance between the two-electrode and three-electrode systems. Figure 2a shows the double layer of electrodes used in the two-electrode system (2E), which represents a real double-layer supercapacitor device and its equivalent circuit. Figure 2b shows the double layer of electrodes used in the three-electrode system (3E), which is used in the lab cell with a reference electrode and its equivalent circuit. Assuming that the weight of each individual electrode is m, then $C_1 = C_2 = C$. The capacitance measured for


Figure 1. Principle of an electric double-layer capacitor.
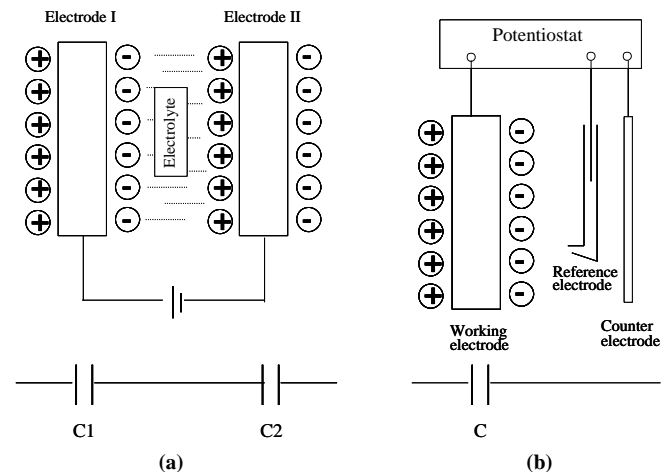

Figure 2. Electric double layer and its equivalent circuit in (a) two-electrode system and (b) three-electrode system.

the two-electrode system is $C_{2E} = \frac{1}{2}C$. The specific capacitance turns out be $C_{\text{spec-2E}} = C_{2E}/(2m) = \frac{1}{4}(C/m)$. However, for the three-electrode system, the double-layer capacitance measured is $C_{3E} = C$ and the specific capacitance is $C_{\text{spec-3E}} = C_{3E}/m = (C/m)$. Thus, the relationship between the specific capacitance measured with the two-electrode and three-electrode techniques is $C_{\text{spec-3E}} = 4C_{\text{spec-2E}}$.

In the double layer at plane electrodes, charge densities of about 16–50 μF/cm^2 are commonly realized [31]. Taking an average value of 30 μF/cm^2, the capacitance of a single polarizable electrode with a typical surface area of 1000 m^2/g for porous materials leads to a specific capacitance of 300 F/g. At 1 V in an aqueous electrolyte, the maximum storage energy, E, is $E = CV_i^2/2 = (300 \times 1^2)/2 = 150$ W-s/g, 150 kJ/kg, or 42 W-h/kg, theoretically. This value is considerably lower than that obtained for available batteries but much higher than that for conventional capacitors. It should be mentioned that the above value depends on the double-layer capacitance, the specific surface area of the respective electrode material, the wetting behavior of the pores, and the nominal cell voltage.

The maximum power density of a supercapacitor is given by $P_{\text{max}} = V_i^2/4R$ [V_i = initial voltage, R = equivalent series resistance (ESR)] [31]. Therefore, the key factors determining the power of supercapacitors are the resistivity of the electrode itself, the resistivity of the electrolyte within the porous layer of electrode, and the contact resistance between the electrode and the current collector, as shown in Figure 3. In evaluating the performance of supercapacitors, the characterization of their energy density and power density is one of the most important factors of rating electrochemical power devices. In addition, from practical and fundamental points of view, there is a question of how the energy density and power density are related for various types of electrochemical power sources, including fuel cells and rechargeable batteries.

3. DIFFERENCES BETWEEN A SUPERCAPACITOR AND A BATTERY

The most important difference between a supercapacitor and a battery is the principle of electrochemical energy storage. Electrochemical energy can be stored in two fundamentally different ways. In a battery, the potentially available chemical energy storage requires Faradic oxidation and reduction of electrochemically active reagents to release charges that can perform electric work when they flow between two electrodes having different potentials; that is, the charge storage is achieved by an electron transfer that produces a redox reaction in the electroactive materials according to Faraday's law [31, 47, 48].

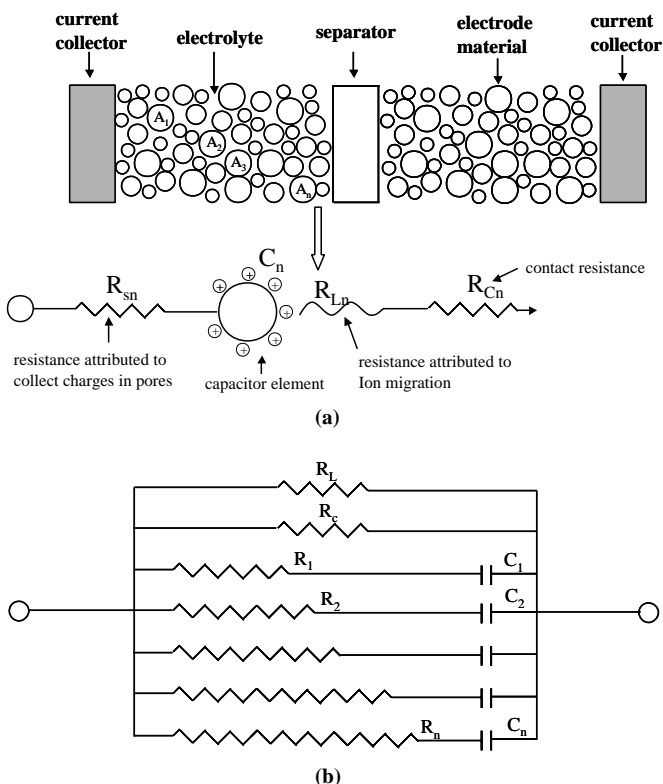
With an electric double-layer capacitor (EDLC), the charge storage process is non-Faradic; that is, ideally, no electron transfer takes place across the electrode interface and the storage of electric charge and energy is electrostatic. Actual electron charges are accumulated on the electrode surfaces with lateral repulsion and involvement of redox chemical changes. Table 1 summarizes the perceived advantages and disadvantages of EDLC energy storage. Because the charging and discharging of such EDLCs involve no chemical phase and composition changes, such capacitors have a high degree of cyclability on the order of 10^6 times and a high specific power density, although the specific energy density is rather small [31]. However, in some cases of the supercapacitor based on pseudocapacitance (redox type of supercapacitor), the essential process is Faradic; that is, the charge storage is achieved by an electron transfer that produces a redox reaction (Faradic reaction) in the electroactive materials according to Faraday's law. The supercapacitors based on pseudocapacitance have higher specific capacitance than the EDLCs, due to the redox reaction as in a battery, although the redox reaction gives rise to


Figure 3. Equivalent circuit of an electrochemical capacitor.

Table 1. Advantages and disadvantages of supercapacitor energy storage.

Advantages
Long cycle life, >100,000 cycles
Excellent power density, >10^6 W/kg
Simple principle and mode of construction
Combines state of charge indication
Can be combined with secondary battery for hybrid applications (electric vehicles)

Disadvantages
Limited energy density
Poor volume energy density
Low working voltage
Requires stacking for high potential operation (electric vehicles)

high internal resistance in supercapacitors, resulting in a decrease in specific power density. The typical electrodes of the supercapacitors based on pseudocapacitance are metal oxides (i.e., RuO_2, IrO_2, Co_3O_4) and conducting polymers (i.e., polypyrrole, polyaniline, polythiophene) [39–45].

A supercapacitor requires two equivalent electrodes, one of which is charged negatively with respect to the other, the charge storage and separation being electrostatic. At each electrode, the charge storage and separations are established across the electrode interface. Usually, the electrodes of supercapacitors have high surface area and porous matrices. However, batteries have bipolar electrode configurations for higher voltage series combinations [31].

For a battery, the maximum Gibbs energy is the product of charge Q and the difference of potential, ΔE, between the Nernstian reversible potentials of the two electrodes, that is, $G = Q \cdot \Delta E$. In the capacitor case, for a given charge Q, G is $\frac{1}{2}QV$. For a given electrode potential difference, $\Delta E = V$, it is then evident that the energy stored by a two-electrode cell accommodating a given Faradic charge Q at voltage $\Delta E = V$, is twice that stored in a capacitor charged with the same Q at the same voltage. In the process of charging a pure electric double-layer capacitor, every additional element of charge has to do electrical work (Gibbs energy) against the charge density already accumulated on the electrodes, progressively increasing the interelectrode potential difference [31, 47–50].

In a battery cell being charged, a thermodynamic potential (ideally) exists independent of the extent of charge Q added, as long as two components (reduced and oxidized forms) of the electroactive material remain coexisting. Thus, the potential difference (electromotive force) of the battery cell is ideally constant throughout the discharge or recharge half-cycles, so that G is $Q \cdot \Delta E$ rather than $Q \cdot \frac{1}{2}\Delta E$ (or $\frac{1}{2}V$) [31, 47–50]. This difference can be illustrated by the discharge curves shown schematically in Figure 4, where the voltage in the capacitor declines linearly with the extent of charge, while that for an ideal battery remains constant as long as two phases remain in equilibrium. The decline in the supercapacitor voltage arises formally since $C = Q/V$ or $V = Q/C$; therefore, $dV/dQ = 1/C$ [31, 47–50]. The ideal battery cell voltages on discharge and recharge, as a function of state of charge, are shown as parallel lines of zero slope in Figure 4. In the slope of the discharge and recharge
Figure 4. Difference in discharge and recharge relationships for a supercapacitor and a battery.

Table 2. Overal comparison of supercapacitor and battery characteristics.

Item	Supercapacitor	Battery
Slope of charge and discharge curve	Declining slope	Constant slope
Intrinsic stage of charge indication	Good	Bad
Energy density	Poor	Good
Power density	Good	Poor
Cyclability and cycle life	Excellent	Bad
Origin of internal *IR*	High area matrix + electrolyte	Active electrode materials + electrolyte
Activation polarization	Little or none	Significant (Faradic resistance)
Lifetime	Long	Poor
Cell stacking by bipolar system	Possible	Impossible

lines for the supercapacitor in Figure 4, there is a significant *IR* drop, depending on the discharging and recharging rates. An overall comparison of electrochemical capacitor and battery characteristics is given in Table 2.

4. ELECTRODE MATERIALS FOR SUPERCAPACITORS

4.1. Metal Oxides

The concept and use of metal oxide as an electrode material in electrochemical capacitors can be traced back to the paper by Trasatti and Buzzanca [41] on ruthenium dioxide (RuO_2) as a new interesting electrode material. Some other oxides, such as IrO_2, Co_3O_4, MoO_3, WO_3, and TiO_2, as electrode materials in electrochemical capacitors have been discovered [51–54].

The cyclic voltammogram of the metal oxide electrodes has an almost rectangular shape and exhibits good capacitor behavior [31, 35, 55, 56]. However, the shape of the cyclic voltammogram is not a consequence of pure double-layer charging, but a consequence of the redox reactions occurring in the metallic oxide, giving rise to the redox pseudocapacitance [31, 35, 55, 56].

A very high specific capacitance of up to 750 F/g was reported for RuO_2 prepared at relatively low temperatures [57]. Conducting metal oxides such as RuO_2 or IrO_2 were the favored electrode materials in early electrochemical capacitors used for space or military applications [31, 35]. The high specific capacitance in combination with the low resistance resulted in very high specific powers. An energy density of 8.3 W-h/kg and a power density of 30 kW/kg was achieved in a prototype 25-V electrochemical capacitor built only with $RuO_2 \cdot xH_2O$ material and electrolyte [31]. These capacitors, however, turned out to be too expensive. A rough calculation of the capacitor cost showed that 90% of the cost resides in the electrode material [31, 35]. In addition, these capacitor materials are only suitable for aqueous electrolytes, thus limiting the nominal cell voltage to 1 V [31, 35].

Several studies have attempted to take advantage of the material properties of such metal oxides at a reduced cost.

The dilution of the costly noble metal by the formation of perovskites was investigated by Guther et al. [58]. Other forms of metal compounds such as nitrides were investigated by Liu et al. [59]. However, these materials are not yet commercially available in the electrochemical capacitor market.

4.2. Conducting Polymers

The discovery of conducting polymers has given rise to a rapidly developing field of electrochemical polymer science. conducting polymers, such as polyacetylene, polyaniline, polythiophene, and polypyrrole, have been suggested by several authors for electrochemical capacitors [43–45, 49]. The conducting polymers have fairly high electronic conductivities, typically of magnitudes of 1–100 S/cm [31, 35, 49].

The electrochemical processes of conducting polymers are electrochemical redox reactions associated with sequential Lewis acid or Lewis base production steps so that the polymer molecules are converted to multiply charged structures through electrochemical Lewis-type reactions involving electron withdrawal or electron donation [31, 35, 49]. Therefore, the pseudocapacitance by Faradic redox processes in conducting polymer-based electrochemical capacitors is dominant, although about 2–5% of double-layer capacitance is included in the total specific capacitance [31, 35].

Such polymer electrode materials are much cheaper than RuO_2 or IrO_2 and can generate comparably large specific capacitance. However, the polymer electrode materials do not have the long-term stability and cycle life during cycling, which may be a fatal problem in applications. Swelling and shrinking of electroactive conducting polymers is well known and may lead to degradation during cycling [31, 35, 49]. Therefore, these electroactive conducting polymers are also far from being commercially used in electrochemical capacitors.

4.3. Carbons

Carbon materials for electrochemical energy devices, such as secondary batteries [60–62], fuel cells [63–65], and supercapacitors [66–69], have been extensively studied. However, each type of electrochemical energy device requires different physical properties and morphology. For supercapacitors, the carbon material for the EDLC type must have (i) high specific surface area, (ii) good intra- and interparticle conductivity in porous matrices, (iii) good electrolyte accessibility to intrapore surface area, and (iv) the available electrode production technologies [31, 35, 36]. Carbons for supercapacitors are available with a specific surface area of up to 2500 m²/g as powders, woven cloths, felts, or fibers [31, 35]. The surface conditioning of these carbon materials for supercapacitor fabrication is of substantial importance for achieving the best performance, such as good specific surface area, conductivity, and minimum self-discharge rates.

Carbons with high specific surface area have many oxygen functional groups, such as ketone, phenolic, carbonyl, carboxylic, hydroquinoid, and lactone groups, introduced during the activation procedure for enlarging the surface area [31, 35]. These oxygen functional groups on activated carbons or activated carbon fibers give rise to one kind of electrochemical reactivity, oxidation or reduction. Oxidation or reduction of the redox functional groups shows pseudocapacitance, which amounts to about 5–10% of the total realizable capacitance [31]. However, the various surface functionalities in activated carbons are one of the factors that increase the internal resistance (equivalent series resistance; ESR) due to the redox reaction [31].

Activated carbons are much cheaper than metal oxides and conducting polymers and they have much larger specific surface area than the others. Activated carbon-based supercapacitors have been commercialized for small memory backup devices. However, activated carbons show lower conductivity than metal oxides and conducting polymers, resulting in a large ESR, which gives smaller power density. In addition, the observed specific capacitances of the carbon-based supercapacitors are about one-fourth the theoretical capacitance in spite of their high specific surface area (2000–3000 m²/g), which is attributed to the existence of micropores [31, 35]. This is a weak point of active carbons as electrode materials in supercapacitors with high energy density and power density.

5. CARBON NANOTUBE-BASED SUPERCAPACITORS

During the last decades, the application of activated carbons as the electrode materials in supercapacitors has been intensively investigated because of their high specific surface area and relatively low cost [31, 35, 36, 66–69]. Since the specific capacitance of a supercapacitor is proportional to the specific surface area, the effective surface area of the electrode materials is important [31, 35, 36]. Theoretically, the higher the specific surface area of an activated carbon, the higher the specific capacitance should be. Unfortunately, the theoretical capacitance of the activated carbons is not in good agreement with the observed value, because a significant part of the surface area remains in the micropores (<20 Å), which are not accessible to the electrolyte ions [31, 35]. Therefore, the pore size distribution together with the surface area is important for the determination of the electric double-layer capacitance. From this point of view, carbon nanotubes have several advantages as the electrode materials of supercapacitors. CNTs have a narrow distribution of mesopore sizes, highly accessible surface area, low resistivity, and high stability, attracting great interest worldwide for building supercapacitors using CNTs [12–14, 20, 21, 25–30].

5.1. Carbon Nanotube Electrodes

A supercapacitor can be classified into two types by the type of electrolyte: organic electrolytes and aqueous electrolytes. The advantage of organic electrolytes is the higher achievable voltage. According to the equation of maximum storage energy, $E = CV^2/2$, the square of the unit-cell operating voltage determines the maximum stored energy. Organic electrolytes allow for a unit-cell voltage above 2 V. Typically the cell operating voltage is 2.3 V with a possibility to increase the voltage for a short time to 2.7 V. On the other hand, organic electrolytes have a significantly higher specific resistance, compared to concentrated aqueous electrolytes

[31, 35]. The higher electrolyte resistance also affects the equivalent distributed resistance of the porous layer and, consequently, reduces the maximum usable power [31, 35].

Aqueous electrolytes limit the unit-cell voltage of the supercapacitors to typically 1 V, thus reducing the available energy density significantly compared to organic electrolytes [31, 35]. However, the advantages of aqueous electrolytes include higher conductance, resulting in a diminished ESR. Therefore, in aiming for high power density, the capacitors using aqueous electrolytes are more appropriate. In addition, the cost of aqueous electrolytes is usually much lower than that of suitable organic electrolytes.

In recent years, high-power supercapacitors based on CNT electrodes using aqueous electrolytes have been reported. Niu et al. [12] realized that supercapacitor electrodes, prepared from catalytically grown multiwalled CNTs whose surface area is 430 m^2/g, show a maximum specific capacitance of 113 F/g and a power density of 8 kW/kg at an energy density of 0.56 W-h/kg in an aqueous electrolyte of 38 wt% H_2SO_4. The sample preparation procedure seems to be a key factor in achieving high capacitance. The CNT surface was chemically functionalized by nitric acid treatment and the individually dispersed CNTs in water were further reassembled into an interconnected, entangled, freestanding structure. This freestanding sheet of the entangled CNTs shows an open porous structure, which cannot be obtained typically with activated carbon or carbon fibers. The nitric acid treatment increases the Brunqeur-Emmett-Teller (BET) surface area from 250 to 430 m^2/g with narrow pore diameter distribution. The surface area of the CNT electrode resides in volumes and crevices larger than 20 Å, which are easily accessible to the electrolyte. These properties are highly desirable for high power and long cycle life of the supercapacitor.

Ma et al. [14] also used CNT electrodes, where the CNTs were prepared similarly to the previous works but in this case they introduced a binder to form solid electrodes. A mixture of CNTs and phenolic resin powders serving as a binder was molded and then carbonized at 850 °C for 2–4 h in a nitrogen gas ambient. The carbonized electrode was finally immersed in a hot mixture of concentrated sulfuric acid and nitric acid for 15 min. The electrode has a bulk density of around 1.0 g/cm^3 and the BET surface area is about 120 m^2/g, which is lower than that of Liu's CNT electrode. They obtained specific capacitances of 15–25 F/g in an aqueous solution of 38 wt% H_2SO_4. They discussed the effect of functional groups induced by the acid treatment. Functional groups, such as —COOH, —OH, and >C=O, enhance the capacitance of the CNT electrode. However, the IR drop at the initial stage of discharging is large due to the Faradic reactions of the functional groups, giving rise to a large ESR. The discharge profile is also different from the typical profile of electric double-layer capacitors. The discharging slope of $\Delta V / \Delta t$ is not linear due to the Faradic reaction by the functional groups.

Frackowiak et al. [15] investigated the electrochemical characteristics of supercapacitors built from multiwalled CNT electrodes with a specific surface area of 430 m^2/g in 1 M KOH aqueous solution and the correlation of the microtexture and elemental composition of materials. They argued that the presence of mesopores due to the central canal and/or entanglement of CNTs is the origin of an easy accessibility of the ions to the electrode/electrolyte interface for charging the electrical double layer. They detected pure electrostatic attraction of ions as well as quick pseudo-Faradic reactions upon varying surface functionality, which was induced during acidic oxidation. The values of the specific capacitance varied from 4 to 135 F/g, depending on the type of nanotubes or/and their posttreatments (acidic oxidation). They demonstrated that even with a moderate specific surface area below 470 m^2/g, due to their accessible mesopores, the multiwalled CNT electrodes represent attractive materials for supercapacitors as compared to the best activated carbons.

Zhang et al. [17] studied a supercapacitor using multiwalled CNT electrodes in an organic electrolyte system. The multiwalled CNT electrodes showed a specific surface area of approximately 100 m^2/g and a measured specific capacitance up to 18.2 F/g (16.6 F/cm^3) with 1 M $LiClO_4$ in a mixture of ethylene carbonate and propylene carbonate (1 : 1 in volume ratio) as an organic electrolyte solution. The measured specific capacitance is relatively lower than that of other groups using aqueous electrolytes, due to the low specific surface area of the multiwalled CNT electrodes and the organic electrolyte solution system. However, the energy density of the supercapacitor can reach up to 20 W-h/kg with a 10-mA discharge current density, due to the high operation voltage in the organic electrolyte solution. The relative volume of mesopores and macropores of the used electrodes exceeds about 92%, and the micropores are nearly negligible. For organic electrolytes, because of their larger molecular structure, only the mesopores and macropores of their electrode pores are accessible and are much larger than those of activated carbons.

Raymundo-Piñero et al. [70] also studied supercapacitors using multiwalled CNTs with a high surface area prepared by KOH activation. Micropores of pure multiwalled CNTs have been highly developed using chemical KOH activation. Depending on the nanotubular material, the burn-off ranged from 20 to 45% after the activation process. The surface area was at least doubled with maximum values of 1050 m^2/g for a treatment condition of KOH : CNT in a ratio of 4 : 1. The activated multiwalled CNTs still possess a nanotubular morphology with many defects on the outer walls, giving a significant increase in the micropore volume, while keeping a noticeable mesoporosity. The high efficiency of KOH activation in the development of the surface area is attributed to the redox reactions between carbon nanotubes and KOH followed by potassium intercalation and separation of the graphitic layers. This process is very efficient for the formation of pores, especially for the multiwalled CNTs with well-graphitized walls, while preserving nanotubular morphology. The creation of defects on the nanotube walls developed microporosity, which is responsible for excellent capacitance behavior. Such activated multiwalled CNTs have been used for the electrode materials of supercapacitors in alkaline, acidic, and aprotic medium. Enhanced values of capacitance are always observed after activation: In some cases, the capacitance increased almost 7 times from 15 F/g (for non-activated nanotubes) to 90 F/g (after chemical activation) in alkaline medium (6 M KOH). In an organic electrolyte, the capacitance of activated multiwalled CNTs reached 65 F/g

with a boxlike shape characteristic of cyclic voltammetric behavior. Such a significant modification of surface microporosity for essentially mesoporous nanotubular materials is of great interest for many electrochemical applications.

Frackowiak et al. [19] also studied supercapacitors comparatively for multiwalled and single-walled CNT electrodes. They obtained a maximum specific capacitance of 40 F/g using single-walled CNTs. This value is twice as small as that for multiwalled CNTs, which have a maximum specific capacitance of 80 F/g. They argued that the low specific capacitance of the single-walled CNT electrodes is attributed to the perfect bundle structure of the single-walled CNTs.

An et al. [20, 21, 27] reported on the key factors determining the performance of supercapacitors using single-walled CNT electrodes, which were synthesized by direct-current (dc) arc discharge. The single-walled CNTs consisted of bundles with diameters of 10–20 nm. The sample purity was roughly estimated to be about 30% [71]. A mixture of the single-walled CNTs and poly-vinylidene chloride or polyvinyl alcohol used as a binder was molded and then carbonized at 500–1000 °C for 30 min in an argon gas ambient. The thickness of the electrode is about 150 μm. The measured apparent mass density of the electrode is 0.75 g/cm^3. They obtained a maximum specific capacitance of 180 F/g and a measured power density of 20 kW/kg at an energy density of 7 W-h/kg in a solution of 7.5 N KOH. They demonstrated that heat treatment at high temperature is necessary to increase the capacitance and reduce the CNT electrode resistance. The increased capacitance is due to the enhancement of the specific surface area and the abundant pore distribution at lower pore sizes of 30–50 Å estimated from the BET(N_2) measurements. They also found that most of the BET surface area of the electrode contributes to the theoretically estimated specific capacitance, unlike activated carbons. They also claimed that minimization of the contact resistance is independent of the specific capacitance but directly related to maximization of the power density.

The performance of several types of supercapacitors using various carbon nanotubes reported in recent years is summarized in Table 3. Table 3 shows that the types of CNTs, the CNT morphologies, and the electrode preparation conditions are critically important in determining the specific capacitance, the specific power density, and the specific energy density of supercapacitors. Although many of them are still to be determined in order to obtain the best performance for real applications, there is plenty of room to improve the performance of supercapacitors using CNT electrodes.

5.2. Carbon Nanotube–Composite Electrodes

Even if the CNT electrodes exhibit a unique pore structure and high usage efficiency of specific surface areas and some processes for disintegrating the bundle structure of the CNTs may enhance the utilization efficiency of their surface area, there is a limitation to widening the effective surface area of the CNTs. The specific capacitance of supercapacitors using CNT electrodes is still smaller than that of supercapacitors using activated carbons and activated carbon fibers (∼250 F/g), which are commonly used as electrode materials for supercapacitors. Therefore, it is necessary to improve the SWNTs for applications that require a high capacitance. The small specific energy density of supercapacitors is a serious drawback to their application in practical devices, and, consequently, the main interest in supercapacitors is their ability to deliver high specific capacitance and energy density.

In the energy storage by supercapacitors, there are two fundamentally different approaches, as discussed in the previous section. A hybrid of an electric double-layer system and a pseudo-Faradic system could be a candidate for a supercapacitor with high specific capacitance and energy density. Currently, there is considerable interest in studying a new type of nanocomposite using CNTs and conducting polymers to improve the conductivity, electronic transport, and electromagnetic properties of organic conducting polymers [72–79]. These nanocomposites are regarded as one of the fascinating candidates for applications in nanoelectronic element and electro-optical devices.

Recently, Jurewicz et al. [18] demonstrated that the composite electrode based on multiwalled carbon nanotubes (MWNTs) coated with polypyrrole (Ppy) can be used in supercapacitors. They realized that a homogeneous layer of Ppy could be deposited on the nanotubular materials by

Table 3. Summary of the performance of many types supercapacitors using various carbon nanotubes reported in recent years.

Type of CNT	Treatment of CNT	Surface area of CNT (m^2/g)	Type of binder	Type of electrolyte	Maximum capacitance (F/g)	Power density (kW/kg)	Energy density (W-h/kg)	Ref.
MWNT	Nitric acid	430	—	38wt% H$_2$SO$_4$	102	>8	—	[12]
MWNT	Sulfuric/nitric acid carbonization	120	Phenolic resin	38 wt% H$_2$SO$_4$	27	—	—	[14]
MWNT	Nitric acid	475	PVDF	1 M KOH	135	—	—	[15]
MWNT	Nitric acid	∼100	PTFE	1M LiClO4/ EC + PC	18	—	20	[17]
SWNT	—	—	PVDF	6 M KOH	40	—	—	[19]
MWNT	KOH activation	1050	PVDF	6 M KOH	95	—	—	[70]
SWNT	Carbonization	360	PVdC	7.5 M KOH	180	>20	7	[20]

Note: MWNT, multiwalled carbon nanotube; SWNT, single-walled carbon nanotube; PVDF, polyvinylidene fluoride; PTFE, polytetrafluoroethylene; PVdC, polyvinylidene chloride; EC, ethylene carbonate; PC, propylene carbonate.

electrochemical polymerization of pyrrole. The composite electrodes in all cases enhanced the specific capacitance. They obtained a maximum value of 163 F/g for MWNTs prepared at 600 °C and modified by a Ppy layer of 5 nm, whereas it is only 50 F/g for the pristine nanotubes. It has been proposed that the nanocomposite electrode favors the formation of a three-dimensional electrical double layer, allowing a more effective contribution to the pseudo-Faradic properties of Ppy.

Frackowiak et al. [19] also reported on composite electrodes based on MWNTs deposited with Ppy for supercapacitors, although they prepared the nanocomposite electrodes of MWNTs and Ppy by chemical polymerization of pyrrole using an oxidant in an acidic solution. The value of the specific capacitance obtained from MWNT electrodes modified by Ppy has reached 172 F/g, about twice that given either by pristine MWNTs (ca. 80 F/g) or by pure Ppy (ca. 90 F/g). They also observed pseudocapacitance and speculated the origin of pseudocapacitance as the surface functionalities, metallic particles, or conducting polymers.

Lee and co-workers [80, 81] introduced SWNT–Ppy nanocomposite electrodes to improve the specific capacitance of the supercapacitor by combining the electric double layer and the redox reaction. The individual nanotubes and nanoparticles are uniformly coated with Ppy by *in-situ* chemical polymerization of pyrrole. In comparison to the pure Ppy and the SWNTs, the SWNT–Ppy nanocomposite electrodes exhibit a specific capacitance that is 5–10 times higher. They show that this large specific capacitance of the SWNT–Ppy nanocomposite is due to the uniformly coated Ppy on the SWNTs, increasing the active sites on Ppy chains. Lee and co-workers emphasized that the pseudocapacitance by the redox reaction and the capacitance by the electric double layer are simultaneously enhanced by the enlarged surface area of Ppy. They also studied the effects of the conducting agent added in the nanocomposite electrodes on the specific capacitance and the internal resistance of supercapacitors. They obtained a maximum specific capacitance of 265 F/g from the SWNT–Ppy nanocomposite electrodes containing 15 wt% of the conducting agent. They argued that the addition of a conducting agent into the SWNT–Ppy nanocomposite electrodes gives rise to the increase in the specific capacitance by reducing the internal resistance of the supercapacitor.

6. CONCLUSIONS

Some of the important challenges in this world are the conversion, storage, and distribution of energy. These are clearly connected with the development of several key technologies such as transportation communications, and electronics. The environmental problems and economical aspects related to the development and use of electrochemical energy storage devices are of significance. Air pollution and abusive use of the earth's natural resources are of major concern. If only 10% of vehicles are electrically powered, petroleum consumption will be cut by 700 million barrels per year, the reduction in expenses would be 14 billion at $20 per barrel, and air pollution would be reduced by 1011 kg of CO_2 [82]. Therefore, new applications and development of supercapacitors are directly related to technologies of an electric vehicle (EV) or a hybrid electric vehicle (HEV). The supercapacitor in an EV or an HEV will serve as a short-term energy storage device with high power capability and will allow us to store the energy obtained from regenerative braking. This energy will be reused in the next acceleration and boost. It also allow us to reduce the size of the primary power sources [batteries (EV), internal combustion engine (HEV), fuel cell] and keep them running at an optimized operation point [31, 35]. High-power supercapacitors for an EV or an HEV will require a high working voltage of 100–300 V with low resistance and high energy density by the series and parallel connections of elemental capacitors. Note also that homogeneous performance in each supercapacitor unit is essential in such a system [31, 35].

The remaining problems in the technology of supercapacitors are connected with the engineering of high-rate production lines for the fabrication of very well matched units for stacking in multicell and high-voltage devices and the production of reliably sealed, low-ESR, bipolar, stacked devices. The lowered ESR for high-power supercapacitors strongly depends on the manufacturing technology. However, the energy density of the supercapacitors is mainly governed by the properties of the electrode materials. Therefore, the development of novel electrode materials will accelerate the supercapacitor having an energy density as high as a secondary battery.

Another future application is the microsupercapacitor for the power source of micro (or nano) electromechanical systems (MEMS or NEMS). In recent years, MEMS (or NEMS) technologies have attracted attention worldwide for many applications, including medical devices, communications equipment, sensors, and actuators. There are many technical problems with the development of these types of microdevices. One of the most important challenges is to develop the optimal micropower source to operate these devices. In many cases, the MEMS (or NEMS) requires extremely low current and power. This may be possible by using microsupercapacitors as the power sources for these devices.

GLOSSARY

Battery A device that stores electrical energy using electrochemical cells. Chemical reactions occur spontaneously at the electrodes when they are connected through an external circuit, producing an electrical current.

Capacitor An electrical device that stores electricity or electrical energy. It has three essential parts: two electrical conductors, which are usually metal plates, separated and insulated by the third part, called the dielectric. The plates are charged with equal amounts of positive and negative electrical charges, respectively.

Carbon nanotubes Graphitic layers rolled into the form of a hollow cylinder whose diameter is an order of nanometer scale.

Cell A device that converts chemical energy into electrical energy or vice versa when a chemical reaction occurs in the cell. Typically, it consists of two metal electrodes immersed into an electrolyte with electrode reactions at the electrode–solution surfaces.

Electric double layer Development of a net charge at the particle surface affects the distribution of ions in the surrounding interfacial region, resulting in an increased concentration of counterions (ions of opposite charge to that of the particle) close to the surface.

Electrodes The two electronically conducting parts of an electrochemical cell.

Electrolyte A chemical compound (salt, acid, or base) that dissociates into electrically charged ions when dissolved in a solvent. The resulting electrolyte solution is an ionic conductor of electricity.

Equivalent series resistance The single resistor that draws the same current as the combination of constituent resistors.

Faradic redox process An oxidation–reduction reaction that occurs in an electrochemical cell. The essential feature is that the simultaneous oxidation–reduction reactions are spatially separated.

Polarizable electrode An electrode that is easily polarizable. That is, the potential of the electrode will change significantly from its equilibrium potential with the application of even a small current density.

Pseudocapacitance The capacitance due to the Faradic redox process in a supercapacitor.

Separator A thin structural material (usually a sheet) used to separate the electrodes of a devided electrochemical cell into two or more compartments.

Supercapacitor A high-energy version of a conventional electrolytic capacitor holding hundreds of times more energy per unit volume or mass than a normal capacitor.

Carbon Nanotubes in Composite Materials

Ch. Laurent, A. Peigney

Université Paul-Sabatier, Toulouse, France

CONTENTS

1. INTRODUCTION

1.1. Carbon Nanotube Discovery and Description

Although hollow carbon fibers have been prepared for several decades, it is the report by Iijima [1] in 1991 on obtaining of carbon tubes with a diameter in the nanometer range, the so-called carbon nanotubes (CNTs), and on their relations to the recently discovered fullerenes that initiated a worldwide research effort devoted to improving their synthesis, determining their structure, and calculating and measuring their physical properties.

Rolling a graphene sheet onto itself so that the open edges match exactly produces a hollow cylinder which is termed a single-walled CNT (SWNT). Two such concentric cylinders form a double-walled CNT (DWNT). A CNT with more walls is named a multiwalled CNT (MWNT). To close the tips, half fullerenes or more complex structures that include pentagons are required. However, the cylindrical part of the CNT, which contains only hexagons, is considered infinite in most studies. There are several ways to roll the graphene sheet, which can be described by a helical vector (or chiral vector, or roll-up vector) represented by a pair of integers (n, m) [2, 3] as described in Figure 1 [4]. The limiting cases are referred to as zizzag $(n, 0)$ and armchair (n, n) SWNTs, with a helical (or chiral) angle equal to 0 and 30°, respectively. Other SWNTs have a helical (often termed chiral) structure. As mentioned in a later section, the helicity has significant implications on the electronic properties of CNTs. For MWNTs, the measured interlayer distance (about 0.34 nm) is close to that measured between graphene sheets in graphite and no particular correlation appears between the helicity of concentric layers.

SWNTs have a diameter in the range 0.4–6 nm and a length reaching several tens or even hundreds of micrometers, resulting in a very high aspect ratio: indeed, the length/diameter ratio could be in the range 1000–100,000, although the upper limit is difficult to evaluate because the length is difficult or impossible to measure. Another notable characteristic of CNTs is the high specific surface area (1315 m^2/g considering the outer surface of infinite SWNTs) which is mostly dependent on the number of walls and, in a lesser way, on the diameter [5]. The hollow structure of the CNTs is of course also interesting because it offers a nanometric cavity which can be filled with various materials.

More on the fundamental relations governing the geometry of CNTs can be found in the early review by Dresselhaus et al. [6] which also highlights the implications of symmetry on the vibrational and electronic structure of one-dimensional carbon. The following sections will very briefly describe the synthesis and the general properties of the CNTs.

1.2. Synthesis

The first report on the preparation of filamentous carbon by the decomposition of carbonaceous gases dates back to the 19th century [7]. Rodriguez [8] reviewed the considerable amount of work done on the topic since then. Although very small hollow nanofilaments were prepared by catalytic chemical vapor deposition (CCVD) in the 1970s [9], Iijima's report [1] and the subsequent development of the field triggered an enormous amount of research aiming at the synthesis of CNTs. We will only briefly describe here the formation mechanisms of the CNTs, the main synthesis methods (arc discharge, laser vaporization, and CCVD), and the characteristics of the so-prepared CNTs. Rakov [10] published a review, with 282 references, on the topic. It is important to note something which was not fully appreciated at the beginning of the development of the "nanotube" field, that is, that each method produces different CNTs samples, that differences subsist depending on the experimental conditions for
Figure 1. The helical (chiral) vector OC or $C_h = na_1 + ma_2$ is defined on the hexagonal lattice of carbon atoms by unit vectors a_1 and a_2 and the helical (chiral) angle θ with respect to the zigzag axis. a given method, and that even different batches from a single source may not be exactly identical. However, the field is evolving extremely quickly.

The formation mechanisms of the SWNTs (and DWNTs) and that of the MWNTs are basically different (see [11] for an early review). Arc-discharge MWNTs are prepared without the use of a metal catalyst, so mechanisms involving the incorporation of carbon atoms (C1, C2, C3) and thickening by lateral growth of graphene planes on existing surfaces were proposed [12–16]. Typically, the outer diameter of arc-discharge MWNTs ranges between 2 and 20 nm and the inner diameter ranges between 1 and 3 nm [3, 15, 17, 18]. The length is of the order of one to several micrometers. MWNTs form regularly organized bundles, which may contain tens or hundreds of individual tubes. The bundles in turn are combined into fibers with a diameter of about 50 μm, which themselves form threads with a diameter of about 1 mm. It was noted that the arc-discharge MWNTs contain many defects [19–21]. When using CCVD, relatively large metal particles (about 10–30 nm) can produce MWNTs with a matching diameter by mechanisms established long ago for hollow filaments [9, 22, 23], resembling the vapor–liquid–solid (VLS) mechanism [24].

For SWNTs, two cases are observed: one particle produces either one CNT or many CNTs, depending on its size and other factors. Accordingly, two formation mechanisms, also bearing a certain relation with VLS, were proposed. The "one particle–many CNTs" mechanism [25] is dominant when using arc discharge or laser vaporization. A large number of SWNTs bundles originate from the surface of a metal particle several tens of nm in diameter [25–27]. All observed SWNTs are narrow (0.8–2 nm). A narrow catalyst particle distribution centered on 15 nm appears to give the highest SWNT yields [28]. The diameter distribution of arc-discharge SWNTs is very narrow, generally in the range 0.7–1.6 nm [14, 29, 30]. However, various carbon species

are found in the deposits including SWNTs, MWNTs, amorphous carbon, spherical metallic nanoparticles, empty or filled graphitic nanoparticles, a few graphitic sheets, as well as round spherical metallic particles. The SWNTs are mostly organized in bundles consisting of a few to a few tens of individual tubes forming a triangular lattice and more or less covered with some carbon soot. Lengths reach up to several micrometers. It is claimed that laser vaporization [31] allows far greater control over growth conditions and produces SWNTs in higher yield (70–90%) and of better quality. The SWNTs are about 1–1.6 nm in diameter, with a very narrow distribution, and are arranged in large bundles that may be 100 μm long. No amorphous coating is observed. The diameter distribution can be slightly changed and SWNTs close to 6 nm in diameter were reported [32, 33].

In the "one particle–one CNT" case, observed when using CCVD, the diameter of the SWNTs is in the range 0.5–5 nm and is directly related to that of the catalyst particle. Hafner et al. [34] calculated a critical diameter of 3 nm above which the formation of concentric carbon layers around the particle is favored, in good agreement with experimental results [34, 35]. The so-called "yarmulke" mechanism [36] allows for a second cap (and thus a second CNT) to form underneath the first one. This is also observed experimentally [34]. CCVD specimens may contain several species in addition to Iijima-type CNTs, including amorphous carbon, carbon particles, and carbidic carbon particles, but tremendous progress on the selectivity has been made in recent years. Several groups have reported progresses in the yield, control of the diameter, and the number of walls [34–49]. The CCVD SWNTs are quite flexible and in general contain more defects than those produced by arc discharge and laser vaporization. Note that CCVD methods are becoming increasingly attractive due to their great potential for the production of large quantities of CNTs at a low cost. Length is in the range between ca. 100 nm and several micrometers (or tens of micrometers) and the surface is free of the amorphous carbon coating typically observed in CCVD MWNTs, which generally are even longer.

Purification procedures are required to eliminate the residual metal catalyst and the nontubular carbon species. Several techniques, usually involving thermal and acidic treatments, have been proposed. The sensitivity of SWNTs to chemical processing was investigated by transmission electron microscopy (TEM) [50]. The chemistry of CNTs, which encompasses the aspects of purification and functionalization, is a very important field for the development of future applications. Rakov [51] published a review with 573 references on the topic. Chemical functionalization was also reviewed by Sinnott [52]. Several methods for attachment of oxygen-containing groups to the CNT surfaces have been developed [53, 54]. Carboxylic, carbonyl, and hydroxyl groups were found covering the CNT walls [55]. The concentration of acid groups on the surfaces of HNO_3 treated CNTs was higher than that found for graphite treated under the same conditions [56]. Sonication of CNTs prior to the functionalization in acids increases the concentration of acid groups. Oxidation of CNTs with a H_2SO_4–HNO_3 mixture also leads to a higher concentration of functional groups on the surface [57]. Long-term acid treatment of CNTs also induces modifications. Functional groups can be removed

from the surface of CNTs by heating. It should be noted that SWNTs obtained by different methods exhibit different behavior in the course of acid treatment and subsequent oxidation.

1.3. General Properties

This section will very briefly highlight some general properties of CNTs which are treated in detail in several books [58–60]. A complete coverage of the electrical, thermal, and mechanical characteristics of the different kinds of CNTs (SWNTs, DWNTs, MWNTs, and bundles) is indeed far beyond the scope of this chapter.

The electrical characteristics of CNTs have been investigated by theoretical and experimental works [2, 3, 61–65] which have brought to light some remarkable features related to the unique one-dimensional nature of the CNTs. A review on the electronic properties of CNTs is published in this Encyclopedia [66]. The most important characteristic to note for use of the CNTs in composites is that either metallic or semiconducting behavior may be observed depending on the helicity. The electrical conductivity of a metallic CNT could reach 10,000 S/cm and that of a semiconducting CNT is in the range 0.1–100 S/cm.

The thermal conductivity of CNTs was addressed both theoretically [67–69] and experimentally [70–72]. Calculations showed that the thermal conductivity exhibits a peaking behavior as a function of temperature and that it strongly depends on CNT diameter but does not or weakly depends on helicity. The extrapolation of measurements on compressed mats of CNTs bundles gave values of thermal conductivity ranging from 1750 to 5850 Wm^{-1} K^{-1}, to be compared with the highest known thermal conductivity, that of the in-plane value of graphite (3000 Wm^{-1} K^{-1}).

Reviews on the mechanical properties of CNTs were published by several authors [73–75]. A low density of defects confers excellent mechanical properties to CNTs. Furthermore, the intrinsic strength of the carbon–carbon sp^2 bond is expected to give CNTs the highest strength and modulus among all existing whiskers.

Theoretical [76–78] and experimental studies have shown that CNTs have excellent elastic properties. Treacy et al. [79] first investigated the elastic modulus (Young's modulus) of MWNTs using thermal vibration experiments performed in a transmission electron microscope. The average value, obtained over 11 isolated MWNTs, was 1.8 TPa. Atomic force microscopy (AFM) was used to perform a direct measurement of the stiffness and strength of individual MWNTs [80]. An elastic modulus of 1.26 TPa was obtained and the average bending strength measured was 14.2 ± 8 GPa. Salvetat et al. [81] measured the properties of SWNT bundles with the AFM. The axial and shear moduli decrease significantly upon an incsrease of the bundle diameter, suggesting slipping of the SWNTs within the bundle. A yield strength of 45 ± 7 GPa was calculated for SWNT bundles from experimental strain measurements on the AFM, with an elastic modulus taken at 1.25 TPa [82]. The Poisson ratio is defined by the variation of the radius of the SWNT resulting from longitudinal deformations along the axis. *Ab initio* calculations indicate that it retains graphitic value (0.17) except for a possible slight reduction for small radii and shows a helicity dependence [74].

The deformation behavior of CNTs under stress is also remarkable. Several studies [83–86] have shown that both thin- and thick-walled CNTs exhibit compressive strengths one order of magnitude higher than any other known fiber. Moreover, the flexibility of CNTs is remarkable [87, 88] and the bending may be fully reversible up to a critical angle value as large as 110° for SWNTs [89]. However, this leads to the formation of kinks and highly strained regions. The flexibility arises from the ability of the sp^2 C–C bonds to reversibly change hybridization when deformed out of plane. Tensile-load experiments on MWNTs ropes found a tensile strength and modulus of 3.6 and 450 GPa, respectively [90]. Other tension tests performed on MWNT [91] and SWNT ropes [92] reported tensile strengths in the range of 11–63 GPa, in reasonable agreement with the theoretical value of about 100 GPa and no apparent dependence on the outer wall diameter. Thostensson et al. [73] noted that 63 GPa is a value 50 to 60 times greater than that of high-quality steels. In the case of MWNTs, the failure of the outermost tube occurred followed by pullout of the inner CNTs. The effectiveness of load transfer to the inner walls or within a bundle and its influence on stiffness is still under debate and was notably studied on DWNTs [67, 93, 94].

A study of the radial compressibility of CNTs by AFM [95] showed that at low pressure, the modulus is similar to that of graphite along the *c*-axis (ca. 10 GPa), while at higher pressure, repulsion forces from the more deformed sides increase the elastic modulus. The collapse of CNTs into nanoribbons has been observed [96], which could account for the competition between the van der Waals attraction and elastic energy.

Regarding the use of CNTs in composites, it is important to note [74] that strengthening but also toughening are major concerns in structural elements involving a brittle matrix. For example, fibers longer than the critical length and a strong interfacial bond are required for fiber–polymer composites with a high fracture strength, whereas a weaker interface will promote a high toughness through fiber-matrix debonding and pullout.

With so many unique or exceptional characteristics, the potential applications of CNTs are plentiful, notably as a component of composite materials. Applications in car body panels [97], car and truck bumpers, bullet-proof jackets, the construction of earthquake-proof buildings, support of a human Martian mission, electromagnetic shielding, waveguides, etc., have already been envisioned [51]. In the following sections, the works reported on composite materials containing CNTs will be addressed, successively reviewing materials with metal, ceramic, and polymer matrix. Earlier reviews on CNT composites were published by Thostenson et al. [73] and Lau and Hui [4]. Note that materials consisting of "simply" filled or coated CNTs will not be considered here. A review on CNT filling was published by Monthioux [98].

2. CARBON NANOTUBE– METAL–MATRIX COMPOSITES

A few papers report the fabrication of CNT–metal composites by powder metallurgy techniques and some results on the stability of CNTs toward the solid metal matrix at high

temperatures or on the influence of CNTs on the electrical and mechanical properties of the materials.

Xu et al. [99] studied the electrical properties of MWNT–Al composites. The MWNTs (CCVD, diameter 30 nm) were ground with an aluminum powder and the resulting mixtures were hot-pressed at 793 K. In the obtained material, MWNTs are located mainly at Al grain boundaries and some aluminum carbides were formed, which was attributed to a reaction between amorphous carbon and Al. The electrical resistivity at room temperature increases slightly (3.4–5.5 $\mu\Omega$ cm) with increasing MWNT volume fraction. From room temperature down to 80 K all the composites show the typical metallic decrease of the electrical resistivity. At about 80 K their resistivity abruptly drops by more than 90%. Kuzumaki et al. [100] also investigated MWNT–Al composites using unpurified arc-discharge MWNTs. The composites (5 or 10 vol% MWNTs) were produced by hot-pressing at 873 K and hot-extrusion at 773 K. The MWNTs were found undamaged and, on the contrary to conventional carbon fiber/systems, no aluminum carbides were detected at the interface with the matrix, even after a heat treament at 983 K. The tensile strength and elongation of the composites are only slightly affected by annealing at 873 K in contrast to those of aluminum.

The same group [101] also studied MWNT–Ti composites using similar samples of MWNTs (diameter 5–50 nm), containing graphitic particles and amorphous carbon. The powders were mixed and hot-pressed at 1208 K. The relative density of a pure Ti specimen prepared as a 13 reference was 98.6% and that of the composite was 95.8%. The formation of TiC was observed but TEM observations showed that the MWNTs themselves did not react with the titanium matrix. Probably, TiC comes from the reaction between amorphous carbon and the matrix. The Young's modulus of the composite is about 1.7 times that of pure Ti. This result may be caused by both TiC formation and the addition of MWNTs. The composite has about 5.5 times the Vickers' hardness of pure Ti. This is associated with the suppression of coarsening of the Ti grains, TiC formation, and addition of MWNTs with an extremely high Young's modulus. It is proposed that the MWNTs play an important role in blocking migration of dislocations.

Dong et al. [102] prepared CCVD MWNT–Cu composites by similar techniques. The hardness of the composites increases while the coefficient of friction and wear loss both decrease with the increase in the MWNT fraction (0–25 vol%). Rolling tests reveal that the composites can reach a deformation of 50–60% and have a good isotropy of the mechanical properties.

The structure and superconductivity of CCVD MWNT–MgB_2 prepared by mixing and heat treatment (950 °C, 2 h, Ar) were reported by Wei et al. [103]. Carbon atoms coming from the MWNTs do substitute for boron in the MgB_2 lattice. Depending on the MWNT content and on the extent of substitution, the composites are either semiconductive or metallic.

Thus, these first works have shown the stability of MWNTs in some solid metal environments during the hot-pressing or hot-extrusion processes. But the homogeneity of the dispersion of CNTs has to be improved and the use of

SWNTs has to be tested. The study of more optimized materials will probably confirm the beneficial influence of CNTs on some mechanical properties of metal–matrix composites.

Li et al. [104] prepared a MWNT–metallic glass $Fe_{82}P_{18}$ composite by rapid solidification of a pressed and melted mixture of MWNTs (CCVD, 3 wt%), Fe–P, and Fe powders. The MWNTs, some of which are filled with an iron alloy, are well dispersed in the so-obtained composite ribbons (40 μm thick). Thus, it seems that techniques involving molten metals can also be considered to fabricate CNT–metal composites.

Coatings with CNTs are also studied with the aim to obtain excellent tribological properties. Chen et al. [105] reported the electrodeposition of CCVD MWNTs and nickel on a carbon steel substrate. The MWNT content in the deposit was increased upon the increase to a maximum value of a number of factors including the concentration of the MWNTs in the solution, the current density, and the agitation rate. Ball-milling the MWNTs to decrease their length was found to be beneficial to increase the maximum concentration in the solution. Observation of fracture surfaces shows that the MWNTs appear well dispersed in the nickel matrix, with one end embedded into it and the other end protruding from the surface. CCVD MWNT–Ni–P composite coatings were prepared by electroless deposition [106–108]. These coatings exhibit a high wear resistance and a low friction coefficient compared to SiC–Ni–P and graphite–Ni–P coatings.

3. CARBON NANOTUBE–CERAMIC–MATRIX COMPOSITES

Studies on CNT–ceramic composites using oxide, carbide, and carbon matrices have been reported and usually involve mixing raw or purified CNT samples with the matrix or a corresponding precursor before a densification step. An alternative route involves composite powders with *in-situ* grown CNTs which are very homogeneously dispersed.

Ma et al. [109] prepared MWNT–SiC composites (10 wt% MWNTs) by hot-pressing mixtures of CCVD MWNTs (diameter 30–40 nm) and nano-SiC powders. A densification of 94.7% was achieved of by hot-pressing at 2000 °C and using 1 wt% B_4C as a sintering aid. It is claimed that the presence of the MWNTs provides an increase of about 10% of both the bending strength and fracture toughness, notably by crack deflection and MWNT debonding.

The application of SWNTs for thermal management in ceramics was reported [110]. Purified laser SWNTs were mixed into a slurry containing partially stabilized zirconia. Samples (1% SWNTs) with thickness over 200 μm were prepared by tape casting. Thermal treatments were performed for binder burnout and sintering. Although the SWNTs do not survive the final treatment, they remain intact long enough to serve as templates to create a SWNT-based microstructure. However, the thermal conductivity of these composites is higher than that of the pure matrix, which is opposed to what was aimed for. This could be a consequence of the presence of residual metal catalyst particles. In contrast, the dispersion of 1 wt% vapor-grown carbon fibers (VGCF), which withstand the sintering, provokes a decrease of about 30% of the thermal conductivity.

MWNTs were included in a TiO_2 matrix by a sol–gel method [111]. CCVD MWNTs (diameter 15 nm) covered by a thin layer of amorphous carbon were dispersed by various methods into a TiO_2-precursor sol. Films were prepared by dip coating and were annealed in air at different temperatures. The MWNTs are preserved for treatments at or below 400 °C and TEM observation reveals that they appear to act as preferential sites for the crystallization of rutile-TiO_2 nanocrystals. The porosity of the films is about 20%.

The effect of CNT addition on the tribological behavior of carbon/carbon composites was reported [112]. Slurries of MWNTs (CCVD, 12–15 walls) were infiltrated into the composites (0–20 wt% CNTs) which were then carbonized in N_2. The surface of the final composite is covered with a CNT/carbon layer. The friction coefficient increases and the wear loss decreases upon the increase in CNT loading, so that the wear resistance is doubled with 20 wt% CNTs compared to the 0 wt% material. Andrews et al. [113] reported the dispersion of purified laser-ablation SWNTs in isotropic petroleum pitch matrices to form composite carbon fibers with a diameter of about 18 μm. SWNTs loadings of 8 and 10 wt% were found to be too high to form a fiber. The tensile strength, elastic modulus, and electrical conductivity of a composite fiber (5 wt% SWNTs) are increased by about 90%, 150%, and 340% respectively, as compared to the corresponding values for unmodified isotropic pitch fibers.

Hwang and Hwang [114] prepared SiO_2 glass rods of micrometer size by using surfactant–MWNT (arc-discharge) co-micelles as templates. The rods were mixed with SiO_2 and dense composites (6 wt%) MWNTs were prepared. It is claimed that the Vickers hardness of the MWNTs/SiO_2 rods–SiO_2 materials is twice that of SiO_2 rods–SiO_2 composites but it is unclear whether this is due to the MWNTs themselves or to the change in rod morphology they provide. Arc-discharge SWNT–SiO_2 glass composites were prepared using a sol–gel technique [115]. The purified and shortened (300–500 nm) SWNTs were functionalized with dendron methyl 3,5-di(methyltriglycoloxy)benzylic alcohol prior to ultrasonic blending in the sol phase and gelification. Heating the glasses to 600 °C produced materials with 80% densification and a good optical transparency, revealing the homogenous dispersion of the SWNTs (0.1–1.0 wt%). Nonlinear optical transmission was observed.

The synthesis of MWNT/sol–gel composites [116] was also performed by adding various silane precursor sols (methyl-, ethyl-, and propyltrimethoxysilane) to CCVD MWNTs and mechanically mixing to ensure a uniform composition. The mixture was packed and allowed to dry for 24–48 h depending on the amount of sol. The final composites contained 34, 44, or 61 wt% of MWNTs. However, the composition of the matrix at this stage is unclear. The authors note that negatively charged silanol groups may be present. SEM observations reveal that the composites are quite porous. The development of electrochemical devices was investigated. It was found that varying the sol and the amount of MWNTs allowed one to obtain a double-layer capacitance on a wide range (0.2–100 mF/cm^2). A high capacitance is required for energy-storage applications while a low capacitance is required for electrochemical sensors. Fast electron-transfer kinetics are observed and it is proposed that the so-called

selectivity of the composite (followed by the shift of the oxidation peak of ascorbic acid on cyclic voltammograms) could be controlled.

The present authors have reported a novel catalytic route for the *in-situ* formation of SWNTs and thin MWNTs in a composite powder by reduction in H_2–CH_4 of an alumina-based solid solution [42]. From the beginning, one of the aims was to further use such composite powders to produce dense composites. Incidentally, to the best of our knowledge, this was the first time that the formation of SWNTs by CCVD of a hydrocarbon was reported. With the aim to favor the formation of tubular carbon (notably SWNTs and DWNTs) with respect to other carbon species (fibers, hollow or filled particles, disordered carbon), several parameters related to the material were studied: allotropic form of the solid solution [117], iron content [118], specific surface area [119]. Parameters related to the reduction treatment such as the composition of the H_2–CH_4 atmosphere [49, 120] and the temperature [35] were also studied in detail. The method was expanded to $MgAl_2O_4$-based solid solutions in order to be able to use divalent cations and therefore compare the catalytic efficiency of Fe, Co, and Ni [121, 122] and their binary alloys [123]. Solid solutions in the form of foams rather than powders were prepared and the formation of SWNTs from such foams was reported for the first time [124]. The method was further expanded to MgO-based solid solutions [43, 44, 125–127]. The CNTs can be extracted without damage from the CNT–metal–MgO composite powders by a mild treatment (soaking in dilute HCl at room temperature). They thus can be used for dispersion in other matrices such as epoxy as mentioned in a following section. The specific surface area of the so-obtained CNTs specimens is very high (over 800 m^2/g) [44], in good agreement [5] with the distributions of the number of walls and diameter.

The CNTs being grown *in-situ* in the powders are thus very homogeneously dispersed between the metal–oxide grains (Fig. 2) in a way that seems very difficult to achieve by methods involving mechanical mixing. The CNTs gather in extensively branched bundles, forming a weblike network between the matrix agglomerates. The bundles are always smaller than 100 nm in diameter, they appear to be very flexible, and some have been traced for 100 μm.

Several studies have dealt with the preparation of dense CNT–Fe–Al_2O_3, CNT–Co–MgO, and CNT–FeCo–$MgAl_2O_4$ composites by hot-pressing [128–131] and hot-extrusion [132] and on the determination of some of their mechanical and electrical characteristics. The precise CNT content in the dense materials is difficult to determine, so the carbon content in the starting composite powders (2–10 wt%) and a unique parameter derived from specific surface area measurements [5, 42, 128] representing the quantity of CNTs were used to compare the different specimens. The early studies [128–130] showed that in comparison to similar carbon-free nanocomposites, the relative densities of the CNT–Fe–Al_2O_3 composites are lower, the matrix grains are smaller, and the fracture strength and fracture toughness are generally markedly lower. Nevertheless, scanning electron microscopy (SEM) observations of composite fractures indicated that the CNT bundles locally act to dissipate some of the fracture energy. The too-low volume fraction of CNTs
Figure 2. Scanning electron micrographs of CNT–Fe–Al$_2$O$_3$ composite powders with micronic (a) and submicronic (b) matrix grains. Long bundles of CNTs are observed.

and the presence of others species, notably large diameter (>15 nm) filamentous carbon, could explain the lack of mechanical reinforcement at the macroscopic scale.

As mentioned, works on the powder synthesis allowed one to increase both the quantity of CNTs and the quality of carbon (much less nanofibers) in the CNT–Fe–Al$_2$O$_3$ powders and to prepare novel composite powders, CNT–Fe/Co–MgAl$_2$O$_4$ and CNT–Co–MgO. Hot-pressed composites were investigated [131]. For the sake of comparison, ceramics (MgAl$_2$O$_4$ and MgO) and metal–oxide composites

(i.e., without CNTs) were prepared in the same conditions. With the Al$_2$O$_3$ matrix, the increase of the quantity of CNTs in the powder leads to a refinement of the microstructure of the hot-pressed specimen. With both the Al$_2$O$_3$ and the MgAl$_2$O$_4$ matrix, a fraction of the CNTs seems to be destroyed during hot-pressing at 1500 °C (in a vacuum). When using the MgO matrix, most CNTs are destroyed during a hot-pressing at 1600 °C, but the CNTs are not damaged if the treatment is limited to 1200 °C. It seems that the quantity of CNTs retained in the massive composite is more dependent on the treatment temperature than the nature of the oxide matrix. CNT damage produces disordered graphene layers which gather at matrix grain junctions. Probably due to a too-low relative density (87–93%), the fracture strength (measured by three-point bending) and the fracture toughness (measure by the single-etched notched beam technique) of the CNT-containing composites (Tables 1 and 2) are generally lower than those of the carbon-free metal–oxide composites and only marginally higher than those of the ceramics.

SEM observations (Fig. 3) showed that some CNTs are trapped inside the matrix grains or at grain boundaries and seem to be wetted by the matrix in the case of alumina. Most of these CNTs are cut near the fracture surface after some pull-out (Fig. 4) and could contribute to a mechanical reinforcement. However, this is not demonstrated at a macroscopic scale.

It was shown that CNTs confer an electrical conductivity to ceramic–matrix composites. Indeed, whereas the corresponding ceramics and metal–oxide nanocomposites are insulators, the CNT–metal–oxide composites are electrical conductors (electrical conductivity in the range 0.2–4.0 S cm^{-1}) due to the percolation of the CNTs. The values of the electrical conductivity are fairly well correlated to the relative quantity of CNTs, the specimens becoming insulators when the CNTs are destroyed. Recently [133], it was found that the percolation threshold is below 1 vol% of CNT and that controlling the CNT quantity in the starting powders allows one to control the electrical conductivity in the range 0.01–10 S cm^{-1}.

Peigney et al. [132] reported that extrusion at high temperatures (in a vacuum) allows one to align CNTs in ceramic–matrix bulk nanocomposites, as opposed to fibers or thin films. The superplastic forming is made easier by the CNTs, which inhibit the matrix grain growth and also

Table 1. Relative density and microstructural characteristics of the hot-pressed ceramics and nanocomposites.

Ceramic or composite	Label	d (%)	G_m (μm)	d_{metal} (μm)	d_{ZrO_2} (μm)
CNT–Fe–Al$_2$O$_3$	CMA1	88.7	0.3	≤0.5	—

act as a lubricating agent. The CNTs withstand the extreme shear stresses occurring during the extrusion up to 1500 °C. In addition to electron microscopy revealing the alignment, the composites show an anisotropy of the electrical conductivity [about 30 times larger in the longitudinal direction (20 S cm^{-1}) than in the transverse direction], which could be adjusted by controlling the amount of CNTs (carbon content in the range 0.6–8 wt%).

Siegel et al. [134] mixed arc-discharge MWNTs with a nanometric alumina powder in ethanol dispersion using an ultrasonic probe. The mixture was dried in two steps, first in an ultrasonic bath and then in an oven. Hot-pressing was performed in argon at 1300 °C. A single composite was prepared (10 vol% MWNTs). It is claimed that the fracture toughness (derived from Vickers microhardness

Figure 3. Scanning electron micrographs of the fractures of CNT–Fe–Al_2O_3 composites. Reprinted with permission from [130], A. Peigney et al., *Ceram. Int.* 26, 677 (2000). © 2000, Elsevier Science.

measurements) is increased by 24% (to 4.2 MPa m$^{1/2}$). However, basic materials characteristics such as the density and grain size are not given, making it difficult to consider this result as evidence for the beneficial role of the MWNTs themselves.

Zhan et al. [135] prepared SWNT–alumina composites using small-diameter SWNT bundles obtained by the HIPCo technique and a nanometric alumina powder (50 nm). The two components were mixed by ball-milling, which produced a reasonably homogeneous dispersion without damaging the SWNTs. Fully dense composites were obtained by the spark plasma sintering (SPS) technique, in which the specimen is annealed at lower temperatures (1150 °C) and during much lower times (3 min) than using other sintering processes. SPS does not damage the SWNTs. The bundles can be seen to be located mainly at the boundaries of the alumina grains and have good contact with the alumina matrix. The authors report a very large gain in fracture toughness (derived from Vickers indentation) in alumina composites containing 10 vol% SWNT (from 3.7 MPa m$^{1/2}$ for pure Al_2O_3 to 9.7 MPa m$^{1/2}$). Moreover, one of these SWNT–Al_2O_3 composites which was not fully densified (about 14% of residual porosity) presented a quite remarkable fracture toughness—about twice that of the fully densified but unreinforced alumina matrix. Sun et al. [136] reported the development of a colloidal process to coat CNTs with alumina prior to another mixing step with a concentrated alumina suspension, so that the final material contains only 0.1 wt% CNTs. SPS was used to fully densify (at 1300 °C) the composite. The Vickers hardness is slightly higher than that of pure alumina (17.6 versus 16.9 GPa) and the Vickers indentation-derived toughness is increased from 3.7 to 4.9 MPa m$^{1/2}$ upon the addition of 0.1 wt% CNTs. It is proposed that coating the CNTs before sintering results in an improved bonding with the matrix. Crack bridging and CNT pullout could also lead to the increase in fracture toughness. These studies [135, 136] have thus demonstrated that CNT–ceramic composites warrant further investigation with respect to the mechanical properties [137]. For example, the preparation of larger specimens to test the fracture strength would be of interest [137].

MWNT–lanthanum cobaltate composites were tested for a possible application as an oxygen electrode in rechargeable zinc/air batteries [138]. La$_{1-x}$M$_x$CoO$_3$ (M = Ca, Sr) particles were coated with a citrate precursor containing more cobaltate with a slight excess of cobalt oxide. The mixture was treated in acetylene (700 °C) to produce MWNTs (diameter 20–30 nm, length about 20 μm) grown on the oxide surface. An electrode was manufactured and promising results were obtained. The CNTs formed directly at the oxide surface could improve the electrical junction between the oxide and the carbon-containing substrate.

MWNTs (arc discharge, 3 wt%) were embedded into Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ (a Bi-2212 superconductor) in order to improve pinning properties [139]. The insulator–supraconductor transition is slightly lower in the composite than in the Bi-2212 material (87 vs 95 K). The increase in current densities shows that the MWNTs function like columnar defects produced by heavy-ion irradiation.

4. CARBON NANOTUBE– POLYMER–MATRIX COMPOSITES

CNT–polymer composites are by far the most studied. In the following sections, we will successively review composites with epoxy, polymethylmethacrylate, and other matrices. Lordi and Yao [140] noted that three key issues affect the performance of a fiber–polymer composite: the strength of the fiber phase, the toughness of the fiber phase, and good interfacial bonding which is crucial for load transfer to occur and fiber orientation. These authors [140] performed calculations related to the interfacial adhesion in CNT–polymer composites. It is shown that interfacial binding energies are only slightly correlated with adhesion in actual composites, as determined by comparison with experimental observations of fiber pullout by various authors. It is also reported that hydroxy side-groups, and to a lesser extent phenyl side-groups, on the polymer seem advantageous for strong interfaces. The key factor in forming a strong bond the CNTs and the matrix lies in the polymer's ability to form large-diameter helices around individual CNTs. The strength of the interface may result from molecular-level entanglement of the two phases and forced long-range ordering of the polymer. In addition, it is proposed that weak frictional interactions between layers of MWNTs and between SWNTs in bundles indicate that isolated SWNTs are desired for dispersion in a matrix. Schadler et al. [141] noted that a high interfacial shear stress between the fiber and the matrix will transfer the applied load to the fiber over a short distance, whereas a low interfacial shear stress will require a long distance. The first main mechanism of load transfer is micromechanical interlocking, which could be difficult with CNTs due to their atomically smooth surface. Other mechanisms include chemical bonding and van der Waals bonding between the CNTs and the matrix.

4.1. Epoxy–Matrix Composites

The first work on a CNT–polymer composite was reported by Ajayan et al. in 1994 [142]. Purified arc-discharge MWNTs were dispersed in a liquid-epoxy base resin by mechanical stirring. After evacuation to remove trapped air

bubbles, pastes of the material were hardened by heating above 6 °C for 2 hours. Thin slices were cut and observed by TEM. It was demonstrated that, during cutting, the majority of MWNTs were straightened in the strain direction rather than broken. These results suggested, first, that MWNTs have excellent mechanical properties and second that anisotropy can be induced by a flow in such a material. Only several years later, in 1998, were other works published on CNT–polymer composites.

Schadler et al. [141] reported the dispersion of 5 wt% MWNTs in an epoxy resin by an ultrasonic treatment. Although the MWNTs were well separated, they remain poorly distributed. Mechanical tests and associated Raman spectroscopy revealed that the load transfers to the MWNTs were much higher in compression than in tension. It was inferred that, under loading, only the outer layers of the MWNTs are stressed in tension because all the inner tubes are sliding within the outer, whereas all the layers are stressed in compression.

Further investigations on the load transfer in such materials were reported. Both laser-ablation SWNTs and arc-discharge MWNTs were used. It was found [85] that the compressive strength of thin- and thick-walled CNTs is more than two orders of magnitude higher than the compressive strength of any known material, which is close to 0.05 GPa. Compressive stresses were induced in composites films, 200 μm thick, from the shrinkage of the matrix due to polymerization and by further quenching from room temperature to low temperatures (223–81 K) [143, 144]. The frequency of some Raman bands being stress-sensitive, it has been demonstrated that this spectroscopy can be used to study the strain distribution in fiber composites and to calculate the Young's modulus [145]. The obtained values were close to those previously reported for SWNTs and MWNTs, about 5 and 1.8 TPa, respectively [79, 146]. The fracture of a SWNT–epoxy composite, observed in real time by TEM, revealed a good polymer–CNT wetting and significant CNT–polymer adhesion [147]. Raman spectroscopy investigations of SWNT–epoxy and MWNT–epoxy composites [148] allowed one to determine the effective modulus of the CNTs (about 1 TPa and 0.3 MPa for the SWNTs and MWNTs, respectively). Stress transfer between the different phases was demonstrated.

The formation of damage doublets in adjacent MWNTs was reported in microtomed thin slices of arc-discharge MWNT–epoxy composite films [149] (Fig. 5). It was concluded that despite the enormous difference in scale, fundamental concepts pertaining to continuum mechanics of fiber composites such as "stress concentration factor" and "effective matrix radius" could be valid at the nanometric level, at least to some degree. Interactions between CNTs should also be taken into account.

Mechanical tests conducted on 5 wt% SWNT–epoxy composites [150] showed that SWNT bundles were pulled out of the matrix during the deformation of the material. In some areas, the SWNTs appeared broken and relaxed but in other regions, they were fully stretched and bridging a crack (Fig. 6).

On the basis of Raman spectroscopy results and SEM observations, the authors inferred that the load transfer is limited because the SWNTs are slipping, under tension
Figure 5. (a) TEM image of aligned MWNTs close to the film surface, revealing CNT fragmentation and the formation of a doublet of adjacent breaks (bottom arrow). A doublet consisting of a CNT end and a nanotube break is also shown (top arrow). (b) TEM picture of two aligned MWNTs in close contact, revealing the formation of two doublets of adjacent breaks (arrows). Reprinted with permission from [149], O. Lourie and H. D. Wagner, *Comp. Sci. Tech.* 59, 975 (1999) © 1999, Elsevier Science.

strain, within the bundles. It was also reported [151] that the combination of standard mechanical tests and Raman scattering tests allows the determination of residual strains due to matrix shrinkage, the elastic properties of embedded SWNTs/bundles, their dispersion, and load transfer effectiveness.

The influence of the interfacial interaction between CNTs and the epoxy matrix was evidenced by Gong et al. [152]. Dynamic mechanical measurements and SEM observations were performed on 1 wt% CNT–epoxy composites, prepared either with or without a nonionic surfactant addition (polyoxyethylene 8 lauryl). For the former composite, the glass transition temperature was increased from 63 to 88 °C and the elastic modulus was also increased by more than 30% in comparison with the matrix. In contrast, the latter composite, prepared without surfactant addition, presents only moderated improvements of these properties. SEM observations confirmed that the surfactant addition improved the dispersion of the CNTs, thus allowing the dramatic effects of CNTs on the properties of the material.

Allaoui et al. [153] claimed to have quadrupled the elastic modulus and the yield strength (measured through tensile test) of an epoxy matrix by the incorporation of 4 wt% of both very large CCVD MWNTs and VGCFs (15–400 nm in diameter). Conductivity measurements revealed that the insulator–conductor transition occurred for MWNT contents in the range 0.5–1 wt%.

CCVD MWNTs (inner diameter 5 nm, outer diameter 10 nm, length a few micrometers) were dispersed in an epoxy matrix (0.0225–0.15 wt% MWNTs) [154]. The exposure to ultrasound early in the process and the subsequent intense stirring of the resin dramatically improved the dispersion of the MWNTs in the matrix. The percolation threshold was found to be between 0.0225 and 0.04 wt% MWNTs. An electrical conductivity of about 10^{-2} S/m, sufficient for antistatic applications, was achieved with 0.04 wt% MWNTs, that is, using a loading about one-tenth of that needed using carbon black (Fig. 7). It is noted that at these low filler fractions, neither the processing behavior of the matrix nor the surface finish of the samples is adversely affected and that the mechanical properties of the epoxy matrix should not be compromised.

Using CCVD CNTs (80% SWNTs or DWNTs) prepared by the solid solution route as mentioned in a previous section, Barrau et al. [155] prepared CNT–epoxy composites,

with CNT fractions in the range 0.04–2.5 wt%. An analysis of the dc and ac electrical conductivity in the temperature range 20–110 °C and frequency range 10^{-2} Hz–1 MHz was reported. There is an increase in dc conductivity of 10 orders of magnitude between 0.2 and 0.6 wt% CNTs, the highest conductivity being 10^{-4} S/cm for 2.5 wt%. A percolation threshold was found at 0.3 wt% CNTs independent of the temperature. The critical exponent β of the scaling law of the percolation theory $\sigma \propto (f - f_c)^\beta$ increases with the temperature (1.71 ± 0.20 at 100 °C) and tends toward the value (1.94) predicted by the tridimensional percolation theory of randomly distributed objects. Indications that tunneling conduction may be the main conduction mechanism are presented. The frequency dependence of the conductivity obeys the universal dynamic response. The behavior of the frequency exponent with the temperature is consistent with the correlated barrier hopping mechanism.

CCVD SWNTs were used to augment the thermal transport properties of industrial epoxy [156]. Samples loaded with 1 wt% unpurified SWNTs (containing 15–25 wt% residual Fe catalyst) showed an increase in thermal conductivity of 70% and 125% at 40 K and at room temperature, respectively. Electrical conductivity data showed a percolation threshold in the range 0.1–0.2 wt% SWNTs. The Vickers hardness rose monotonically with SWNT loading up to a factor of 3.5 at 2 wt%. It is noted that these results suggest that the thermal and mechanical properties of SWNT–epoxy composites are improved without the need to chemically functionalize the SWNTs.

Thostenson et al. [157] reported the direct growth of MWNTs on carbon fibers by CCVD. Embedding the coated fibers in an epoxy matrix produces a multiscale composite. Single-fiber composites were prepared. It is reported that the MWNT coating improves the interfacial load transfer, possibly by local stiffening of the polymer matrix near the fiber/matrix interface.

4.2. Polymethylmethacrylate–Matrix Composites

Unpurified and purified laser-ablation SWNTs were dispersed and aligned in polymethylmethacrylate (PMMA) using a combination of solvent mixing and melt mixing, a method expected to be applicable to most thermoplastic polymers [158]. Composite films (1–8 wt% SWNTs) showed a higher electrical conductivity along the flow direction than perpendicular to it. The conductivity increases with SWNTs loading. In addition, composite fibers with well aligned SWNTs were prepared by melt spinning. The highest draw ratio was achieved for pure PMMA and specimens with 1% SWNTs. However, the fiber diameter is not uniform along the axis and specimens with the higher SWNT contents tend to fracture during the melt-spinning process, revealing a much increased viscosity of the melt. The weight fraction of SWNTs necessary for percolation increases as the SWNTs are aligned.

Unpurified arc-discharge MWNTs (diameter 30 nm) melt-blended with PMMA were compressed (8–9 MPa, 210 °C, 5 min) to produce transparent films [159]. Different contents (4–30 wt%) of MWNTs were used and it is claimed that they are well dispersed in the matrix with no apparent damage. Thermogravimetric analysis (TGA) shows that, compared to pure PMMA, the thermal degradation occurs at a slightly higher temperature when 26 wt% MWNTs are added. The dynamic mechanical behavior was investigated, showing that the storage modulus (E') is increased upon the incorporation of MWNTs, particularly at high temperatures (120–140 °C) (Fig. 8). It was, however, thought necessary to improve the wetting between the MWNTs and the PMMA, so the MWNTs were mixed and therefore coated with poly(vinylidene fluoride) prior to melt blending with PMMA [160]. The presence of a small amount of poly(vinylidene fluoride) indeed results in an increased storage modulus, but this effect diminishes at higher temperatures.

Jia et al. [161] mixed purified CCVD MWNTs with a free radical initiator (2,2′-azobisisobutyrontrile) and the monomer MMA to obtain MWNT–PMMA composites by an *in-situ* process. Two kinds of MWNTs were used: as-purified specimens and ball-milled purified samples. The ball-milling treatment produces much shorter and better separated MWNTs. It is claimed that the MWNTs take part in the polymerization reaction, obstructing the growth of PMMA. C–C bonds are formed between the MWNTs and PMMA results in a strong interface. The tensile strength, toughness, hardness, and deflection temperature of the ball-milled MWNT–PMMA composites are improved compared to pure PMMA up to 7 wt% MWNTs. A higher loading is reported to generate residual stresses in the matrix which causes the composite to become very brittle. In contrast the as-purified MWNT–PMMA composites show weaker mechanical properties because of a poor dispersion of the MWNTs.
MWNT–PMMA (arc-discharge MWNTs, diameter 10–15 nm, length 2–3 μm) and SWNT–PMMA composites (laser-ablation SWNTs, diameter 1.4–2 nm, length 200–400 μm, in bundles) were prepared using a dry powder mixing method [162]. The final step of the preparation was to extrude the materials in order to align the CNTs. The efficiency of the method is demonstrated by SEM, TEM, and Knoop hardness analyses. In particular, the Knoop hardness is at a maximum when the long diagonal of the indenter is perpendicular to the orientation of the CNTs. The tensile modulus was almost insensitive to the presence of the CNTs while the impact strength was significantly increased with only 0.1 wt% of SWNTs. It is proposed that this apparent increase in toughness is due to a weak interfacial adhesion, to the high flexibility of the SWNTs, and to the pullout and sliding of individual SWNTs within a bundle.

The characterization by Raman spectroscopy of SWNT–PMMA composite films (2.5–20 wt% SWNTs) prepared by spin casting was reported [163, 164]. The SWNTs, prepared by different methods (arc discharge, laser ablation, and solar energy), are organized in bundles. In the case of arc discharge, composites were prepared with SWNT samples from different parts of the so-called collaret. Comparing the Raman spectra allowed one to get a diameter distribution of the SWNTs and to confirm the presence of armchair SWNTs. Is was shown that the diameter distribution slightly changes from one collaret sample to the other, whereas spectra from composites with laser ablation or solar energy SWNTs are rather similar. Furthermore, for low SWNT loadings, the amorphous carbon formed during the synthesis of the SWNTs was found to be dispersed in the PMMA and the bundles appeared to be undone. It is expected that such composite films could be used in multilayer diodes. The transport properties of SWNT–PMMA composite films (10 μm thick) were studied in great detail [165, 166]. The SWNTs (diameter 1.3–1.5 nm) are produced by arc discharge with a typical purity of about 70–90%. Most SWNTs form bundles with a typical size of 7–12 nm. The electrical conductivity strongly depends on the SWNTs content. It increases by nine orders of magnitude from 0.1 to 8 wt% (Fig. 9). The room-temperature conductivity is well described with the standard percolation theory. Transport is due to localized carriers originating from the metallic SWNTs. The critical behavior $\sigma \propto (f - f_c)^\beta$ is observed

Figure 8. Storage moduli of PMMA and various composites. Reprinted with permission from [159], Z. Jin et al., *Chem. Phys. Lett.* 337, 43 (2001). © 2001, Elsevier Science.
Figure 9. Dependence of the room-temperature (RT) composite conductivity with the SWNT content. Inset: RT power law dependence of σ versus the reduced mass fraction of SWNTs. Reprinted with permission from [165], J. M. Benoit et al., *Synth. Met.* 121, 1215 (2001). © 2001, Elsevier Science.

with a percolation threshold $f_c = 0.33 \pm 0.03\%$ and a critical exponent $\beta = 2.1 \pm 0.1$. The low value of f_c arises from the very high aspect ratio of the SWNTs, estimated at about 850. The critical exponent β is in good agreement with the conventional 1.94 exponent found for random tridimensional connectivity. This quasi-ideal percolation behavior confirms the good dispersion of the SWNTs in the matrix. The temperature (4–300 K) dependence of the resistivity of some composites was studied, revealing a behavior usually ascribed to hopping in the presence of Coulomb interactions opening a soft Coulomb gap. This suggests that a distribution of intertube/interbundle barriers is superposed to the topological percolation network. It is proposed that the Coulomb gap is due to the Coulomb charging energy involved in the transport process from one bundle (or one SWNT) to the neighboring one. It is further suggested that using composites close to the percolation threshold may be a way to access intrinsic SWNT properties at a macroscopical level and that this approach may be developed for the thermal conductivity as well.

Grimes et al. [167] investigated SWNT–PMMA composite films (thickness about 500 μm) with much higher SWNT loading. Indeed 0–23 wt% of arc-discharge SWNTs (diameter 10 nm, length 1 μm) were dispersed. The electrical conductivity varied over nine orders of magnitude and the percolation threshold was found to be close to 3 wt%. Addition of the SWNTs has a dramatic effect on the measured permittivity spectra (for example at 500 MHz, the real permittivity increases by a factor of 35 and the complex permittivity increases by over three orders of magnitude upon increasing the SWNT loading from 0 to 23 wt%). Both sets of data (electrical conductivity and complex permittivity) fall on a reasonably smooth curve indicating a good dispersion of the SWNTs in the matrix. It is, however, noted that no percolation threshold is observed in the 500 MHz data. Comparison of the permittivity measurements (500–5500 MHz) with theoretical predictions using an effective medium theory were found to be in reasonable agreement.

4.3. Polymer Composites with Other Matrices

Shaffer and Windle [168] prepared CCVD MWNT–polyvinyl alcohol (PVA) composite films with a wide range of MWNT loadings (5–60 wt%). The dry film thickness varied from 53 to 44 μm, with increased loading. SEM images revealed an even dispersion of the MWNTs and pullout lengths of about 100 nm were observed on fracture surfaces. TGA showed that although there is a retardation of the onset of PVA decomposition, resulting possibly from the absorption of the decomposition-generated free radicals by activated carbon surfaces, the subsequent progress of the degradation of PVA is not affected. Below the glass transition of the matrix, the tensile elastic modulus increases due to the presence of the MWNTs. The stiffness of the MWNTs was evaluated at about 150 MPa, well below values reported for isolated tubes. This low experimental value could reflect defects in the MWNTs or the difficulty of shear stress transfer between the walls. Above the glass transition, a large proportion of the stiffness observed below is retained, denoting a much more significant effect of the MWNTs. The onset of the glass transition was not affected by the MWNTs but the high-temperature side was broadened, because polymer molecules near the MWNT surface would have a reduced mobility. The percolation threshold was found to be in the range 5–10 wt%. It is noted that the electrical conductivity is rather lower compared to that of MWNT–epoxy composites containing very low MWNTs loadings [154], possibly because the adsorbed layer of polymer on each MWNT reduces the quantity and quality of electrical contacts between the MWNTs.

Vigolo et al. [169] proposed an original method for the fabrication of macroscopic composite fibers and ribbons incorporating flow-aligned SWNTs. The elastic modulus was found to be equal to 15 GPa, lower than that of individual CNTs or conventional carbon fibers, but nevertheless giving hope for future improvements. It was shown that such fibers can be netted and even knotted.

Starting with arc-discharge MWNTs randomly dispersed in a thermoplastic polymer (polyhydroxyaminoether) prepared by solution casting, Jin et al. [170] prepared composites with aligned MWNTs by mechanical stretching above the glass transition temperature of the polymer. X-ray diffraction (XRD) analysis showed that the fraction of aligned MWNTs increased with increasing stretching ratio. Decreasing the MWNT content also favored alignment, due to a higher mobility. Interestingly, no alignment was achieved with SWNTs using similar stretching ratios. A further study [171] revealed that buckling was observed in bent MWNTs of large curvature, some being completely collapsed. Buckling is thought to be caused by the shrinkage of the polymer during cooling down to room temperature in the final stage of preparation. In some cases, heating by electron irradiation in the TEM restored the cylindrical shape, showing that buckling is an elastic deformation, at least at moderate strain. The onset buckling strain was estimated at about 5%, in good agreement with results from AFM lateral force measurements [80]. The observation of fractured surfaces revealed that failure occurred from MWNT pullout and fracture of the matrix but that the load transfer was not

sufficient to fracture the MWNTs. The fracture strain was found to be greater than 18%.

Wagner et al. [172] prepared arc-discharge MWNT–polyurethane acrylate films 200 μm thick. Tensile test were performed and subsequently thin slices (70 nm) cut in a direction parallel to the film surface were observed by TEM. A progressive fragmentation process was detected which was thought to originate in the large stresses induced in the MWNTs during the tensile tests. The MWNT-matrix stress transfer efficiency was estimated to be at least one order of magnitude larger than in fiber-based composites. This could arise from a strong reactivity of MWNTs toward double bonds in the polymeric chains upon ultraviolet (UV) curing of the specimen. The macrofragmentation and microfragmentation phenomena were studied in detail in a further work [173].

Wood et al. [174] prepared 0.1 wt% SWNT–polyurethane acrylate films 150 μm thick using a flow orientation technique to align the SWNTs. Micro-Raman spectra for specimens cut both parallel and perpendicular to the flow direction were significantly different, as a function of mechanical strains, allowing one to probe the alignment. It is proposed that the adhesion between the SWNTs and the polymer exceeds the shear yield strength of the matrix. A further work [175] showed that using polarized resonance Raman spectroscopy allows one to use unoriented SWNTs as strain sensors. The Raman spectral shifts of the SWNTs were also used to study the glass transition and secondary transitions in the polyurethane acrylate and polycarbonate polymers [176].

The rheological behavior of MWNT–polycarbonate composites was reported by Pötschke et al. [177]. CCVD MWNTs (diameter 10–15 nm, length 1–10 μm) were used. One-kilogram mixtures of polycarbonate with the MWNTs were extruded at 240 °C using a twin-screw extruder. Composites with MWNTs loadings of 0.5, 1, 2, and 5 wt% (corresponding to about 0.34, 0.68, 1.37, and 3.40 vol%, respectively) were formed into bars by compression molding. SEM observations showed that the MWNTs are randomly dispersed in the matrix and that a layer of polycarbonate covers the MWNTs, indicating some wetting and phase adherence. MWNT–polyamide-6 prepared for the sake of comparison did not exhibit the same MWNT-covering features. Electrical resistivity measurements revealed that the percolation threshold is between 1 and 2 wt%. The rheological behavior was investigated by oscillatory rheometry at 260 °C. The viscosity of composites with less than 2 wt% MWNTs had similar frequency dependency than pure polycarbonate and reached a Newtonian plateau at low frequencies. Above 2 wt%, the viscosity decreases to a greater extent with frequency and a non-Newtonian behavior is obtained to much lower frequencies. The coincidence between the electrical and rheological thresholds indicates that the rheology of the material is sensitive to the interconnectivity of the MWNTs. The increase in viscosity with MWNT content is much higher than that reported for nanofibers and carbon black, because of the higher aspect ratio of the MWNTs. The viscosity increase appears along an increase of the elastic melt properties, the increase of the storage modulus being much more important than that of the loss modulus.

MWNT–polycarbonate and MWNT–polybutylene terephthalate (CCVD MWNTs, 8–15 walls, loading 3.5 and 5.0 wt%) were reported [178] to have improved mechanical and electrical properties compared to the corresponding pure polymer. It is noted that the MWNTs must be untangled for optimized performance, which can be done by high shear in a compounding operation.

The synthesis of MWNT–polyaniline composites by *in-situ* polymerization was reported [179]. Arc-discharge MWNTs (10, 20, 30, and 50 wt% with respect to aniline monomer) were used. A composite of 30 wt% MWNTs and *ex situ* polymerized polyaniline was also prepared for comparison. In this process, polyaniline exists in its primary doped form called emeraldine salt. X-ray diffration analysis showed that no additional order had been introduced. Comparison of the different Raman spectra revealed that a site-selective interaction between the quinoid ring of the doped polymer and the MWNTs occurs as a consequence of the *in-situ* polymerization. This interaction may influence charge-transfer processes. The transport properties of MWNTs, polyaniline and the different composites were studied between 300 and 1.25 K. At the higher temperatures, the electrical conductivity is dominated by the polyaniline. At low temperatures, the MWNT network which shows a very weak temperature dependence becomes more conductive than the matrix. Interestingly, it is shown that the conductivity of both the polyaniline and the MWNTs has increased during the *in-situ* polymerization, indicating improved electrical contacts between the MWNTs and the polyaniline grains. Thus the composite material is more conductive than the starting components. Studies using arc-discharge SWNTs [180] revealed that the dispersion in polyaniline is poor for all SWNT contents (2, 5, 10, 20, 30, 50 wt% with respect to aniline monomer), probably because the SWNTs contain residual catalyst particles and amorphous carbon, as well as form entangled bundles.

Qian et al. [181] reported the preparation of MWNT–polystyrene films about 400 μm thick by a solution-evaporation method. One wt% of MWNTs 30 nm in diameter and either 15 or 50 μm long were used. Tensile tests revealed a 25% increase in break stress and a 36–42% increase in elastic modulus. A higher elastic modulus being achieved with longer MWNTs reveals that the external tensile loads are successfully transmitted to the MWNTs through the interface with polystyrene. It is claimed that the MWNTs are superior to VGCF and high-modulus carbon fibers due to their very large length-to-diameter ratio. *In-situ* TEM observations showed that cracks tend to nucleate at low MWNTs density areas then propagate along weak interfaces or relatively low MWNT density areas. The MWNTs align perpendicular to the crack direction and bridge the crack faces. They break and/or pull out from the matrix when the crack opening displacement exceeds 800 nm.

A theoretical study on the interfacial characteristics of SWNT– and DWNT–polystyrene composites using molecular mechanics simulations and elasticity calculations was reported by Liao and Li [182]. It is found that in the absence of atomic bonding between the CNTs and the matrix, the nonbond interactions (electrostatic and van der Waals interactions), the deformation induced by these forces, and the stress/deformation arising from the thermal expansion

coefficient mismatch all contribute to the interfacial stress transfer ability, which is the critical parameter controlling material performance. The interfacial shear stress derived from a CNT pullout simulation is about 160 MPa, significantly higher than for most carbon fiber reinforced polymer composites. Fisher et al. [183] showed by a combined finite element and micromechanical approach that curved CNTs significantly reduce the effective reinforcement when compared to straight CNTs. The model that is developed suggests that the so-called CNT waviness limits the modulus enhancement of CNT–polymer composites.

Watts et al. studied the electrical behavior of polystyrene–matrix composites loaded with boron-doped MWNTs [184] and Fe-filled MWNTs [185]. In the first report [184], arc-discharge MWNTs (diameter 5–40 nm, length 4–10 μm) and B-MWNTs (1–5% boron, diameter 5–40 nm, length over 20 μm) were mixed with a solution of polystyrene in toluene (2.5, 5, 7.5, 10, 12.5 wt% carbon-to-polymer). The solutions were sonicated and evacuated to remove toluene, resulting in the formation of composite films ca. 300 μm thick. The electrical conducting path is established via bundling or tube–tube crossing. Polymer-coated CNTs were also observed. Impedance measurements were carried out under compression or bending. The composites exhibited relatively low resistance, being essentially ohmic conductors at frequencies 1–10^4 Hz. The B-MWNTs showed a lower resistivity because boron doping results in an increase in charge density on MWNTs. In the second work [185], Fe-filled MWNTs are prepared by CCVD. Encapsulated Fe nanowires over 1 μm long were frequently found inside the MWNTs. Current–voltage measurements showed that the film resistivity decreased with increasing MWNT content. Impedance measurements (1 MHz–0.1 Hz) revealed that the composites exhibit inductive, capacitive, and resistive phases. The extent of inductive phase increases with the increase of Fe content, while the extent of the capacitive phase increases with the decrease of MWNT content. It is proposed that electromagnetic induction arises from the encapsulation of long Fe crystals in helical MWNTs that form a solenoid-like structure.

Frankland et al. [186] reported simulations on load transfer in (10, 10) SWNT–polyethylene composites. It is predicted that in the case of nonbonded SWNT–matrix interactions, SWNTs longer than 10–100 μm are needed for significant load-bearing ability. In contrast, SWNTs crosslinked to the matrix should increase the shear yield by one or two orders of magnitude, the critical SWNT length thus being reduced to 1 μm. A further study [187] showed that the introduction of a relatively low density (<1%) of chemical bonds between the SWNTs and the matrix can increase the shear strength at the interface by over an order of magnitude. The change in tensile modulus of a (10, 10) nanotube is then predicted to be negligible. Interestingly, it is noted that inadvertent chemical bonding between CNTs and polymer matrices during processing may in part account for the enhanced stress transfer observed in some systems. Another study on the topic of load transfer in SWNT–polymer composites was reported by Wagner [188]. It is notably shown that for SWNT diameters above 2–3 nm, the interfacial shear strength loses its sensitivity to the diameter. Below this diameter a strong effect is predicted. Also, for a given

diameter, the SWNT strength variability leads to strong interfacial shear strength variability. Minute defects in the otherwise perfect hexagonal structure of the SWNT should considerably lower the SWNT tensile strength. It is likely that defects are limiting the working length of SWNTs. Thus, it is predicted that a large variability will therefore exist and should be experimentally observed in the interfacial strength of apparently identical SWNTs. Large values compared to those in current advanced fiber–polymer composites should be attainable.

The thermostructural behavior of SWNT–polyethylene composites was investigated theoretically [181]. Classical molecular dynamics simulations employing the Brenner potential for intra-SWNT interactions and van der Waals forces for the SWNT–polyethylene interface were used to investigate the thermal expansion and diffusion characteristics of the composites, below and above the glass transition temperature (T_g). However, it is to be noted that most simulations use (10, 0) SWNTs only 2 nm long (204 atoms) embedded in the polymer matrix with a volume fraction of about 8%. The addition of SWNTs is found to increase T_g, thermal expansion, and diffusion coefficients in the composite above T_g. Simulations on a larger system using (10, 0) SWNTs 20 nm long (1804 atoms) have verified the increase of the thermal expansion coefficient.

Pirlot et al. [189] reported the preparation of CCVD MWNT–polyacrylonitrile composites films. The method involved three steps: (i) dissolving the polyacrylonitrile in dimethylformamide, (ii) adding the purified MWNTs and mixing using either an ultrasonic bath or ultrasonic finger, and (iii) evaporating the dimethylformamide to produce a film 50 μm thick (4 and 25 wt% MWNTs). A better dispersion of the MWNTs is achieved when the ultrasonic finger is used. XRD and X-ray photoelectron spectroscopy studies demonstrated the nonalteration of the structures of the MWNTs and the polyacrylonitrile.

The photoconductivity of MWNT–oxotitanium phthalocyanine (TiOPc) films was investigated by Cao et al. [190]. Purified and cut CCVD MWNTs were used. Some samples were chemically modified to graft dodecylamine groups at the surface of the MWNTs, which enhanced the solubility and miscibility in the polymer matrix. The charge-generation layer of photoreceptor devices consisted of 1 μm thick composite films. The photosensitivity of the photoreceptor with modified MWNTs/TiOPc was higher than that with pristine TiOPc and increased with increasing the content of modified MWNTs in the composites. By contrast, the photosensitivity of unmodified MWNTs/TiOPc was lower than that of pure TiOPc. It is proposed that the intramolecular charge transfer occurred in the modified MWNT/TiOPc composite, which favored charge-carrier generation.

Curran et al. [191] worked on CNT–polymer composites for applications as materials for molecular optoelectronics. The conjugated polymer used is poly(*m*-phenylenevinylene-*co*-2,5-dioctoxy-*p*-phenylenevinylene) (PmPV), whose structure is a variation of that of polyphenylenevinylene (PPV).

The polymer tends to coil, forming a helical structure. Arc-discharge MWNTs (diameter 20 nm, length 500 nm–1.5 μm) and PmPV were mixed together in toluene and sonicated briefly. A TEM image revealing the pullout of coated CNTs is shown in Figure 10. It was thought probable
Figure 10. TEM image showing the edge of the CNT–polymer composite film and the pullout of CNTs. Notice that a thin membrane of polymer has enveloped the CNTs, suggesting good wetting and hence mechanical strengthening of the composite film. The diameter of the protruding nanotubes is approximately 15 nm. Reprinted with permission from [191], S. A. Curran et al., *Adv. Mater.* 10, 1091 (1998). © 1998, Wiley–VCH.

that the coiled polymer conformation allows it to surround the MWNTs, favoring π–π interactions. This kind of physical doping is thought to be desirable compared to chemical doping.

The wrapping by the polymer was evidenced by further spectroscopic investigation [192] and was also observed for arc-discharge SWNT–PmPV and CCVD MWNT–PmPV composites [193]. The electrical conductivity of the composite films (4–36 wt% MWNTs) prepared by spin-casting is increased by eight orders of magnitude compared to that of PmPV, reaching 10^{-2} S/m for the 36 wt% MWNT–PmPV specimen [191]. Light-emitting diodes were prepared by casting the composite onto indium tin oxide and then sputtering an aluminum electrode on top. Electroluminescence was achieved in such diodes which use the composite as the emissive layer. It is reported that the MWNTs act as a heat sink, preventing the buildup of large thermal effects which would degrade the conjugated polymer. Using the MWNT–PmPV composites as the electron-transport layer in light-emitting diodes allows for a significant increase in brightness, but with the undesirable increase in the operating voltage [194]. A further work [195] on the electrical conductivity of 0.5–36 wt% MWNT–PmPV films revealed a percolation threshold at 8.4 wt%.

Below this value, a mixed conduction process is probable, with both carrier doping and partial conductive parts. Results obtained from absorption and luminescence spectra of 0–12 wt% MWNT–PmPV films [196] revealed a drop

in quantum efficiency for a low MWNT fraction (1 wt%) compared to the undoped PmPV, then an increase in quantum efficiency upon the increase in MWNT content. However, the opposite effect was reported [197] for 0–7 wt% SWNT–PmPV films. More work [198] on SWNT–PmPV films incorporated in light-emitting diodes with various device structures notably showed that the SWNTs act as a hole-trapping material blocking the holes in the composites, the traps probably being induced through long-range interactions within the matrix. Woo et al. [199] reported the photoluminescence and current–voltage characteristics of light-emitting-diode devices using arc-discharge SWNT–polyethylene dioxythiophene (PEDOT) composite layers (thickness 80 nm). PEDOT is a hole-conducting buffer polymer. Notably, there is a significant decrease of the electroluminescence compared to devices using pure PEDOT. It is proposed that electronic interaction originates from the hole-trapping nature of the SWNTs dispersed in the hole-conducting PEDOT.

Photovoltaic devices using a MWNT–PPV composite were investigated by Ago et al. [200]. MWNTs films were prepared by spin-coating using thin or thick CCVD MWNTs that were submitted to prior chemical oxidation to improve their dispersion in water. It is noted that MWNTs are advantageous over SWNTs since the inner walls remain unreacted and thus retain their electronic characteristics. The composite films were prepared by addition and subsequent conversion of a layer of pure PPV. This procedure is reported to produce composites with highly interpenetrating networks. The external quantum efficiency was found to be about twice as high compared to the standard indium-tin-oxide-based devices. It was found that the MWNT layer acts as a hole-collecting electrode. The enhanced efficiency was explained in terms of the high surface area of the MWNT film and a stronger built-in field. Further studies [201] led to the conclusion that the predominant electronic interaction is a nonradiative energy transfer of singlet excitons from the polymer to the MWNTs, in contrast to other results [198].

A preliminary study [202] of arc-discharge MWNT–poly(3-octylthiophene) composite films revealed an increase of the electrical conductivity by five orders of magnitude compared to the undoped polymer. A higher hardness, determined only qualitatively, and an increased stability under the electron beam were also reported. SWNT–poly(3-octylthiophene) composite films were also studied [203]. Several loadings (0–35 wt%) of arc-discharge SWNTs (purity of about 60 wt%) were used. Composite films of 100 nm were prepared by drop-casting for UV-infrared transmission and reflection studies and measurement of the electrical conductivity. There is no change in the absorption spectra in the loading range 0–8 wt% showing that there is no charge transfer between the SWNTs and the polymer. The electrical conductivity is increased by five orders of magnitude from 0 to 35 wt% SWNTs. The maximum value is close to 10^{-3} S/m for the 35 wt% composite, approaching that measured for a mat of SWNTs (0.05 S/m). The percolation threshold was found at 11 wt%, a much higher value than those reported for other systems. The critical exponent β of the scaling law of the percolation theory is approximately close to the value (1.94) predicted for tridimensional percolation theory.

This group also tested such composite films as field emitters [204]. The materials were formed on n^+-Si by mixing the SWNTs and the polymer after they had been dissolved in chloroform. Three different structures were tested: a SWNT mat, a SWNT mat on a 30 wt% SWNT–polymer composite, and a SWNT mat on pure polymer. The electrical conductivity of the SWNT–polymer composite is very much lower than that of the SWNT mat but the field emission threshold is lower and the emission current higher. Comparing the field enhancement factors and the expected aspect ratios shows that enhancement due to an additional field enhancement mechanism other than that due to the geometrical shape of the SWNTs must exist. It is proposed that the field due to the surface potential modification at the triple junction between SWNTs, polymer, and vacuum is adequate to create additional field emission from such sites.

Yoshino et al. [205] dispersed large CCVD MWNTs (diameter 40–200 nm, length 20–40 μm) in poly(3-hexylthiophene). The mixture (1–20 vol% MWNTs) was sonicated and films several micrometers thick were cast on a quartz plate. The electrical conductivity increases over about six orders of magnitude. A relatively high value was reported for the critical exponent of percolation ($\beta = 2.6$). An analysis according to a model based on a Fermi–Dirac distribution gave a percolation threshold at about 5.9 vol%.

5. CONCLUSIONS

CNTs combine some very particular electrical, thermal, and mechanical characteristics with a low density and a very high aspect ratio. Composite materials with CNTs are increasingly studied due to the many interesting applications that are envisioned in some key areas such as the aerospace, automotive, building, and electronics industries. Metal (notably Al, Cu, Ti)–matrix and ceramic (mostly oxides and SiC)–matrix composites containing CNTs have so far been much less studied than polymer (chiefly epoxy and PMMA)–matrix composites. Powders, thin and thick films, as well as bulk materials have been prepared and tested.

Key issues to overcome include:

- achieving the homogeneous dispersion of the CNTs, especially at the relatively high loadings that may be required for applications as structural materials,
- achieving a total (or very high) densification of the composite,
- achieving a certain degree of bonding between the CNTs and the matrix,
- understanding and/or controlling the reactivity between the CNTs and the surrounding materials, both during the processing and during in-service conditions.

It is to be remembered that basic CNT characteristics such as the diameter, number of walls, extent of bundling, length, and defect density depend very strongly on the synthesis method. Thus choosing the appropriate CNTs for a particular application will be of the utmost importance. The development of CNTs composites is still hampered by the unavailability of large quantities of CNTs, and also by the price of high-quality specimens. The emergence of industrial production methods is expected to drastically cut the price from ca. 500 US\$/g down to 20 US\$/kg. It is anticipated that nanocomposites with CNTs, combining several unusual or exceptional properties, will find technological applications in the near future.

GLOSSARY

Carbon nanotube (CNT) Made up of one or several concentric cylinders (rolled graphene sheets).

Catalytic chemical vapor deposition (CCVD) A CVD technique using a catalyst to activate the decomposition of the appropriate gas.

Chemical vapor deposition (CVD) A technique to deposit a solid by the thermal or chemical decomposition of a gas (or mixture of gases) containing the desired element(s).

Double-walled carbon nanotube (DWNT) Made up of two concentric cylinders.

Multiwalled carbon nanotube (MWNT) Made up of several concentric cylinders.

PmPV (*m*-Phenylenevinylene-*co*-2,5-dioctoxy-*p*-phenylenevinylene), a polymer whose structure is a variation of that of polyphenylenevinylene.

Single-walled carbon nanotube (SWNT) Made up of only one cylinder.

Vapor-grown carbon fiber (VGCF) A filament of carbon that is not necessarily hollow nor nanometric in diameter.

Vapor–liquid–solid (VLS) A mechanism to explain the formation of long, hollow filaments.

Yarmulke Yiddish word meaning skull-cap, used to describe a monolayer of carbon (graphene) covering a fraction of the surface of a catalyst particle; the formation of a yarmulke is a key step in a proposed mechanism for the formation of carbon nanotubes.

Catalysis by Gold Nanoparticles

Masatake Haruta

National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

CONTENTS

1. INTRODUCTION

Since iron-based heterogeneous catalysts were commercially used for ammonia production, a variety of metal oxides, metal sulfides, and metals have been used in inorganic chemical syntheses, petroleum refinery and other chemical processes, and in environmental protection. Metal catalysts are most widely used for a variety of reactions [1] including hydrogenation, complete and partial oxidation, and reduction of NO_x with hydrocarbons [2]. They are usually dispersed in the form of small particles on stable metal oxides such as Al_2O_3 and SiO_2. Elements used as metallic catalysts are actually limited to 12, which belong to the groups VIII and Ib of the periodic table. Most widely used are the 3d metals of Fe, Co, Ni, and Cu, the 4d metals of Rh, Pd, and Ag, and a 5d metal of Pt. Ruthenium (4d) and Ir (5d) have only limited applications. Osmium is usually excluded as a catalyst component because its oxide is toxic. Gold (5d) is the only exception and has been regarded to be poorly active as a catalyst.

The intrinsic catalytic capabilities of group VIII metals can be ascribed to the optimum degree of d-band vacancy. The elements of group Ib, so-called coinage metals, Cu, Ag, and Au have fully occupied d-bands. Owing to relatively low ionization potentials, Cu and Ag readily lose electrons to yield d-band vacancies. In fact, in the chemical industry, Cu is used for the hydrogenation of carbon oxides to produce methanol, and Ag is used for the reaction of ethylene with molecular oxygen to produce ethylene oxide. On the other hand, Au has a high ionization potential and accordingly has poor affinity towards molecules such as H_2 and O_2.

Surface science investigation [3–6] and density functional theory calculations [7] have proved that no dissociative adsorption of H_2 and O_2 takes place over the smooth surfaces of Au at temperatures below 473 K, indicating that Au should be catalytically inactive for hydrogenation and oxidation reactions. Indeed, the conventional supported Au catalysts were much less active than supported Pt group metal catalysts. But it should be noted that Au particles were usually larger than 30 nm when prepared by the impregnation method, while Pt particles were distributed at around 3 nm in diameter [8]. This is partly because the melting point of Au is much lower than those of Pd and Pt (Au: 1336 K, Pd: 1823 K, Pt: 2042 K). Due to the quantum-size effect, the melting point of Au particles with a diameter of 2 nm is estimated to be lowered to 600 K [9], so that these small Au nanoparticles tend to coagulate with each other to form much larger Au particles during calcination of catalyst precursors. Therefore, no answer has yet been given to the question whether the rough surfaces or nanoparticles of Au, having substantial number of steps, edges, and corners, are catalytically inactive or not.

An indication that Au might not always be poorly active when dispersed as small particles was presented in the 1970's by Bond and Sermon for the hydrogenation of alkenes and alkynes at temperatures below 473 K over Au/SiO_2 [10, 11] and by Cha, Paravano, and Galvano for oxygen and hydrogen transfer reactions over Au/MgO and Au/Al_2O_3 catalysts [12, 13]. These landmarks concerning the catalysis by Au until 1981 were reviewed by Schwank [14]. On the other hand, pioneering attempts were made on the reactivities of Au clusters and atoms. Ozin et al. reported that atomic Au species reacted with a solid matrix of CO and O_2 at 10 K to form a complex, which was subsequently decomposed at temperatures above 30 K to produce CO_2 [15]. Cox et al. reported Au clusters were reactive with O_2, H_2, and CH_4 depending on the number of atoms [16].

We reported in 1987 that some composite oxides of Au with three-dimensional transition metals prepared by co-precipitation exhibited surprisingly high catalytic activity

for CO oxidation even at 200 K [17]. Later, it was revealed that these active gold catalysts were composed of Au nanoparticles homogeneously dispersed on metal oxide supports such as Fe_2O_3, Co_3O_4, and NiO [18–20]. This finding, followed by the first commercial application to an odor eater for toilette in 1992, has gradually evoked renewed interests in Au catalysts [21–26].

This article deals with preparation methods for Au nanoparticles deposited on metal oxides, the correlation between nano structure and catalytic properties, a probable reaction mechanism, and ongoing and future applications.

2. PREPARATION OF GOLD NANOPARTICLES

A variety of methods have been developed to deposit Au nanoparticles on metal oxides and activated carbon. They are classified into three categories [27]. The first category is characterized by the preparation of well-mixed precursors, for example, hydroxide, oxide, or metal mixtures of Au with the metal component of the support by co-precipitation [17, 18], co-sputtering [28], or amorphous alloying [29], respectively. These precursor mixtures are then transformed during calcination in air at temperatures above 550 K into metallic Au particles strongly attached to the crystalline metal oxides such as α-Fe_2O_3, Co_3O_4, or ZrO_2. Gold catalysts are advantageous over other noble metal catalysts in that reduction treatment by H_2 is, in principle, not necessary.

The second category is based on the deposition or adsorption of Au compounds, for example, Au hydroxide by deposition-precipitation (DP) [30], or organogold complexes by gas-phase grafting (GG) [31, 32] and liquid-phase grafting (LG) [33, 34]. The last category is to use monodispersed Au colloids stabilized by organic ligands or polymer compounds [35, 36]. Although none of the former six techniques of the first and second categories are effective for depositing Au nanoparticles on activated carbon, this can be realized by dipping activated carbon in Au sols stabilized with polyvinyl pirrolidone or tetrakis (hydroxymethyl) phosphonium chloride [36].

In the preparation of well-defined model catalysts for surface science studies, size-selected Au anion clusters can be deposited with homogeneous dispersion on single crystals of TiO_2 (rutile) and MgO [37, 38]. Surface defect sites or specific surface cages are suggested to be the sites for stabilizing Au clusters on metal oxides or Si support [38, 39].

The DP method is of the easiest handling and, therefore, is used for producing commercial Au catalysts. Due to the amphoteric properties of $Au(OH)_3$, the pH of aqueous $HAuCl_4$ solution is adjusted at a fixed point in the range of 6 to 10, which is selected by taking into account of the isoelectric points (IEP) of the metal oxide supports. Careful control of the concentration (around 10^{-3} M), pH (6 ~10), and temperatures (323 K~363 K) of the aqueous $HAuCl_4$ solution enables the selective deposition of $Au(OH)_3$ only on the surfaces of support metal oxides without precipitation in the liquid phase. Because the precursor can be thoroughly washed before drying, Na and Cl ions are removed to a level of a few

tens ppm. The removal of Cl ions is indispensable because Cl ions markedly promote the coagulation of Au nanoparticles. The only constraint of DP is that it is not applicable to metal oxides, the IEPs of which are below 5 and to activated carbon. Gold hydroxide cannot be deposited on SiO_2 (IEP = 2), SiO_2-Al_2O_3 (IEP = 1), and WO_3 (IEP = 1). In contrast, GG using dimethyl-goldaceytylacetonate is unique because it can deposit Au nanoparticles even on SiO_2 and SiO_2-Al_2O_3 [32].

A catalyst sample of Au/α-Fe_2O_3 prepared by co-precipitation and by calcination at 673 K had relatively narrow size distribution of Au particles, giving mean diameters in the range of 3 to 5 nm with standard deviation of about 30% [18]. A major reason why Au particles remain as nanoparticles even after calcination at 673 K is the epitaxial contact of Au nanoparticles with the metal oxide supports, as typically shown by Figure 1 [18]. Gold particles always exposed its most densely packed plane, (111) plane, in contact with α-Fe_2O_3 (110), Co_3O_4 (111), NiO (111) [20], anatase TiO_2 (112), and rutile TiO_2 (110) [40].

In the case of Au/TiO_2 (anatase), the surface atomic configuration is better matched for Au (111) plane sitting on the oxygen layer of anatase TiO_2 than on the Ti layer. Three-dimensional nanostructure analyses by electron holography together with high-resolution transmission-electron microscopy (TEM) revealed that smaller hemispherical Au particles with diameters below 2 nm had contact angles with the support below 90° (wet interface), whereas larger Au particles with a diameter of 5 nm had that angle above 90° (dry interface) [41]. This difference in the wettability of Au particles may come out of the change in the electronic state of the contact interfaces with the particle size. With an increase in the calcination temperature above 573 K, Au particles coagulated with each other forming larger particles mostly gathered at the valleys of junction between the TiO_2 particles [42].

3. CATALYTIC PROPERTIES OF GOLD NANOPARTICLES

Except for H_2 oxidation and hydrocarbon hydrogenations, most reactions are remarkably structure-sensitive over supported Au catalysts. Two typical reactions are CO oxidation
Figure 1. TEM for Au/α-Fe_2O_3 prepared by co-precipitation and calcination at 673 K.

and propylene epoxidation. The oxidation of CO is the simplest reaction and has been most intensively studied [43]. This reaction is practically important in the purification of engine exhaust gases and of hydrogen produced by steam reforming of methanol and hydrocarbons for polymer electrolyte fuel cells [44]. The direct epoxidation of propylene to produce propylene oxide is regarded as a Holy Grail of sorts because current industrial processes require two-stage reactions [45]. These two reactions over Au catalysts are remarkably sensitive to the contact structure of Au particles with the support, the type of metal oxide support, and the size of Au particles.

3.1. Effect of the Contact Structure of Gold Particles

Figure 2 shows turnover frequencies (TOFs), the reaction rate over one single surface metal atom per second, of CO oxidation at 300 K over Au/TiO_2 and Pt/TiO_2 catalysts prepared by DP, photocatalytic deposition, and impregnation (IMP) methods [8]. The DP method yields hemispherical metal particles with their flat planes strongly attached to the TiO_2 support, while photocatalytic deposition and IMP methods yield spherical particles simply loaded on the TiO_2 support and, therefore, much larger particles particularly in the case of Au. Over Pt/TiO_2, the reaction of CO with O_2 takes place preferentially on the Pt surfaces and the metal oxide support is not directly involved in the reaction. This can account for why different preparation methods do not make any appreciable difference in the TOF of Pt catalysts. On the other hand, the TOF of Au/TiO_2 markedly depends on preparation methods and changes by four orders of magnitude. The TOF of strongly attached hemispherical Au particles exceeds that of Pt by one order of magnitude. The dramatic difference suggests that the contact structure is the most critical factor in supported Au catalysts.

The strong contact of Au particles is also indispensable for the epoxidation of propylene in the gas phase containing O_2 and H_2 [46]. Figure 3 shows that spherical Au particles simply loaded on TiO_2 (prepared by IMP) need higher temperatures for reactions to occur, and causes complete oxidation to produce only CO_2 and H_2O with the yield of H_2O much larger than that of CO_2. These facts indicate that H_2 oxidation and the complete oxidation of propylene take
Figure 3. Product yields as a function of catalyst temperature in the reaction of propylene with O_2 and H_2 over Au/TiO_2 prepared by different methods. Reactant gas: $C_3H_6/O_2/H_2/Ar = 10/10/10/70$; space velocity: 4000 h^{-1} · ml/g-cat.

place separately and the former proceeds much faster. On the other hand, hemispherical Au particles strongly attached to the TiO_2 support (prepared by DP) produce propylene oxide with almost 100% selectivity at a lower temperature—323 K. The H_2 consumption is only about three times that of propylene conversion and appreciably smaller than that over spherical Au partial catalysts. Because epoxidation of propylene does not proceed without H_2, the simultaneous reaction among C_3H_6, O_2, and H_2 takes place, probably at the periphery of Au particles with adsorption at the surfaces of Au particles and the TiO_2 surfaces.

The sharp contrast between spherical and hemispherical Au nanoparticle catalysts in CO oxidation and propylene epoxidation suggests that the reactions may take place at the perimeter interfaces around Au particles. To confirm this hypothesis, Liu and Vannice prepared an inversely supported catalyst, namely, TiO_2 layers deposited on Au substrate, and observed appreciable catalytic activity [47]. A catalyst sample of Au/TiO_2 was also prepared by mechanically mixing a colloidal solution of Au particles of 5 nm in diameter with TiO_2 powder and by calcination in the air at different temperatures [48]. Calcination at 873 K promoted the coagulation of Au particles to form larger particles with diameters above 10 nm, but at the same time with stronger contact (observed by TEM), leading to much higher catalytic activity than calcination at 573 K.

3.2. Support Effect

For CO oxidation, many oxides, except for strongly acidic materials such as Al_2O_3-SiO_2 and activated carbon, can be used as a support and bring about activity even below 300 K. In the case of Pd and Pt, semiconductive metal oxides lead to enhanced catalytic activities but at temperatures above 300 K. Semiconductive metal oxides such as TiO_2, Fe_2O_3, and NiO provide more stable Au catalysts than insulating metal oxides such as Al_2O_3 and SiO_2. Among Au supported on Al_2O_3, SiO_2, and TiO_2, TOFs at room temperature are nearly equal, indicating that the contribution of metal oxide supports is more or less similar in intensities [49]. The difference appears in the moisture effect: Al_2O_3 and SiO_2 needs higher H_2O concentration above 10 ppm than TiO_2 for CO oxidation to proceed at room temperature [50]. Alkaline earth-metal hydroxides, such as $Be(OH)_2$ and $Mg(OH)_2$, are

Figure 2. Turnover frequencies for CO oxidation at 300 K over Au/TiO_2 and Pt/TiO_2 prepared by different methods [8].

the best in exhibiting the highest activity at a temperature as low as 196 K [20, 51]. In contrast, when acidic materials, such as Al_2O_3-SiO_2, WO_3, activated carbon, are used as a support, gold exhibits poor activity and even at temperatures above 473 K the conversions are far below 100% [49].

For the selective oxidation of hydrocarbons in the co-presence of O_2 and H_2, only TiO_2 and Ti-silicates act as effective supports [46, 52–58]. Other metal oxide supports result in producing acetone and CO_2. The requirements to the crystalline structure of support are very strict. Only anatase TiO_2, neither rutile nor amorphous TiO_2, makes Au selective to epoxidation at temperatures below 373 K [52]. Transmission electron microscopy observations showed that Au particles were more often epitaxially contacted on anatase than on rutile, indicating that the location of Ti cations around Au particles is more regular on the anatase surfaces [40]. When Ti cations are isolated from each other on the surfaces or in the bulk network of SiO_2, namely, the atomic ratio of Ti/Si is below 3/100 in Ti-MCM-41, Ti-MCM-48, Ti-β-zeolite, and TS-1, Au is also selective to epoxidation up to 473 K, giving propylene conversions higher than 3%. The distance between Ti cations may be important; on the surfaces of anatase and Ti silicate, Ti cations are separated from each other at a distance of the diameter of oxygen anion or much far, while on the rutile surface, they are located closer.

3.3. Size Effect of Gold Particles

Figure 4 shows that the main product in the reaction of propylene with O_2 and H_2 switches from propylene oxide to propane at a critical diameter of 2 nm [46]. Over Pd and Pt catalysts, the major product is only propane, irrespective of the size of metal particles and of the presence or absence of O_2, while propane is formed over Au catalysts only when Au particles are smaller than 2 nm in diameter and O_2 is present. This implies that a change in the surface property of Au clusters must be induced by donating an electron to O_2 to form negatively charged oxygen species. The critical diameter, 2 nm, corresponds to a layer of three atoms thick when the Au clusters are hemispherical in shape. The bandgap measured with scanning tunneling spectroscopy shows that the electronic state of Au clusters deviates from that of bulk at two or three atoms in thickness [59, 60].
Figure 5 plots the TOFs of CO oxidation over Au/TiO_2, Au/Fe_2O_3, and Au/Co_3O_4 as a function of mean diameter of Au particles [19]. The TOFs sharply increase with a decrease in the diameter of Au particles from 4 nm, indicating that minimizing the size of Au particles is very rewarding owing to the increases in both TOF and specific surface area. In contrast, Pt group metals usually show decreasing or steady TOF; thus smaller particles are not always beneficial [61]. The increased TOFs of smaller Au particles can be explained by assuming that the adsorption sites for CO on the Au surfaces are edge, corner, or step sites and the reaction zone is the periphery around Au particles, because the fractions of these sites on and around hemispherical Au particles increase with a decrease in the size of Au particles [62].

Among supported noble metal catalysts, Au supported on $Mg(OH)_2$ is the most active for CO oxidation at a temperature as low as 196 K; however, it suddenly dies after 3 to 4 months, losing activity even at 473 K [63]. Estimation of the most probable size distribution of Au particles by using Debye functional analyses of X-rays scattered by Au particles for fresh and aged catalysts suggested that the active Au species were 13-atom Au clusters. When they grew to 55-atom clusters with truncated decahedral structure, the catalytic activity was completely lost. Among the two structures of 13-atom clusters, it is likely that the icosahedron is active, whereas the cubo-octahedron inactive [51]. The active $Au/Mg(OH)_2$ catalyst, which was assumed to be mainly composed of icosahedral Au clusters of 13 atoms, showed negative apparent activation energy in the temperature range from 196 K to 273 K [64]. This can be explained by the enhanced transformation of the icosahedron into the cubo-octahedron with a rise in reaction temperature.

Heiz and Abbet et al. prepared model catalysts by depositing size-selected Au anion clusters onto a single crystal of MgO. Although the size and structures of Au clusters deposited were not confirmed by STM, appreciable size dependency of CO adsorption was reported with a maximum for 11 atoms [65]. The higher activity of Au clusters on defect-rich MgO than on defect-poor MgO was observed and *ab initio* simulations indicate that partial electron transfer from the surface of the Au clusters to oxygen-vacancy defects in the support play an essential role for the genesis of catalytic activity [66, 67].

Figure 4. Product yields as a function of mean diameter of Au particles in the reaction of propylene with O_2 and H_2 over Au/TiO_2 catalysts at 353 K. Reactant gas: $C_3H_6/O_2/H_2/Ar$ = 10/10/10/70; space velocity: 4000 $h^{-1} \cdot$ ml/g-cat.
Figure 5. Turnover frequencies for CO oxidation over Au/TiO_2, Au/Fe_2O_3, and Au/Co_3O_4 at 273 K [19].

4. MECHANISM FOR LOW-TEMPERATURE CO OXIDATION

Figure 6 shows Arrhenius plots for CO oxidation over noble metal catalysts. A unique feature of Au catalysts is that apparent activation energies (Ea) are very low. At temperatures below 300 K, Ea is 20∼40 kJ/mol and is nearly zero at temperatures above 300 K. In contrast, Pt group metals have Ea ranging from 80 to 170 kJ/mol [68] and are more active than Au only at temperatures above 500 K. At room temperature, Au is more active by more than four orders of magnitude.

The rate of CO oxidation over Au/TiO_2, Au/Fe_2O_3, Au/Co_3O_4 is independent of the concentration of CO and is slightly dependant on the concentration of O_2 (0∼0.25 order) [19]. This feature is beneficial for the removal of dilute CO from air, because the conversion of CO increased with a decrease in the concentration of CO. Over unsupported Au powder with mean diameters of primary Au particles of 17 nm, the rate is almost independent of the concentrations of CO and O_2 [69]. These independencies suggest that both CO and O_2 are adsorbed on the catalyst surfaces nearly to saturation and the reaction of the two adsorbed species is the rate-determining step.

Figure 7 shows FT-IR spectra for CO adsorption at 90 K over Au/TiO_2 calcined in air at different temperatures [70]. The most active sample (calcined at 573 K, mean diameter of Au particles 2.4 nm) has the largest intensity of the peak at 2110∼2120 cm^{-1}, which is assigned to CO linearly adsorbed on the metallic Au sites. When Au particles become larger than 10 nm in diameter (sample calcined at 873 K), the intensity of this peak is markedly reduced, indicating that CO adsorption takes place only on steps, edges, and corners of Au particles, not on the smooth surfaces. This is in agreement with what has been discussed based on self-consistent density functional theory calculations by Mavrikakis et al. [62].

No direct experimental evidence has yet been presented where oxygen is activated for reacting with CO adsorbed on the Au surfaces, and whether oxygen molecules are dissociatively or nondissociatively adsorbed. A temporal analysis of products (TAP) study of O_2 adsorption and the reaction of O_2 with CO [71, 72], $^{18}O_2$ isotope experiments [71–73], and ESR measurements [73, 74] indicates that molecularly
Figure 7. FT-IR spectra for CO adsorption at 90 K over Au/TiO_2 calcined in air at 573 K and 873 K [70].

adsorbed O_2, most likely O_2^- at the perimeter interface, is involved in the oxidation of CO. When $C^{16}O$ was introduced to Au/TiO_2 at 300 K after preadsorption of $^{18}O_2$ [70], $C^{16}O_2$ is formed with quantity comparable to that of $C^{16}O^{18}O$, indicating that oxygen species (^{16}O) contained in the surface layer of the TiO_2 support are also involved in CO oxidation at room temperature.

There are still other arguments about the active species of Au, especially in the case of Au/Fe_2O_3: oxidized Au species, either Au^+ [75] or $Au^{\delta+}$ [76], or metal-oxide support surfaces with modified reducibility by the interaction with Au nanoparticles [77, 78]. It is unlikely that oxidic Au species are major catalytically active phases, because the most active supported Au catalysts are usually prepared by calcination in the air at 573 K, where Au precursors (hydroxides or organo complexes) can be transformed mostly into metallic particles. A certain fraction of Au species remain as atomically dispersed species in the matrix of the support, which was proved by EXAFS [24, 76, 79, 80], XPS [77], Mössbauer [78, 81], IR for adsorbed CO species [70, 75]; however, no correlation between the amount of oxidic Au species and catalytic activity has yet been presented. It is speculated that the samples that mainly consisted of oxidic Au could exhibit high catalytic activity probably because oxidic Au species are transformed into metallic particles during reaction or storage of the sample after preparation.

Even though metallic Au particles are indispensable, a question arises why the periphery of Au particles can activate O_2 molecules at low temperatures. As proposed by Bond and Thompson [82], it is probable that the perimeter interfaces contain oxidic Au species, most probably $Au(OH)_3$ or $Au(OH)$ under usual conditions where H_2O is present at concentrations above 1 ppm. These hydroxides may be stabilized and reversibly formed and decomposed by the aid of the metal-oxide supports.

Another argument proposed by Goodman et al. is that the nonmetallic nature of Au clusters leads to the enhanced catalytic activity [37, 59]. This mechanism is questionable because the transition of the electronic state was measured for one specific Au cluster of a defined diameter by scanning tunneling spectroscopy, whereas the catalytic activity was measured for a whole specimen of Au/TiO_2 model catalyst with a mean diameter of all Au clusters. A maximum in catalytic activity with respect to the mean diameter of hemispherical Au clusters was observed at 3.5 nm (this might not be reproducible), which corresponded to two or three atoms

Figure 6. Arrhenius plots for CO oxidation over noble metal catalysts. The data for Pt group metals are taken from [68].

thick, where the transition of the electronic state of the specific Au cluster occurred from a metallic to nonmetallic one. This result can be more reasonably explained by assuming that metallic Au surfaces are necessary for CO adsorption and the peripheries act as reaction zones with O_2. A maximum in the perimeter sites and the number of step sites of metallic Au clusters is obtained at a thickness of two atoms [62], where the transition to a nonmetallic state begins.

Based on the above arguments, a most probable pathway for CO oxidation over supported Au catalysts can be depicted as shown in Figure 8. The rates over Au/TiO$_2$ were about one order of magnitude larger when measured by lowering the temperature from 353 K than when measured by raising the temperature from 203 K [26, 69]. This difference is assumed to arise from the accumulation of carbonate species on the surfaces of the support at low temperatures resulting in the loss of the activating power of the perimeter interfaces for O_2. Therefore, the rate over Au/TiO$_2$ that was deactivated during experiments at lower temperatures is regarded to be close to the rate of CO reaction with O_2 over the surfaces of Au particles without the contribution of O_2 activation at the perimeter interfaces. The one order of magnitude difference in the rate between fresh (obtained by high-temperature measurements) and deactivated (after low-temperature measurements) Au/TiO$_2$ can be ascribed to the contribution of the TiO$_2$ support.

5. CATALYTIC CAPABILITIES AND APPLICATIONS OF SUPPORTED GOLD NANOPARTICLES

Gold catalysts can also promote many reactions other than CO oxidation and propylene epoxidation when suitable support materials are selected. Table 1 lists such reactions catalyzed by Au at much lower temperatures or with much higher selectivities than by other metals.

The complete oxidation (combustion) of hydrocarbons, Co$_3$O$_4$, which is the most active catalyst among base metal oxides, brings about the highest catalytic activity to Au as a support [83, 84]. In the oxidative decomposition of nitrogen-containing hydrocarbons, ferric oxides and nickel ferrites lead to the highest catalytic activities owing to their strong affinities to nitrogen [85]. The oxidative decomposition of trimethylamine, which is a typical odor compound, proceeds
Figure 8. Schematic representation for a probable pathway of CO oxidation over supported Au catalysts.

over Au/NiFe$_2$O$_4$ at temperatures below 373 K, yielding mainly N$_2$ and CO$_2$, while N$_2$O is mainly produced over Pd and Pt catalysts even at higher temperatures. Gold deposited on Fe$_2$O$_3$, which was supported on a zeolite wash-coated honeycomb, has been commercially used as an odor eater in modern Japanese toilets since 1992.

A characteristic feature of Au catalysts for the hydrogenation of unsaturated hydrocarbons is that partial hydrogenation takes place very selectively—butadiene to butene, acetylene to ethylene [10, 11, 86, 87]. Hydrocarbon hydrogenations are known to be structure-insensitive, proceeding at approximately the same TOF on metal particles of various sizes [88]. It was also the case of the hydrogenation of butadiene over Au catalysts as far as Al$_2$O$_3$, SiO$_2$, and TiO$_2$ were concerned as a support [86], because TOF only differed by a factor of three among Au particles with mean diameters ranging from 3.5 to 7 nm. In the hydrogenation of α, β unsaturated aldehyde, selectivity to the hydrogenation of C=O against that of C=C can reach 80% when Au particles are deposited on ZnO [89]. For methanol synthesis by the hydrogenation of CO and CO$_2$, ZnO, which has been used as a support for commercial Cu catalysts, also works as the best support [90, 91].

Gold supported on activated carbon, γ-Al$_2$O$_3$, or TiO$_2$, is more active and selective than other noble metal catalysts for the oxidation in a MeOH-H$_2$O (6:4) solvent of diols to α-hydroxy acids, which are used in the cosmetics and food industries [36, 92, 93].

The reduction of NO with hydrocarbons to N$_2$ in the co-presence of excess O$_2$ and H$_2$O is an important reaction for the exhaust gas treatments of gasoline and diesel engines. This reaction takes place over some supported Au catalysts [94, 95]. Alkenes (C$_2$H$_4$, C$_3$H$_6$) are more effective as a reductant than alkanes (CH$_4$, C$_2$H$_6$, C$_3$H$_8$) because the formers can adsorb on the Au surfaces more strongly. The optimum temperature and maximum efficiency for NO reduction depends on the kind of metal-oxide supports and increase in the order of α-Fe$_2$O$_3$ (523 K, 12%), ZrO$_2$ (523 K, 32%), ZnO (523 K, 49%), TiO$_2$ (623 K, 30%), MgO (623 K, 42%), Al$_2$O$_3$ (673 K, 80%). The NO conversion to N$_2$ obtained over Au/Al$_2$O$_3$ in the presence of 5 vol% O$_2$ and 10 vol% H$_2$O is comparatively higher than the other catalysts reported so far [2]. The reaction passes through NO oxidation with O$_2$ to form NO$_2$, which then reacts with propylene. Therefore, enhanced activity is obtained with a mechanical mixture of Au/Al$_2$O$_3$ with Mn$_2$O$_3$, which is active for NO oxidation to NO$_2$ [96]. Gold wire [97] and film [98] were known to be active for N$_2$O decomposition to N$_2$ and O$_2$. Recently, Au/Co$_3$O$_4$ has been reported to be active for this reaction even at 523 K in the co-presence of 10 vol% O$_2$ and 5 vol% H$_2$O [99].

Owing to ongoing applications of polymer electrolyte fuel cells to automobiles and to residential co-delivery systems for electricity and heat, low-temperature, water-gas shift reaction is attracting renewed interest. In comparison to commercial catalysts based on Ni or Cu, which is operated at 900 K or at 600 K, respectively, Au supported on TiO$_2$, Fe$_2$O$_3$, or ZrO$_2$ appear to be advantageous in operating at a temperature as low as 473 K [100–102]. For selective CO removal in H$_2$ stream, Au supported on Al$_2$O$_3$, TiO$_2$, Mn$_2$O$_3$, and Fe$_2$O$_3$ [44, 103, 104] are stable and potentially

Table 1. Reactions Catalyzed by Gold.

Type of Reaction	Reactant	Temperature (K)	Support	Comments	Ref.
Complete oxidation	CO	200~400	$Be(OH)_2$, $Mg(OH)_2$, Mn_2O_3, Fe_2O_3, etc.	acidic metal oxides are excluded as a support	[51] [18, 19, 44, 103]

advantageous over other noble metal catalysts because only supported Au catalysts are much more active for CO oxidation than for H_2 oxidation.

Because of the stability of Au against halogens, some supported Au catalysts have been reported to be more active and stable for reactions involving halogens such as oxidative decomposition of chlorofluorocarbons and dioxins than other noble metal catalysts [105–108]. It should be noted that $AuCl_3$ supported on activated carbon is the most active among metal chloride catalysts for the hydrochlorination of acetylene to produce vinylchloride [105].

The characteristic features of supported gold catalysts are: remarkable structure sensitivity of reactions, low apparent activation energies (active at low temperatures), and activation by moisture. By taking advantage of these properties, the first direction of future approaches is the discovery of new capabilities for Au particles larger than 2 nm which are stable up to 673 K. The combination with other metal catalysts can expand the capabilities of Au catalysts. Gold supported on Fe_2O_3 or La_2O_3 is the most active among noble metal catalysts for the oxidative decomposition of dioxin at temperatures below 473 K. As shown in Figure 9, the integration of Ir, Pt, and Au catalysts supported on La_2O_3, SnO_2, and TiO_2, respectively, resulted in 95% decomposition of dioxin from the outlet gases of an incinerator even at 423 K, at an hourly space velocity of 12,000 $h^{-1}\cdot$ ml/g-cat. It is interesting that the least active Ir catalyst exhibits an excellent booster effect [108].

The second direction is the extension of the catalytic mechanism and the preparation techniques for Au catalysts to other noble metals. The genesis of the catalysis by Au is, in most cases, ascribed to the perimeter interfaces around Au particles. This presents a new guiding principle to create a wide range of new catalytic systems, because combination of catalytic metals with a variety of support materials should present a great deal of novel catalysts. Good examples are Pd/CeO_2 and Pt/ZrO_2 prepared by co-precipitation for the low-temperature decomposition and synthesis of methanol [109] and for the low-temperature oxidation of CO and reduction of NO [110].
Figure 9. Oxidative decomposition of ortho-chlorophenol over supported, noble metal catalysts at 423 K [108]. The integration of different noble metal catalysts led to improved performance in the conversion of dioxin in a small incinerator at 423 K.

The third direction is the fundamental study of cluster physics and chemistry for Au particles smaller than 2 nm. Significant work has recently been emerging to understand the unique catalysis of Au and its size- and structure-dependency. By means of surface science techniques using well-defined catalytic materials (most often size-selected Au clusters deposited on single crystalline metal oxides such as MgO [65] and TiO_2 [37, 59, 111–115]) an atomic scale understanding is being accumulated in combination with theoretical calculations [7, 62, 66]. It is also instructive that the catalytic activity may change dramatically depending on the three-dimensional structure of 13 atoms Au clusters [51]. In this approach, Au may be the best target of research because Au itself is poorly active and the detectable activity is obtained only when the specific structure and size of Au particles are given. It is also advantageous in Au model catalyst studies that the activity is usually detectable at lower temperatures where designed structures can be maintained.

In order to combine experimental work using both real catalysts and model catalysts with theoretical calculations more effectively [116], the effect of moisture should be taken into account. Most surface science work is carried out in ultra-high vacuum, while catalytic activity measurements for real catalysts are carried out in a fixed bed flow reactor using reactant gas containing moisture at least 1 ppm, usually in the order of 10 ppm. It is reasonable to assume that the catalyst surfaces are covered with OH groups and water molecules at room temperature. For CO oxidation, which does not produce H_2O and proceeds at temperatures below 373 K, moisture markedly changes the catalytic activity of metal oxides and Au catalysts. Under a dry condition with H_2O concentration of 80 ppb, CO oxidation can take place even at 210 K over Co_3O_4 without Au [117, 118], while supported Au catalysts prefers moisture [50].

6. CONCLUSIONS

Three factors define the catalytic properties of gold—strong contact between Au particles and the support, selection of the support, and the size of Au particles. Perimeter interfaces provide the sites for reaction, while metallic Au surfaces are still necessary as a reservoir for one of the reactants. Gold catalysts are advantageous in environmental applications because of very low apparent activation energies and enhancement by moisture. Gold is the best sample for fundamental studies on the size effect below 2 nm through model catalysts and theoretical calculations.

GLOSSARY

Au clusters When the number of Au atoms is smaller than 300 with a diameter below 2 nm, physicochemical properties often differ markedly from those of Au nanoparticles with a diameter above 2 nm.

Epitaxial contact The contact interface where the atomic configuration of the two phases fits well two dimensionally with each other, leading to the growth of crystallite in a specific direction.

Isoelectric point (IEP) The pH where the surfaces of solid in an aqueous solution are charged equally with positive ions and negative ions. Acidic materials have low IEP, whereas basic ones have high IEP.

Structure sensitive reaction Reactions whose rates per active site (TOFs) are dependent on the crystal planes, size, and shape of catalytic materials. In the case of supported metal catalysts, TOF is usually expresses by rate divided by the number of surface-exposed metal atoms.

Turnover frequency (TOF) Reaction rate per one single active site, TOF, is a common parameter to compare the catalytic activity among a variety of catalysts, for example, single crystal, metal oxide particles, and supported metal catalysts.

CONTENTS

1. INTRODUCTION

Carbon nanotubes and nanofibers are graphitic filaments/whiskers with diameters ranging from 0.4 to 500 nm and lengths in the range of several micrometers to millimeters. Carbon nanofibers and nanotubes are grown by the diffusion of carbon (via catalytic decomposition of carbon containing gases or vaporized carbon from arc discharge or laser ablation) through a metal catalyst and its subsequent precipitation as graphitic filaments [1–6]. Three distinct structural types of filaments have been identified based on the angle of the graphene layers with respect to the filament axis [5, 7], namely *stacked*, *herringbone* (or *cup-stacked* [8]), and *nanotubular* [9] as shown in Figure 1.

It can be seen that the graphite platelets are perpendicular to the fiber axis in the stacked form, the graphene platelets are at an angle to the fiber axis in the herringbone form, and tubular graphene walls are parallel to the fiber axis in the nanotube. In the literature today, the common practice is to classify the stacked and herringbone forms of graphitic filaments under the general nomenclature of "nanofibers" whereas "nanotube" is used to describe the case where tubular graphene walls are parallel to the filament axis. In some instances, large diameter (>20 nm) nanotabular structures or structures containing defects/amorphous carbon have also been classified as nanofibers. In this work, we prefer to use the term nanotube to describe carbon filaments with tubular graphene walls parallel to the axis and use the term nanofiber for carbon filaments with graphene layers at other angles. This is because special physical properties arise from the "nanotube" structure which distinguish it from the "nanofiber" structure, which itself has other advantageous properties, as will be described later.

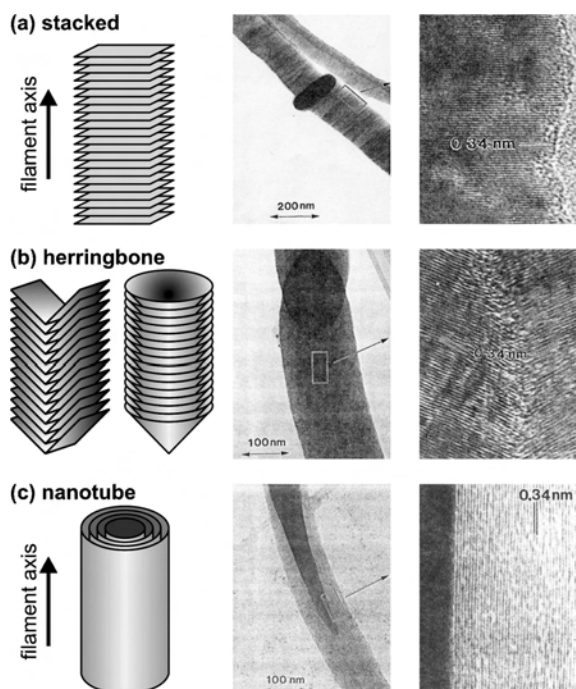
Carbon nanofibers and nanotubes have been synthesized since the 1960s, but why has one particular form (i.e. the nanotube) received so much attention recently? In 1991, Iijima reported that highly graphitized carbon nanotubes, formed from the arc discharge of graphite electrodes, contained several coaxial tubes and a hollow core [9]. This important discovery led to the realization that with graphene tubes parallel to the filament axis, these highly crystallized tubular carbon structures would inherit several


Figure 1. The three structural forms of carbon nanofibers, classified by the angle of the graphene layers/platelets with respect to the filament axis. Adapted with permission from [5], N. M. Rodriguez et al., *Langmuir* 11, 3862 (1995). © 1995, American Chemical Society.

important properties of "intraplane" graphite. In particular, a nanotube exhibits high electrical conductivity, thermal conductivity, and mechanical strength along its axis. As there are very few open edges and dangling bonds in the structure, nanotubes are also very inert and species tend to be physically adsorbed onto graphene walls rather than chemically react with them. Note that carbon nanotubes are completely covalently bonded which implies that as electrical conductors, they would not suffer from electromigration or atomic diffusion like metals. These properties make carbon nanotubes a technologically important material for various electronic and mechanical applications as will be listed later. The stacked and herringbone nanofibers tend to be investigated solely for energy storage applications such as electrodes for lithium batteries or fuel cells as small

ions/molecules can enter via open edges and intercalate between the graphene layers. Already, large amounts of nanofibers can be purchased commercially from companies such as Hyperion Catalysis International, Applied Sciences Incorporated, Catalytic Materials, Showa Denko, and Nanomirae [10]. Nanotubes are also available commercially from companies such as Carbon Nanotechnologies Inc., Iljin Nanotech, and NanoLab among many others listed in [11].

Nanotubes are further classified into two types, namely multiwall and single wall [9, 12, 13]. The multiwall carbon nanotube contains several concentric, coaxial graphene cylinders with interlayer spacings of ~0.34 nm [14]. Note that this spacing is larger than single crystal graphite (0.335 nm). Recent studies have shown that the intershell spacing can actually range from 0.34 to 0.39 nm, where the intershell spacing decreases with increasing carbon nanotube diameter, and this effect is more pronounced in small diameter nanotubes (<15 nm) due to the high curvature [15, 16]. The geometrical constraints in forming the seamless "honeycomb" graphene cylinders cause the layers to be uncorrelated with respect to one another, which is in contrast to crystalline graphite that exhibits perfect "ABAB" layer stacking [17]. Thus, multiwall carbon nanotubes tend to exhibit the properties of turbostratic graphite whose layers are essentially uncorrelated. For example, in highly crystallized multiwall carbon nanotubes (such as those obtained by arc discharge), it has been shown that if contacted on the outside, the electric current is conducted through its outermost shell only [18].

In the case of single wall carbon nanotubes, the structure consists of a single graphene cylinder and special properties emerge from the strong one-dimensionality and crystalline perfection of the structure. Single wall carbon nanotubes can be metallic (0 eV bandgap) or semiconducting (typically 0.4–0.7 eV bandgap) depending on the geometrical characteristics of their structure, namely the orientation of the hexagons with respect to the nanotube axis (i.e., chirality) and inversely proportional to the diameter [19–21]. Reviews on the electronic properties of carbon nanotubes are presented in [22–24]. In the case of a multiwall carbon nanotube where conduction occurs through the outermost shell, the large diameter of the outer nanotube causes the gap to approach 0 eV and the nanotube is essentially

Table 1. Properties of carbon nanotubes; see also [34].

Mechanical properties		Thermal properties at room temperature	
Young's modulus of multiwall nanotubes	~1–1.2 TPa [25, 26]	Thermal conductivity of single wall nanotube	1750–5800 W mK [28]
Young's modulus of single wall nanotube ropes	~1 TPa [27]	Thermal conductivity of multiwall nanotube	>3000 W mK [29]
Tensile strength of single wall nanotube ropes	~60 GPa [25]		
Electrical properties		Electronic properties

nonsemiconducting. Table 1 lists several reported properties of carbon nanotubes.

Carbon nanotubes and nanofibers are being investigated for a wide range of applications today. Reviews of carbon nanotube applications are presented in [24, 35–42], and only an overview is presented in this chapter. Let us first consider the nanotube as a high aspect ratio, electrically conductive wire with diameter in the nanometer range. These structures are highly desirable as field emission tips for applications such as field emission displays [43–48], X-ray tubes [49], electron sources for microscopy and lithography [50], gas discharge tubes [51], and vacuum microwave amplifiers. The use of nanotubes as a field emission electron source has recently been commercialized in a portable X-ray source by Oxford Instruments [52]. Nanofibers have also been investigated as electron sources [53, 54]. The high aspect ratio and small diameter of the nanotube is also desirable for scanning probe tips [55–57]. In fact, nanotube-based scanning probe tips ("Probemax") are commercially available today from nPoint (also known as Piezomax) [58].

Single wall carbon nanotubes, which can be electronically semiconducting, are also being investigated as transistors or logic elements [59–62]. Containing only one carbon tube, the electronic properties of the carbon nanotubes are highly sensitive to adsorbed molecules/species [63, 64]. Although this implies that in logic circuits, the nanotubes must be suitably encapsulated, the high sensitivity of the nanotubes can be advantageously utilized in chemical or biological sensors to detect poisonous or dangerous gases in the environment. In addition, the coherent nature of electron transport in well-crystallized nanotubes would find these structures applicable in spin–electronic devices [65]. Carbon nanotubes could also be used as electromechanical sensors as their electrical characteristics respond to mechanical deformation of their structure [66].

Another interesting application for these structures is as electrodes in electrochemical supercapacitors [35, 67–71]. When nanotubes/fibers are produced enmasse (i.e., woollike or forestlike), they have large surface areas which could lead to higher charge storage capabilities than standard capacitors and batteries [35, 72]. The cycle characteristics of lead acid and lithium ion batteries can also be improved when carbon nanofibers are used as fillers in the battery electrodes [73]. The high electrical conductivity and relative inertness of nanotubes make them potential candidates as electrodes in electrochemical reactions too [74, 75]. The large surface area of nanotubes, both inside and outside, can be usefully employed to support reactant particles in catalytic conversion reactions [76, 77]. It was also proposed that hydrogen could also be stored among and inside nanotubes/nanofibers for fuel cell applications [7, 76–81], although recent results show that the amount of hydrogen stored is not as high as originally anticipated [82]. Nanotubes can also mechanically deflect under electric stimulation (e.g., due to charge induced on the nanotubes) and this opens up applications such as cantilevers or actuators [35, 83–85]. The use of nanotubes and nanofibers as filters or membranes for molecular transport has been recently proposed [86].

The exceptional mechanical properties and low weight of nanotubes and nanofibers make them potential filling materials in polymer composites. Nanotubes and nanofibers

can improve the strength and stiffness of a polymer, as well as add multifunctionality (such as electrical conductivity) to polymer based composite systems [87–95]. Carbon nanotubes should be ideal reinforcing fibers for composites due to their high aspect ratio and high in-axis strength [96]. Furthermore, carbon nanotubes, unlike macroscopic carbon fibers, are short enough to flow through conventional polymer processing equipment so that complicated shapes or small parts could be molded from their composites [96, 97]. As fillers for composites, single wall carbon nanotubes are preferred to multiwall nanotubes because the inner layers of the multiwall nanotubes contribute little under structural loading and thus would reduce the stiffness for a given volume fraction of tubes [26, 96].

It is evident that for the various different applications, nanotubes or nanofibers of different morphologies are required. For instance, scanning probe applications require a single high aspect ratio nanotube whereas polymer strengthening requires "masses" of nanotubes/nanofibers. Field emission applications ideally require vertically aligned nanotubes which are spaced about twice their height apart [98–100], whereas horizontally aligned nanotubes are more suited for electrical transport or electronic (transistor/spin) applications. The great flexibility of catalytic chemical vapor deposition (CVD) is that this technique can be adapted to producing nanotubes and nanofibers for *virtually all* these applications.

In the case of nanotubes, chemical vapor deposition is very different from the other two common methods used for nanotube production, namely arc discharge [101, 102] and laser ablation [30]. Arc discharge and laser ablation can be classified as high temperature (>3000 K) and short time reactions (μs–ms), whereas catalytic chemical vapor deposition is a medium temperature (700–1400 K) and long time reaction (typically minutes to hours). Although carbon filament/nanofiber growth by catalytic chemical vapor deposition was established in the 1960s–1980s [3, 4, 103–105], much of the fundamental work on the properties of nanotubes in the early 1990s was performed on nanotubes produced by arc discharge and laser ablation because of their superior straightness and crystallinity due to the high temperature deposition. The main technological drawbacks with arc discharge and laser ablation were that the nanotubes had to be produced separately (i.e., not directly on substrates), purified [106, 107], and then manipulated onto substrates before use. At that time, most CVD-grown nanotubes were "spaghetti-like" and largely defective, but the potential of the technique to satisfy technological requirements was recognized. From 1998 onward, substantial and rapid progress was made in the development of CVD to establish it as a highly controlled technology for the production of carbon nanotubes and nanofibers: today, it is possible to fabricate high quality single wall carbon nanotubes [108, 109] or multiwall carbon nanotubes [110], horizontally [111, 112] or vertically aligned [113–115], as an individual nanotube [116–118] or "en masse" [110, 119], with controlled diameter [120, 121] and length [122, 123], structurally as a tube or stacked layered nanofiber form [5, 124], directly onto substrates or in bulk as a raw material [4, 125]. A major advantage of CVD is that the nanotubes/nanofibers can be used directly without

further purification unless the catalyst particle is required to be removed, methods for which will be discussed later.

The rest of this chapter discusses the growth mechanism of carbon nanotubes and nanofibers, the various methods of catalyst preparation, and variations in the chemical vapor deposition technique. This provides the technologist with a repertoire of techniques from which he/she can choose the most suitable one for his/her specific application.

2. GROWTH MECHANISM OF CARBON NANOTUBES AND NANOFIBERS

2.1. General Mechanisms

In general, carbon nanotube and nanofiber growth by the catalytic CVD method require catalyst nanoparticles (usually Fe, Co, or Ni), a carbon feedstock (e.g., hydrocarbon or CO), and heat. The diameter of the filament produced is often closely related to the physical dimension of the metal catalyst. The peculiar ability of these transition metals to form graphitic carbon is thought to be related to a combination of factors that include their catalytic activity for the decomposition of volatile carbon compounds, the formation of metastable carbides, and the diffusion of carbon through the metal particles [126]. We present some of the growth models that have been proposed both for nanotubes and nanofibers which are widely accepted by the research community.

The most commonly accepted mechanism was postulated by Baker et al. in the early 1970s, who explained the growth of carbon filaments by catalytic decomposition of the carbon feedstock and bulk diffusion of carbon [1]. According to this mechanism (Fig. 2a), the hydrocarbon gas decomposes on the front-exposed surfaces of the metal particle to release hydrogen and carbon, which dissolve in the particle. The dissolved carbon diffuses through the particle and is precipitated at the trailing end to form the body of the carbon filament. Due to the exothermic decomposition of hydrocarbons, it is believed that a temperature gradient exists across the catalyst particle. Since the solubility of carbon in a metal is temperature dependent, precipitation of excess carbon will

C$_x$H$_y$ / CO   C$_x$H$_y$ / CO   C$_x$H$_y$ / CO

(a)   (b)   (c)

Figure 2. The growth of carbon nanotubes and nanofibers involves the catalytic decomposition of a carbon feedstock (hydrocarbon or CO), carbon diffusion, and its precipitation as a filament. In (a), the carbon diffuses through the bulk of the metal catalyst "M" as proposed by the Baker model [3]. In (b), the carbon diffuses over the surface of the metal catalyst and forms a tubular structure from the circumference of the catalyst as proposed by the Oberlin model [134]. In (c), angled graphene layers are precipitated from a faceted catalyst particle to form a nanofiber as proposed by Rodriguez and Terrones [5, 147].

occur at the colder zone behind the particle, thus allowing the solid filament to grow with the same diameter as the width of the catalyst particle. Such a process will continue until the leading tip of the catalyst particle is "poisoned" or deactivated. A common cause of catalyst poisoning is the formation of carbon around it, thus preventing the gas from reaching the catalyst particle. Support for this bulk diffusion model comes from experiments on the kinetics of growth of carbon filaments from acetylene (C$_2$H$_2$) catalyzed by Ni particles, which yielded an activation energy of (eV) 140 kJ mole^{-1} [2]. This value is similar to the activation energy for bulk diffusion of carbon through solid Ni (i.e., 133 kJ mole^{-1}) [127]. Similarly, the enthalpies for the growth of filaments with α-Fe, γ-Fe, Ni, Co, Fe–Ni, and Cu catalyst were found to be similar to the enthalpy of diffusion. Thus, the rate limiting step in the growth is believed to be the diffusion of carbon through the catalyst. In general, the filament length depends on the duration of the catalytic process, where longer durations result in longer filaments [128, 129]. This general bulk diffusion mechanism accounts for the formation of both nanofibers and nanotubes.

However, two irregularities of this growth mechanism should be noted. First, not all hydrocarbon dehydrogenation reactions are exothermic (e.g., methane), and yet growth has been observed from these hydrocarbons. Moreover, it is unlikely that there is a temperature gradient across such a small metal particle. This is because the metal particle has a high thermal conductivity and thus a small temperature gradient implies that a massive heat flow is occurring through the particle, which is physically intangible. The exothermic decomposition of the hydrocarbon probably raises the temperature of the entire filament, and the growth of the carbon filament is also probably driven by a concentration gradient of carbon across the particle.

One common question asked is whether the catalyst is a liquid or solid during nanotube/nanofiber growth. If we assume Fe as the metal catalyst, most of the growth experiments are typically well below the melting temperature of iron (1534 °C) and also below the iron–carbon eutectic temperature (1147 °C). The formation of graphite platelets from certain crystallographic faces of the catalyst particle (see Section 2.2) suggests that the catalyst is in a solid form. The agreement between the enthalpy for the growth of filaments and the enthalpy of diffusion for the bulk catalyst metals as discussed earlier also suggests that the catalyst is in the solid phase. Although growth is performed below the eutectic temperature and metal melting point (N.B. usually these temperatures are quoted at 1 atm and will change with operating pressure), one should note that the catalyst metal nanoparticles will behave completely differently than their bulk metal form because these small particles will have exceptionally high surface energy, area, and mobility. For example, Hou et al. reported that annealing iron encapsulated carbon particles in argon between 1000 to 1100 °C completely removes the iron, indicating that these small iron particles were highly mobile at these temperatures [130]. Because of the high mobility and reactivity of the metal atoms, the catalyst nanoparticles are often in the shape of metallic clusters or have been observed to undergo certain surface reconstruction. If temperatures above the metal–carbon eutectic are used, the growth would be similar to the

general vapor–liquid–solid mechanism proposed by Wagner [131, 132] where diffusion through a liquid-phase particle is responsible for the synthesis of filaments.

Instead of bulk diffusion, another common growth model is a catalytic process involving the surface diffusion of carbon around the metal particle [133–135] as shown in Figure 2b. The carbon atoms diffuse over the catalyst surface to form a tubular structure which emanates from the circumference of the catalyst. Note that the tubular structure is favored for carbon filaments with nanometric diameters. A single graphene layer of finite size has many dangling bonds which correspond to high energy states, and for such a small structure, there would be an enormous percentage of dangling bonds if a stacked planar graphite was formed [17, 136]. By the formation of closed tubular carbon shells, the total energy of the system is reduced [136].

An alternative model based on the minimization of surface energy of nanoparticles was suggested by Dai et al. [137]. Nanoparticles contain a very high percentage of surface atoms; as a result a large amount of surface energy exists. Excess carbon can help solve this problem by assembling a graphene cap on the particle surface, called a "yarmulke," with its edges strongly chemisorbed to the metal. Since the basal plane of graphite has an extremely low surface energy (10–20 times smaller than most metals), the total surface energy diminishes. A crucial feature of the yarmulke mechanism was its avoidance at all stages of growth of any open graphene edges, which would expose energetically costly dangling bonds. It also provides an automatic solution to forming caps and resulting structures are tubes which have no seams. Carbon can add to the cylindrical section of a growing layer. Once the smallest yarmulke has formed, insertion of new carbon between the tube edge and the catalytic particle is the best solution, as long as complete overcoating of the particle (i.e., encapsulation) is avoided which would deactivate it.

The actual composition of the active catalyst particle is a widely debated issue, and further research could be performed in this area. High carbon content carbides were determined to be a prerequisite for carbon fiber growth [138–140]. However, there are many conflicting reports concerning the actual composition of the catalyst particle; for example, in the case of an iron catalyst, a hexagonal form with composition $Fe_{2.2}C$ or Fe_2C was postulated, rather than Fe_3C [134]. There are also arguments as to whether a carbide particle is indeed the active catalyst [103]. These are based on the findings that the loss of catalytic activity of iron was accompanied by a gradual conversion of the catalyst to a stable carbide. The catalyst could be reactivated by treatment with hydrogen, reducing the carbide back to iron.

2.2. Nanofiber Growth

Let us now focus our discussion on catalysts used for nanofiber growth and why nanofibers form. The ability to control and tailor the structure of nanofibers (stacked or herringbone) has been demonstrated by Rodriquez et al. [5, 124]. The general concept used here is the creation of a faceted catalyst particle [5, 124, 141] so that carbon feedstock decomposition occurs at certain faces whereas carbon precipitation (in the form of graphite layers) occurs at other

faces as shown in Figure 2c. The graphitic platelets are precipitated parallel to the surface of the faceted catalyst particle, and hence the angle between the planes and the fiber axis is determined by the shape of the catalyst particle, as proposed by Boellard et al. [138]. Under certain conditions of gas composition, temperature, and catalyst composition, the catalyst particles undergo surface reconstruction to form unique geometrical shapes which drive the formation of nanofibers [5, 124, 142, 143]. For example, the herringbone structure was found to grow from Fe–Cu (7:3) particles in a C_2H_4–H_2 (4:1) gas mixture at 600 °C, whereas the stacked structure formed from Fe-based catalyst in a CO–H_2 (4:1) gas mixture at 600 °C [5]. The formation of herringbone structures is favored when the catalyst particle is an alloy [124, 144–146], although Pd has also been used alone under certain growth conditions to yield similar structures [147]. Nolan et al. [148] have suggested that hydrogen plays a significant role in the formation of nanofibers. This is because the presence of hydrogen in abundance can terminate the large number of dangling bonds at the edges of the stacked graphite platelets, whereas without hydrogen termination, the more stable form of the carbon filament would be closed tubular graphene shells where there are no dangling bonds. In plasma enhanced CVD, the carbon filaments formed are often nanofibers rather than nanotubes. This is thought to be due to the large amount of atomic hydrogen formed in the gas phase due to plasma decomposition of the hydrocarbon gas or the use of hydrogen as a dilution gas. Delzeit et al. showed that by controlling the relative amount of hydrogen in the gas phase via altering the plasma parameters, one could change the structure from nanotubes to herringbone nanofibers, with high hydrogen content favoring the latter [149].

2.3. Multiwall and Single Wall Nanotube Growth

Let us now concentrate on the formation of nanotubes. Without an abundance of dangling bond terminating species (e.g., H) in the gas phase, carbon nanotubes will tend to form when the diameter of the filaments is ~50 nm or less. This is because a single graphene layer of finite size has many dangling bonds, and these dangling bonds correspond to high energy states [17, 136]. The total energy of a small number of carbon atoms is reduced by eliminating these dangling bonds, even at the expense of increasing the strain energy, thereby promoting the formation of the closed tubular structure [17, 136, 150]. The catalytic activity of the metal catalyst in the formation of nanotubes has also been studied in considerable detail. Besides the commonly used Fe, Co, and Ni catalysts, other metals (such as Mo, Cu) or metal mixtures (Fe–Ni, Fe–Mo, Fe–Co, Co–Ni, and Co–Mo) have been used for nanotube synthesis [109, 113, 122, 128, 137, 151–162]. Using thermal CVD, Co and Fe catalysts generally tend to form hollow and well-graphitized nanotubes, whereas Ni and Cu produced structures which were not as well graphitized [158, 163]. One should note that different metal catalysts would have their optimum catalytic activity at different temperatures [128, 129, 163]. The yield and crystallinity of nanotubes can be improved by the use of metal

catalyst mixtures such as Co–Fe or Co–Ni [158, 164]. Furthermore, it has also been reported that the addition of Mo to Fe or Co [109, 122, 151–157] increases the yield of single wall nanotubes compared to when a single metal catalyst is used [161]. A Co to Mo ratio of 1:2 is reported to be optimal for a high synthesis yield of single wall carbon nanotubes.

Figure 3 shows various forms of nanotubes. Here, the nanotubes are examined using transmission electron microscopy and hence we are looking at a cross section of the nanotubes. The solid black lines in the micrographs represent the hexagonal sheets of carbon atoms which make up the walls of the nanotubes. Under ideal growth conditions, the nanotubes produced should be straight (e.g., Fig. 3a) and contain graphene walls parallel to the tube axis without
Figure 3. (a) TEM of straight nanotubes grown from the floating catalyst method using ferrocene–toluene at 760 °C. (b) Helical nanotubes grown from CVD of C_2H_2/Ar at 700 °C with Ni catalyst. (c) Straight nanotube with bamboo compartments grown by plasma enhanced CVD of C_2H_2/NH_3 at 700 °C with Fe catalyst.

any defects. Dai proposed that a high growth temperature is required to anneal out defects so that well-crystallized and straight nanotubes could be obtained [165]. The occurrence of defects (e.g., pentagons or heptagons) would cause the nanotube to bend during growth. When carbon nanotubes are formed by the electric arc or laser ablation, temperatures of ~3000 K are obtained and this possibly explains why mostly straight and well-crystallized nanotubes are obtained from these processes. In lower temperature CVD processes (~700–1400 K), "curly" and "coiled" nanotubes (Fig. 3b) are common variations to the perfectly linear nanotube. The growth of various shapes of nanotubes, especially wavy and helical tubes, was investigated by Amelinckx et al. [166]. The concept of a spatial velocity was introduced to describe the extrusion of carbon from the catalyst particle to form the nanotube. Essentially, when the extruded carbon material was uniform, straight nanotubes are obtained, whereas nonuniform extrusion caused the nanotube to deform elastically into complicated patterns such as the helix shape. Nanotubes containing bamboo compartments are also commonly observed, as shown in Figure 3c. A growth model for bamboo-shaped carbon nanotubes was proposed by Lee and Park [167]. Their transmission electron microscopy (TEM) evidence showed that the bamboo-shaped compartment layers were due to the surface geometry of the catalyst particle and the precipitation of carbon sheets from the bulk of the catalyst particle. Li et al. found that when using a higher deposition pressure of carbon feedstock, the nanotubes became bamboo in structure [168]. They argued that at high pressures, the carbon concentration was sufficiently high to cause bulk diffusion of carbon through the catalyst, forming the bamboo compartments behind the catalyst particle. In the literature, bamboo structures are sometimes called "nanofibers." However, note from Figure 3c that the bamboo structure actually contains graphene walls parallel to the filament axis, which suggest that these structures would inherit the physical properties of the "nanotube." It is possible to obtain the growth of straight nanotubes by close-packed growth, use of porous templates, electric field directed growth, or plasma-induced alignment as will be discussed later.

Under what conditions is the growth single wall carbon nanotubes preferred? The size of the catalyst is probably the most important parameter for the nucleation of single wall carbon nanotubes. Conclusive evidence on the dependence of catalyst size on the formation of single wall carbon nanotubes has been reported in [159, 160, 169]. Li et al. (Duke University) prepared catalyst nanoparticles of uniform diameters (between 3 to 14 nm) by thermal decomposition of metal carbonyl complexes using a mixture of long-chain carboxylic acid and long-chain amine as protective agents [169]. Their results indicate that the upper limit for single wall nanotube growth occurred at catalyst sizes between 4 and 8 nm. Above 8.5 nm, no more single wall structures were observed [169]. Li et al. (Stanford University) also grew single wall carbon nanotubes from discrete catalytic nanoparticles of various sizes [159]. Discrete nanoparticles were prepared by placing a controllable number of metal atoms into the cores of apoferritin. Their TEM studies indicated that the nanotube diameters were closely correlated to the size of the catalytic nanoparticles.

Furthermore, the nanotubes grew by a base-growth mechanism with the nanoparticles seen to be anchored to the support material. Smaller nanoparticles ($<\sim$1.8 nm) were more active in producing single wall nanotubes, while nanoparticles with diameters of $\sim$7 nm did not show single wall nanotube growth, consistent with the group at Duke University [169]. Cheung et al. prepared monodispersed nanoclusters of iron with diameters of 3, 9, and 13 nm [160]. After growth using C_2H_4, single wall and double wall nanotubes were nucleated from the 3 and 9 nm diameter nanoclusters, whereas only multiwall nanotubes were observed from the 13 nm nanoclusters. These works clearly suggest that single wall nanotubes are favored when the catalyst particle is $\sim$5 nm or less. However, it is worth mentioning that there are reports which suggest that single wall carbon nanotubes can be grown from larger catalyst particles. One hypothesis put forward was that bundles of nanotubes could be precipitated from a single larger metal particle and that the bundle formation would be linked to the nature of the metal surface [161]. Note that when arc discharge and laser ablation are used to synthesize nanotubes, bundles of single wall nanotubes are commonly observed to emerge from a large catalyst particle [6]. There is a report of single wall nanotubes grown from $\sim$10 nm diameter colloids, suggesting that the size of the metal nanoparticles may not need to be the same as the diameter of the nanotube [170]. Such reports, however, are rare for the case of CVD and in general, the diameters of the nanotubes and nanofibers grown are often correlated with the size of the catalyst particle.

As mentioned earlier, binary catalyst mixtures have also been reported to increase the yield of single wall carbon nanotubes. A mixture of Co and Mo gives a higher yield of single wall nanotubes than if a single metal catalyst is used [154, 155]. Using X-ray absorption spectroscopy, it was found that Co, originally in an oxide state, is gradually reduced to a metal whereas Mo transformed to its carbide after growth. The role of Mo in the catalyst is to stabilize the small particles of oxidized cobalt species (Co^{2+}), which are highly active for the production of single wall carbon nanotubes [155, 156]. Adding a small amount of Mo to Fe catalyst also increases the yield of single wall nanotubes [152, 153, 171].

Another common observation is that single wall nanotubes are produced via the base-growth mechanism [108, 151, 159] (except for the floating catalyst technique discussed later where there is no base support material). The base growth model is based on TEM evidence which shows that the nanotube tip ends are particle free. Multiwall nanotubes are commonly deposited by both the tip-growth and base-growth mechanisms (see later).

The choice of the carbon feedstock also affects the growth of carbon nanotubes. Baker and Harris [104] reported that unsaturated hydrocarbons such as C_2H_2 had much higher yields and higher deposition rates than more saturated gases (e.g., 100 times that of C_2H_4). They also observed that saturated carbon gases tended to produce highly graphitized filaments with fewer walls compared with unsaturated gases. Thus, hydrocarbons such as methane and carbon monoxide are commonly used for single wall carbon nanotube growth [108, 137, 154–156, 172] whereas hydrocarbons such as acetylene, ethylene, and benzene, which are unsaturated and thus have high carbon content, are typically used for multiwall carbon nanotube growth [122, 129, 158, 164, 173–175].

Hafner et al. further suggested that the growth rate of single wall nanotubes is limited by the carbon supply to the catalyst particles, whereas for multiwall nanotubes, the growth is limited by the diffusion of carbon through the catalyst particle [109]. The authors demonstrated that single wall carbon nanotubes could in fact be grown from a highly diluted gas mixture of C_2H_4. A limited carbon supply will likely allow the structures to form more slowly, giving each carbon atom more time to anneal to its lowest energetic configuration as shown by energetics calculations. Cheung et al. reported that the partial pressure of C_2H_4 had to be increased accordingly in order to nucleate nanotubes from larger nanoclusters [160].

Methane is commonly used as the carbon source for single wall carbon nanotube growth because it is a kinetically stable hydrocarbon and undergoes the least pyrolytic decomposition at high temperatures, typically 900 °C [108, 137]. A small amount of hydrogen or benzene present in the methane flow can enhance the growth yield, as discussed in [176, 177], but too much of these additives impede nanotube growth. Recall that high temperatures are favored for less defective and well crystallized nanotubes, and hence it is important to select a hydrocarbon which does not thermally decompose to form unwanted amorphous carbon (i.e., lower the purity of nanotubes) at high temperatures. Similarly, CO has been used to grow single wall nanotubes at elevated temperatures [172].

Lastly, although it is possible to control the filament structure to obtain nanofibers, multiwall nanotubes, or single wall nanotubes, at the writing of this chapter it is not possible to control the chirality (i.e., electronic properties, either metallic or semiconducting) of the single wall nanotubes through synthesis.

In some applications, the catalyst which was used for growth is not desired. This can be removed by oxidation (to remove carbon layers which may have encapsulated the catalyst particle after growth) followed by acid treatment, similar to what is usually done to purify arc discharge or laser ablated nanotubes [106]. For nanotubes or nanofibers which are tip grown (i.e., catalyst on top), plasma etching could also be used to remove the catalyst particle [178]. It is also possible to run the catalyst back down the nanotube and hence open it by exposing it to hydrogen after growth [3].

Now that we have discussed the growth of carbon nanofibers, multiwall nanotubes, and single wall nanotubes, we shall describe the practical processes for preparing the catalyst and the techniques used for growth.

3. CATALYST PREPARATION

3.1. Growth of Nanotubes/Nanofibers on Substrates

The first step is to prepare the catalyst nanoparticles—it is worthwhile to remember that it is the size of the nanoparticle which approximately determines the final diameter of the nanofiber/nanotube (in some cases also whether a single wall or multiwall nanotube is formed). Hence,

for some applications, it will be necessary to control this parameter. There are several routes for catalyst preparation depending on the final application of the nanotubes. Let us first examine substrate growth or "supported catalyst" growth. There are essentially two reasons to use substrate growth. First, for some applications, it is desirable to coat nanofibers/nanotubes directly onto a particular surface. For example, when carbon nanotubes or nanofibers are used as field emission electron sources for vacuum microelectronic applications, it is desirable to deposit the nanotubes/nanofibers directly within gated apertures to ensure that the structures are as close as possible to the gate so that low operating voltages may be obtained [45, 46, 54, 179–181]. Second, for the large-scale production of nanotubes, it is desirable to anchor the metal catalyst firmly to a support to impede the formation of larger catalyst clusters. Large catalyst clusters are the result of the sintering/coalescence of the metal catalyst particles due to the high surface mobility of the metal atoms and their strong cohesive forces. At the growth temperature, typically 500 to 900 °C, these metal catalyst particles have sufficient mobility to coalesce into larger particles. This effect is especially unwanted if structures of a particular diameter or small diameter (e.g., single wall nanotubes) are required.

Two different growth modes (Fig. 4a and b) can result based on the interaction of the catalyst with its support as described by Baker [3] and Rodriguez [124]. The interaction of the catalyst with the support can be characterized by its contact angle at the growth temperature, analogous to "hydrophobic" (weak interaction) and "hydrophilic" (strong interaction) surfaces. For example, Ni on silica (SiO_2) has a large contact angle (i.e., weak interaction) at 700 °C and thus tip growth is favored in this system [182] as shown schematically in Figure 4a. On the other hand, it is reported that Co or Fe on silicon [110, 183, 184] favors base growth (Fig. 4b), indicating that a strong interaction exists between Co or Fe and Si. Thus, the surface interaction between the catalyst and its support is an important consideration which dictates the growth mode.

Furthermore, one should consider the chemical interaction between the catalyst and its support material which can vary for different temperature ranges. The support/substrate
should not react or alloy with the catalyst at the growth temperature. This is because the catalyst can be "consumed" by the support/substrate if such a reaction occurs. Typical support materials are alumina and silica, which are stable at the range of temperatures used for nanotube growth [152, 153, 155]. Recently, however, much work has focused on the use of silicon substrates in order to reap the benefits of silicon processing to create nanotube electronic devices. Co, Fe, and Ni are known to diffuse into silicon at temperatures near those used for nanotube growth. For example, poor growth yield (or no growth) occurs when Ni catalyst is deposited directly on cleaned Si and reacted with acetylene at 700 °C. This is because Ni diffuses into the Si to form $NiSi_X$ at temperatures above 450 °C [185]. To achieve high yield and uniform growth on Si substrates using Ni catalyst, a diffusion barrier (sometimes called a buffer layer) such as a thin insulating SiO_2 layer (~8 nm) or a conductive titanium nitride (TiN) layer (~20 nm) is used to support the Ni on the Si substrate [186, 187]. On the other hand, Co and Fe are known to have higher diffusion temperatures with silicon [185] and so they can be directly used on silicon substrates at ~700 °C [110, 183, 184]; however, the use of a diffusion barrier (e.g., TiN or SiO_2) is still recommended with these catalysts as it can significantly improve the nanotube yield [188]. This example illustrates the need for careful selection of the catalyst and its support, given the constraints of growth temperature and the particular application of the nanotubes (e.g., on a particular substrate material). Note that a similar problem may arise when Fe/Co/Ni are used directly on metal substrates because the metals may form an alloy at high temperatures. The solution is again to use a diffusion barrier (e.g., conductive metal nitrides or more stable metals) or lower the growth temperature.

Interestingly, for some applications, it is advantageous to use a support layer which does react with the catalyst so that the yield and density of the resultant nanofibers/nanotubes can be controlled. For example, for field emission applications, a densely packed forest of nanotubes/fibers is undesirable because the screening of the applied electric field from the adjacent nanotubes/fibers reduces the overall geometric field enhancement obtained from the high aspect ratio of the nanotube/nanofiber. Instead, sparsely spread structures, roughly spaced twice their height apart [98–100], overcome field screening problems. The growth of sparsely spread nanotubes/nanofibers is achieved by using an "imperfect" barrier layer which only consumes some of the catalyst, as described in [186].

There are several routes to the production of catalyst nanoparticles, and the most commonly used methods are described in the following sections.

3.2. Wet Catalyst

In the wet catalyst method, a liquid solution containing the catalyst in salt form is applied to the substrate via dipping the substrate, spray coating [189], spin coating [190], or microcontact printing [191]. Soluble salts are typically used, such as acetates or nitrates (e.g., in [191] iron, nickel, or cobalt nitrates [$Fe(NO_3)_3 \cdot 9H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Co(NO_3)_2 \cdot 6H_2O$]). After application to the substrate, the salt solution is often reduced to oxide nanoparticles by calcination (i.e., heating in air) [192].

Figure 4. Two types of growth, namely tip or base growth, resulting from different catalyst–support interactions. Adapted with permission from [3], R. T. K. Baker, *Carbon* 27, 315 (1989). © 1989, Elsevier Science.

Metal oxides are stable and improve the catalyst–support interaction at growth temperature—in some cases, metal oxides are used directly as the catalyst [108]. During growth, these oxides are reduced to metal nanoparticles (e.g., using hydrogen) which catalyze the subsequent growth of carbon nanotubes or nanofibers. Note that catalyst decomposition and reduction can occur as part of the deposition process because the nanotube growth is usually performed at elevated temperatures. The density of the nanotubes/nanofibers is simply controlled by the concentration of the catalyst solution, which is typically in the range of 1 to 500 mM [98]. Selective growth on substrates with wet catalysts often involves the use of inked stamps/molds, inkjet printing onto desired areas, or wet coating of a resist-masked substrate [151].

Mixtures of different metal salts have also been used as catalysts for nanotube growth. The combination of different metal catalysts can enhance the yield of nanotubes as described in the previous section. However, with different combinations of metal salts, it becomes increasingly difficult to find an optimum "recipe." One method to overcome this challenge is to use high-throughput inkjet printing or microarray printing to transfer different catalyst mixtures onto a substrate [193–195]. Microarray printing has the advantage of being relatively low cost when applied over large areas, and it can provide relatively high spot density ($>10^3$ spots per cm^2) and experimental flexibility with different mixtures of catalyst solutions. For example, this method was used to study the effectiveness of different metal salts to determine the optimal catalyst composition for the growth of multiwall and single wall carbon nanotubes [194, 195].

It is also possible to deposit catalyst nanoparticles onto a substrate by electrochemical deposition with a metal salt solution. Tu et al. used a solution of 0.01 M of Ni(SO$_4$) and 0.01 M of H$_3$BO$_3$ to electroplate Ni nanoparticles onto a Si substrate which was metallized with Cr [196]. By changing both the current density and time during electrochemical deposition, it is possible to control the density of the particles and hence the density of the carbon nanotubes on the substrate.

The catalyst support for nanotubes/nanofibers could also be in the form of a powder/nanoparticles (typically alumina, silica, or graphite). In the wet catalyst method, these powders are impregnated with the catalyst [163, 173]. For example, graphite can be impregnated with a 40 vol% ethanol/60 vol% water of iron (III) oxalate to form a 2.5 wt% Fe/graphite sample as described in [173]. This sample was next dried in nitrogen at 250 °C and reduced in hydrogen to form metallic iron which was then used to catalyze the growth of multiwall nanotubes using acetylene at 700 °C. The impregnation method has also been used to prepare catalyst for single wall nanotubes as well [161, 197]. The most promising catalyst that has been reported by such a method is a Co–Mo metal supported on silica as described previously [155, 157]. The impregnation technique is often used for the bulk production of nanotubes and nanofibers. At the end of the reaction, the support can be removed by dissolution in strong acid or alkali to yield the carbon structures.

Another wet catalyst preparation route is co-precipitation which involves the reaction of metal salt solutions with ammonium bicarbonate to form metal carbonates. The metal carbonates can be reduced to metal oxides by calcination [5] and further reduced to the metal catalyst during growth using hydrogen.

Wet catalysts are especially useful for coating nonplanar geometries such as wires or tips [198–201]. These surfaces can either be dipped in the catalyst solution or the solution can be spin-coated onto the substrate.

3.3. Thin Film Metals

Another common technique of depositing the metal catalyst is by physical vapor deposition. A very thin film of Fe, Co, or Ni is carefully deposited on a substrate using sputtering or evaporation. The film thickness is usually in the few nanometer range and is monitored during deposition using a quartz oscillator-type film thickness monitor for accuracy. When this thin film is heated up to a high temperature (such as the growth temperature), the thin film breaks up and coalesces to form nanoclusters due to increased surface mobility and strong cohesive forces of the metal atoms [117, 183]. These nanoclusters then catalyze the growth of the carbon nanotubes or nanofibers. In general, the size of the nanoclusters formed can be controlled by the thickness of the catalyst film [182, 183, 202], by the temperature [203, 204], or by the annealing time. Thicker films, higher temperatures, and lengthy annealing times lead to the formation of larger metal clusters due to increased surface migration of the metal atoms. Although these parameters may be used to control the average size of the nanoclusters (i.e., diameter of resultant nanofibers/nanotubes), one should note that the formation of nanoclusters from the metal film is a random process and thus there will still be a distribution in the diameters of the structures [183, 202].

Multilayer metal films have also been used to catalyze nanotube growth. A noncatalyst metallic underlayer can be used to control the surface properties of the catalyst or the deposition yield as discussed earlier. Single wall nanotubes have been grown using a three layer metal film containing 0.2 nm Mo on 1 mm Fe on 10 nm Al on a silicon substrate [171]. These authors showed that the metal films formed Fe/Mo catalyst particles of ∼2 nm diameter which seeded the single wall nanotubes.

The advantage of using catalyst thin films is that they can easily and accurately be patterned by using masking or etching techniques based around photolithography or electron beam lithography. In fact, individual freestanding nanotubes and nanofibers have been deposited using this process [116–118]. Figure 5 shows some examples where a 7 nm thin Ni film was patterned with lines and dots, which were then used to nucleate nanotubes. To obtain single freestanding structures, the Ni film must be patterned into dots of ∼300–350 nm or less [117, 205]. When the Ni film dots are heated up to the growth temperature (700 °C), the film forms a single catalyst cluster of equal volume and catalyzes the growth of the nanotube. The vertically standing nanotubes of Figure 5 were deposited by plasma enhanced chemical vapor deposition which will be discussed later.

Note that when the metal film thickness exceeds a few tens of nanometers, nanoclusters are no longer formed and the film forms islands a few micrometers in size. These large
Figure 5. A 7 nm film of Ni catalyst, prepared by sputtering, was patterned using lithography into lines (a,b) and dots (c). The substrate used was Si, and hence a TiN diffusion barrier (also prepared by sputtering) was used to support the catalyst as Ni reacts with Si at the growth temperature. The growth was performed by plasma enhanced CVD of C_2H_2:NH_3 at 700 °C. The nanotubes formed are straight, vertically aligned, and typically bamboo in structure (like the TEM shown in Fig. 3c). Using plasma enhanced CVD, it is also possible to attain slightly conical shaped structures by altering the synthesis conditions which is described in [268].

micrometer-size islands/particles usually do not catalyze filament growth but instead absorb carbon into their bulk. Nanotube/nanofiber growth is usually found around the grain boundaries of metal islands. This is because smaller (submicrometer) catalyst particles are often present around the grain boundaries. Baker et al. also observed that carbon filament growth occurred only from the edges of macroscopic Fe foil [192]. In this case, the catalyst material probably easily detached at the metal foil edges to form small catalyst particles which nucleated the carbon filaments. Note that large (micrometer-sized) catalyst grains or thick continuous catalyst films do not nucleate nanotubes. The uniform growth of nanotubes inside large metal grains or catalyst metal substrates is only possible if nanoparticles are present on the surface of the metal as described in the next section.

3.4. Thick Metal Catalyst Films or Metal Catalyst Substrates

Nanotubes or nanofibers can be grown with high yield on thick catalyst metal films or catalyst metal substrates when surface treatment techniques are first used to roughen the substrate surfaces. Mechanical roughening (e.g., by using sandpaper) or electrochemical etching may be used to generate a coarse surface. Plasma etching or ion bombardment has also been used to increase the roughness of the metal surface and to generate submicrometer metal islands/particles [113, 206–208]. These surface roughening

techniques generate the small catalyst particles needed to grow carbon filaments. An alternative technique is to oxidize the metal surface through heating in oxygen or by rusting [192]. During growth, the metal catalyst nanoparticles are formed from the rusty, porous oxide surface by decomposing it with a reducing gas (e.g., H_2).

3.5. Colloids

Colloidal metal (or oxide) particles have also been used to catalyze the growth of nanotubes. Colloids are usually synthesized (or bought) in liquid suspensions where the colloids are separated by adsorbed charged species or organic molecules. The advantage of using colloids is that these can be highly homogenous in size and can be synthesized in diameters down to 2 nm. Thus, the use of colloidal catalysts allows the growth of nanotubes with well defined diameters, in contrast to the other techniques mentioned above which tend to produce nanotubes with a significant variation in diameter (except for the growth of single nanotubes from a small catalyst patterned dot where the catalyst is essentially fixed in size/volume). Cheung et al. describes the preparation of monodisperse Fe clusters with different diameters and uses these to catalyze the growth of single wall nanotubes supported on an oxidized Si substrate [160]. Li et al. have also synthesized colloids of diameters varying from 3 to 14 nm to catalyze nanotube growth [169]. Colloidal metal suspensions can in general be applied to the substrate using similar techniques as for the wet catalyst. Additionally, colloidal solutions in which the particles are separated by charge can be easily applied/adhered to substrates which have been functionalized with oppositely charged surface layers [209].

3.6. Sol–Gel Technique

The sol–gel technique has also been used to prepare catalyst for both multiwall and single wall carbon nanotube synthesis [153, 158]. Sol–gels impregnated with metal catalysts have very high surface area, high porosity, and ultralow density—these characteristics lead to a high yield of nanotubes during growth. For example, a Fe–Mo catalyst was prepared by the sol–gel technique based on supercritical CO_2 drying and then used for single wall carbon nanotube synthesis, as described in [153]. This catalyst was reported to be capable of deposition yield of over 200% compared with the original weight of the catalyst for a 1 hour deposition. The catalyst was active for 6.5 hours of growth, yielding 600% weight gain in total. The high yields were the result of the aerogel having a high surface area, high porosity, and good metal–support interaction. As yet, no other research group has been able to exceed the yields of single wall carbon nanotubes on a supported substrate by sol–gel [153].

3.7. Unsupported/Floating Catalyst Method

The floating catalyst method is commonly used for the bulk/mass production of nanotubes/nanofibers by CVD. The main advantage of using this technique is that purification is not required to recover nanotubes from the substrate. The simplest method is to inject catalyst nanoparticles (e.g., in the form of a colloidal/particle suspension or organometallic precursors with a carbon feedstock) directly into the CVD

chamber. In this case, a vertical CVD chamber is usually used so that the nanotubes/nanofibers grow as the catalyst particles fall from top to the bottom of the chamber. This technique has been used to prepare vapor grown carbon fibers for over 20 years [4, 105, 210–212].

Organometallic compounds are often used as precursors for the catalyst. Examples of organometallic compounds that have been commonly used are metallocenes, iron pentacarbonyl, and iron (II) phthalocyanine [4, 172, 211–219]. These precursors are usually sublimed and catalyst nanoparticles are formed *in-situ* when the compound is decomposed/reduced by heat or hydrogen. A double stage furnace is typically needed because of the different temperatures needed for organometallic sublimation and nanotube growth. In general, the sublimation of metallocenes offers little control over the structural parameters of the nanotubes such as length and diameter, although it has been shown that by varying the relative concentration of the metallocene to carbon in the gas phase the average diameter of the structures may be changed [219, 220]. An improvement over the double stage furnace is to use a syringe pump and atomizer to continuously feed a metallocene–liquid carbon feedstock solution into a single stage furnace where nanotube growth occurs [219, 221–223]. Aligned, high yield and pure multiwall carbon nanotubes can be obtained with conversion rates of 25% of the carbon input using this method. Very often, the floating catalyst technique leads to highly dense/close-packed nanotube deposition where essentially only upward (i.e., "aligned") growth of the nanotubes is possible.

Interestingly, the floating catalyst method can also be used to selectively grow nanotubes on substrates [224, 225]. It was observed that multiwall carbon nanotubes grown by CVD of ferrocene and xylene at 800 °C only occurred on silica (SiO_2) surfaces and not on Si surfaces. Thus, by using lithographic means to pattern SiO_2 on a Si substrate, selective growth of nanotubes was obtained [225]. The multiwall nanotubes were aligned and grew perpendicularly from the SiO_2 surfaces. In this case, it was suggested that it was the good catalyst–support interaction between SiO_2 and Fe that led to the growth of nanotubes. If metal layers of nickel (Ni) were patterned onto Si, the nanotubes were seen to lift these metal patterns during growth [226]. Such aligned nanotubes have also been grown on gold and MgO substrates and palladium seeds [227–229].

Typically, metallocene assisted chemical vapor deposition of hydrocarbons (e.g., benzene, xylene) produces multiwall carbon nanotubes at lower temperatures (∼700 °C) whereas a combination of multiwall and single wall nanotubes are produced at much higher (>900 °C) temperatures. For example, pyrolysis of iron pentacarbonyl with benzene at 900 °C leads to single wall nanotube formation [220]. Nickelocene and cobaltocene were reported to be more favorable for single wall nanotube synthesis than ferrocene, although no differences in single wall nanotube yields were observed when binary mixtures of metallocenes were used, except that the nanotubes appeared to be "cleaner" when mixtures were used [230].

The addition of trace amounts of thiophene (sulfur containing compound) to liquid hydrocarbons has also been reported to promote the growth of single wall carbon nanotubes [170, 231, 232], although higher concentrations of thiophene were reported to revert the growth back to multiwall in structure (>5 wt%) [170, 231]. Recently, extremely long ropes (several centimeters in length) of high purity single wall nanotubes have been synthesized with the vertical floating catalyst method using a ferrocene, *n*-hexane, and thiophene mixture with hydrogen as the carrier gas [232–234]. These macroscopic ropes will definitely enable the use of single wall nanotubes in mechanical applications.

"HiPCO," developed at Rice University, is also a process involving a high pressure gas phase catalytic process for single wall nanotube growth [172, 235]. The catalyst is formed *in-situ* by the thermal decomposition of iron pentacarbonyl in a heated flow of CO, and growth is performed at pressures ranging from 1 to 10 atmospheres (atm) and temperatures ranging from 800 and 1200 °C. The optimum condition for maximum yield was at 1200 °C and 10 atm. The rate at which the reactant gases were heated also had substantial effects on the amount and quality of nanotubes produced. The addition of small amounts of methane (0.7% by volume) produced clean nanotubes and increased the yield as well. Although milligram quantities were obtained, such a process is continuous and is being currently scaled up to produce larger quantities of single wall nanotubes (marketed as HiPCO™ single wall carbon nanotubes by Carbon Nanotechnologies Inc.).

4. CHEMICAL VAPOR DEPOSITION CONFIGURATIONS AND CONSIDERATIONS

4.1. Horizontal Furnace

The horizontal furnace is the most popular configuration for the production of carbon nanofibers and nanotubes [4, 124, 137, 173]. In its simplest form, it is a heated quartz tube in which the substrates/catalyst are placed. The reactant gases are flowed over the substrates/catalyst which sit in a removable ceramic boat/holder in the center of the quartz tube (see Fig. 6a). The horizontal furnace is advantageous because there is no (or small) temperature gradient within the heated zone. In most cases, the length of the nanotubes/nanofibers can be simply controlled by the length of the deposition time.

When samples are first put into the chamber, the quartz tube is first flushed with a "carrier" gas. The most popular carrier gases are argon, hydrogen, and nitrogen [4, 115, 158, 161, 221, 232]. Argon is mostly used as it easily displaces air and therefore easily forms an inert atmosphere in the chamber. The furnace is then heated up to the growth temperature in the inert atmosphere. Hydrogen is often added to the gas flow to reduce the catalyst particles (e.g., oxides) during heating. Even if the chamber is evacuated by a pump, it is important to maintain a forward flow of inert/reducing gases during heating as it is possible that nanotubes may undesirably grow from the catalytic cracking of pump oil (e.g., from back streaming). When the growth temperature is reached, the carbon feedstock is introduced. As discussed in the growth mechanism section, the choice of carbon feedstock and other additives is based on whether nanofibers, multiwall nanotubes,
Figure 6. Types of chambers used for catalytic CVD of nanofibers and nanotubes. The most commonly used is the horizontal furnace (a). For mass production, the vertical furnace (b) has been employed. (c) The fluidized bed reactor and (d) a basic plasma enhanced CVD system based around a vacuum chamber.

Figure 7. The free enthalpy of formation of some carbon compounds, calculated from [236, 237].

or single wall nanotubes are desired. Reactions are usually conducted at temperatures below 1000 °C to reduce the formation of undesirable carbon deposits such as amorphous carbon [151]. The amorphous carbon is deposited from the thermal decomposition (pyrolysis) of the carbon feedstock gas, whereas the carbon nanotubes/nanofibers are grown from the catalytic decomposition of the carbon feedstock gas. In most cases, "clean" (i.e., amorphous carbon-free) growth of highly crystallized structures is desired and hence the highest deposition temperature without significant self-decomposition of the carbon feedstock is preferred.

In order to determine the highest growth temperature possible using a particular carbon feedstock, it is necessary to consider the thermodynamic stability of the compound depending on temperature. The driving force for the pyrolytic reactions involving gaseous components can be derived from plots of the free enthalpy of formation versus temperature (generated using [236]) as shown in Figure 7. The term pyrolytic is defined as converting the carbon feedstock to solid carbon as the main product and to different

volatile compounds as by-products [237]. The stability of the compound increases with the free enthalpy, whereas the driving force for breaking the compound into its elements decreases. For example, the forward reaction producing elementary carbon from carbon monoxide is favored at temperatures below 700 °C.

In general, there is a compromise between obtaining high purity carbon nanotubes/fibers and high crystallinity. The growth temperature affects the crystallinity of the structure produced, but too high a temperature leads to the formation of pyrolytic amorphous carbon. Furthermore, the diffusion of carbon through the catalyst is a thermally activated process, and hence, in general, higher temperatures lead to higher growth rates which may be desirable for mass-production processes.

One strategy to reduce the formation of amorphous carbon is to decrease the contact time between the carbon feedstock and the substrates. This is achieved by using very high gas flow rates (in cases where only carbon feedstock is used in the flow) or high dilution [129, 163, 175, 238]. Thus, the carbon feedstock is often diluted by the carrier gases. Normally there is an optimum ratio of carbon feedstock to carrier gas; for example, using acetylene and nitrogen, the optimized combination was 9% by volume of the total gas flow. If the acetylene combination is increased, amorphous carbon begins to form due to the self-pyrolysis carbon feedstock and the increased exposure of the sample to the carbon feedstock [129].

A small amount of hydrogen in the gas flow is useful in keeping the catalyst particle active by reducing it. It is well known that the growth of nanofibers is enhanced in a hydrogen atmosphere [4, 148, 189, 239]. Hydrogen also reduces the formation of undesirable carbon deposits from the pyrolysis of carbon feedstock [159]. This is because hydrogen rehydrogenates the reactive carbon species in the gas phase. Franklin et al. found that for clean single wall carbon nanotube growth at 900 °C, the optimum flow of hydrogen was between 100 and 150 ml/min in a predominantly CH_4 flow (CH_4 = 1500 ml/min) [176]. The flow of hydrogen had to be increased to 200 ml/min to maintain

"clean" growth when a temperature of 950 °C was used. In the absence of hydrogen flow, the CH_4 was found to pyrolyze and form amorphous carbon deposits all over the substrate.

Alternatively, the floating catalyst method can also be used in the horizontal furnace configuration for carbon nanofiber or nanotube growth [4, 212]. As discussed before, the catalyst can be sublimed in a preceding furnace stage and flowed into the main furnace for growth or injected directly into the growth furnace using a syringe pump or atomizer spray [4, 213–219, 221–223, 240]. The growth of nanotubes would then occur all over the walls of the quartz tube and also on any substrates placed inside the furnace. This technique is very useful for bulk production since the material can simply be removed from the walls of the chamber or from the substrates after growth. Note that selective area growth is also possible with the floating catalyst technique by using different substrate materials; for example, SiO_2 supports nanotube growth whereas Si does not [224, 225].

Finally, note that a furnace is not necessarily required to generate the heat needed for nanotube growth. It is possible to grow nanotubes on wires through direct heating with electrical current [241]. Furthermore, plasma or radio-frequency (rf)-induced heating of the catalyst particle can also generate sufficient temperature locally for carbon nanofiber/nanotube growth at lower process temperatures [242].

4.2. Vertical Furnace

The vertical furnace configuration, as shown in Figure 6b, is usually employed for the continuous production of carbon fibers, nanofibers, and nanotubes [4, 125, 211, 232, 243]. The catalyst and carbon source is injected at the top of the furnace and the resultant filaments grow during flight and are collected at the bottom of the chamber. The vertical furnace can be run continuously for the mass production of carbon nanotubes and nanofibers. Ultrafine metal catalyst particles are either introduced into the reactor directly or formed *in-situ* using precursors such as metallocenes as discussed previously. Note that the residence time of the catalyst particle in the vertical furnace is relatively short compared to the horizontal furnace.

As discussed earlier, the growth of multiwall or single wall nanotubes is dependent on the temperature and gases used, with higher temperatures and the addition of a sulfur containing compound (e.g., thiophene) favoring single wall nanotube production [170, 231, 232]. The main advantage with the vertical furnace configuration is the continuous nature of nanofiber/nanotube production and high purity product eliminating the need for purification or removal from the substrate. The vertical furnace technique has been commercialized for the production of multiwall nanotubes and nanofibers, in quantities of tons per year. Most of this material is used in the electrodes of lithium-ion batteries [73] and as fillers in conductive polymers [35].

The fluidized bed reactor (Fig. 6c) is a variation of the vertical furnace. Fluidization is defined as the transformation of solid particles into a fluidlike state through suspension in a gas or liquid. As seen in Figure 6c, supported catalysts are usually placed in the center of the furnace and an upward flow of carbon feedstock gases is used.

The fluidization process involves the supported catalysts to remain much longer in the furnace than in the vertical floating technique. The fluidization method is relatively new for the bulk production of carbon nanotubes [244–246], and thus far, production rates up to tens of kilograms of multiwall carbon nanotubes a day have been achieved [244].

4.3. Aligned and Directed Nanotube Growth

In some applications, the deposition of well aligned carbon nanotubes or nanofibers on substrates is desired. In this area, chemical vapor deposition is uniquely superior to the other nanotube production techniques (i.e., electric arc discharge and laser ablation) in that nanotube/nanofiber alignment on substrates is readily achievable during growth. Whenever very dense and closely packed nanotubes are deposited (see Fig. 8a), they are forced to grow in an upward ensemble (i.e., perpendicularly) from the substrate—this is sometimes referred to as "self-oriented" or "self-assembled" growth. It is generally believed that the nanotube ensemble is held together by van der Waals interaction and that the nanotubes are so closely packed that the only possible
Figure 8. Methods of aligning nanotubes during growth. In (a), densely packed nanotubes grow approximately vertically aligned, as shown in this peeled section of a nanotube "film." This was deposited using the floating catalyst technique employing a ferrocene–toluene solution injected into a heated furnace (750 °C). In (b), perfectly straight, same diameter, and same length nanotubes are grown in the pores of a nanochannel alumina template. In (c), a lateral electric field of 0.5 V/μm is used to guide these single wall nanotubes horizontally between electrodes during growth. In (d), straight, vertically aligned carbon nanotubes were grown using plasma enhanced CVD. It is believed that the electric field in the plasma sheath which forms over the substrate aligns the structures during growth. (b) Reprinted with permission from [250], J. Li et al., *Appl. Phys. Lett.* 75, 367 (1999). © 1999, American Institute of Physics. (c) Reprinted with permission from [111], Y. G. Zhang et al., *Appl. Phys. Lett.* 79, 3155 (2001). © 2001, American Institute of Physics.

growth direction is upward. Thus, the key factor in achieving this type of dense, aligned growth is the preparation of dense and active catalyst particles on the substrate surface. One of the most spectacular examples of this was reported by a Chinese research group [114, 119]. The authors prepared iron oxide nanoparticles in the pores of mesoporous silica, which was then reduced to iron particles by H_2/N_2 flow at 550 °C, followed by reaction with C_2H_2 at 700 °C for nanotube growth. Dense arrays of nanotubes grew perpendicularly outward from the mesoporous silica, and bundles of nanotubes up to 2 mm in length were synthesized [119].

Fan et al. also synthesized "towers" of densely packed nanotubes by using a 5 nm thin film of evaporated iron on electrochemically etched porous silicon [110]. The authors explained that during growth, the walls of the nanotubes interact with their neighbors via van der Waals to form a rigid bundle during growth. In fact, close examination of these nanotube "towers" revealed that there were no nanotubes which "branched out" from the main tower. As the catalyst was rooted at the base of the structure (i.e., base growth), the porous substrate played a key role in the growth as it allowed the deposition gas to continuously feed the catalyst. The strong interaction between the substrate and the catalyst also meant that the catalyst was well rooted and did not sinter to form larger catalyst particles at the growth temperature. Dense and aligned nanotube growth on substrates has also been observed with evaporated iron on oxidized Si [167], from laser-ablated Co catalyst on silica substrates [115], and from substrates coated by nanotubes from the floating catalyst method as discussed earlier [218, 220, 221, 225]. In general, the close-packed nanotubes are not perfectly straight and exhibit some degree of waviness as seen in Figure 8a.

Another common means of achieving aligned growth is through the use of templates, the most popular of which are vertical nanopores created by the electrochemical processing (anodization) of aluminum. Porous alumina membranes typically contain vertical nanopores which are a few to hundreds of nanometers in diameter and lengths which can range from a few micrometers to hundreds of micrometers. The electrochemical parameters can be varied to control the pore diameter, length, and density—a review of the template preparation and growth of nanomaterials in templates is given in [247]. The intent is to grow nanotubes within the alumina pores so that the diameter, length, density, and alignment of the structures reflect that of the original template. The use of porous alumina in the synthesis of carbon nanotubes was first reported in 1995 [248]. In general, two types of template grown structures are possible, namely catalyzed and pyrolytic (no catalyst). The latter usually requires higher temperatures in order to decompose the carbon feedstock gas. Che et al. prepared carbon nanotubes with diameters ∼20 nm using an alumina template in ethylene/pyrene with a Ni catalyst at 545 °C or without catalyst at 900 °C [249]. After growth, the alumina template can be removed by dipping in HF or NaOH solution to reveal an array of well-ordered carbon tubules standing perpendicular on the substrate. Figure 8b shows what is possible with this technique—a well-aligned, hexagonally packed nanotube ensemble with highly homogenous diameter and lengths. This was prepared by Li et al. using an alumina

template together with Co/Ni catalysis of acetylene at 650 °C [250]. The smallest nanotubes, 4 Å (0.4 nm) in diameter, have been fabricated using zeolite templates [251].

Another strategy of obtaining vertical nanotube/nanofiber growth is through the use of electric fields. Avigal et al. used a vertical electric field during growth to achieve vertical alignment of nanotubes [252]. A similar effect arises during plasma enhanced chemical vapor deposition (see Fig. 8d) which is discussed in the next section.

The above techniques yield the growth of vertically aligned structures—but what about horizontally aligned ones? Horizontally aligned nanotubes are necessary for the mass production of nanotube electronic and spintronic devices. The group led by Dai, at Stanford University, is a pioneer in this area. In their early work, straight, single wall nanotubes were grown from patterned catalyst but in random directions [151]. In some cases, the nanotubes grew in the correct direction (e.g., between electrical contacts) which allowed the fabrication of nanotube electronic devices [63, 253, 254]. Clearly there was a need to control the growth direction in order to achieve a higher fabrication yield of nanotube devices. In [177], they fabricated silicon pillars and contact printed the catalyst for single wall nanotubes on top of the pillars. A suspended network of nanotubes was observed from the pillars after growth. Fascinatingly, the direction of the suspended nanotubes followed the pattern of the pillars—for example, when the pillars were lined up in rows, nanotubes would be found to be suspended from the pillar tops resembling a power line. Using this technique, 100–150 μm long single wall nanotubes were grown. If four pillars were arranged in a square, a square arrangement of suspended nanotubes would join the tops of the pillars. The authors reasoned that the nanotubes growing toward a pillar would adhere to the pillar and become suspended, whereas nanotubes growing in other directions do not meet a pillar and would fall down toward the substrate. Thus, the arrangement of pillars essentially defined the growth direction of the nanotubes.

Lateral electric fields can also be used to guide nanotubes during growth. Zhang et al. prepared electrode and catalyst "fingers" on a quartz substrate which were biased during chemical vapor deposition in order to create a lateral electric field [111, 112]. The authors found that electric fields of 0.13–0.5 V/μm were needed to guide and align the single wall nanotubes during growth, as shown in Figure 8c. The mechanism of alignment was due to the electric dipole polarization of the nanotubes which made them align in the applied electric field.

Lee et al. also presented a technique for the directed growth of lateral nanotubes. These authors made a sandwich structure comprised of SiO_2–Ni–Nb on silicon [255]. Using microfabrication, only one face of the sandwich was left exposed to the gases and it was from this face that the Ni catalyzed the outward/lateral growth of multiwall nanotubes in C_2H_2/N_2 at 650 °C.

4.4. Plasma Enhanced Chemical Vapor Deposition

Plasma enhanced chemical vapor deposition (PECVD) is a relatively new technique of producing vertically aligned carbon nanotubes and nanofibers, and it is considerably

different from the horizontal and vertical furnace techniques. A plasma is an excited/ionized gas, and the processing plasmas, usually known as "cold" plasmas, are generated using dc, rf, or microwave excitation. The simplest plasma system to implement is the dc plasma which is shown in Figure 6d. The dc glow discharge plasma is generated by grounding the anode and applying a negative dc bias of a few hundred volts to the cathode (note that the substrate for nanotube/nanofiber growth is on the cathode in this case such that the plasma would form a sheath over it with a large voltage drop). Plasma systems are commonly used in semiconductor processing for etching or low temperature deposition of thin films. A review presenting the different configurations of plasma systems is presented in [256]. Today, carbon nanotube/nanofiber growth has been demonstrated with hot filament assisted PECVD [113, 206–208], microwave PECVD [257–262], dc glow discharge PECVD [117, 182], inductively coupled plasma PECVD [74, 149], and rf PECVD [242, 263]. Plasma depositions are very stable—this leads to highly controllable and reproducible growth conditions. PECVD is usually used to produce vertically aligned carbon nanotubes/nanofibers or grow nanofibers at low temperatures.

Chen et al. used a combination of hot filament and dc PECVD (via negative bias on the substrate) to grow aligned carbon nanofibers using a single crystal Ni$\langle 100 \rangle$ surface with CH_4 and N_2 gases [206]. This process was later refined using 3% C_2H_2 in N_2 and a polycrystalline Ni substrate to grow nanofibers of 60–70 nm average diameter and few micrometers in length [207]. The structures produced by Chen et al. were classed as nanofibers because their TEM showed that the graphene planes were slightly tilted/herringbone, although the nanofiber was hollow in the center. These films showed excellent field emission characteristics with low turn-on electric fields and high emission currents.

A major application for carbon nanotubes is the electron source in field emission displays (a flat panel display technology). The major drawback, however, is that nanotube growth typically requires temperatures of 700 °C or higher which exceeds the strain point of the best "display" glass (by Corning) of 666 °C. Hence, there was great excitement in 1998 when Ren et al. demonstrated that vertically aligned carbon nanotubes could indeed be deposited below that temperature on glass, using hot filament assisted dc-PECVD of C_2H_2 and NH_3 [113]. The aligned nanotubes produced were uniform and very straight and stood "individually" as shown in Figure 8d, in contrast to the aligned nanotubes produced by dense growth in which nanotubes were bundled together and wavy. The authors used a thin film Ni catalyst which was sputtered onto the glass substrates and also showed that plasma bombardment could be used to break up the thin film into islands. Furthermore, this work also demonstrated that the initial film thickness of the film could be used to control the diameter of the resultant nanotubes. Huang et al. later used this process to grow nanotubes uniformly on a polycrystalline Ni substrate which was pre-etched to create Ni islands [208]. Ren et al. [116] later used electron beam lithography to pattern submicrometer Ni dots directly on a silicon substrate and achieved the growth of single, freestanding vertical nanotubes. These nanotubes, however, were not very uniform in terms of height and yield which

could be due to the absence of a diffusion barrier between the Ni catalyst and Si substrate. Huang et al. [264] next studied thin film Co, Fe, and Ni catalysts on a Ti substrate using the hot filament dc-PECVD process and found that the nanotubes produced with Ni were structurally the best in terms of graphitization, straightness, lack of amorphous carbon overcoating, and structural defects such as openings in the walls. The nanotubes nucleated from Ni also had the fastest growth rate (in terms of length). The authors noted that the diameters of the Ni catalyzed nanotubes were larger than the nanotubes catalyzed by Co and Fe, indicating that Ni had the weakest interaction with the Ti substrate and hence formed the largest catalytic clusters. Huang et al. studied the growth of individual nanotubes from patterned Ni dots and forests of nanotubes from a larger area Ni film [265]. They found that the Ni catalyst particle attained a particular orientation after growth, namely with the $\langle 220 \rangle$ orientated in the direction of the plasma. The individual nanotubes were also better crystallized with tubular walls, compared with the forests of nanotubes which had herringbone-like structures (i.e., nanofibers). They suggested that plasma focusing and heating of the catalyst particle in the case of the individual nanotube were responsible for its different structure.

Bower et al. devised an elegant set of experiments to investigate the alignment mechanism of the nanotubes [257]. A microwave PECVD system was used to grow carbon nanotubes catalyzed from a Co thin film on a Si substrate. Carbon nanotubes were deposited using PECVD and then the plasma was stopped for conventional thermal CVD to continue. The resultant nanotubes were thus straight for the plasma-grown section and curly for the thermally grown section. Additionally, when nonplanar or angled substrates were introduced into the plasma, the nanotubes still grew perpendicularly from the substrate surfaces because the microwave plasma formed a sheath around these objects. The authors concluded that the alignment was indeed a plasma induced effect and that it was probably the electric field in the plasma sheath formed around objects which guided the growth of the nanotubes perpendicularly from the objects. The electric field in the plasma sheath was estimated to be 0.1 V/μm, which is of the same order of magnitude as the electric field used to align single wall carbon nanotubes laterally during growth discussed previously.

Chen et al. [266], who used a hot filament dc-PECVD system, showed that by placing a substrate at an angle to the biased cathode electrode, nanotubes also grew at an angle which followed the direction of the electric field in the plasma sheath. Tsai et al., who used a microwave plasma to synthesize aligned nanotubes, proposed a model based on anisotropic etching in order to explain the vertical alignment of the nanotubes [267]. They suggested that nanotubes which grew in random orientations were unprotected by their metal catalyst particle and were hence anisotropically etched away in the plasma [267].

Merkulov et al. developed a simple dc-PECVD system to grow vertically aligned carbon nanofibers [117]. The system used a resistively heated cathode which was biased at −550 V to generate a dc glow discharge. The gases used were C_2H_2 and NH_3, and Ni, deposited on top of a Ti

barrier layer on silicon substrates, was used as the catalyst. They investigated the lithographic conditions necessary to nucleate single, freestanding nanofibers as well as single-file lines of nanofibers. The maximum catalyst dimensions were determined to be 350 nm for a catalyst dot and 200 nm for the width of a catalyst line (i.e., for a single file line of nanofibers). Above these dimensions, the catalyst was observed to break into multiple nanoclusters at the growth temperature which nucleated more than one nanofiber. Merkulov et al. named their filaments nanofibers because they were highly disordered and bamboolike. In further studies, these authors found that the thickness of the catalyst layer controlled the average diameter of the nanofibers grown by PECVD [202], the ratio of C_2H_2 in the gas flow caused the nanofibers to attain a conical shape due to amorphous carbon buildup on walls of the nanofiber as it grew upward [268], and the direction of the nanofiber growth was determined by the local electric field in the plasma sheath [269]. The authors studied the field emission properties of their nanofibers and also fabricated gated microelectronic field emitters and electrochemical electrodes based on single nanofibers [54, 75, 270–272].

Chhowalla et al. performed a parametric study of the dc-PECVD growth of carbon nanotubes using C_2H_2 and NH_3 gases with Ni catalyst [182]. The structures were termed nanotubes because the filaments had well crystallized graphene walls parallel to the filament axis (see Fig. 3c for a typical TEM), with bamboo compartments along their axis. They studied the effect of the initial catalyst thickness (with thicker films leading to larger diameter nanotubes which were shorter and of lower areal density), the effect of the C_2H_2 ratio in the gas flow (with higher ratios leading to conical structures), the effect of pressure and deposition time (with higher pressures and longer times leading to longer nanotubes), and the effect of the dc bias on the substrate (with higher biases leading to straighter, aligned nanotubes). By examining the plasma characteristics, it was determined that 0.15 V/μm was the minimum electric field in the plasma sheath necessary for vertical alignment of the nanotubes. Clearly, to obtain a high degree of vertical alignment, one should thus maximize the electric field in the plasma sheath by increasing the substrate bias or by increasing the gas pressure (which increases ionization, leading to a higher field in the sheath). By investigating the effect of the growth temperature, it was found that the activation energy for PECVD growth was less (i.e., 0.76 eV) than that for thermal CVD (i.e., 1.21 eV), the latter being close to the bulk diffusion of carbon through Ni [204]. This indicates that the plasma plays a role in lowering the activation barrier necessary for nanotube growth. Teo et al. used the dc PECVD process to demonstrate the high yield and uniform growth of patterned areas of nanotubes and individual nanotubes [118, 273], examples of which are shown in Figure 5. In patterned growth especially, the C_2H_2 to NH_3 ratio was found to be important in achieving amorphous carbon free growth. During growth, the C_2H_2 is continuously being decomposed by the plasma (at a rate much faster than thermal pyrolysis) to form amorphous carbon on the substrate surface, and the role of NH_3 in the plasma is to etch away this unwanted amorphous carbon. The N and H species in the NH_3 plasma react with the amorphous carbon to form

volatile C–N and C–H species. Hence, there exists an optimum condition, which was determined to be a flow ratio of 40:200 sccm of C_2H_2:NH_3 at 700 °C, where the production and etching of amorphous carbon is balanced, thus yielding substrates which are free of amorphous carbon. Teo et al. also found that individual vertical nanotubes, nucleated from Ni clusters of controlled size/volume, could be grown with a high degree of uniformity in terms of tip radius and height. The standard deviations in the tip diameter and height were found to be 4.1 and 6.3% of the average respectively [205]. This high degree of structural uniformity leads good uniformity in terms of field emission characteristics from adjacent nanotubes in an array [205, 274].

Delzeit et al. performed a parametric study of vertically aligned carbon nanotube and nanofiber growth in an inductively coupled plasma [149]. The authors used thin film Fe catalyst which was deposited on an aluminum layer on Si substrates, and the nanofibers/nanotubes were grown using CH_4, H_2, and Ar gases. By varying the process conditions, the authors found a clear transition between two structural forms of carbon filaments grown (i.e., the nanotube with parallel graphene walls and nanofiber with walls which were inclined to the filament axis). Until then, it was known that some plasma processes produced nanotubes (which were mostly bamboo), but other plasma processes produced nanofibers (with angled graphene layers but mostly hollow inside). The authors conclusively found that it was the relative amount of hydrogen species in the gas phase which determined whether nanotube or nanofiber growth was favored. Nanofiber growth was favored under process conditions which contained a large amount of hydrogen because the hydrogen could terminate the large number of dangling bonds protruding from angled graphene layers. The lack of hydrogen (e.g., achieved by Ar dilution) in the gas phase produced nanotubes which have closed, tubular graphene shells with few dangling bonds.

One of the most significant results recently is the demonstration of room temperature growth of nanofibers using rf-PECVD [242]. The authors used a CH_4 and H_2 plasma with Ni powder catalyst to grow nonaligned nanofibers at room temperature and at 100 and 250 °C. The authors claimed that instead of thermal energy, the energy of the plasma and induced rf heating of the catalyst particle allowed the formation of the carbon nanofibers at ambient temperature.

4.5. Growth of Branched Structures

The growth of branched filaments allows direct "wiring" of nanotube/nanofiber structures. Y-branched nanotubes would also allow switching and rectification behavior over a network of wires, similar to neural networks in biological systems. The growth of Y-branched nanotubes and nanofibers has been reported by several groups using the catalytic CVD [275–280]. Using the catalytic methods, the Y-junctions are generally formed at high temperatures (1000–1100 °C) [277, 279] or by using mixed metal or Cu catalysts [275, 276, 280–282]. For example, Chambers et al. found that branching is promoted when Co catalyst is alloyed with 2% Cu [275, 276] while Li et al. [280] observed branching when the catalyst is doped with Si or Ca. Another method for fabricating Y-junctions is to use a nanochannel
Figure 9. Branched structures as a result of a rapid drop in temperature from 700 to 550 °C during growth. The drop in temperature caused the Ni catalyst here (bright dot at the tip of the structure) to break up. After the temperature perturbation, the temperature was brought back to 700 °C for normal growth.

alumina template that has been prepared such that the pores are Y-shaped [283, 284]. The electrical measurements on these Y-junction nanotubes showed nonlinear conductance and reproducible rectification [284].

It is also possible to grow branched structures without catalyst additives, templates, or high temperatures. In fact, all that is required is a simple perturbation during deposition in order to promote the formation of smaller catalyst particles (to catalyze branches) from a single, larger catalyst (which forms the main "stem"). In Figure 9, the branched nanofiber structures were formed by growth using dc-PECVD of C_2H_2:NH_3 with Ni catalyst at 700 °C for 3 minutes, then rapidly decreasing the growth temperature from 700 to 550 °C and then normal deposition at 700 °C again for 3 minutes. As the solubility of carbon in the catalyst decreases at lower temperatures, the rapid drop in temperature causes the catalyst to become oversaturated and to split up to form more surface area to expel the carbon. After the catalyst has been broken up by the rapid drop in temperature, further growth at the normal temperature (700 °C) is used to extend the length of the nanofiber branches.

5. SUMMARY

Catalytic chemical vapor deposition is an extremely versatile technique for the production of carbon nanofibers and nanotubes. This chapter has shown that by controlling the catalyst and synthesis conditions, one can control many aspects of the growth, such as the structure (nanofiber vs nanotube), diameter, length, and alignment. The catalytic CVD technique can be adapted for mass production purposes or for the controlled growth of nanotubes/fibers at particular sites on a substrate for various applications.

GLOSSARY

Carbon nanofiber The carbon nanofiber is a generic term used to describe filaments/whiskers of carbon which have diameters less than 500 nm. The term fiber usually implies that the structures have a high aspect ratio, and hence the lengths of nanofibers are usually in the range of few micrometers or more. Although the carbon nanotube (see next) can be classed as a form of nanofiber, the carbon nanotube is typically used to describe structures which are comprised of tubular graphene walls parallel to the fiber axis. Hence,

recently, the term carbon nanofiber is used to imply filaments which is are comprised of graphene layers which are stacked at an angle to the fiber axis (such as the herringbone, cup-stacked, or stacked type filaments). Also, carbon nanofibers can be used to describe filaments of disordered/amorphous carbon.

Carbon nanotube The carbon nanotube is comprised of graphene sheets (containing hexagonally arranged, sp^2 bonded carbon atoms) which have been rolled up to form a seamless tubular structure. The simplest form is known as the single wall carbon nanotube in which the structure consists of a single graphene shell/tube. Multiwall carbon nanotubes consist of multiple, concentric tubular graphene shells.

CONTENTS

1. INTRODUCTION

Nanotechnology has been viewed as the "little big science" [1], which is considered the impetus for the next industrial revolution. The ability to work at the molecular level, atom by atom, to create large structures with fundamentally new properties and functions is the core of nanoscale science, engineering, and technology [2]. One of the building blocks of nanotechnology is nanostructured materials such as nanoparticles [3].

Nanoparticles may be defined according to their physical dimensions as *particles with a size range of 1 to 100 nm* [3, 4]. A typical nanoparticle most often consists of several small "primary particles" [5]. The size of nanoparticles usually refers to the "secondary" particle size. Primary particles agglomerate into these "secondary" particles [5]. The primary particles have a very high surface-to-volume ratio. The proportion of atoms on the surface and at the grain boundaries of a nanoparticle is significant. Nanoparticles have about 98, 40, and 10% of their atoms on the surfaces or at the grain boundaries if their primary particles are 1, 5, and 20 nm, respectively. The high proportion of surface and grain boundary atoms is responsible for the different properties (electronic, optical, electrical, magnetic, chemical, and mechanical) of nanoparticles with respect to the bulk materials [6, 7]. This represents new opportunities in science, such as the change of properties and laws as the dimensions of the nanomaterials become comparable to, or smaller than, relevant length scales, such as the mean-free path or the coherence length. New material properties result when the surface and the grain boundary atoms represent a large proportion of the total number of atoms, or when processes become dominated by quantum effects, or—in general—by the transition from atomic and molecular behavior to condensed matter behavior [8].

The size range for nanoparticles may be more accurately defined as the size range from 1 nm to the largest nanometer dimension, where the ratio of the number of atoms on surfaces and at grain boundaries to those at the center is such that new physical, chemical, and biological properties occur, compared to bulk materials [9]. The upper limit of the nanoparticle size may be different from 100 nm, depending upon the sizes of the atoms and molecules in question.

Nanoparticles have large surface areas [7] and high reactivity due to the unsaturated bonds on their pristine surfaces. Nanoparticles tend to react among themselves to form necking, and hence agglomerate into large secondary particles. This imposes extreme challenges for industry to produce large quantities of nanoparticles with identical properties inexpensively and reliably. Selecting the proper manufacturing methods for a specific application requires a thorough understanding of the fundamental aspects of nanoparticle formation.

There are numerous reported synthetic methods for the production of nanoparticles [10]. The challenge is to control the nanoparticle size, size distribution, morphology, crystallinity, shape, and properties, to assemble the nanoparticles for a given purpose, and to make them from a variety of materials. The synthetic methods reported can be classified according to synthesis strategies, the branches of science involved in the process, sources of energy input, and the media in which nanoparticles are formed.

2. METHODS FOR CATEGORIZING NANOPARTICLE SYNTHESIS

2.1. By Synthesis Strategy

Strategies are important for the synthesis of nanoparticles. There are two basic strategies used in the syntheses of nanoparticles: bottom up and top down [9, 11].

2.1.1. Bottom-Up Strategy

This strategy is more in line with the basic strategy of nanoscience and technology. Here, nanoparticles are built up atom by atom, or molecule by molecule, at the will of their creators. Most nanoparticle syntheses belong to this category. A simple example of this approach is the flame synthesis of TiO_2 from gaseous $TiCl_4$ and oxygen according to

$$TiCl_4 + O_2 \rightarrow TiO_2 + 2Cl_2.$$
It has been shown that nucleation and surface growth determine the primary particle size of titania [12–14]. Other studies [15, 16] show that coagulation of the primary particles of titania could also dominate particle growth during flame synthesis of TiO_2. The molecular TiO_2 formed in the flame can grow into particles through nucleation and surface oxidation of $TiCl_4$, aggregation, or the combination of both mechanisms. Under certain processing conditions, either one of the mechanisms could dominate the overall particle growth.

2.1.2. Top-Down Strategy

This strategy is most applied in the traditional particle-making process. Here, nanoparticles are synthesized by breaking down bulk materials gradually into smaller sizes until they are nanosized. The end results could also be achieved by leaching out one type of molecule in a bulky homogeneous molecular solid mixture.

Mechanical breakdown, such as high-energy ball milling, is a simple case of the top-down strategy. γ–Al_2O_3 powders have been ball milled into nanocrystalline alumina powders with different surface areas of up to 100 m^2/g, depending on the milling atmosphere of air or inert gases [17]. High-energy ball milling is useful for deriving nanocrystalline materials of high-temperature phases without going to extreme heat treatment, which would promote significant grain growth and surface area loss. For example, nanocrystalline α–Al_2O_3 with a high surface area was obtained through ball milling [18].

Another example of the top-down strategy is illustrated by the synthesis of nanosize yttrium-stabilized zirconia by leaching bulky yttrium-doped $BaZrO_3$ or bulky yttrium-doped Na_2ZrO_3 [19]. In this approach, yttrium-doped $BaZrO_3$ or yttrium-doped Na_2ZrO_3 is first synthesized from $BaCO_3$, ZrO_2, and Y_2O_3, and from Na_2CO_3, ZrO_2, and Y_2O_3 by a conventional solid-state reaction method. The synthesized yttrium-doped $BaZrO_3$ or yttrium-doped Na_2ZrO_3 is then boiled to leach away the unwanted species, BaO or Na_2O, either in a diluted HNO_3 solution for $BaZrO_3$ or in water for Na_2ZrO_3. The residues of the skeleton form fine, nanosize yttrium-stabilized zirconia of 3–15 nm.

2.2. By Nature of the Process

Different nanoparticle-making techniques may involve different scientific processes, such as physical, chemical or biological, or some combination of these processes.

2.2.1. Physical Methods

A physical process involves only changes in physical state, such as size, shape, and phase of the matter. Mechanical size reduction is a physical process. Condensing gaseous metal vapor into nanoparticles is another example. The formation of nanoparticles in the gas phase is accomplished by a rapid quenching of supersaturated metal vapors with room-temperature or cold inert gas [20].

2.2.2. Chemical Methods

Most nanoparticle syntheses involve chemical changes. For instance, a sol–gel process converts metal alkoxides into oxide particles [21]. A hydrothermal process converts titanium isopropoxide and barium hydroxide into $BaTiO_3$ [22]. Other chemical methods will be described in more detail in following discussions.

2.2.3. Biological Methods

Nanostructured materials are synthesized in nature by a process known as biomineralization (the *in vivo* formation of inorganic crystals and/or amorphous particles in biological systems [23, 24]). In nearly all cases, the growth of the inorganic phases is controlled by biologically produced membranes or templates, which are usually composed of proteins and/or polysaccharides [25]. In some cases, the phase of the inorganic element is dictated by the organic template, by molecular complementarities, or by epitaxial matching of the organic and inorganic surfaces. In some cases, the biological membrane may act to limit the size and morphology of the resulting crystal by providing a defined space and chemical environment within which precipitation can occur. Fendler [26, 27] has shown that a mimetic approach in nanoparticle synthesis addresses the essential requirement of biomineralization. It is to have compartments capable of providing structural, spatial, and chemical controls for nanoparticle generation and stabilization. The mimetic approach using aqueous micelles, reverse micelles, microemulsions, vesicles, polymerized vesicles, monolayers, self-organized multilayers, and bilayer lipid membranes has successfully generated nanocrystalline Ag_2O [28], and less than 10 nm monodispersed Pt, Pd, Rh, and Ir particles [29, 30]. Pierre et al. have also demonstrated the synthesis of nanoscale ($<$10 nm) iron oxide using protein cages and polysaccharide networks [31].

2.2.4. Combination Methods

Most of the synthetic methods for nanoparticles are a combination of both physical and chemical processes. The biological method discussed above is more often a combination of chemical and physical (structural and spatial) control. Many of the synthetic methods to be discussed in detail below are combinations of chemical and physical processes.

2.3. By Energy Sources

Energy is always involved in the synthesis of nanoparticles. Nanoparticle synthesis methods can then be classified based on the types of energy input used in the synthetic processes. Laser synthesis, for example, refers to lasers being used as the energy source in the production of nanoparticles. Lasers could be used for evaporating materials into gas phases, promoting chemical reactions among gas molecules, and decomposing molecules. The following are examples of synthetic methods that are named after energy sources:

- laser
- plasma
- joule heating
- sputtering
- electron beam
- microwave
- hydrothermal
- freeze drying
- high-energy ball milling
- combustion
- flame
- supercritical

2.4. By Media in which Nanoparticles are Formed

Nanoparticles are always formed in a medium of either gas phase, liquid phase, or solid phase. The classifications based on the media where nanoparticles are formed are perhaps the most important and most widely used classification [32, 33]. By focusing on the media in which nanoparticles are formed, many issues common to all of the techniques within each specific medium arise. By summarizing the very different techniques used for synthesis in any one medium, one may perhaps learn and incorporate the best attributes of the different techniques to develop a nanoparticle synthesis method most suitable for one's own applications. The media for nanoparticle syntheses are usually classified as

- gas phases
- liquid phases
- solid phases

The detailed discussion in this chapter is arranged according to this medium classification.

3. DESCRIPTIONS OF MAJOR SYNTHESIS METHODS BY MEDIA

3.1. Gas-Phase Synthesis

Gas-phase syntheses described here are those methods where particles are formed as a result of reactions among gaseous molecules, gas molecule condensation and/or decomposition, nucleation, growth, and possibly agglomeration. In general, gas-phase syntheses using gases as reactants involve low concentration because of the low density of gases. This has an advantage for producing nanoparticles because nucleating particles in such low concentrations tend to be less agglomerated [34]. It is also generally true that

gas-phase methods are not as convenient for multiple components as are solution methods. This is because of the difference in saturated gas vapor pressures and the difficulty of controlling the reaction rates among different gases.

Gas-phase syntheses can be further divided into two broad types: vapor condensation and vapor reaction (the latter includes vapor decomposition).

3.1.1. Vapor Condensation Synthesis

This technique involves the physical conversion of gaseous vapor into solid clusters and particles. Research on the vapor condensation method for nanoparticles started in the 1960s [35–37]. Siegel [38] has summarized the early development of this type of synthesis, and Kimura has provided a review of its more recent development [20]. Two growth mechanisms have been proposed: the absorption growth process, where particle nuclei grow with the absorption of metal atoms; and the coalescence growth process, where particles grow by collision of particle nuclei and clusters. The advantages of these methods have been noted as having

1. ultrafine sizes
2. particle surface cleanness
3. applicability to metals, alloys, intermetallic compounds, ceramics, and semiconductors
4. flexibility in controlling crystallinity.

Inert-gas condensation has been suggested as the best method for making ultrafine metal particles [36]. Fuchs and Sutugin [39] have pointed out the difficulties of such methods, which arise from the presence of the more highly volatile impurity oxides that become the first particles formed, and also from impurities from the evaporation of the chamber materials. Brock [40] has raised further concern that the condensation method has not been shown to preserve stoichiometry. It is reasonable to suppose that the more volatile species will evaporate first, but condense last.

Vapor condensation synthesis includes many different methodologies:

1. inert gas evaporation technique [35], in which the target material is heated in a vacuum chamber with an atmosphere of several torr inert gas
2. matrix isolation method, where a cold substance instead of a room-temperature wall is used to control particle agglomeration [38, 41, 42]
3. gas flow/cold trap method, where a vapor of organic liquid is introduced into a particle carrier gas, and then trapped on a liquid-nitrogen-cooled wall [20]
4. gas flow/solution trap method, where nanoparticles in a carrying gas are bubbled through a precooled solvent, such as ethanol, at −30 to 140 °C, depending on the organic solvent(s) [43].

Much of the vapor condensation work has used resistance heating [38]. More and more work has been done with laser [44, 45], plasma discharging [46, 47], sputtering [48, 49], and electron beam [50].

3.1.2. Vapor Reaction Synthesis

This is perhaps the most important technology in gas-phase synthesis. It usually involves the reaction of two or more gaseous molecules to generate ceramic nanoparticles. Even

the simple decomposition of gaseous molecules, such as the chlorides and nitrates, usually involves the reaction of the salt with oxygen molecules, as in the following example:

$$SiCl_4 + O_2 \rightarrow SiO_2 + 2Cl_2.$$
This technique can be further divided into flame synthesis and chemical vapor reaction.

Flame Synthesis   Flame synthesis refers to a synthesis in which gaseous reactants react in a flame to produce particles. The flame contains fuel molecules and oxidizing molecules. Flames are exothermal systems, which provide the energy for particle formation. Flame technology is an established industrial process for the manufacture of carbon blacks and ceramic commodities, such as fumed silica, pigment titania, zinc oxides, and alumina powders. The current production volume using this technology is on the order of several million metric tons per year [51]. Pratsinis [52] provided a detailed review of this technology. Fumed silica is synthesized by feeding gaseous $SiCl_4$ together with air and hydrogen into the burner to form a silica aerosol [53]. The silica is separated from the HCl-containing gases by cyclone separators or filters. The specific surface area of fumed silica is 50–380 m^2/g. The particles consist of aggregates of amorphous spherical primary particles up to a few nanometers [54]. Amorphous and δ–Al_2O_3 powders of size 10–200 nm were obtained by reacting $AlCl_3$ vapor in an oxygen–hydrogen diffusion flame [55]. Pratsinis [52] has pointed out that: (1) the role of gas or surface reaction on particle formation and growth in flame synthesis is very important since surface growth favors a much narrower size distribution compared to pure coagulation; (2) the competition between collision and coalescence is responsible for aggregation, and aggregates collide much faster than equivalent spheres; (3) reactant mixing is a critical variable in controlling flame temperature and, subsequently, the chemistry, size, and composition of aggregate and primary particles over a wide spectrum in diffusion flame reactors, which are widely used in industry; and (4) it appears that electric fields across the flame provide one of the best means for precise control of primary particle size and crystallinity—and even aggregate size [56].

Janzen and Roth [57] prepared 4–20 nm single-crystal γ–Fe_2O_3 nanoparticles via a gas-phase route using an $H_2/O_2/Ar$ low-pressure flame. The burner-stabilized flame was doped with different amounts of Fe–pentacarbonyl (Fe $(CO)_5$), with concentrations in the range of 262–2096 ppm. The particles were analyzed *in-situ* according to their mass and charge by a particle mass spectrometer.

The advantages of flame synthesis include: simple oxides easily produced in short residence time; scale up demonstrated for SiO_2, TiO_2, Al_2O_3, and other oxides; and high purity. The disadvantages may include: formation of hard agglomerates under most of the conditions; broad particle size distribution; nonuniform temperature and residence time profiles; and difficulties in producing other particles such as nitrides, borides, and so on.

Kleinwechter et al. [58] have synthesized 4–8 nm ZnO in a low-pressure flame reactor and a microwave reactor in $Zn(CH_3)_2$-doped $H_2/O_2/Ar$ flames and $Zn(CH_3)_2$-doped Ar/O_2 plasmas, respectively.

Chemical Vapor Reactions   Chemical vapor reactions for gas-phase nanoparticle syntheses usually involve a mixture of gas reactants in a reaction chamber, and the chemical reactions among the gas molecules are induced by an input of energy such as resistant heating, laser, and plasma. Chlorides are popular reactants for the formation of both nonoxides and oxides because of their generally low vaporization temperature and low cost. Some of the typical reactions include

$$6\ TiCl_4\ (gas) + 8\ NH_3\ (gas) \rightarrow 6\ TiN\ (solid) + 24\ HCl\ (gas)$$
$$+ N_2\ (gas)\ [59,\ 60]$$

$$SnCl_4\ (gas) + 2\ H_2O\ (gas) \rightarrow\ SnO_2\ (solid)$$
$$+ 4\ HCl\ (gas)\ [61]$$

$$M(\beta\text{–diketonate})_2\ (gas) + H_2\ (gas) \rightarrow M\ (solid\ metal)$$
$$+ 2H((\beta\text{–diketonate})\ (gas)\ [62]$$

$$SiH_4\ (gas) \rightarrow\ Si\ (solid) + 2H_2\ (gas)\ [63].$$
Di Lello et al. [64] synthesized 30 nm AlN nanoscale particles from the vapor phase using ammonia and aluminum chloride vapor as reactants. van der Waals forces and the tendency for surface energy minimization cause the particles to hold together, and what the SEM, in fact, revealed are small particle aggregates. TEM observations, however, confirm the nanoscale nature of such particles, with an average particle size of 30 nm of single crystals.

Jiang et al. [65] prepared Si-based nanopowders from $((CH_3)_3Si)_2NH$ by chemical vapor decomposition (CVD). The powders synthesized at 1000–1500 °C were all amorphous. The particles synthesized were near spherical, with sizes of 8–10 nm. After annealing at high temperatures, the powders synthesized at low temperatures formed whiskers of mainly SiC with a small amount of Si_3N_4, while the powders synthesized at high temperatures formed 20–40 nm particles of mainly β–SiC, with a small amount of α–SiC.

The energy input can be thermal plasma [66, 67], laser [63, 68], or furnace heating [69]. Furnace-heated tubular flow reactors have the advantages of simplicity, easy scale up, and the ability to produce oxides, nonoxides, semiconductors, and metals. The disadvantages include hard agglomeration at high aerosol loading. The primary advantage of a laser-driven process is the production of high-purity products, and its disadvantage is the requirement for complex and expensive systems. The plasma process is unique in its use of high melting point materials and rapid cooling, with the disadvantages of broad particle size distribution and high-energy input.

3.1.3. Aerosol Synthesis

In general, *gas-phase synthesis* refers to those methods where gaseous molecules and atoms are directly converted into nanoparticles through gas-phase reaction [14, 52], condensation, and/or decomposition, nucleation, growth, and possibly agglomeration. However, in an aerosol process, a homogeneous liquid starting material is converted into an aerosol

(i.e., small liquid droplets suspended in gas phase) [70–72]. This aerosol is then converted into solid particles suspended in a gas stream by heating. The aerosol syntheses discussed here are only pseudogas-phase syntheses. These pseudogas-phase syntheses can be further classified into the following two broad types: aerosol pyrolysis and flame–aerosol pyrolysis.

Aerosol Pyrolysis An aerosol pyrolysis process is also called spray pyrolysis [73] or vapor pyrolysis. It consists of three parts: aerosol generation, particle formation inside a furnace, and particle collection, as shown in Figure 1. A homogeneous liquid solution (organic, aqueous, or a mixture) containing the reactants is converted into an aerosol using air, nitrogen gas, or a mixture of gases. The sizes of the droplets formed in the aerosol depend on the types of aerosol generators used, the carrying gas volume, and the nature of the liquid [20, 74]. An ultrasonic generator usually gives very fine droplets that may be suitable for making nanoparticles [73]. The aerosol is then carried by the gas into a preheated furnace, where the liquid droplets go through solvent evaporation, solute precipitation, solute decomposition, and oxide sintering to final particles, as shown in Figure 1. Eventually, the particles are carried out by the gases into a particle collection section, where the particles may be quenched with cold gases and collected by filters or bags (Fig.1).

In order to generate uniform and small droplets of aerosol, the first step of the process is to prepare a uniform solution. In the case of making nano-BaTiO$_3$, the solution contains barium and titanium. This solution can be made from simple inorganic salts such as TiCl$_4$ and BaCl$_2$ [75], or TiCl$_4$ and Ba(NO$_3$)$_2$ [76], in a mixture of water and ethanol. The starting materials can also be a mixture of Ti alkoxides and barium salts such as Ba(NO$_3$)$_2$ in a mixture of water and alcohols [77, 78]. The sources of titanium and barium have also been tried with both organometallic compounds such as titanium alkoxides with barium acetate [78] and titanium lactate and barium acetate [79].

The different starting materials affect the BaTiO$_3$ formation mechanism and the characteristics of the BaTiO$_3$ formed. TiCl$_4$ has a strong tendency to dissociate and hydrolyze according to the following solution reaction, in a bulky solution or in aerosol droplets [75]:

$$TiCl_4 + H_2O \rightarrow TiO^{2+} + 2H^+ + 4Cl^- \rightarrow TiOCl_2 + 2HCl.$$
Figure 1. Schematic representation of an aerosol pyrolysis process.

When the droplets are carried into the furnace, the solvent begins to evaporate, and further hydrolysis occurs according to

$$TiO^{2+} + (x+1) H_2O \rightarrow 2H^+ + TiO_2 \cdot xH_2O$$

or

$$TiOCl_2 + (x+1) H_2O \rightarrow TiO_2 \cdot xH_2O + 2HCl.$$

Upon further heating [77],

$$TiO_2 \cdot xH_2O \xrightarrow{\sim 380\ °C} TiO_2 \text{ (anatase)} + x \cdot H_2O.$$

If BaCl$_2$ is involved,

$$BaCl_2(s) + TiO_2 \text{ (anatase)} + H_2O(g) \rightarrow BaTiO_3(s) + 2HCl.$$
If Ba(NO$_3$)$_2$ is used, the above reaction may also be involved due to the formation of BaCl$_2$:

$$Ba(NO_3)_2 + 2HCl \rightarrow BaCl_2 + 2HNO_3.$$
The following reaction has also been reported:

$$Ba(NO_3)_2 + TiO_2 \text{ (anatase)} \xrightarrow{540-650\ °C} BaTiO_3(s) + 2NO_2 + \frac{1}{2}O_2.$$
On the other hand, BaO is formed if organic barium sources are used [78]:

$$Ba(CH_3COO)_2 + 4O_2 \xrightarrow{600\ °C} BaO + 4CO_2 + 3H_2O$$

$$BaO + TiO_2 = BaTiO_3.$$
Ogihara et al. [78] obtained dense spherical BaTiO$_3$ of 930 nm using Ti(iso-OC$_3$H$_7$)$_4$ and Ba(CH$_3$COO)$_2$, while hollow spherical BaTiO$_3$ was produced using Ti(iso-OC$_3$H$_7$)$_4$ and Ba(NO$_3$)$_2$ using aerosol pyrolysis at 900 °C. They contributed such a difference in the BaTiO$_3$ due to the fact that reaction (9) occurs much more easily than reactions (5) and (7) at temperatures below 700 °C.

Milosevic and co-workers [75] produced 530 nm BaTiO$_3$ by aerosol pyrolysis of an ethanol/water solution of BaCl$_2$ and TiCl$_4$ using an ultrasonic atomizer. Cho et al. [76] prepared BaTiO$_3$ of size 300–900 nm by ultrasonic aerosol pyrolysis of solutions containing Ba(NO$_3$)$_2$ and TiCl$_4$.

BaTiO$_3$ particles were prepared in our laboratory using Ti isopropoxide and barium acetate in an aerosol pyrolysis process, as shown in Figure 2 [80], where particles of 50–600 nm were obtained. These particles are tetragonal in crystal structure, with a Ba/Ti ratio of 0.9999.

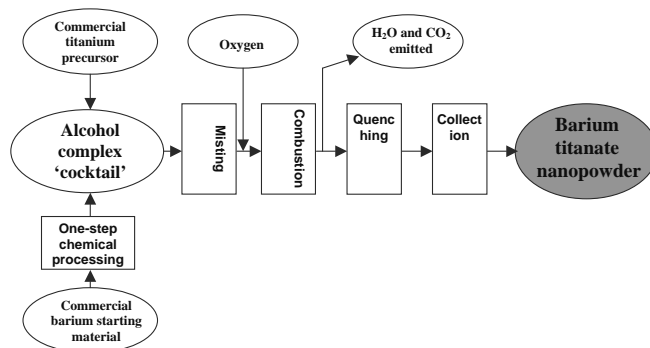
At issue in aerosol processes is the extent of agglomeration (particle adhesion) and aggregation (particle sintering), the latter referring to clusters of primary particles being cemented together by interparticle necks. While it is virtually impossible to eliminate the agglomeration of pristine nanopowders due to the strong van der Waals forces of attraction that keep the particles together, aggregation can
Figure 2. BaTiO₃ made from an aerosol pyrolysis process [80].

Figure 3. Flowchart of a flame–aerosol pyrolysis process [83].

be restricted by controlled powder synthesis. Singhal et al. [81] developed a vapor-phase synthesis method, called combustion flame/chemical vapor condensation. It involves the pyrolysis of chemical precursors in a low-pressure flat flame, and is used to produce nanoparticles of TiO_2 and Al_2O_3. Nanoparticles of oxides that have an average secondary particle size of approximately 100 nm, and an average primary particle size less than 25 nm, were produced by controlling the time–temperature history of the particles in the hot zone of the flame.

In aerosol processes, it is important to analyze how the gas-phase molecules react, nucleate, agglomerate and sinter, and how these steps control the size distribution and morphology of particles. Nakaso et al. [82] studied the thermal decomposition of titanium tetraisopropoxide and oxidation of $TiCl_4$ by using a laminar-flow aerosol reactor. The effect of reaction temperature on the size and morphology of the generated particles was investigated under various conditions. The size distributions of agglomerates were measured using a differential mobility analyzer/condensation nuclear counter system. The growths of both agglomerates and primary particles were modeled simultaneously, using a two-dimensional discrete-sectional representation of the size distribution.

The advantages of aerosol pyrolysis for nanoparticle making include: (1) high purity, (2) spherical particles, (3) an easy and quick one-step process, and (4) minimal agglomeration. The disadvantages are: (1) a large size distribution, as shown in Figure 2, (2) the necessity of a large amount of carrying gas dilution in order to reduce agglomeration and aggregation, (3) low production rates, and (4) difficult scale up.

Flame–Aerosol Pyrolysis Flame–aerosol synthesis is a process in which an aerosol of starting materials is burned in a flame [73]. A flowchart of a flame–aerosol pyrolysis is shown in Figure 3 [83]. The chemistry in a flame–aerosol system is similar to that described for an aerosol pyrolysis process. The differences include the source of heating: flame–aerosol is heated by the burning of the fuel gases and organic solvents which are in direct contact with the precursor materials. The heating in an aerosol process is usually external and indirect by resistance heating or gas heating


through a heat-conducting wall. The burning of the fuels in a flame process directly affects the product's oxidation states and purity, while the heating source in an aerosol process does not introduce impurity into the final products, except that contamination may come from the heat-conducting walls.

Brewster and Kodas [84] have demonstrated the formation of chemically pure, crystalline (primarily tetragonal with hexagonal and cubic polymorphs), and unagglomerated dense BaTiO₃ particles of about 1400 nm by flame–aerosol of a 0.5 M solution of barium acetate titanium lactate and water at a flame temperature of >1500 °C (adiabatic).

These aerosol synthesis methods, aerosol pyrolysis and flame–aerosol pyrolysis, have produced BaTiO₃ particles less than 100 nm. The BaTiO₃ particles in Figure 2 also show broad particle size distributions. In general, these aerosol syntheses can produce spherical particles with clean surfaces, desired Ba/Ti ratio control, and good crystallinity via a continuous process. There are many reported studies in which nanoparticles of a few nanometers are produced [52, 74, 85–87]. In many cases, these are academic studies involving the collection of a few particles on a TEM grid. These nanoparticles are extremely reactive, and agglomerate quickly into large particles in an industrial collection system. The industrial process for producing large quantities of particles of nanosizes may require such a large dilution of the particle stream with the carrying gas as to make this process inefficient. The scale up to the production of tonnage quantity for the flame–aerosol process is much easier than for that of aerosol pyrolysis. In general, it is extremely challenging to make unagglomerated particles with a narrow size distribution.

3.2. Liquid-Phase Synthesis

Liquid-phase syntheses are the most common and diverse methods for nanoparticle synthesis. The critical particle formation step occurs in the liquid phase; however, under supercritical conditions, the particle formation phase is at both the liquid and gas phase since there is no distinction between gas and liquid under those conditions. The most common solvent is water, but more and more organic solvents are also used in an effort to reduce the agglomeration of nanoparticles. Common to all of the liquid-phase syntheses is that they begin with solution preparation. A true solution means homogeneity at the atomic or molecular scale.

The central goal for the diverse solution synthetic methods is to preserve as much of this homogeneity as possible in the particle formation process.

Liquid-phase syntheses are generally wet-chemical solution syntheses, sometimes called soft solution-processing routes. There is an increasing role that solution synthesis plays in the preparation of ceramic powders, particularly nanometer-sized particles with controlled size and morphology [88]. Wet-chemical processes have been widely recognized as an efficient approach to prepare nanocrystalline fine particles at low temperatures. In relation to other methods such as vapor-phase synthesis and physical methods (such as laser ablation and electron beam evaporation), major advantages of the liquid-phase synthesis include: (1) the process can be scaled up easily due to its bulk-processing nature; (2) the process is more controllable because chemical reactor technologies developed for chemical synthesis may be adapted and applied to the production of nanoparticles; (3) some processes require only mild conditions such as low temperature and atmospheric pressure; (4) the chemical composition of nanoparticles can be tailored in a liquid phase; (5) in the liquid phase, surface-controlling agents can be applied during and after nanoparticle formation to control the size and prevent unnecessary agglomeration; and (6) monodispersed nanoparticles can be made in the liquid phase via a homogeneous nucleation, growth, and aggregation mechanism. Uniform particle size is extremely important to nanoparticle self-assembly-based systems.

Wet-chemical syntheses are particularly suited to the synthesis of nanoparticles (solid, core–shell, or hollow) with tightly controlled parameters, such as: (1) the size and shape, (2) the monodispersity, (3) the chemical composition and purity, (4) the bulk substructure, (5) the crystallinity (polycrystalline, single crystalline, or amorphous), (6) the surface functional group (thus, the interfacial free energy and surface-charge density), (7) the shell-layer thickness in a core–shell nanoparticle, or even (8) the size and shell thickness of a hollow sphere particle. For ceramic processing, the above characteristics of nanoparticles will affect the processing behavior, as well as the properties of the final, casted, sintered ceramic materials.

The use of "nanoparticle(s)" as a popular technical term in the literature of wet-chemical synthesis of truly nanosized (i.e., <100 nm in particle size or crystallite size) ceramic particles did not appear until less than a decade ago. However, research on ultrafine, monodispersed colloid particles has been conducted as a major goal of colloidal science since the beginning of the 20th century. Some excellent review articles on monodispersed particles can be found [89, 90–94]. Colloids are typically defined as particles with a particle size ranging from 1 nm to 1 μm, which is more or less defined by the importance of Brownian motion. Colloidal particles, (hydrous) oxides in particular, have long been utilized as models or tools in scientific research; applied in fields such as drug delivery, biodiagnostics, and combinatorial synthesis; and used as the major components of industrial products such as paints, ink, foods, cosmetics, coatings, catalysts, pigments, papers, photographic films, recording materials, films, and rheological fluids. Some of these monodispersed

colloid studies have indeed produced nanosized monodispersed particles.

Major synthesis methods for ideal ceramic nanoparticle formation in the liquid phase depend on "controlled precipitation" or "homogeneous precipitation" reactions involving sequential nucleation and growth processes. As a general rule, a homogeneous solution system (consisting of ideally one phase where the monomer reservoir is normally built in the form of a solute) is necessary for generating uniform-size nanoparticles. Reactions belonging to this category include [94]: (1) the redox reaction, (2) precipitation by poor solvents, (3) direct reaction of ions, (4) reaction of chelates, (5) decomposition of compounds, (6) hydrolysis in organic media, and (7) hydrolysis in aqueous media. The particle growth process can be either by *molecular diffusion/addition* to the nuclei surface or by a *particle aggregation* mechanism, both of which have been demonstrated to generate monodispersed particles [95–99]. To obtain uniform particle size in a diffusional growth process, the nucleation stage must be separated from the particle growth stage. Seeding is one approach to achieve the separation of nucleation from growth.

In addition to the desirable goal of monodispersed particles, anisotropic particles are also strongly needed for important applications, such as the fabrication of composite materials and flat panel optical displays. Control of the size distribution, shape, and aspect ratio is a complex process requiring a fundamental understanding of the interactions among solid-state chemistry, interfacial reactions and kinetics, and solution chemistry [100].

Regardless of the methods used, achieving homogeneous reaction or precipitation in homogeneous solutions is the key to producing uniform colloids or nanoparticles (either isotropic or anisotropic). Precipitation of alkoxide solutions and forced hydrolysis of some metal salt solutions surely satisfy the "homogeneous" criteria. Enough attention has been paid to the preparation of "ideal" sinterable ceramic nanopowders with improved densification properties compared with conventionally derived ceramic powders. In most literature studies of nanoparticle synthesis, particle size may not be monodispersed (due to the broad range of particle size distribution). The wet-chemical synthesis methods that have been reported so far in the recent literature to produce ceramic (oxide or hydrous oxide) nanoparticles or nanocrystalline powders can be mainly classified as chemical precipitation and coprecipitation, hydrothermal synthesis, forced hydrolysis, sol–gel synthesis, synthesis in microemulsion or reverse micelles, solvothermal synthesis and nonhydrolytic routes, microwave heating-assisted synthesis, sonochemical synthesis, electrochemical synthesis, and synthesis in supercritical fluids. Historically, the above-mentioned methods have been developed or studied for ultrafine ceramic particle synthesis. However, the majority of studies on these methods for the synthesis of truly nanosized particles appeared well within the last decade. In the following sections, each synthesis method will be reviewed and discussed, with a focus on its application in ceramic (oxide and hydrous oxide) nanoparticle or nanopowder production.

3.2.1. Chemical Precipitation and Coprecipitation

Chemical, or reactive, precipitation can be generally described by the solid phase formation from reactions of soluble reactive species (M_1, M_2, A) in a solution (aqueous or nonaqueous)

$$M_1(aq) + A(aq) \rightarrow M_1A(s)$$
where M_1 is a metal cation species and A (aq) represents an anion species from a precipitating agent such as NH_4OH, NaOH, carbamate ($NH_2CO_2NH_4$), H_3PO_4, etc. When more than one metal cation species is involved, for example, a second metal species, M_2(aq), could be coprecipitated

$$M_1(aq) + M_2(aq) + A(aq) \rightarrow M_1M_2A(s)$$
If A(aq) happens to be oxygen or a hydroxyl group, M_1A (s) will be a single metal oxide or hydrous oxide, while M_1M_2A (s) represents a mixed metal oxide.

A chemical precipitation process consists of three main steps: chemical reaction, nucleation, and crystal growth. Chemical precipitation is generally not a controlled process in terms of reaction kinetics and the solid phase nucleation and growth processes. Therefore, solids obtained by chemical precipitation have a wide particle size distribution plus uncontrolled particle morphology, along with agglomeration. In the preparation process of particles via reactive precipitation ($A + B \rightarrow P$), the chemical reaction is so fast that a high degree of supersaturation of the product solute P will be achieved in local sites in the reactor. This causes the nucleation to be dominated by homogeneous nucleation mechanisms, where the value of the power order in the nucleation rate expression equation can be in the range of 5–18 or so. Any tiny variation of the supersaturation of product P will lead to a significant change in the nucleation rate because of this high value of powder order. However, because of its simplicity, rapid solid formation kinetics, and bulk processing capability, chemical reaction is still a viable option for nanoparticle production as long as strategies are considered for controlling the kinetics (reactions between ions), reaction uniformity, and agglomeration. To obtain nanoparticles with a narrow size distribution, one should do as much as possible to meet the requirements of: (1) a high degree of supersaturation, (2) a uniform spatial concentration distribution inside a reactor, and (3) a uniform growth time for all particles or crystals [101].

Recently, chemical precipitation and coprecipitation have been reported in the active literature for nanoparticle synthesis. Table 1 summarizes some of the major research work on chemical precipitation of (hydrous) oxides, and Table 2 for chemical coprecipitation of mixed oxides. Most of the chemical precipitation processes are conducted in aqueous solutions, but a few are in nonaqueous solutions.

Zhou et al. [102] used NH_4OH to precipitate cerium nitrate at room temperature. They tried to obtain a high value for the supersaturation ratio (S), in order to establish an environmental condition that favors homogeneous nucleation, which typically results in the "burst" formation of uniform nuclei with a critical size which can be calculated from

$$r^* = 2\nu\gamma/[k_BT \ln(S)]$$

where ν = molecular volume of the precipitated embryo (m^3), γ = surface energy (J/m^2), k_B = Boltzmann's constant (J/K), T = temperature (K), and S = supersaturation value.

A three-stage process was developed to produce ZnO nanoparticles [103], involving: (1) the formation of metastable zinc complexes through a slow addition of ammonia; (2) the partial phase transformation of metastable zinc precursors to zinc oxide after washing the initial colloidal suspension with ethanol, Zn–OH (s) + $C_2H_5OH(l)$ → Zn–O–C_2H_5(s) + $H_2O(l)$; and (3) the complete transformation to ZnO by thermal treatment. The main strategy used is the *controlled release of cations* from a homogeneous suspension.

Water-soluble polymeric dispersants, such as poly (N–vinylpyrrolidone) (PVP), polyvinyl alcohol (PVA), and polyacrylic acid (PAA), have been utilized as stabilizers in chemical precipitation to prevent particle coagulation/agglomeration and to control size. Zhang and Guo [104] prepared antimony oxide nanoparticles by a refluxing reaction between $SbCl_3$ and NaOH in the presence of PVA: $Sb^3 + OH^- \rightarrow Sb_2O_3 + H_2O$. Rasmussen et al. [105] precipitated nanoscale aluminum hydroxide particles from sodium aluminate solutions by dilution and neutralization with water and oxalic acid in the presence of the surface-active polymers PVP and PVA. In the wet-chemical precipitation of needle-shaped hydroxyapatite nanocrystals, Bouyer et al. [106] used the following reaction

$$10Ca(OH)_2 + 6H_3PO_4 \rightarrow Ca_{10}(PO_4)_6(OH)_2 + 18H_2O$$
In precipitating europium oxide nanoparticles with NaOH, trioctyl phosphine oxide (TOPO) was used for the following three possible reasons [107]: (1) it prevents particle agglomeration (via steric passivation), (2) it achieves electrical passivation of surface dangling bonds (trap states); and (3) it controls particle size at the nanometer level. Chen and Chen [108] used PAA in the coprecipitation of strontium ferrite nanoparticles (34–41 nm for calcined powders). Pardoe et al. [109] used dextran and PVA in the coprecipitation of nanoscale iron oxide particles by ammonia.

Some chemical precipitation of nanoparticles was conducted in nonaqueous background solutions. Carnes et al. [110] attempted an "alkoxide-based" synthesis involving the NaOH precipitation of metal chloride in ethanol background solutions. Chemical precipitation produces metal hydroxide solids which are converted to oxides by heating. Wakefield et al. [107] precipitated europium oxide by NaOH in a methanol background solution. Meulenkamp [111] prepared ZnO nanoparticles by the dropwise addition of LiOH (dissolved in ethanol) into an ethanolic zinc acetate solution under vigorous stirring at 0 °C. The presence of a small, but strictly limited, quantity of water (from the acetate salt) appeared necessary to warrant good particle growth. Manorama et al. [112] coprecipitated $SnCl_4$ and copper

Table 1. Nanoparticle synthesis by chemical precipitation.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Applications	Ref.
CeO_2	4–5 nm, round-shaped, single crystals	Room-temperature homogeneous nucleation; cerium nitrate solution was added into aqueous NH_4OH precipitant	Raman-allowed modes shifting and broadening; pressure-induced phase transformation	[102]
CuO, NiO	7–9 nm CuO and 3–5 nm NiO crystallites, aggregate to form larger spherical particles	Precipitated by NaOH in ethanol background; "alkoxide-based" synthesis involving metal chlorides, ethanol, and water	CuO: in catalysis, metallurgy, high-temperature superconductors; NiO: electronic/magnetic properties, catalysis, p-type semiconductor	[155]
ZnO	~1 μm particle self-assembled with nano-crystals Microspheres consisting of aggregates of nanoscale (10–15 nm) rod-shaped primary particles 2–7 nm clean sol	Acidified zinc acetate aqueous solution titrated with NH_4OH solution to pH 9 Ammonium carbamate as a precipitating agent; flow injection synthesis Addition of LiOH (in ethanol) to an ethanolic zinc acetate solution	Pigments, rubber additives, gas sensors, varistors, transducers; used in photocells, as UV-absorbing material, in sunscreen lotions, as insulator, light-emitting diodes, ceramics, ion-insertion batteries, electrochromic devices	[103, 117, 111]
Sb_2O_3	10–80 to 200 nm sizes, polyhedral-shaped, polycrystalline cubic phase	Reaction between $SbCl_3$ and NaOH in the presence of polyvinyl alcohol in water solution	Flame retardants; optic materials; high proton conductivity; humidity-sensing materials	[104]
Fe_2O_3	Spherical-shaped nanoparticles	Ammonium acetate as precipitating agent	Magnetic materials	[95]
$Al(OH)_3$	80–300 nm in PVP; 200 nm–1.2 μm in PVA Nanofibrils (1–10 nm in diameter and 50–300 nm in length)	Oxalic acid as precipitating agent High-gravity reactive precipitation	Bayer process Nanocomposites, pharmaceutics	[105, 101]
Hydoxyapatite	Needle-shaped, aspect ratio (= length/width) = 2–10	$Ca(OH)_2$ precipitated by H_3PO_4, 25–85 °C	Bioceramic for biomedical applications such as bone substitute	[106]
Eu_2O_3	2–40 nm, passivated with trioctyl phosphine oxide (TOPO)	At room temperature; precipitation of $EuCl_3$ by NaOH in a methanol background solution in the presence of TOPO	Luminescent phosphors for flat-panel displays based on field-emitting arrays	[107]
$In(OH)_3$	Multiple morphology precipitates which were peptized into 80–8000 nm powders (round-shaped) Uniform colloidal rod-like particles (aggregates of nanosize subunits)	Hydrolysis of indium chloride in EG/aqueous NaOH solutions, plus peptization Controlled double-jet precipitation	Semiconductor and optical properties	[114, 118]
$CaCO_3$ or $SrCO_3$	$CaCO_3$ (17–36 nm particle size) $SrCO_3$ (~40 nm particle size)	High-gravity reactive precipitation	In many industries such as electronics, opticals, pulp and paper, pharmaceutics, etc.	[101]

Table 2. Nanoparticle synthesis by chemical coprecipitation.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Applications	Ref.
Strontium ferrite ($SrFe_{12}O_{19}$)	3.1 nm for mixed hydroxide precipitates; 34–41 nm for calcined powder	Polyacrylic acid (PAA) sodium salt used as protective agent; NaOH added to the mixed aqueous solution of PAA and corresponding nitrates salts	Magnetic material with high coercivity	[108]
Barium ferrite ($BaFe_{12}O_{19}$)	4.5 nm for precipitate precursor; 23–82 nm for calcined powder	Same as above		[282]
$LiMn_2O_4$	<100 nm crystal size, agglomerated for the calcined powder	Mn and Li acetate salts dissolved in citric acid were precipitated by NH_4OH	Cathode material for lithium rechargeable batteries	[115]
$Ba_2Co_2Fe_{28}O_{46}$	10–25 nm grain size	Nonaqueous coprecipitation by cooling the mixed metal salt solution/sol (in stearic acid background) from 80–100 °C to ambient temperature to gel	Magnetic material with unique phenomena such as superparamagnetism and quantum tunneling of magnetization	[116]
Fe_3O_4	6–8 nm particle size and 1–6 nm crystal size, surfactant (Na oleate) coated	Iron source (Fe^{3+} and Fe^{2+}) was added dropwise into alkali source (NaOH) under vigorous mechanical stirring; complete precipitation ~pH 7.5–14 while maintaining $Fe^{2+}/Fe^{3+} = 1/2$ under nonoxidizing environment	Magnetic material, ferrofluids, biomedical and diagnostic applications, MRI contrast agents	[283]
	Cluster- and necklace-like chain aggregates (~100–200 nm length)	Coprecipitation of Fe(III) and Fe(II) by NH_4OH in the presence of polymer-dispersant PVA or dextran		[109]
	PVA coated (oxide core 5–10 nm, 108–155 nm outside PVA shell)	Coprecipitation of Fe(III) and Fe(II) by NH_4OH in the presence of polymer-dispersant PVA		[284]
	5 nm stable uncoated nanoparticle	Precipitation of an aqueous solution of iron salts by tetramethylammonium hydroxide (TMAOH)		[285]
	1.5–12.5 nm particle size, free from polymer, surfactant, or ligands	Using NaOH, NH_3, or $N(CH_3)_4OH$ to precipitate, adjusting pH and ionic strength to control particle size		[286]
Sb-doped SnO_2	4–9 nm particle size, spherical to ellipsoidal shaped, tend to form string-like agglomerates	$SnCl_4$ dissolved in HCl, $SbCl_3$, and $SbCl_5$ was added, dropped into cold water, and precipitated by aqueous ammonia until pH 3–4 was reached	High n-type conductivity, high absorption coefficient in the NIR and IR regions (thus high reflective for IR radiation); applications in photovoltaic and optoelectronic devices, flat-panel displays	[287]
CuO-doped SnO_2	3–5 nm crystallite size	"Alkoxide-like" hydrolysis: copper acetate added into mixture of equal molar solution of $SnCl_4$ in water and ethanol, aged at 50 °C to precipitate	Catalyst for the oxidation of organics, solid-state sensors for reducing gases, transparent conductive thin-film coatings	[112]
Spinel ferrite $MgFe_2O_4$	A few nanometer to 20 nm grain size	Aqueous solutions of $FeCl_3$ and $MgCl_2 \cdot 6H_2O$ precipitated by NaOH solution, digested in boiling water, washed until pH neutral	Superparamagnetism; magnetic resonance contrast agents, high-density information storage, ferrofluids, magnetocaloric refrigeration	[288]
In-doped $CaZrO_3$	Powder with nanocrystallites	$(NH_4)_2C_2O_4 \cdot H_2O$ as coprecipitating agent	High-proton conduction in atmosphere containing water at high temperature; as electrolyte in solid-state electrochemical devices	[289]
ZrO_2(3Y)	Powder, 11–15 nm particle size, with weak agglomeration	Heating of $ZrOCl_2$ and $Y(NO_3)_3$ solution with an alcohol–water mixture, plus NH_4OH as precipitating agent and PEG as dispersant	High strength and toughness for structural ceramics	[290]

acetate to obtain CuO-doped SnO_2 via "alkoxide-forming" reactions in the presence of ethanol:

$$SnCl_4 + 4C_2H_5OH \rightarrow Sn(-OC_2H_5)_4 + 4HCl$$

$$Sn(-OC_2H_5)_4 + 4H_2O \rightarrow Sn(OH)_4 + 4C_2H_5OH$$

$$Sn(OH)_4 \rightarrow SnO_2 + 2H_2O.$$
Sen et al. [113] prepared ferrite nanoparticles by a nonaqueous precipitation route: a homogeneous solution of stearic acid and iron (III) nitrate was treated with tetrahydrofuran to obtain precipitates.

In some cases, chemical precipitation will generate large micrometer-size precipitates. Upon *peptization*, however, precipitates will be converted into nanosize particles. For example, Perez-Maqueda et al. [114] have prepared nanosize (as small as 80 nm) indium hydroxide by the peptization of colloidal precipitates. Precipitation was accomplished by the dropwise addition of an aqueous NaOH solution into indium chloride dissolved in ethylene glycol (EG) at 175 °C. For the peptization, the colloidal precipitate was washed to eliminate the EG, and then dispersed in distilled water (or isopropanol) in an ultrasonic bath. Organic solvents such as ethanol or EG have a significant effect on the shape and other properties of particles obtained by precipitation. Thus, mixed solutions of ethanol and water or EG and water have been utilized as a strategy to produce colloidal oxides of different morphologies. EG offers two useful advantages: (1) a high dielectric constant, which enhances the solubility of inorganic salts; and (2) a high boiling point (195 °C at atmospheric pressure), which makes it possible to carry out the preparation of inorganic compounds at relatively high temperatures using an open vessel.

For coprecipitation of multiple cations, the use of complexing or chelating agents seems important for controlling the chemical stoichiometry of the precipitated solid. Hwang et al. [115] used citric acid in the coprecipitation of Mn and Li by NH_4OH. Xiong and Mai [116] used stearic acid to dissolve mixed Ba, Co, and Fe salts at high temperature to prepare a sol, which precipitated to form a gel upon cooling.

In addition to chemical strategies, such as using dispersants and the controlled release of reactants, *engineering approaches* have been integrated into the chemical precipitation process to achieve bulk processing and homogeneous precipitation. Wang and Muhammed [117] used a flow injection synthesis (FIS) technique to prepare ZnO nanoparticles with rod-shaped morphology via precipitation by carbamate

$$5ZnCl_2 + 5NH_2CO_2NH_4 + 8H_2O \rightarrow Zn_5(OH)_6(CO_3)_2(s)$$
$$+ 3CO_2(g) + 10NH_4Cl$$
The solid precipitate decomposes upon calcination to ZnO:

$$Zn_5(OH)_6(CO_3)_2(s) \rightarrow 5ZnO + 2CO_2 + 3H_2O.$$
FIS borrowed the concept from the flow injection analysis (FIA) method in analytical chemistry. In an FIS process, a precise volume of reactant-containing solution is swept along by the carrier stream into the system. The main advantage of the FIS technique is that the precipitation process is only allowed to continue for a limited period of

1–2 min. The chemical reaction commences at the moment the solutions are mixed, and precipitation takes place and is complete in a confined zone. In this way, agglomeration is greatly limited since the short residence time allows only primary nucleation. The mixing of solutions *A* and *B* can be performed under reproducible conditions, and thus, powders with identical properties can be obtained. Chen et al. [101] have demonstrated a high-gravity reactive precipitation (HGRP) technology to produce nanoparticles of $CaCO_3$, $Al(OH)_3$, and $SrCO_3$ with a very narrow size distribution and a controlled morphology. Per chemical engineering analysis, micromixing (mixing on the molecular scale) and macromixing (mixing on the macro scale) have a significant effect on particle size distribution (PSD) in a reactive precipitation process. Micromixing is a key factor determining the degree of the supersaturation concentration of the solute and its local spatial distribution. The reaction rate and subsequent nucleation in precipitation will be controlled by the intrinsic kinetics without the influence of micromixing in the region of $t_m < \tau$, where t_m is the micromixing time and τ is the induction time, defined as the time from the first creation of the conditions for homogeneous nucleation to that of the establishment of a steady-state nucleation rate. The region $t_m < \tau$ should be chosen such that the rates of nucleation at different locations in a precipitator will be nearly the same, and so the PSD can be controlled at a uniform level. On the other hand, micromixing has little effect on crystal growth. Therefore, a rule for selecting a precipitation reactor is: a combination of a well-micromixed plug flow reactor (to separate the reaction and nucleation zones from the crystal growth zone) and a well-macromixed reactor (to locate crystal growth in a well-macromixed region). High-gravity technology in the form of a rotating packed bed of the earth is ideal to satisfy the above rule because it is effective in intensifying mass transfer, and is helpful in the generation of higher supersaturated concentrations of the product in the gas–liquid-phase reaction and precipitation process. Another engineering process, controlled double-jet precipitation (CDJP), has also been successfully utilized to produce uniform colloidal rod-like $In(OH)_3$ particles (aggregates of nanosize subunits) from relatively concentrated solutions [118]. Her and co-workers [119–123] have used CDJP to prepare colloidal spherical particles of SiO_2, $Al(OH)_3$, CuO, and $BaTiO_3$ of narrow size distributions. They [123] mixed $TiCl_4$ directly with 6 M NaOH/KOH to form $BaTiO_3$ at 85 °C within 3 min with the ability to control particle size between 70 and 400 nm. The optimum condition identified was pH 14, 85 °C, and with 0.1% cyclodextrin. The $BaTiO_3$ had a cubic structure with dielectric constants up to 18,000. They also established a growth mechanism for the uniform colloid formation under the CDJP condition [121]: nanosized primary particles formed immediately after mixing the reactants, followed by aggregation into larger uniform particles.

3.2.2. Hydrothermal Synthesis

"Hydrothermal process" (also called thermal hydrolysis or hydrothermal hydrolysis process) generally refers to processing aqueous solutions of metal salt(s) (metal and/or metallorganic) or autoclaving of precursor materials such as gels

at elevated temperatures (typically 100–300 °C) and pressures above 1 atm. In this method, ceramic sols are produced by chemical reactions in an aqueous or organoaqueous solution under the simultaneous application of heat and pressure in the presence of an alkali or acid that has a pseudocatalytic effect upon the reaction [124]. The reaction equilibrium of a metal salt aqueous solution changes with temperature, which results in the formation of metal hydroxide or metal oxides. Mineralization in nature, which has resulted in deposits and rocks, could have occurred by a hydrothermal process. In the laboratory, hydrothermal synthesis is typically used with a batch-type autoclave, in which an aqueous solution is heated up slowly to the target temperature, and then aged for several hours or days.

Hydrothermal synthesis has been considered a cost-effective and less complicated synthesis technique, suitable for large-scale production. There has been a trend to develop "mild hydrothermal processes" (100 °C $\leq T \leq$ 200 °C, under autogenous pressure) for the synthesis of advanced ceramic powders, extending from zeolites and metal phosphates to binary and ternary transition metal oxides [125]. The low-temperature technique is critical to the formation of metastable phases not obtainable using traditional high-temperature methods. Process parameters, such as the pH of the reaction medium, temperature, and the cations in solution, determine what solid phases are formed. Cations such as medium-size spherical organic cations (e.g., tetramethyl ammonium) and large surfactants may act as the structure-directing species or template for the synthesis of nanoporous or mesoporous (2–50 nm) materials.

By changing the conditions of the solutions (pH, ionic strength, surfactant concentrations, cation concentrations, anion concentrations, and solvents) and processing conditions (temperature, duration, and stirring), one can effectively control the nanoparticle size and shape, and the extent of agglomeration. Nanoparticle CeO$_2$ can be made in different sizes and shapes by changing these reaction conditions [126], as shown in Figure 4.

Synthesis under hydrothermal conditions offers some significant advantages over other chemical synthesis techniques [124]: (1) it is easy to control particle size and morphology by varying synthesis conditions; (2) many materials can be synthesized directly in the desired crystalline phase at low temperature (hydrothermal synthesis offers a low-temperature, direct route to ultrafine oxide powders with a narrow size distribution, avoiding the calcination step required in sol–gel processing); and (3) the resulting sols can be used directly in the production of green bodies via pressure filtration or extrusion.

There is an enormous amount of literature on the hydrothermal processing of inorganic materials such as ceramic powders. Zeolite nanoparticles are a classic example of hydrothermal synthesis [127]. Here, we only focus on a review of the most recent work on the synthesis of true nanosize oxide particles (see Table 3).

Hydrothermal synthesis can also be conducted in the presence of other nonaqueous additives or solvents. Dong and Zhu [128] prepared α–Fe$_2$O$_3$ nanoparticles by dropping a mixture of ethylene oxide (EO) and ethanol into an aqueous
Figure 4. CeO$_2$ nanoparticles made from hydrothermal process [126].

solution of FeCl$_3$, followed by aging and heating at 200 °C and the completion of phase transformation at 300 °C

$$FeCl_3 + 3H_2O \rightarrow Fe(OH)_3(s) + 3HCl(hydrolysis)$$

$$Fe(OH)_3 \rightarrow \beta\text{–}FeOOH \rightarrow \alpha\text{–}Fe_2O_3(\text{phase transformation})$$
In this process, ring-opening polymerization of EO may take place with FeCl$_3$ as a catalyst or with iron alkoxide as an intermediate, which can be formed by the reaction of ethylene glycol with FeCl$_3$ or of EO with FeCl$_3$. Also, the possible byproduct of ethylene glycol may effect the prevention of Fe(OH)$_3$ nanoparticle agglomeration.

In contrast to "mild hydrothermal synthesis," synthesis under high temperature and pressure, as found in supercritical water conditions, also shows promise for the continuous and rapid production of nanocrystals [129].

3.2.3. Forced Hydrolysis

This method can be essentially considered a subcategory of the hydrothermal synthesis process at a relatively low-temperature range and using inorganic salt solutions, which are usually diluted (10^{-4}–10^{-2} M). In this method, aqueous metal salt solutions are aged (hydrolyzed) at elevated temperatures (usually over the range 80–100 °C per Matijevic [92] and 50–150 °C per Sugimoto [94]) for different periods of time, depending on the hydrolysability of the cation in question. Forced hydrolysis takes advantage of the ability of many metals ions (especially of polyvalent cations) to readily hydrolyze in aqueous solutions at elevated temperatures.

Table 3. Nanoparticle synthesis by hydrothermal synthesis.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Applications	Ref.
Mullite ($3Al_2O_3 \cdot 2SiO_2$)	55 nm–7.1 μm particle size, irregular shaped	Mixture of TEOS and Al tri-sec-butoxide, 170 °C 2 h	Monolithic or fiber-reinforced mullite components for high-temperature applications	[124]
Boehmite (γ–AlOOH)	Needle-like particles from low-pH acid solution; platelet-shaped particles (40 nm diameter and 5 nm thickness) from high-pH alkaline conditions	Sols prepared from dispersion Al acetate, then autoclaved at 200–300 °C	Precursor for preparing high-purity and high-strength monolithic α–alumina ceramics by sol–gel technology, applications as substrate for electronic circuits, abrasive grains, high-temperature refractory materials, fibers and thin films; fillers in plastics and polymers, adsorbents and catalysts	[124]
	≤100 nm nearly monodispersed microcrystals of boehmite with a parallelogram shape	Prepared from amorphous hydrated alumina gels at 255 °C for 24 h		[291]
ZrO_2	20–60 nm particle sizes, near spherical shape	Zr acetate solution heated to 220 °C to produce a sol	Structural and functional ceramics; application as pump parts, engine parts, pressing dies, refractories, oxygen sensor in molten steel,	[124]
Yttria-doped zirconia	~45 nm tetragonal 3mol% Y_2O_3-doped ZrO_2 powder (uniform aggregates) ~95 nm grain after sintering	Sol from ammonia-precipitated gel (containing both Zr and Y) + urea, heated at 150 °C, followed by a washing–drying and calcination	for ceramic fiber coating, solid electrolyte	[292]
TiO_2 doped with ZrO_2	9–13 nm crystallite size	Direct precipitation by cohydrolysis of acidic precursor solutions of $TiOSO_4$ and $Zr(SO_4)_2$ at 200–240 °C	Catalyst for photodecomposition and solar energy conversion, white pigment materials, UV protection	[293]
TiO_2	<20 nm anatase particle size (round shaped); rod-like rutile nanocrystallites (9–32 nm diameter, 26–73 nm length)	Using amorphous titania as starting material and various acids (HF, HCl, HNO_3, citric acids) as catalysts	Photocatalysis, sensors	[294]
	<50 nm round shaped	Hydrothermally treating the titania sols after peptization with tetraalkylammonium hydroxide at 240 °C		[295]

Table 3. Continued

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Applications	Ref.
Cerium oxide (CeO$_2$)	<5 nm particle size, well dispersed	Citric acid as protective agent against particle growth	Polishing agents, sunscreens, solid electrolytes in solid oxide fuel cells, automotive exhaust catalysts (supports), additives for glass, stabilizers for ZrO$_2$	[296]
	~6 nm cubic primary particle, <10 nm uniform size agglomerate of indefinite shape or large spherical agglomerate particle (~150–180 nm)	Thermal hydrolysis of cerium ammonium nitrate solutions at 150–240 °C		[297]
	10–25 nm, cubic or octahedral	Sulfate ions cause spherical agglomeration of nanoparticles		[298]
		Heating solutions of cerium salts + urea (120–180 °C)		
Mg(OH)$_2$ and MgO	Nanocrystallines with rod-, tube-, needle-, or lamella-like morphologies, maintained during decomposition	Using different magnesium precursors and solvents as the reactants Decomposition: Mg(OH)$_2$ → MgO	Use in catalysis, toxic waste remediation, or as additives in refractory, paint, and superconductor products	[299]
Maghemite (γ–Fe$_2$O$_3$)	Highly crystalline, monodispersed nanoparticles (4–16 nm)	High-temperature (300 °C) aging of iron–oleic acid metal complex that was prepared by the thermal decomposition of iron pentacarbonyl in the presence of oleic acid at 100 °C, or direct oxidation of iron pentacarbonyl in the presence of oleic acid with trimethylamine oxide as an oxidant	Magnetic memory devices, ferrofluids, refrigeration systems, medical imaging, drug targeting, catalysis	[300]
Hematite (α–Fe$_2$O$_3$)	20–50 nm particle size	Mixture (FeCl$_3$ + EO + ethanol) heated at 200 and 300 °C		[128]
ZnGa$_2$O$_4$	Needle or rod-like particles plus 10–20 nm nanoparticles	>180 °C treatment of mixed metal sulfate salt solutions +NH$_3$	Transparent and conductive materials, phosphors	[297]
BaTiO$_3$	Nanocrystalline powders	Amorphous Ti gel or anatase precursor in Ba(OH)$_2$ solution	Dielectric or ferroelectric materials	[301]

A commonly written equation for the hydroxylation of metal ions (M^{z+}) is

$$M^{z+}(\text{aq}) + z\text{OH}^+(\text{aq}) \rightarrow M(\text{OH})_z.$$
It only represents the mass balance of a precipitation process. In fact, metal complexes (also called solutes) $\{[M_n(\text{H}_2\text{O})_{np-m}(\text{OH})_m]^{(nz-m)+}\}$ act as precursors to nucleation and affect particle growth. In other words, the hydrolyzed species are intermediates to the precipitation of the corresponding hydroxides [130, 131]

$$n[M(\text{H}_2\text{O})_p]^{z+} + m\text{OH}^- \rightarrow [M_n(\text{H}_2\text{O})_{np-m}(\text{OH})_m]^{(nz-m)+} + m\text{H}_2\text{O}$$

or

$$n[M(\text{H}_2\text{O})_p]^{z+} \xrightarrow{\text{OH}^-} [M_n(\text{H}_2\text{O})_{np-m}(\text{OH})_m]^{(nz-m)+}$$
$$\xrightarrow{\text{OH}^-} nM(\text{OH})_z$$
During forced hydrolysis, the hydroxide ions are formed *in-situ* by the deprotonation of water molecules coordinated by the metal ions [131–133] according to

$$n[M(\text{H}_2\text{O})_p]^{z+} \rightarrow [M_n(\text{H}_2\text{O})_{np-m}(\text{OH})_m]^{(nz-m)+} + m\text{H}^+$$
At elevated temperatures, the above forced hydrolysis can occur in the absence of base. Raising the temperature and adjusting the initial pH of the solution affects the hydroxylation of metal ions and the generation of complexes responsible for particle nucleation and diffusional growth. Typically, the pH decreases in the course of the reaction due to deprotonation of the hydrated cations, eventually leading to the formation of solid hydrous oxides. The low pH used in these systems is particularly important in order to keep a relatively low supersaturation with hydroxide ions that are constantly furnished by dissociation of water as their reservoir. Coagulation is prevented mainly by the repulsive force of the electric double layer exerted from the positively charged surfaces of each particle in the low pH range, which is effective at low ionic strength [94]. To consistently obtain particles with controlled characteristics, it is necessary to control the pH, the concentration of reactants, the temperature, the anions or counterions of a given metal salt solution, the method of mixing, etc. Anions could be highly responsible for the particle morphology. Forced hydrolysis can yield particles of different shapes (spherical, cubic, ellipsoidal, etc.), either of the same or different chemical composition.

In summary, the forced hydrolysis method requires an acidic solution containing a metal salt at a given concentration to be heated in order to produce hydroxide ligands *in-situ* by the deprotonation of bound water.

With less strongly hydrolysable cations, it is necessary to raise the pH somewhat by the addition of a weak base in order to promote or accelerate hydroxylation, and thus precipitation. For example, the hydrolysis of cations can be achieved by the *controlled release of anions (hydroxide ions)* into a metal salt solution [92] by gradual decomposition of certain organic compounds such as urea, formamide, or hexamethylenetetramine (HMTA). When urea is heated in a solution, carbonate ions are produced, accompanied by a simultaneous increase in the pH homogenously throughout the whole solution, leading to the precipitation of metal basic carbonates.

$$(\text{NH}_2)_2\text{CO} + 3\text{H}_2\text{O} \rightarrow \text{CO}_2 + 2\text{NH}_4^+ + 2\text{OH}^-$$
The gradual and uniform rise in pH can result in the nucleation and growth of uniformly nanosized particles. Calcination is usually required to transform the carbonates to metal oxides. Rojas and Ocana [134] used HMTA to enhance the forced hydrolysis of ceria (Pr doped). Song and Kang [135] have taken advantage of the gradual urea decomposition in aqueous solutions of SnCl$_4$ to prepare nanosized tin oxide particles. Similarly, uniform colloids can be obtained by the *controlled release of cations* approach—the slow release of cations from organometallic complexes, which then react with hydroxide ions in solution [133].

Another entirely different approach is the thermal decomposition of complex solutes in solution. Metal chelates or similar organometallic compounds can be decomposed in strongly alkaline solutions to yield uniform metal (hydrous) oxides. Complexing agents, such as triethanolamine (TEA), nitrilotriacedic acid (NTA), and (ethylenedinitrilo) tetra-acetic acid (EDTA), appear to prevent both nucleation and coagulation during particle growth by shielding the metal ions. Meanwhile, complexes may liberate metal ions by degrees with the progress of precipitation. The decomposition of metal chelates typically requires much higher temperatures (i.e., similar to hydrothermal conditions) due to the stability of metal complexes. Particles obtained by this method show a relatively large size and a different crystal shape, other than spheres.

Some examples of using forced hydrolysis in (hydrous) oxide nanoparticle synthesis are shown in Table 4.

Most of the forced hydrolysis processes use aqueous solutions of inorganic salts. However, hydrolysis and inorganic polymerization can be carried out on salts dissolved in a nonaqueous medium such as a polyol medium. For example, Ammar et al. [136] have used this polyol approach to prepare monodispersed cobalt ferrite nanoparticles.

Instead of using a pure aqueous solution, the addition of alcohol to the solution could significantly affect the solid nucleation and growth kinetics, as well as the particle morphology. Hu et al. [137] have demonstrated that the addition of alcohol to an aqueous solution of metal salts can dramatically enhance the solid phase nucleation and growth rate, although the solid phase and morphology of the particles may be different from those obtained from forced hydrolysis of alcohol-free aqueous solutions. Li and Gao [138] prepared nanocrystalline zirconia in a water–ethanol mixture solution.

A forced hydrolysis process has been coupled with microwave heating (using a particularly fast heating rate) to enhance the process kinetics and uniformity of the nanoparticles. For example, Bellon et al. [139] prepared zirconia sols (i.e., colloidally stable suspensions) and powders by the microwave heating of ZrCl$_4$ solutions at 180 °C. Zhu et al. [140] prepared tin oxide nanoparticles, and Liao et al. [141] prepared amorphous hematite nanoparticles via this method.

Table 4. Nanoparticle synthesis by forced hydrolysis.

Nanoparticle materials	Brief process description	Characteristics of nanoparticle	Applications	Ref.
SnO_2	Forced hydrolysis (160 °C) of aqueous $SnCl_4$ solutions for 2–24 h	~4 nm particle size	Gas sensors (H_2, CO, hydr4ocarbon, alcohol), catalysts, electrode materials (transparent electrode, glass-melting electrode), applications in solar energy conversion (dye-based solar cells), photocatalysis, electrochromic devices, and in optoelectronics	[302]
	Homogeneous precipitation, aqueous $SnCl_4$ + urea, 90 °C	3–4 nm in diameter		[135]
	Microwave heating (refluxing) of aqueous solution of $SnCl_4$ and urea for 15 min	~3 nm particle size, 4–60 nm crystallite size in annealed powder (200–800 °C)		[140]
Pr-doped ceria	Aging at 100 °C for 2 h aqueous solutions of cerium (III) nitrate, praseodymium (III) chloride, and hexamethylenetetramine (HMTA). HMTA is the precipitating agent	~12 nm uniform, nonagglomerated nanoparticles	Three-way automotive catalysts, red ceramic pigments, high-conducting solid electrolytes used in high-temperature fuel cells and oxygen sensors	[134]
CeO_2 (20–100mol%)–ZrO_2	Forced cohydrolysis of acidic aqueous solutions of $ZrOCl_2$ and $(NH_4)_2Ce(NO_3)_6$ at 100 °C	2–3 nm particle size, cubic and/or tetragonal fluorite-type structure	Catalytic supports for automotive exhaust	[303]
$CoFe_2O_4$	In a polyol medium by forced hydrolysis of ionic Co(II) and Fe(III) salts at 160 °C	5.5 nm particle size, monodispersed, almost equiaxial	Ferro fluids, magnetic drug delivery, magnetic high-density information storage	[136]
ZrO_2	Heating (95–120 °C) of aqueous $ZrOCl_2$ solution without and with addition of isopropanol	10–200 nm particle size, near monodispersed, monoclinic phase	Nanophase ceramics for high refractriness and corrosion resistance, mechanical strength and fracture toughness, and ion conduction	[137]
	Flash synthesis by microwave-forced hydrolysis of $ZrCl_4$ and HCl for 2–10 min	randomly shaped 30 nm particle (aggregates of 3–4 nm tetragonal and monoclinic crystallites)		[139]
ZrO_2 (3% Y_2O_3)	Zr and Y salts dissolved in water–ethanol mixture, PEG added as dispersant, heated to high temperature, followed by ammonia precipitation	nanocrystalline, tetragonal phase, 300–500 nm particle size		[138]

Table 4. Continued

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Applications	Ref.
ZrO_2 (3%, 12% Y_2O_3)	8–10 nm crystallite size	Hydrolyzing $ZrOCl_2$ aqueous solution, then the resulting acidic sol was neutralized and coagulated with ammonia solution		[304]
Mn_3O_4, α–MnOOH, Mn_2O_3	~20 nm colloid (equiaxial)	Forced hydrolysis (80 °C) of aqueous Mn(II) acetate solutions	Catalysts in environmental reactions and in synthesis of organic compounds, electrodes in alkaline batteries	[305]
	or elongated (length <2 μm and width <0.4 μm)	In the presence of HCl, particle is elongated. $Mn_3O_4 \rightarrow Mn_2O_3$ (800 °C) α–MnOOH $\rightarrow MnO_2$ (250–450 °C) $\rightarrow Mn_2O_3$ (800 °C)		
TiO_2	40–400 nm monodispersed particles (aggregates with primary particle size 3–10 nm)	Forced hydrolysis of $TiOCl_2$ (from dilution of $TiCl_4$) at 17–230 °C	Titania (rutile phase) as white pigments, coating materials for optical and electronic devices, photocatalysts	[306]
	Nanosized (70–100 nm), near monodispersed spherical powder	Forced hydrolysis of $Ti(SO_4)_2$ at boiling reflux for 5 h		[307]
Fe_2O_3	3–5 nm primary particle size (amorphous), 12 nm crystallite in sintered powder (400 °C)	Microwave refluxing (10 min) of mixture solution containing PEG, $FeCl_3$, and urea	Solar energy transformation, magnetic storage media, catalysts	[308]

3.2.4. Sol–Gel Synthesis

Metal alkoxides dissolved in homogeneous alcohol–water solutions are typically used in a sol–gel process, which is so named because it usually involves a stage of sol (solids suspended in a continuous liquid phase) formation, and then a stage of gellation (liquid particles/pockets suspended in a continuous solid phase) process. Sol–gel also refers to processing in a liquid medium to obtain solid matter (such as particles) which does not settle under the effects of gravity [142]. Water and alkoxides are immiscible, and thus a mutual solvent such as alcohol is utilized. Catalysts such as mineral acids (such as HCl) or bases (such as ammonia) are mostly used, as well as many others (acetic acid, KOH, amines, KF, and HF). Acid-catalyzed processes tend to yield primarily linear or randomly branched polymers for use as coatings, while base-catalyzed processes yield highly branched clusters for making particles.

The sol–gel process typically involves alkoxide hydrolysis and a condensation reaction [143]

$$M(OR)_x + yH\text{–}OH \rightarrow M(OR)_{x-y}(OH)_y + yROH$$
where R represents an alkyl group. The partially hydrolyzed species are then linked to form M–O–M bonds by condensation via dehydration or dealcoholation

$$-M\text{–}OH + HO\text{–}M\text{–} \rightarrow -M\text{–}O\text{–}M\text{–} + H_2O \text{ (dehydration)}$$

$$-M\text{–}OH + RO\text{–}M\text{–} \rightarrow -M\text{–}O\text{–}M\text{–} + ROH \text{ (dealcoholation)}$$
True metal alkoxides are highly sensitive to hydrolysis. Condensation reactions can be controlled via the chemical modification of metal alkoxides with complexing/chelating ligands such as acetyl acetone (acacH) [144, 145] and others (polyols, organic acids, β–diketones, and allied derivatives). The M–acac bond, stabilized by chelation, and β–diketonates, is much more difficult to hydrolyze than alkoxy groups. This process, involving hydrolysis → polymerization → nucleation → growth, condenses the molecular units together into small clusters (the "sol"), eventually leading to the formation of an insoluble three-dimensional network (the "gel"), which can be further condensed into a solid.

Sol–gel processes, based on the hydrolysis and condensation of molecular precursors, have historically played a significant role in glass and ceramic coating applications. Through these processes, homogeneous oxide materials with desirable properties like hardness, optical transparency, chemical durability, tailored porosity and thermal resistance can be produced at room (or low) temperatures. This process contrasts to the much higher melting temperatures required in the production of conventional inorganic glasses. Factors that affect the rate of hydrolysis and condensation reactions (and thus the microstructure of the solid sol–gel-derived materials) include the pH, temperature, and time of reaction, reagent concentrations, catalyst nature and concentration, water/metal molar ratio, aging temperature and time, and drying. In addition, the chemical design of the molecular precursors provides an interesting tool to control condensation reactions and tailor the nanostructure of the oxide materials [145].

Sol–gel chemistry presents many advantages for the powderless processing of ceramics, the molecular design of advanced materials, or the synthesis of hybrid organic–inorganic compounds. The sol–gel process has also been reported for making nanophase ceramics (ceramic layers containing individual <10 nm nanoparticles) by using inverse micelle reaction media or acacH-modified alkoxides [144]. Pierre [142] has specifically discussed the principles for achieving monodispersity during the sol–gel processing of ceramic powders.

Some recent efforts in the sol–gel synthesis of nanosized oxide particles or nanocrystalline powders are summarized in Tables 5 and 6. A classic example of sol–gel processes for making ultrafine particles is the one developed by Stöber and Fink [146] for the production of monodispersed silica using an alkoxide (tetraethoxy silane, TEOS) and ammonia catalysis. The sizes of these so-called "Stöber spheres" range from a few nanometers to a few micrometers, depending on the conditions (concentrations of reactants such as TEOS, ammonia, and water; reaction temperature and time; method of mixing, etc.). Livage et al. [145] used acacH to tailor the alkoxide condensation reaction kinetics, and thus the zirconia nanoparticle size. The mean diameter increases when the ratio of [H_2O]/[Zr] increases and the ratio of [acac]/[Zr] decreases.

Some sol–gel processes do not have to use alkoxides as starting precursors. Chen and He [147] used all inorganic metal salts (with PAA as a complexing agent to couple the two metal species together) to achieve sol and gel formation, and thus produced nickel ferrite nanoparticles. In some other cases, transient alkoxide-like species were formed from reactions of inorganic metal salts and alcohol. Dong and Zhu [128] and Manorama et al. [112] prepared nanoparticles with transient alkoxide formation processes. Metallorganic compounds such as metal formates have also been used as precursors in the sol–gel synthesis of multicomponent nanosize ceramic powders [148–151].

For mixed metal oxide powder synthesis, the use of single molecular multimetallic alkoxide precursors has certain advantages, such as precise control of chemical stoichiometry and composition homogeneity. Narayanan and Laine [152] developed the use of a trimetallic double alkoxide precursor to prepare phase-pure potassium aluminosilicate. O'Brien et al. [153] used a bimetallic alkoxide to synthesize monodispersed barium titanate nanoparticles in the 4–12 nm particle size range.

In addition to chemistry, other process strategies were taken into account to tailor the sol–gel synthesis of nanoparticles. Kim and Kim [154] developed a "semibatch-batch two-stage reaction" to decrease the size of titania nanoparticles. The particle size was reduced to 132 nm in the first stage, and decreased to 42 nm in the second stage. Better uniformity was another benefit.

Sol–gel processes at low temperatures generate mostly amorphous nanoparticles or gels, which require further high-temperature treatment such as calcination to obtain nanocrystalline powders. Some sol–gel processes are coupled with hydrothermal processing (in an autoclave reactor) to produce some as-prepared particles with the desired crystalline phases [155–157].

Table 5. Synthesis of single metal–oxide nanoparticles by sol–gel processes.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Ref.
SiO_2	Amorphous monodispersed nanoapheres	Ammonia-catalyzed hydrolysis and condensation of TEOS–ethanol–water homogeneous solutions	[146]
	13.7 nm monodispersed nanoparticles	Semibatch method using TEOS, ammonia, ethanol, HPC, and water	[309]
ZrO_2	Sol of amorphous, monodispersed nanoparticles (∼3 nm hydrodynamic dia.) <10 nm	Acetylacetone ($CH_3–CO–CH_2–CO–CH_3$) added to the $Zr(OPr^i)_4$ solution prior to hydrolysis to decrease reactivity: $Zr(OPr^i)_4 + x$ acacH $\rightarrow Zr(OPr^i)_{3-x}$ $(acac)_x + x$ Pr^iOH	[145] [144]
	Gel calcined into nanocrystalline phase (10–32 nm crystallite size)	Zr n–butoxide in terbutilic alcohol, with hydrolysis catalyst HCl, $C_2H_4O_2$, or NH_4OH, dried and annealed, then sulfated with H_2SO_4	[310]
SnO_2	2–12 nm particle sizes, 2.4–5.5 nm crystallite sizes	Hydrolysis of Sn (IV)–isopropoxide dissolved in ethanol	[302]
TiO_2	Porous anatase nanoparticles, 9–15 nm particle size · crystallite size	Heating (348 K) of ethanol solution of Ti tetra isopropoxide and H_2O_2 $\rightarrow$ Ti–peroxy compounds $\rightarrow$ Ti–peroxy gel, which was treated at 348 K for 6–48 h	[311]
	42 nm particle size	Semibatch reaction ($Ti(OC_2H_5)_4$/HPC/ethanol feed into H_2O/ethanol, stir for 60 min), followed by batch reaction (add additional $Ti(OC_2H_5)_4$/HPC/ethanol and H_2O/ethanol, stir 60 min), then drying at 70 °C for 12 h	[154]
	10.7 nm particle size	Semibatch method	
	1–5 nm core sizes (anatase), particle surface coated	Hydrolysis at 60 °C of Ti butoxide in the presence of acetylacetone and para-toluenesulfonic acid; particle surface protection through: (1) complexation by acetylacetonato ligands, and (2) adsorbed organic–inorganic layer made with acetylacetone, para-toluenesulfonic acid, and water.	[309]
	5–12 nm crystallite sizes	Hydrolysis of Ti(IV) isopropoxide; stabilized by hydroxylpropyl cellulose (HPC)	[312]
			[313]
ZnO	3–5 nm zincite crystallites, which aggregate into larger spherical particles	Alkoxide-based synthesis involving diethylzinc, tert-butyl alcohol, ethanol, and water: $Zn(CH_2CH_3)_2 + 2(CH_3)_3COH \rightarrow Zn[OC(CH_3)_3]_2 + 2CH_3–CH_3$ $Zn[OC(CH_3)_3]_2 + 2H_2O$ (in ethanol) $\rightarrow Zn(OH)_2 + 2(CH_3)_3COH$ $Zn(OH)_2 \rightarrow ZnO + H_2O$ (heating: RT $\rightarrow$ 90 °C 15 min $\rightarrow$ 250 °C 15 min)	[314]
∀–Fe_2O_3	Nanosized	Sol–gel process using ethylene oxide and $FeCl_3$ as starting materials in ethanol	[315]
Sc_2O_3, ScOOH	<80 nm, lozenge-shaped platelets (66 × 37 × 4.5 nm)	$Sc(acac)_3$ dissolved in 2–methoxyethanol, in which water/methoxyethanol was added, refluxed until yellow color vanished, and a light bluish aspect appeared.	[316]

Table 6. Synthesis of mixed metal-oxide nanoparticles by sol-gel processes.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Ref.
$NiFe_2O_4$	5–30 nm crystallite sizes	Aqueous solution of Ni nitrate and Fe (III) nitrate, mixed with aqueous solution of PAA (as a chelating agent), then add nitric acid → transparent green solution, evaporation at 50 °C → transparent sol, 50 °C 10 h → viscous brown gel, calcined → spinel nickel ferrite nanopowders	[147]
$BaTiO_3$	Monodispersed nanoparticles (4–12 nm particle sizes)	Single bimetallic alkoxide molecular precursor method: barium titanium ethyl hexano–isopropoxide is injected into a mixture of diphenyl ether at 140 °C under argon or nitrogen. The mixture is cooled to 100 °C and 30% H_2O_2 is injected, stirred over 48 h to promote further hydrolysis and crystallization of the product in an inverse micelle condition.	[153]
	Crystalline fine powders	Dissolve Ba metal in 2–methoxyethanol → add Ti isopropoxide → reflux under nitrogen at 135 °C → hydrolyze with water (water/alkoxide = 3/1) → amorphous gel powder → dry → calcine → powder	[317]
$PbZr_xTi_{1-x}O_3$ (PZT)	~17 nm nanocrystal size, free standing	Sol–gel synthesis using lead acetate, Ti(IV) ethoxide and Zr(IV) butoxide	[318]
Al_2O_3–TiO_2	Nanocrystalline powder (1–150 nm grain sizes), spherical or cubic shaped	Poly(ethylene glycol) (PEG) sol–gel method	[319]
Binary and ternary oxide nanopowders	Calcined nanocrystalline powders of BaO–SiO_2 (60–150 nm), mullite (85–15 nm), eucryptitite (140–205 nm), spodumene (150–200 nm)	Aqueous sol–gel method with formates and TEOS as precursors	[148, 150, 151]
IrO_2–Ta_2O_5	Ultrafine, irregular shaped	$IrCl_3$ dissolved in ethanol under nitrogen → Ir ethoxide → mixed with $Ta(OC_2H_5)_5$ → add ammonia → slow addition of H_2O_2 (to oxidize Ir precipitates) → dried, calcined	[320]
RuO_2–SnO_2	Ultrafine, irregular shaped	Hydrolysis and condensation of metal alkoxides in ethanol	[321]
Al_2O_3 and Al_2O_3/MgO	<2 nm crystallites in powders	Sol–gel + autoclaving thermal conversion: modified aerogel synthesis involving Al and Mg alkoxides, toluene, methanol, ethanol, and water → gel → autoclave at 265 °C	[155]
TiO_2	Dispersed colloids of tightly aggregated secondary particles (10 nm primary particle size, 100 nm secondary particle size)	Hydrothermal sol-gel	[157]
	<10 nm particle size	Sol–gel synthesis → peptization → growth under hydrothermal treatment in a basic environment at 190–270 °C	[156]

3.2.5. Solvothermal Synthesis and Nonhydrolytic Route

While water is used for the hydrothermal synthesis of hydrated oxides, other nonaqueous solvents have also been utilized for liquid-phase thermal processing. Nonaqueous solvothermal processes and some nonhydrolytic approaches have been proven to play a significant role in the synthesis of advanced nonoxide ceramic materials by using reactions in nonaqueous solutions [158–160].

Parala et al. [161] have described a nonhydrolytic sol–gel approach to the preparation of uniform, quantum-confined titania nanocrystals using an intramolecular adduct-stabilized alkoxide precursor. The organic passivating ligand TOPO was used as the reaction medium for the nucleation and growth of nanocrystals, and as a capping agent. Titanium alkoxide was modified by replacing one or more isopropoxide groups with donor functionalized alkoxide ligands such as dimethylaminoethoxide (dmae) or diethyl aminoethoxide (deae), leading to the formation of more fully saturated compounds that have reduced air/moisture sensitivity compared to the parent alkoxides. In a typical synthesis, TOPO was heated to 200 °C, degassed (flushed with argon), and heated to 325 °C. Then the modified alkoxide precursor was injected rapidly into the reaction flask under an argon atmosphere, and the reaction was maintained at 300 °C for 15 min. The resulting nanocrystals (3–5 nm, spherical shape) can be readily dispersed in polar solvents like toluene or hexane. In contrast to aqueous sol–gel

processes, the nonhydrolytic sol–gel technique in hydrocarbon solvents at high temperatures allows access to very small free-standing crystallites, and opens up new possibilities for control over size distribution, surface chemistry, and particle agglomeration.

Nonaqueous solvothermal processes can be defined as chemical reactions or transformations in an organic solvent under elevated temperature and pressure conditions, such as supercritical conditions or near such a pressure–temperature domain. The specific physicochemical properties of solvents in supercritical conditions in particular can markedly improve the diffusion of chemical species [160]. The chemical composition of the solvent must be adapted to the material to be prepared. Solvothermal processes have been developed for: (1) the shaping of materials (crystal growth or the preparation of fine microcrystallites), (2) the synthesis of new materials with interesting properties, and (3) the development of new processes for preparing functional materials. In particular, the solvothermal technique provides an alternative approach that allows the economical synthesis of fundamentally important well-defined nanometer-sized materials under mild conditions [162]. On the other hand, the direct precipitation of metal oxides from high-boiling-point organic solvents, as in "glycothermal synthesis," presents an alternative to wholly aqueous hydrothermal material synthesis routes [160, 163, 164]. These processes have used nonaqueous solvothermal processes to synthesize phyllosilicate-like oxides without the OH groups and stabilized nitrides (such as Mo2N and/or MoN fine particles and C_3N_4) in nitriding solvents (NH_3 or NH_2NH_2). Yin and Wang [165] prepared cobalt and cobalt oxide (CoO) nanocrystals by the chemical decomposition of $Co_2(CO)_8$ in toluene (at 130 °C), in the presence of sodium bis(2–ethylhexyl) sulfosuccinate as a surface active agent. Adair et al. [163] synthesized alpha-alumina of controlled particle size and shape in 1,4–butanediol solutions (with a high boiling point). The glycothermal synthesis technique allows for the production of anisometrically shaped particles with controlled morphology and size distribution [164].

Hong et al. [162] developed a so-called "alcohol-thermal" route under mild conditions (110 °C) to prepare CuO nanoparticles (∼3–9 nm, depending on reaction temperature) using copper acetate as the starting material. Hai et al. [166] prepared SnS_2 nanoparticles (∼150 nm average particle size, laminar shape) by a solvent–thermal synthesis method using the precursor salts $SnCl_2$ and CS_2 dissolved in absolute alcohol autoclaved at 200 °C for 16 h. Qiu et al. [167] synthesized nanosized Y–TZP powders (∼15 nm crystallite size) by a coprecipitation, followed by the distillation of the resulting gel in n–butanol. In some cases, a small quantity of water may be involved. For example, Kominami et al. [168] synthesized nanocrystalline tantalum (V) oxide powders by a solvothermal reaction of Ta pentabutoxide in toluene at 473–573 K in the presence of water.

Organic solution-phase decomposition of iron precursors at high temperatures has been widely used in iron oxide nanoparticle synthesis. Recent advances have demonstrated the synthesis of high-quality, monodispersed γ–Fe_2O_3 and Fe_3O_4 nanoparticles (<20 nm in diameter); one such method uses the high-temperature (265 °C) reaction of Fe(III) acetylacetonate in phenyl ether in the presence

of alcohol, oleic acid, and oleylamine [169]. By performing the reaction in propylene glycol under reflux, Rajamathi et al. [170] were able to hydrolyze $FeCl_3$ in the presence of n–octylamine to obtain soluble, monodispersed γ–Fe_2O_3 (∼5 nm).

3.2.6. Microwave Heating Synthesis

Microwave-assisted synthesis for the production of inorganic compounds has been studied since 1986. As compared to conventional oven heating (with a slow heating rate and heat transfer), microwave "volumetric" heating of liquids is an alternative heating approach with specific advantages. Microwave heating of the hydrothermal reactor was found in some cases to cut the reaction time significantly, to generate remarkable size uniformity, and to produce some new phases as well as known ones [171].

Recently, there have been some reports on microwave dielectric heating for the liquid-phase synthesis of nanoparticles [172]. This literature is summarized in Table 7.

3.2.7. Synthesis in Microemulsions or Reverse Micelles

Microemulsions are thermodynamically stable, fluid, and optically clear dispersions (10–100 nm subphases) of two immiscible liquids such as water and oil. Microemulsions form when a surfactant, or more commonly a mixture of surfactants and cosurfactants, lowers the oil/water interfacial tension to ultralow values, allowing thermal motions to spontaneously disperse the two immiscible phases. Unlike conventional emulsions, however, microemulsion domains fluctuate in size and shape, and undergo spontaneous coalescence and break up [173]. *Miniemulsions* are systems where small droplets with high stability are created in a continuous phase by using high shear [174]. Reverse micelles are molecular self-assemblies from surfactants or block copolymers, which have a spherical shape with a hydrophilic (water-loving) core and a hydrophobic tail on the sphere surface.

Microemulsion synthesis is probably the most popularly reported method, in recent literature, for the synthesis of nanosized inorganic particles (oxides, mixed oxides, semiconductor nanocrystals, metal nanocrystals or nanoclusters, coated nanoparticles, etc.). It is still an active research topic. We, however, will mainly focus on the review of work on ceramic (oxide) nanoparticles. Self-assembly systems such as water-in-oil microemulsions (or reverse micelles), or other self-assembled structures of surfactants and block copolymers, have been utilized as "nanoreactors" that confine a solid phase formation [175–177]. The application of a microemulsion as a precipitation medium yields much smaller particles (with narrower size distribution) than can be obtained from homogeneous solutions [178, 179]. In addition, reverse micelles or water-in-oil (W/O) microemulsion methods have been utilized for the growth of anisotropic nanoparticles (such as plate-like oxides) and core–shell nanoparticles (via arrested precipitation) [180].

In a typical process for nanoparticle synthesis by a microemulsion technique, the organometallic and/or metal salt precursors are dissolved inside the water pools of the reverse spherical micelles, and are allowed to react via droplet collision and rapid intermicellar exchange of their

Table 7. Microwave heating liquid-phase synthesis of nanoparticles and nanocrystalline powders.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Ref.
ZrO_2	Polymer stabilized ZrO_2 nanopowders with average crystallite size of 2.0 nm	Microwave heating in an aqueous solution containing $Zr(NO_3)_4$, PVA, and NaOH	[322]
	Randomly shaped particles of roughly 30 nm, which are aggregates of 3–4 nm crystallites of tetragonal and monoclinic phases	Flash synthesis by microwave-forced hydrolysis	[139]
SnO_2	~3 nm particle (or crystallite) size in as-prepared powders; 4, 12, 18, and 60 nm avg. particle sizes for powders annealed at 200, 400, 600, and 800 °C	Microwave irradiation heating-forced hydrolysis of an aqueous solution in the presence of $SnCl_4$ and urea	[140]
CeO_2	Nanocrystalline powder (2.6 nm crystallite)	Microwave-assisted heating routes from aqueous solutions containing $(NH_4)_2Ce(NO_3)_6$, hexamethylenetetramine, and poly(ethylene glycol)-19000 (PEG)	[323]
	Monodispersed nanocrystalline powders (2.0 nm crystallite size)	Microwave irradiation of aqueous solution containing $(NH_4)_2Ce(NO_3)_6$, PEG, and NaAc	[308]
$\forall$–Fe_2O_3	Monodispersed red hematite spherical particles (30–66 nm in diameters)	Microwave hydrothermal treatment of solution containing $FeCl_3$ and HCl at 100–160 °C 2–8 h	[324]
	Monodispersed hematite nanoparticles	Microwave thermohydrolysis of nitrate iron (III) solutions	[325]
	Uniform nanoparticles (coarse ~70 nm particle size, tetragonal shape 80 nm diagonal length, or ellipsoidal 50–100 nm particle sizes)	Microwave refluxing of mixed solutions of $Fe(NO_3)_3$ and HNO_3, $Fe(NO_3)_3$ and NaOH, or $Fe(NO_3)_3$ and NaH_2PO_4	[326]
Amorphous Fe_2O_3	~3–5 nm particle sizes in amorphous powder (agglomerate); sintered $\forall$–Fe_2O_3 riziform particles (10 nm diameter × 30 nm length)	Microwave irradiation heating of an aqueous solution containing ferric chloride, polyethylele glycol-2000 and urea	[308]
Binary oxides $BaTiO_3$, $Ba_6Ti_{17}O_{40}$, $BaZrO_3$, $PbTiO_3$	Particle sizes for as-prepared (heated) powders (nm): 10 (20–30), 15 (40–50), ~200 × 600 (same), and 5–7 (20–30), respectively. Crystallite sizes in as-prepared (heated) powders (nm): 9 (19), 11 (26), 1.8 (24), and 1.2 (17), respectively	Microwave-assisted soft-chemical route: using precursor salts $BaCl_2$ hydrate, $Pb(Ac)_2$, $Ti(Opr^i)_4$, and $ZrOCl_2$	[327]
$\forall$–Al_2O_3	Crystalline powders (60–990 nm particle sizes)	Microwave-assisted "combustion" of redox solution mixtures containing the desired metal ions (from Al nitrate), urea as oxidizing reactant and fuel	[328]
$BaTiO_3$	Ultrafine tetragonal-phase powders	Microwave heating of solutions containing $BaCl_2$, TiO_2, NaOH, and deionized water	[329]

water content [181]. The nanoparticle formation in the microemulsion process is controlled mainly by diffusion, and is also dependent on the nature of the surfactant. Two major procedures have been reported: (1) the catalyst is already contained in the water phase, and the precursor (such as an alkoxide), dissolved in the continuous medium, progressively enters the water pools of the reverse microemulsion; and (2) the precursor and the catalyst are prepared as two separate microemulsions, and are mixed together to allow the reaction to proceed via micellar exchange of two microemulsions.

Instead of water, an ethanol-in-oil microemulsion has been prepared for the synthesis of zinc oxide nanoparticles [182]. Some nanoparticle synthesis work has also been done with oil-in-water microemulsions (or normal micelles) involving ionic surfactants, in which counter ions are replaced by ions participating in the chemical reactions [175, 181]. This technique demonstrated the use of triblock copolymer spherical micelles in tetrahydrofuran/hexanes as templates for the preparation of inorganic nanoparticles (iron oxide, ~4–16 nm particle sizes).

Tables 8 and 9 summarize some major microemulsion synthesis work from recent years, with a focus on the nanoparticles of oxides and mixed oxides.

3.2.8. Sonochemical Synthesis

Ultrasound has been applied to enhance chemical reactivity, particularly in synthetic materials chemistry. The chemical effects of ultrasound are derived primarily from acoustic cavitation. Bubble collapse in liquids results in an enormous concentration of energy from the conversion of the kinetic energy of the liquid motion into heating of the contents of the bubble. The high local temperatures and pressures, combined with extraordinarily rapid cooling, provide a unique means for driving chemical reactions under extreme conditions [183].

Table 8. Single-(hydrous)oxide nanoparticle synthesis in microemulsions (or reversed micelles).

Nanoparticle	Characteristics of nanoparticle	Brief process description	Ref.
SiO_2	30–70 nm diameters, monodispersed spheres	Hydrolysis of TEOS in water-in-oil microemulsion consisting of polyoxyethylene (5) monylphenyl ether (NP5)/cyclohexane/ammonium hydroxide	[330]
	Monodispersed, 0.1–1.5 m avg. sizes	Mix W/O catalyst(NH_3)-containing microemulsion with TEOS containing microemulsion	[331]
	Particle sizes: 70–640 nm	Microemulsion using block copolymers and nonionic surfactant	[332]
ZrO_2	Amorphous as-prepared particles	Reverse microemulsion: water–cyclohexane–hexanol–Triton X-100	[333]
	Crystallized (tetragonal) at 450 °C~4 nm 5–50 nm particle size (by TEM)	Two-emulsion precipitation technique: two solutions of reverse emulsion, one containing Zr^{4+} aqueous droplets, and the other aqueous ammonia (or HMTA) droplets, with the same water/oil ratio are prepared separately and mixed together to form a slurry of ZrO_2 precursors	[334]
	5–8 nm spherical nonaggglomerated particles Zn oxalate precursor nanoparticles (5–13 nm)	Ethanol-in-oil microemulsion: Zn-AOT/ethanol/isooctane, Na–DEHSS (diethylhexyl) sulfosuccinate as surfactant, Zn nitrate as salt precursor dissolved in ethanol	[335, 182]
Al oxide–hydroxide	Amorphous, mean particle sizes of 1.0–2.4 nm	Hydrolysis of Al isopropoxide in the L-2 phase of amphiphilic (PDMS–POE) polydimethylsiloxanepolyoxyethylene Silwet L-7607–octanol/acetylacetone–water mixtures	[336]
TiO_2	Nanoparticles (both anatase and rutile phase)	Hydrolysis of tetrabutyl titanate in water core of a water-in-oil microemulsion, provided by a functionalized surfactant Span-Tween 80 (mixture of sorbitol monooleate and polysorbate 80)	[337]
	20–50 nm particle sizes in agglomerated powders	Mix of microemulsions. Precipitation of Ti hydroxide by NH_4OH in microemulsion (water/Triton X-100/hexanol/cyclohexane).	[338]
Sb_2O_4	Nanorods (50–175 nm diameter and several micrometer length)	Aqueous solution of $SbCl_3$ and HCl $\rightarrow$ mixed with toluene containing AOT $\rightarrow$ ultrasonication $\rightarrow$ add NaOH slowly $\rightarrow$ take upper layer transparent yellow-colored solution and reflux $\rightarrow$ organosol $\rightarrow$ evaporation to get zerogel$\rightarrow$ drying to get powder	[339]
Fe_3O_4	<10 nm particle size, equiaxial morphology	O/w microemulsion using cyclohexane as the oil phase, NP5 + NP9 as the surfactant phase, and a Fe(II)/Fe(III) salt solution as the aqueous phase	[340]
	~4 to ~16 nm sphere	Use of triblock copolymer micelles with hydrophilic cores as templates	[175]
	2–8 nm particle size range	Use cyclohexylamine to precipitate Fe(II) and Fe(III) by mixing two microemulsions (inverse micelles), a ternary system cyclohexane/Brij-97/water	[341]
–Fe_2O_3	~10 nm spherical particle, coated with DBS and CTAB (cetyltrimethyl ammonium bromide)	Precipitation of $FeCl_3$ by NaOH in microemulsion water sodium dodecyle benzene sulphonate (DBS)/toluene: $Fe^{3+} + OH^- \rightarrow ∃–FeOOH \rightarrow –FeOOH \rightarrow –Fe_2O_3$	[342]
TiO_2	As small as 2 nm, amorphous powder	Sol–gel reaction with Ti tetraisopropoxide in miw/o microemulsion containing water, cyclohexane, or octane, and surfactant such as polyoxyethylene (10) octylphenyl ether (TX-100), polyoxyethylene lauryl ether, or bis (2-ethylhexyl) sodium sulfosuccinate	[343]
Er_2O_3	5–30 nm in diameters	Inverse microemulsion technique: cyclohexane as the oil phase, NP5 + NP9 as the surfactant phase, and a Er(III) nitrate salt solution as the aqueous phase	[344]

Table 8. Continued

Nanoparticle	Characteristics of nanoparticle	Brief process description	Ref.
BiOCl	Monodispersed 250 nm long arrowhead-shaped particles (from hexagonal phase) or roughly spherical 5 nm particles (from lamellar phase)	Lyotropic liquid crystal nanoreactors: 3-D percolated hexagonal liquid crystal and 2-D percolated lamellar liquid crystal	[345]
SnO$_2$	30–70 nm particle sizes for precursor hydroxide particles, dried powder is agglomerated	Water-in-oil microemulsion: water, AOT (surfactant), and n–heptane (oil) SnCl$_4$ containing microemulsion was mixed with ammonia-containing microemulsion	[346, 347]
GeO$_2$	Polyhedron (43–342 nm particle sizes), Spindle (445–838 nm), Cube (612–947 nm)	Hydrolyzing Ge tetraethoxide in a 2,2,4–trimethylpentane solution of sodium bis(2–ethylhexyl) sulfosuccinate (AOT) as a function of water content	[348]
CeO$_2$	8–48 nm mean particle sizes	Precipitation of Ce(NO$_3$)$_3$ by ammonia in Titron N-101/ n–pentanol/n–octane/water microemulsion	[349]

The sonochemical decomposition of volatile organometallic precursors in low-volatility solvents has been a major technique in producing various nanostructured materials (such as metals/alloys, oxides, carbides, sulfides, nanosize colloids, etc.). Examples of decomposition include: (1) the decomposition of W(CO)$_6$ and Fe(CO)$_5$, and (2) the decomposition of urea to precipitate metal ions in solution.

Table 10 summarizes some of the most recent efforts in the sonochemical synthesis of inorganic nanoparticles (mainly oxides) from liquid-phase reactions.

3.2.9. Electrochemical Synthesis

Electrochemical processes take advantage of not only solution chemistry, but also of electrical current-enhanced phenomena through electrode(s) and electrochemical reactions at the electrode–solution interface.

There are some recent reports on the synthesis of oxide ceramic nanoparticles using electrochemical routes. Borgohain et al. [184] prepared cuprous oxide (Cu$_2$O) quantum particles as small as 2 nm by a novel electrochemical route. A Cu anode and a Pt cathode were used in an electrolytic bath consisting of a mixture of acetonitrile (CH$_3$CN) and tetrahydrofuran (TMF) bubbled with nitrogen. The supporting electrolyte, tetra–n–octyl ammonium bromide (TOAB), also served as a stabilizer. On application of an electric current, the anode slowly dissolves, leading to the formation of Cu ions, which get oxidized immediately after formation by the residual oxygen in the bath, and subsequently get passivated by the active TOAB species. The cluster size of Cu$_2$O was found to decrease with an increase in current density. Pascal et al. [185] performed electrochemical synthesis in an organic medium for nanoparticles of maghemite α–Fe$_2$O$_3$ (with narrow size distribution, average sizes varying from 3 to 8 nm).

Electrochemical routes were also reported for the synthesis of nanostructured mixed oxides. Amigo et al. [186] synthesized magnetic nanoparticles of Sr–Fe oxides (average sizes from 2 to ~50 nm) in the shape of inverse cubic spinels. The nanoparticles were precipitated from nitrate media in the pH range of 1–3, and from chloride media within the pH range of 1–12, by electrolysis of nitrate and

chloride solutions with Sr^{2+} and Fe^{3+} salts, using commercial Fe electrodes. This electrochemical procedure is based on the coprecipitation of oxides of Sr^{2+}, Fe^{3+}, and Fe^{2+} (supplied from the Fe anode) in the solution and electrodes under the action of the applied electrical field

$$\text{Fe} \rightarrow \text{Fe}^{2+} + 2e^- \quad \text{(anode reaction)}$$

$$2\text{H}_2\text{O} + 2e^- \rightarrow \text{H}_2 + 2\text{OH}^- \quad \text{(cathode reaction)}$$

Maghenite and magnetite are assumed to be produced in the alkaline region near the cathode

$$2\text{Fe}^{3+} + 6\text{OH}^- \rightarrow \gamma\text{–Fe}_2\text{O}_3 + 3\text{H}_2\text{O}$$

$$\text{Fe}^{2+} + 2\text{Fe}^{3+} + 8\text{OH}^- \rightarrow \text{Fe}_3\text{O}_4 + 4\text{H}_2\text{O}$$
The resulting mixture of these oxides is further doped by Sr^{2+}, which partially substitutes the Fe^{2+} in the magnetite to yield the final insoluble Sr–Fe oxide

$$\text{Sr}^{2+} + [(\gamma\text{–Fe}_2\text{O}_3)_a(\text{Fe}_3\text{O}_4)_b] \rightarrow [(\gamma\text{–Fe}_2\text{O}_3)_a(\text{Fe}_3\text{O}_4)_{b-1} \\ \times (\text{SrFe}_2\text{O}_4)] + \text{Fe}^{2+}$$
Similarly, Torres et al. [187] prepared Mn–Zn–Fe mixed oxides (<50 nm nanoparticle size) as precipitates from chloride and nitrate solutions of pH 1.5 with Mn^{2+}, Zn^{2+}, and Fe^{2+} or Fe^{3+} at temperatures between 40 and 80 °C using electrodes of commercial iron.

In addition to oxides, the electrochemical route also has been utilized for the synthesis of nonoxides. Griffiths et al. [188] recently reported that the electrochemical oxidation of a titanium electrode in a solution of potassium amide in liquid ammonia resulted in the deposition of titanium nitride as nanoparticles or as a thin film.

Nyffenegger et al. [189] reported a hybrid "electrochemical/chemical (or E/C) method," which is a relatively new wet-chemical method, for the synthesis of zinc oxide (ZnO) nanoparticles (with mean diameters of nanocrystallites in the range of 1.5–10 nm) and films (10–40 nm thickness, polycrystalline). The E/C procedure involves two steps: (1) zinc metal is first electrochemically deposited at basal-plane-oriented graphite electrode surfaces from dilute aqueous

Table 9. Mixed-oxide nanoparticle synthesis in microemulsions (or reversed micelles).

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Ref.
$CoFe_2O_4$	Oval-shaped, avg. radius of 4.8 nm	Templating synthesis: self-assembly of mixed-metal oxides in block copolymers	[350]
	1–15 nm particle sizes	AOT reverse micelles: adding aqueous solutions of Fe(II) and Co(II) salts to AOT dissolved in isooctane	[351]
MFe_2O_4 (M = Mn, Fe, Co)	5.5 nm uniform size particle	Two potions of solution of AOT in isooctane were mixed with aqueous solutions of the reactants, one containing metal salts and another one containing the precipitating agent NH_4OH	[352]
	10–20 nm particle sizes, spherical shape	Two potions of solution of AOT in isooctane were mixed with aqueous solutions of the reactants, one containing metal salts and another one containing the precipitating agent NH_4OH	[353]
$CoLn_{0.12}Fe_{1.88}O_4$ (Ln = Ce, Sm, Eu, Gd, or Er)	~20 nm particle size	O/w micelles using sodium dodecyl sulfate as the surfactant	[354]
$MnFe_2O_4$	uniform ~10 nm particle size	AOT (bis(2–ethylhexyl) sodium sulfosuccinate) in isooctane reverse micelle solutions containing the reactants $FeSO_4$, $MnSO_4$, NH_4OH (precipitant), and H_2O_2 (oxidant)	[355]
$Eu_xY_2O_3$	10–100 nm particle sizes, red-emitting nanophosphor	Microemulsion containing petroleum ether (60–80 °C), nonionic surfactants NP_5/NP_9, aqueous yttrium nitrate/europium nitrate and ammonium hydroxide solution	[356]
	Spherical shape, narrow size distribution, high crystallinity, strong photoluminescence	Precipitation of aqueous yttrium nitrate/ europium nitrate solution using ammonium hydroxide in the reverse microemulsions based on polyoxyethylene (5) nonylphenyl ether/polyoxyethylene (9) nonylphenyl ether, cyclohexane, and water	[357]
Ba-stabilized alumina	High thermal stability, high surface area, uniform, long-shaped particles (~20 nm length and ~8 nm width)	Microemulsion + hydrothermal techniques	[358]
$PbBi_2Ta_2O_9$	Precursor powders are soft agglomerates with nanosized primary particles (near spherical, 40 nm primary particle size after calcinations)	Colloid emulsion process	[359]
Strontium ferrite	3.8 nm precursor particle sizes and 50–100 nm calcined particle sizes	Coprecipitation of Sr^{2+} and Fe^{3+} in a water-in-oil microemulsion of water/CTAB/n–butanol/isooctane → mixed hydroxide precursor → calcinations at 700 °C 5 h → pure strontium ferrite	[360]
$PbCrO_4$	3–100 nm uniform particles (spherical) 240 × 140 nm (rectangular shaped)	W/o microemulsion: water/sodium bis(2–ethylhexyl)sulfosuccinate (AOT)/n–heptane Dropwise addition of $Pb(NO_3)_2$ containing microemulsion (colorless) into orange-colored K_2CrO_4-containing microemulsion	[361]
Barium hexaaluminate	~10–30 nm (calcined at 500–1300 °C)	Sol–gel processing (controlled hydrolysis and condensation of B and Al alkoxides) in reverse microemulsion media	[362, 363]
	3–10 nm precursor particle sizes		[364]

Table 9. Continued

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Ref.
Barium ferrite ($BaFe_{12}O_{19}$)	Nanosized	Mix two microemulsions: coprecipitation of ferri/barium salts by ammonium carbonate in microemulsion containing an aqueous phase, CTAB surfactant, n–butanol cosurfactant, and octane (oil).	[365]
SiO_2-coated iron oxide	As small as 1–2 nm iron oxide uniform particle size, coating as thin as 1 nm	W/O microemulsion using nonionic surfactants (Triton X-100, Igepal CO-520, and Brij-97), by coprecipitation of Fe(II)/ Fe(III) salts by NaOH or ammonia. Coating was with TEOS sol–gel reaction in microemulsion	[366]
Titania-coated silica	∼60 nm monodispersed spheres	Controlled hydrolysis of TEOS and Ti n–butoxide in Triton X-45/cyclohexane/water reverse (w/o) microemulsions	[367]
Silica–copper oxide composite	20–50 nm with uniform elemental distribution, narrow distribution of mesopores (3–6 nm), 320–379 m^2/g	Controlled hydrolysis/polymerization of Na_2SiO_3 and $Cu(NO_3)_2$ · $3H_2O$ via partial-microemulsion and double-microemulsion processes at 28 °C, consisting of sodium 1,4–bis(2–ethylhexyl) sulfosuccinate and sodium dodecyl sulfate, cyclohexane, and water.	[368]
Indium–tin oxide (ITO)	Monodispersed, 9–12 nm as-prepared particle size 25 nm crystalline agglomertates after calcinations at 700 °C	Two emulsion mixing: ammonium hydroxide coprecipitation of aqueous solution of indium nitrate and tin chloride in AOT-based reverse microemulsions	[369]
$Cu_2L_2O_5$ (L = Ho, Er)	Spherical calcined nanoparticle (15–25 nm in size) Precipitated $Cu_2Ho_2(CO_3)_4(OH)_2$ (25–30 nm) and $Cu_2Er_2(CO_3)_4(OH)_2$ (10–40 nm)	Mixing $(NH_4)_2CO_3$-containing microemulsion with microemulsion containing both $Cu(NO_3)_2$ and $L(NO_3)_3$ for coprecipitation. W/O microemulsion: water/CTAB/n–octane/1–butanol	[370]
$BaTiO_3$	Near-monodispersed, 6–17 nm sizes, nonagglomerated, cube-shaped crystals	Sol–gel reactions in W/O microemulsion without any sintering process (cyclohexane + 1–octanol + Tergitol™ + water) + (Ti isopropoxide + Ba isopropoxide)	[371]
Binary and ternary metal oxides	8–19 nm crystallite sizes in nanopowders Binary: TiO_2, ZrO_2 Ternary: $BaTiO_3$, $BaZrO_3$, $SrTiO_3$, $SrZrO_3$	Sol–gel chemistry plus W/O microemulsion technique	[372]
Perovskite-type metal oxides	∼20 nm diameter metal oxalate particles, calcined into single phase into $LaNiO_3$, La_2CuO_4, and $BaPbO_3$	Oxalate precipitation in inverse micro-emulsion	[373]

solutions; and (2) this deposit is then permitted to spontaneously oxidize and dehydrate at an open circuit in the pH = 1.0 plating solution. Most recently, Penner [190] utilized the hybrid electrochemical/chemical (or E/C) method for synthesizing oxide and semiconductor nanoparticles or quantum dots on graphite surfaces. This E/C method for the synthesis of quantum dots of the generic semiconducting salt MX typically involves three steps:

1. electrochemical deposition of size-monodispersed nanoparticles of the metal M^0 from a solution of metal ions M^{n+}

2. electrochemical oxidation of these metal particles to $MO_{n/2}$
3. displacement of the oxygen from $MO_{n/2}$ using HX (for example) to yield nanoparticles of semiconductor MX.

The conversion from metal to metal oxide to metal salt occurs on a particle-by-particle basis. The quantum dots thus prepared by the E/C method possess many of the attributes of quantum dots synthesized using molecular beam epitaxy, including epitaxial orientation on a substrate surface, a narrow size distribution, and strong, particle size-tunable photoluminescence.

Table 10. Liquid-phase sonochemical synthesis of metal–oxide nanoparticles.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Ref.
Tungsten oxide	Amorphous as-prepared particles (100–200 nm sizes), globular agglomerates composed of <5 nm dense primary particles)	Sonochemical decomposition: ultrasound irradiation of a solution of tungsten hexacarbonyl $W(CO)_6$ in diphenylmethane in the presence of an Ar(80%)–O_2(20%) gaseous mixture at 90 °C	[374]
Ceria	Nanocrystalline powder (2.6 nm crystallite)	Sonochemical-assisted heating routes from aqueous solutions containing $(NH_4)_2Ce(NO_3)_6$, hexamethylenetetramine, and poly(ethylene glycol)-19000 (PEG)	[323]
	Monodispersed, mean particle size of ca. 3.3 nm	Sonochemical synthesis using cerium nitrate and azodicarbonamide as starting materials, and ethylenediamine or tetraalkylammonium hydroxide as additives	[375]
Nickel aluminate spinel	Nanosized $NiAl_2O_4$ particles with a size of ~13 nm (crystallite size)	Sonicating an aqueous solution of nickel nitrate, aluminum nitrate, and urea yields and precursor, which on heating at 950 °C for 14 h yields nanosized particles	[376]
Yttria-stabilized zirconia (YSZ)	Monodispersed, 4.7 nm nanocrystal size, on the surface of $SrCO_3$ nanoparticles	Sonochemical treatment to induce crystallization of self-assembled hydrous YSZ on the surface of $SrCO_3$ nanoparticles	[377]
∀–nickel hydroxide	Scaly particles with a length of ca. 120–200 nm and a width of ca. 10–15 nm	Ultrasound radiation of an aqueous solution of Ni nitrate and urea (purged with Ar, 80 °C)	[378]
CuO in PVA	~5–10 nm particle sizes	Ultrasonication of poly(vinyl alcohol) (PVA) and copper(II) acetate dissolved in water–dimethylformamide (DMF) under Ar at room temperature for 3 h	[379]
Amorphous iron oxide Fe_2O_3	Stable colloids of undecenoate, dodecyl sulfonate, and octyl phosphonate coated Fe_2O_3 nanoparticles of 5–16 nm in diameters	Sonochemical decomposition of volatile precursor $Fe(CO)_5$ solution in decane, in the presence of different surfactants, under air atmosphere at 273 K for 3 h	[380]
	Particle size of ~25 nm	Neat $Fe(CO)_5$ or a solution in decalin was irradiated ultrasonically under air atmosphere at 0 °C for 3 h	[381]
Co_3O_4, ZnO	20–30 nm cobalt oxide particle sizes, 250–340 nm zinc oxide particle sizes	Sonochemical irradiation of metal acetate solutions in doubly distilled deoxygenated water or 10% water–DMF, under 1.5 atm of argon at room temperature for 3 h	[382]
Fe_3O_4	Pure nanocrystalline phase, particle size of ca. 10 nm, minimal agglomeration	Sonication of iron (II) acetate in water under an argon atmosphere at 25 °C for 3 h	[383]
$RuS_{1.7}$	Particle sizes of ca. 25 nm, nanocrystalline powders with certain aggregation	Sonication of an aqueous solution of ruthenium chloride and thiourea → X-ray amorphous product → heating at 650 °C → nanocrystalline ruthenium sulfide	[384]

3.2.10. Synthesis in Supercritical Fluids

Supercritical fluid (SCF) processing has been considered for particle design [191] and as a new route for materials synthesis, such as for the formation of novel inorganic nanoparticles, and for the preparation of different open-structure oxy(hydroxy)fluorides [192]. There are certain advantageous features of using SCF processes for materials processing [129]: (1) the ability to form nanoparticles, (2) the ability to control particle morphology to some extent with pressure

and temperature, and (3) the ability to provide homogeneous reducing or oxidizing atmospheres by introducing gases or additional components (O_2, H_2, H_2O_2).

When the fluid is water, the technique is called supercritical hydrothermal processing. The fluid could also be another solvent, such as CO_2. Some solvothermal processing is, in fact, a subcategory of supercrical or subcritical fluid (solvent) processing. In particular, supercritical CO_2 and supercritical water (SCW) are chemically stable and

environmentally benign. SCF exhibits the combined characteristics of both gas and liquid solvents to provide a medium with densities characteristic of liquids, and with gas-like viscosities and diffusivities. Thus, mass-transfer rates approach those of gases, while solvation properties resemble those of conventional liquid solvents. Furthermore, supercritical fluids exhibit unique tunable solvation characteristics, as subtle changes in pressure and temperature in SCFs alter the solvent density. This property might be utilized to improve many aspects of nanocrystal processing, such as size-selective separations, synthesis, and self-assembly [193].

Hydrothermal synthesis under supercritical conditions has been studied for the synthesis of nanosize crystals of metal oxides such as CeO_2 and $AlO(OH)$ [129]. In water, the dielectric constant dramatically decreases when heated and pressurized above the critical point ($T_c = 374$ °C, $P_c = 221$ bar). The solubility of salts decreases, and the solubility of organics increases [193]. The lower dielectric constant at supercritical conditions possibly results in enhancement of the hydrothermal reaction. There are two reasons why nanoparticles are formed at supercritical conditions: (1) larger particles are produced at subcritical conditions due to Ostwald ripening, that could not be observed in supercritical water because of the extremely low solubility; and (2) the nucleation rate is faster in supercritical water because of the lower solubility and the extremely fast reaction rate [129]. The use of stabilizing ligands to bind nanocrystal surfaces, or using compartmentalized heterogeneous media (such as micellar solutions) to control growth have recently been extended to SCFs with general success. When water is heated and pressurized above the critical point, it becomes a suitable solvent to employ organic capping ligands (such as alkanediols) to control and stabilize the synthesis of nanocrystals. Ziegler et al. [193] have prepared monolayer-stabilized copper nanocrystals (∼7 nm in diameter) in the presence of 1–hexanediol and $Cu(NO_3)_2$. It is also reported that metal oxides can be prepared in SCW using metal nitrate salts, which decompose via a two-step mechanism of hydrolysis and dehydration [194]. The high temperature of SCW promotes crystallization, which eliminates the need for postprocess annealing. Oxidizers/reducers can be added to the reaction mixture to influence the product chemistry.

Water-in-sc–CO_2 microemulsions have been used as "microreactors" to produce nanocrystals of cadmium sulfide and silver [195, 196], while water-in-sc–ethane and water-in-sc–propane microemulsions have been similarly used to produce copper nanocrystals [197, 198]. Arrested precipitation methods have also recently been utilized in SCFs to produce sterically stabilized silicon nanocrystals (in sc–octanol and sc–hexane) [199] and silver, copper, palladium, platinum, and iridium nanocrystals (in sc–CO_2) [200].

Supercritical antisolvent precipitation (SAS), based on the fast dissolution of a liquid solution in a supercritical fluid, has been tested to produce nanoparticles of yttrium, samarium, europium, gadolinium, and neodymium acetates to be used as precursors for high-temperature superconductors [201, 202] and as a zinc oxide precursor (zinc acetate) [203]. Rapid expansion of supercritical solution (RESS) is another technique that has been tested for the preparation of nanoscale PbS particles. In this technique, one: (1) expands the supercritical solution into a liquid solution instead of a gas,

and (2) uses a reacting system in which one reactant is dissolved in the supercritical solution and one in the liquid receiving solution [204]. Supercritical ammonia, methanol, and acetone solutions have also been used for RESS. Most recently, a supercritical-assisted atomization (SAA) technique was also proposed and demonstrated for producing nanoparticles of different kinds of compounds (superconductor and catalyst precursors, ceramics, and pharmaceutical compounds) using different liquid solvents such as water, methanol, and acetone [205]. The chemical transformation of metallic precursors in a supercritical fluid (a mixture of CO_2/C_2H_5OH or NH_3) has been developed as a new route for obtaining ultrafine homogeneous ceramic powders (oxides [Cu_2O, Fe_3O_4, Ga_2O_3] and nitrides [Cu_3N, Fe_4N] [206]). This process consists of the solubilization and subsequent thermal decomposition of acetylacetonates of metals in SCF.

3.3. Solid-Phase Synthesis

Solid-phase syntheses are those methods in which nanoparticles are formed directly from solids or semisolids (such as viscous liquids). Most of these types of syntheses belong to the top-down approach, which includes traditional mechanical grinding and solid-state reactions. In the effort to produce nanoparticles, some new innovations have been added to these traditional methods, such as introducing reactive materials into the milling process, as shown in Figure 5, and combining milling with solid-state synthesis. Some new approaches include the extraction of soluble molecules from a uniform molecular solid mixture by acid/base leaching or evaporation to leave molecular skeleton residues that become nanoparticles.

3.3.1. Mechanical Milling

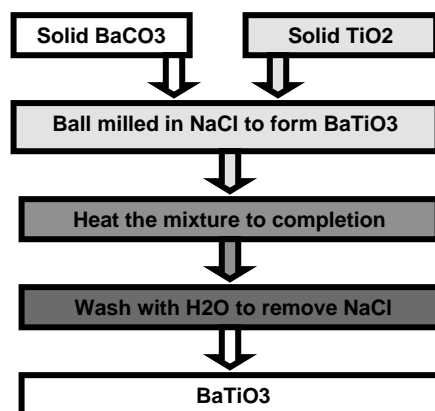
Mechanical forces, such as those involved in high-energy ball milling, are used to break bulk materials down. Plastic deformation and dislocation of cell structures are responsible for producing highly strained amorphous particulate materials. Crystalline nanoparticles can be produced when the dislocation of cells disappears. High-energy ball milling is already commercialized for generating magnetic [207], catalytic [208], and structural [209] nanoparticles.


Figure 5. Flowchart for a mechanochemical synthesis.

Bohwmik et al. [210] have obtained 16 nm nanoparticles of antiferromagnetic spinel $CoRh_2O_4$ by the mechanical milling of bulk materials for up to 60 h. Magnetic measurements suggest that the antiferromagnetic ordering at TN at 27 K exists in bulk as well as in nanoparticle samples. Nanoparticle $Co_{0.2}Zn_{0.8}Fe_2O_4$ spinel oxide was also synthesized by room-temperature mechanical milling [211]. The system is stabilized mainly in the spinel oxide phase after 78 h of milling time, and no other phases have been observed.

The simplicity of mechanical milling has shown its potential in nanoparticle synthesis without complex capital equipment. The development of new technologies such as bead mills with very small beads, and their use in combination with classification/filtration, make this technology applicable to nanoparticle synthesis. A drawback in this technology is contamination from media.

3.3.2. Mechanochemical Processing

Mechanochemical processing is considered the natural extension of mechanical processing. Here, the process not only involves physical reduction in a material's size, but it also uses the milling energy to initiate chemical reactions between the materials that are being milled. It usually involves two or more solid reactants. Sometimes, the starting materials are milled together in the presence of a large amount of sacrificial salt, such as NaCl, which prevents the agglomeration of the resulting nanoparticles, as shown in Figure 5 [212]. More and more mechanical milling processes are incorporating chemical reactions to make the process more amenable to nanoparticle syntheses [213]. Table 11 shows examples of nanoparticles of ferrites, $CaTiO_3$, SnO_2, Ag, Fe_2O_3, $CaCO_3$, Cu, Al_2O_3, $PbTiO_3$, ZnO, CeO_2, Cr_2O_3, Gd_2O_3, ZrO_2, and Group II–VI semiconductors that were made using mechanochemical methods.

Mechanochemical synthesis uses mechanical energy to activate chemical reactions, and to cause surface and structural change of the materials [214]. As a consequence, chemical reactions which otherwise require high temperatures can occur at low temperatures in a ball mill without external heating or with low external annealing.

Abe and co-workers [215, 216] made submicron $BaTiO_3$ by ball milling TiO_2 with $Ba(OH)_2 \cdot 8H_2O$ in acetone for 6 h without external heating. A boundary–reaction-controlled interface contracting kinetics, and contraction kinetics with a crystallinity gradient inside the TiO_2 particles, have been proposed for the formation of $BaTiO_3$.

van Hal et al. [217] showed the feasibility of making submicron $BaTiO_3$ by ball milling BaO_2 with TiO_2 for 256 h. The products are $BaTiO_3$ agglomerates consisting of 50% particles with a crystallite size of 12 nm, 30% particles with a crystallite size of 2 nm, and 20% amorphous particles. Heating of these agglomerates at 800 °C did not significantly improve the crystallinity.

McCormick and Tzuzuki [218] made truly nanosized $BaTiO_3$ by milling $BaCO_3$ and solid TiO_2 with a large amount (three times the mass of $BaCO_3$ plus TiO_2) of sacrificial salts, such as NaCl, for a few hours. Such milling induces reactions between $BaCO_3$ and TiO_2, as well as mixing of $BaCO_3$ and TiO_2. The diluent phase NaCl may have

two roles. The major role is to dilute or coat the $BaTiO_3$ particles formed so that the nanosized $BaTiO_3$ will not agglomerate together. The second role may be to promote the chemical reaction between $BaCO_3$ and TiO_2. To complete the reaction, the milled products were subjected to external heating for 30 min at 700 °C. A final washing to remove NaCl with large amounts of water is needed to recover $BaTiO_3$. $BaTiO_3$ of 50–100 nm was produced. However, there are still issues regarding the ability to achieve phase-pure materials with the proper Ba/Ti ratio, the need to prevent contamination from milling media and NaCl, and the desire to reduce the amount of waste water from extensive water washing. Furthermore, it is difficult to keep the nanosized $BaTiO_3$ from agglomerating again during washing, filtering, and drying after the $BaCl_2$ is dissolved away.

Mechanochemical processing has been demonstrated to be very versatile in making a broad range of nanoparticles (as shown in Table 11), including metals, oxides, carbonates, and sulfides. The chemical reactions for particle synthesis could happen during milling, but it is not necessary that they happen during this phase of the process. It is only necessary for the crystal size to be refined to the nanometer level during milling, after which the chemical reactions can be induced with a low-temperature heat treatment. Particle size control in this process is achieved via the milling conditions, and also by the addition of diluents, and this process has been shown to produce a range of sizes from 4 to 500 nm. It is cost effective in that it uses simple starting materials and simple milling equipment. The disadvantages of this process include contamination from milling vessels and media. The washing of the byproducts after heat treatment also presents challenges because a large volume of water is consumed, and because agglomeration of the particles may occur during washing and drying.

3.3.3. Cryochemical Processing

Cryochemical processing is a low-temperature process in which rapid cooling is applied to preserve the homogeneity of atomic-level mixtures. The cooling is usually very fast in order to prevent separate crystallization of solutions such as soluble nitrates. This is usually achieved by spraying the solution into liquid nitrogen. Removal of frozen water is usually accomplished by physical (freeze drying) or chemical means. Many cryochemical techniques have been developed for powder processing [219–222]. The process can be described by the following diagram:

Preparation of a clear solution

↓

Rapid freezing of the solution

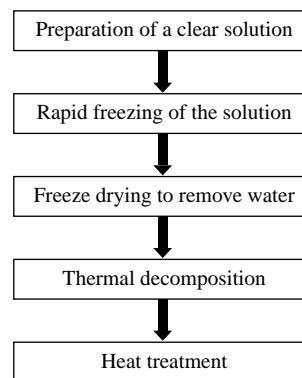
Heat treatment


Table 11. Nanoparticle synthesis by mechanochemical process.

Nanoparticle materials	Characteristics of nanoparticle	Brief process description	Applications	Ref.
Ferrites (Fe_3O_4/Fe_2O_3, $CoFe_2O_4$, $Ni_{0.5}Zn_{0.5}Fe_2O_4$)	20–30 nm, spinel structure	Mechanochemical reaction in aqueous solution of various corresponding chlorites and NaOH in a horizontal mill	Wide field of technological applications	[385]
$CaTiO_3$	20–30 nm crystallite	Mixture of CaO and TiO_2 was milled in a planetary mill at 200–300 rotations/min for 2–10 h	Dielectric materials and other applications	[386]
SnO_2	5–30 nm, tetragonal and orthorhombic SnO_2 formed after heat treatment	Mechanochemical milling of SnCl2 and Na_2CO_3 followed by heat treatment in air	Various applications	[387]
Ag	50–1000 nm metallic silver with minor quantity of Ag_2Na	A solid-state displacement reaction between AgCl and Na by ball milling in a planetary-type ball mill. The byproduct NaCl was washed out	Electrode material, pigment, etc.	[388]
Fe_2O_3		Ammonium acetate as precipitating agent	Magnetic materials	[95]
$CaCO_3$	80–140 nm, crystalline	Milling of a $CaCl_2$–Na_2CO_3 powder mixture, followed by heat treatment of the as-milled powder at 350 °C. NaCl was washed away	Various applications	[389]
Cu	Cu crystallite size of 28 nm with 3vol% $CuO \cdot Al_2O_3$	Milling CuO–$CuO \cdot Al_2O_3$ mixture for 8 h	Electronic materials, pigments, etc.	[390]
Al_2O_3	10–50 nm amorphous alumina	Milling ZnO and Al powder	Coating, paints, and various applications	[391]
$PbTiO_3$	10 nm grain size	High-energy ball mill of lead oxide and titanium oxide for 20 h without any posttreatment	Electric applications	[392]
ZnO, CeO_2, SnO_2	28, 10, 40 nm crystalline nanoparticles, respectively	Milling of chlorides and carbonates, followed by water washing	In many industries	[393]
Cr_2O_3	10–80 nm crystalline	Milling of $NaCr_2O_7$ with S powder to form amorphous Cr_2O_3; crystalline Cr_2O_3 was formed after annealing under vacuum at 520 °C. Water washing to remove Na_2SO_4 formed	Various applications	[394]
II–VI semiconductor	<10 nm	Milling of chloride salts and alkali or alkaline earth chalcogenides, postheat treatment, and washing	Various applications	[395]
Gd_2O_3	20 nm cubic structure	Milling $GsCl_3$ with NaOH in the presence of NaCl, followed by calcinations at 500 °C	Various applications	[396]
ZrO_2	15–18 nm crystallite size stabilized zirconium in c–ZrO_2 polymorph with 5 mol% Cr^{3+} and Cr^{4+}	Milling (NH4)2Cr_2O_7 with amorphous precipitation of Zr(=4) oxyhydroxide, followed by heating at 500 °C	Coatings and other applications	[397, 398]

Tretyakov and Shlyakhtin [222] have provided an excellent review of recent progress in the cryochemical synthesis of oxide materials. A broad range of materials has been synthesized using cryochemical methods. These materials include ferrites, catalysts, resistive materials, high-temperature superconductors, magnetic semiconductors, superionics, and phosphors. One unique feature of this synthesis is that there is a large difference between the specific molar volumes of the frozen precursor salt and the oxide product formed after thermal decomposition of the precursor salt. Thermal decomposition transforms the salt crystallites into a porous oxide framework of almost the same size and shape as the initial salt crystallites. Subsequent heat treatment causes the rearrangement and sintering of framework elements of 10–40 nm in size into larger aggregated particles of 50–300 nm.

McHale et al. [223] recently demonstrated the synthesis of nanocrystalline $BaTiO_3$ using cryochemical methods. They first prepared a titanyl nitrate solution of pH 1.2 by dissolving hydrolyzed titanium isopropoxide with a diluted nitric acid. $BaCO_3$ was added to this acidic solution to achieve a molecular mixture solution of Ba:Ti = 1:1. This nitrate solution was then atomized using an ultrasonic spray nozzle, and was rapidly frozen by allowing the aerosol to fall into stirred liquid nitrogen. The fine white-to-pale-yellow particles ("snow") were then dried in a freeze dryer at about $-30\,°C$. The highly reactive precursor powder obtained from this freeze drying could be completely converted into 10–15 nm nanocrystalline $BaTiO_3$ of cubic structure by heating at $600\,°C$ for 10 min. Prolonged heat treatment at $600\,°C$ for up to 24 h resulted in little grain size growth. Higher temperature calcination and annealing, however, significantly grew the grain size (500 nm at $1000\,°C$), and resulted in the appearance of the tetragonal form of $BaTiO_3$.

Kirchnerova and Klvana [224] synthesized submicron lanthanum–strontium transition metal-based perovskites based on cryochemical methods. They used a reactive aqueous slurry of lanthanum (or another rare earth metal) hydroxides and of metal nitrate solution as a starting material. This well-homogenized suspension was then spray frozen, freeze dried, and calcined at as low as $627\,°C$ to form the perovskite phase.

Thierauf et al. [225] produced superconducting YBCO powders of less than 300 nm via a freeze-drying process using the dissolved acetates as precursors. A crystallization temperature as low as $720\,°C$ in air was realized due to the short diffusion lengths in the freeze-dried precursor materials.

The cryochemical method has broad applications; however, freeze drying itself cannot form the final products directly. A final calcination and annealing are always needed. This thermal treatment always aggregates, agglomerates the particles, and grows large crystals, which makes it difficult to synthesize monodispersed nanoparticles.

3.3.4. Self-Combustion Method

The self-combustion method has been widely used in the synthesis of oxides/ceramic particles. It is known by different names, such as self-sustaining/propagating high-temperature synthesis (SHS) [226], the combustion method

[227] and autoignition process [228], or is sometimes more specifically called glycine–nitrate synthesis [229, 230], and the organometallic polymer precursor method [231]. This method utilizes rapid exothermic reactions to form solid fine particles directly. It involves a molecular mixture of oxidizers (e.g., metal nitrates, ammonia nitrates, or ammonia perchlorate) and reducers (e.g., carbonaceous materials such as urea, carbohydrazide, glycine, PVA, sucrose, and EDTA), which can be ignited at relatively low temperatures. The ratio of oxidizer to reducer is usually calculated according to Jain and Adiga's methods [232]. The combustion reaction can be initiated in a lab muffle furnace or even on a hot plate at temperatures of lower than $500\,°C$. The process can be illustrated by the following diagram:

In the above diagram, the route ending on the right side usually involves polymers such as polyvinyl alcohol (PVA), carboxylated starch (PAA) or sucrose, or complexing agents such as organic acids or organic amines and metal nitrates [227, 233, 234]. The route ending on the left side usually involves an unstable system such as metal nitrates and glycine, which could initiate self-combustion at temperatures as low as $200\,°C$ [235–237].

Pathak and Pramanik [227, 238] have synthesized over 50 different ceramic oxides using combustion methods. These oxide systems include

- metal oxides: $Fe_2O_3\cdot NiO$, $Fe_2O_3\cdot CuO$, $Fe_2O_3\cdot TiO_2$
- metal phosphates: $Co_3(PO_4)_2$, $Ni_3(PO_4)_2$, $Cu_3(PO_4)_2$, $Ba_3(PO_4)_2$, $AlPO_3$, $CrPO_4$, $FePO_4$
- metal vanadates: $Ca_3(VO_4)_2$, $Co_3(VO_4)_2$, $Ni_3(VO_4)_2$, $Cu_3(VO_4)_2$, $CrVO_4$, $FeVO_4$, $MnVO_4$
- metal molybdates: $CaMoO_4$, $NiMoO_4$, $CoMoO_4$, $MgMoO_4$, $Sm_3(MoO_4)_3$, $Gd_3(MoO_4)_3$
- metal tungstates: $CaWO_4$, $MgWO_4$, $NiWO_4$, $CoWO_4$
- rare-earth aluminates: $LaAlO_3$, $SmAlO_3$, $NdAlO_3$
- PZT and PLZT.

Their methods involve the combustion of a polymer (PVA or sucrose) and/or complex-based (EDTA/TEA/DEA) nitrate solution(s). The polymer plays a dual role in the process: it acts as a dispersing agent for the cations in the solution, and it also serves as a fuel that provides heat through combustion during calcination of the precursor powders. The principle of their methods is to atomistically disperse the metal ions in a matrix provided by a polymeric reagent or through complexation with various chelating agents that possess good coordination properties with metal ions. Evaporation of the precursor solutions results in a fluffy, voluminous carbonaceous mass that constitutes the precursor materials. The resulting particles from combustion of the precursor powders are 10–90 nm in diameter, have a narrow size distribution of high purity, and are obtained at relatively lower pyrolysis temperatures than those obtained from direct calcinations.

Chick and co-workers [229, 230, 235, 236, 239–242] have prepared nanosized metal powders such as Ni, Cu, and Fe, or the two-metal system containing Ni and Cu, using a glycine–nitrate combustion method. Their method consists of two steps. First, metal nitrates and a low molecular weight amino acid are dissolved in water. Second, the solution is boiled until it thickens and autoignites, undergoing self-sustaining combustion. The ash from the combustion is

composed of the oxide products. The glycine molecule has a carboxylic acid group at one end, with an amine group at the other, and serves two purposes: it prevents selective precipitation as water is evaporated, and it serves as fuel for the combustion, being oxidized by nitrate ions. The fuel-rich mixtures produce 10 nm spherical Ni (with 15% NiO), 30–40 nm Cu. The disadvantage of this method is that, in general, the glycine–nitrate combustion tends to produce agglomerated particles.

McKittrick et al. [243] prepared yttrium aluminum garnet ($Y_3Al_5O_{12}$, YAG) using a combustion process. They dissolved the metal nitrates with carbohydrazide in water, and placed the container in a muffle furnace preheated to 560 °C. The reaction proceeds as the precursor solution first boils, dehydrates, decomposes, and ruptures into a flame after 5–10 min, with the flame being sustained for about 15 s. The gaseous products that exist in greatest abundance are N_2, CO_2, and H_2O if the ratio of fuel to oxidizer is stoichiometric. The powders produced are single phase and well crystallized. The combustion-synthesized powders have an unusual morphology, forming a porous, foamy network in the as-synthesized state, due to the rapid release of gaseous products. The porous powders were easily reduced to a small particle size with light mixing. Combustion synthesis produces powders that are luminescent in the as-synthesized state, an attribute unattainable by conventional methods.

Another modification of combustion synthesis has been explored by Salze et al. [231] for synthesizing ZrO_2, La_2NiO_4, and $BaTiO_3$. The initial organometallic solution is obtained by first making an organic solvent solution (dissolution of 400 g citric acid in 500 mL of ethylene glycol). The solution is mechanically stirred until it becomes clear. To prepare tetragonal zirconia, zirconium n–propoxide and yttrium carbonate are dissolved in this organic solvent solution. To prepare pure $SrTiO_3$ or $BaTiO_3$, the corresponding titanium isopropoxide and $SrCO_3$ or $BaCO_3$ (dissolved in formic acid) are dissolved in the above-mentioned organic solvent solution. To prepare doped $SrTiO_3$ or $BaTiO_3$, niobium ethoide is also added to the solutions cited for preparation of pure $SrTiO_3$ or $BaTiO_3$. To prepare lanthanum nickelate, lanthanum and nickel hydroxides freshly precipitated from nitrate solutions are dissolved. After polymerization at 110 °C in an Al_2O_3 crucible, a translucent resin having a homogenous chemical composition is obtained. This resin is then combusted in air or pure oxygen to obtain the desired powders. The mean diameters of individual particles observed by TEM are 10–60 nm for ZrO_2 combusted in oxygen at 400–950 °C, 10 nm for $SrTiO_3$ in air at 600 °C, 10 nm for $BaTiO_3$ in air at 800 °C, and 35 nm for La_2NiO_4 in air at 600 °C.

Zhou et al. [228] have synthesized 10 nm ZrO_2 containing up to 20mol% CeO_2 using the autoignition method. Zirconyl nitrate, cerous nitrate, and urea powders with stoichiometric composition are dissolved in water, and are then converted to tetragonal ZrO_2 by evaporation and combustion in a 600 °C furnace. The result is a foamy yellow powder with the characteristic color of ZrO_2 (CeO_2) powders.

Rajan et al. [244] recently synthesized 4–16 nm barium holmium zirconate, a new complex perovskite ceramic oxide, using a modified self-propagating combustion process. XRD
Figure 6. CeO_2 nanoparticles prepared from a combustion method [246].

and electron diffraction studies have shown that the as-prepared powder is phase-pure $Ba_2HoZrO_{5.5}$, and has a complex cubic perovskite ($A_2BB'O_6$) structure with a lattice constant $a = 8.428$ Å. The nanoparticles of $Ba_2HoZrO_{5.5}$ could be sintered to 98% theoretical density at 1500 °C.

Yu et al. [245] prepared nanosized $PbTiO_3$ powders using the self-combustion technique. $Pb(CH_3CHOHCOO)_2$ was used as the Pb precursor, and was formed from the reaction between PbO and $CH_3CHOHCOOH$, with viscous lactic acid as the solvent. The system lead lactate–lactic acid–ethanol–titanium butoxide was selected as the precursor for processing of $PbTiO_3$.

Feng [246] synthesized spherical CeO_2 using a combustion method, as shown in Figure 6. He prepare an $(NH_4)_2Ce(NO_3)_4$ aqueous solution, and added acetyl acetone and isopropanol as fuel and as complexing agents. This clear solution was turned into a viscous liquid by evaporation, and further heating on a hot plate induced vigorous self-combustion to form 15–80 nm crystalline CeO_2 particles directly.

Self-combustion synthesis has been widely demonstrated as effective for synthesizing ceramic powders [228, 237, 240, 247–256]. The technique may need more development to prevent agglomeration and aggregation of the powders during synthesis. Safe scale up to a commercial process demands further optimization studies.

3.3.5. Solid-State Synthesis

This is the most traditional approach for making many ceramic powders such as $BaTiO_3$. It involves milling $BaCO_3$ with TiO_2 to achieve comminution and mixing. This mixture is then calcined at 900–1200 °C to generate $BaTiO_3$. The reaction mechanism has been described in the literature to have the following steps [257–259]:

1. interface reaction by diffusion of Ba into TiO_2 to form a $BaTiO_3$ shell (layer) around TiO_2; the shell also limits Ba diffusion into TiO_2:

$$BaCO_3 + TiO_2 \rightarrow BaTiO_3 + CO_2$$
Figure 7. Solid-state reaction through interdiffusion to form BaTiO$_3$ during calcination.

2. formation of the orthotitanate phase:

$$BaCO_3 + BaTiO_3 \rightarrow Ba_2TiO_4 + CO_2$$

$$BaCO_3 + TiO_2 \rightarrow Ba_2TiO_4 + 2CO_2 \text{(less likely)}$$
3. final formation of BaTiO$_3$:

$$Ba_2TiO_{4+}TiO_2 \rightarrow 2BaTiO_3.$$
The high calcination temperature is needed to promote the interdiffusion of barium and titanium, which results in the solid-state reaction to form barium titanate, as shown in Figure 7. The distance of the interdiffusion depends on the sizes of the raw materials BaCO$_3$ and TiO$_2$ used for synthesis. After milling, these particles are usually in the range of 0.5 μm, and the interdiffusion distance is usually larger than 1 μm in the traditional solid-state synthesis. The reaction rate is controlled by this diffusion [260]. The interdiffusion is usually incomplete during calcination due to the large diffusion length, and therefore the final products usually contain titanium-rich and barium-rich intermediate particles [257, 261].

It has also been well known that BaTiO$_3$ is formed through a sequence of reactions and intermediate phases [258], and that prolonged calcinations at high temperature are usually needed to reduce the heterogeneities in the final products. This usually results in large and agglomerated particles which need extensive milling before BaTiO$_3$ can be used in the various forming processes. Milling introduces high levels of impurities from the milling equipment and media, such as alumina, silica, zirconia, and phosphorus. These impurities are known to have a deleterious effect on the electrical and mechanical properties of barium titanate-based products [262].

Current efforts in solid-state methods for synthesizing ultrafine particles of BaTiO$_3$ have been aimed at reducing the interdiffusion distance by utilizing finer starting materials or through intensive milling or utilization of precipitation to produce the solid starting materials *in-situ*.

High-energy ball milling of BaCO$_3$ and TiO$_2$ (rutile) has reduced BaTiO$_3$ formation temperatures down to 730 °C, and the resulting BaTiO$_3$ has a crystallite size of 40 nm [263]. The detrimental phases, like Ba$_2$TiO$_4$ (orthotitanate), have only been revealed as an intermediate minor phase that disappears by annealing at temperatures as low as 750 °C.

It has also been shown that milling does change the reaction sequence between BaCO$_3$ and TiO$_2$ [264]. However, milling reduces the formation temperature and accelerates the formation rate of BaTiO$_3$.

Instead of using solid TiO$_2$ particles, Han and Koo [265] precipitated titanium hydroxide/oxide particles directly onto the surface of BaCO$_3$. TiCl$_4$ or Ti alkoxide solutions were added directly to an aqueous slurry containing fine particles of BaCO$_3$ and ammonia at pH 9.5–10.3. The nanoparticles of titanium hydroxides/oxides were deposited or coated on the surface of BaTiO$_3$, which effectively reduced the interdiffusion distance. The filtered slurry was then calcined at 950 °C for 2 h to produce 180 nm BaTiO$_3$.

In a similar study, coprecipitation of a mixture of BaCl$_2$ and TiCl$_4$ with a solution of ammonium carbonate has also been studied [266]. It was found that crystallization of amorphous barium tetratitanate was observed when the precipitates were heated above 600 °C. At the same time, the following reaction is also suggested:

$$BaTi_4O_9 + BaCO_3 = 2BaTiO_3 + 2TiO_2 + CO_2.$$
The newly formed TiO$_2$ begins to react with BaCO$_3$ directly at 800 °C:

$$BaCO_3 + TiO_2 \rightarrow BaTiO_3 + CO_2.$$
The above reactions approached completion at 1100 °C.

Li et al. [267] used a solid-state reaction process to prepare perovskite-type LaCoO$_3$ nanocrystals with grain diameters of 15–40 nm. In the first step of the process, 5 nm composite hydroxide nanoparticles were prepared by the solid-state reaction of La(NO$_3$)3·nH$_2$O and Co(NO$_3$)$_2$6·H$_2$O with KOH at ambient temperature. A perovskite-type rhombohedral LaCoO$_3$ phase appeared at 550 °C after the hydroxide was calcined at various temperatures. The phase transformation process was complete at about 800 °C, yielding a single-phase binary oxide.

Wang et al. [268] developed a one-step solid-state reaction in the presence of a nonionic surfactant, PEG 400, to synthesize CuO nanowhiskers with diameters of approximately 2–10 nm and lengths of more than 100 nm.

Zhuang et al. [269] prepared a precursor Co$_2$(OH)$_2$CO$_2$ by the solid-state reaction of Co(NO$_3$)$_2$6·H$_2$O with NH$_4$HCO$_3$ at ambient temperature. Nanophase Co$_3$O$_4$ with an average particle size of 13 nm was obtained by decomposition of the precursor at 250 °C for 3 h.

Yu et al. [270] prepared CeO$_2$ ultrafine particles by solid-state reactions at room temperature. These particles were found to have very fine particle sizes ($\sim$3 nm) with a fluorite structure ($a = 5.42$ Å). BET measurements showed that the surface area of the particles was 96.2 m^2/g.

All of these current efforts in solid-state synthesis focus on minimizing the interdiffusion distances of solid-state reactions through intensive milling, coating particles with nanoparticles, and coprecipitations. The reduced interdiffusion effectively lowered the BaTiO$_3$ formation temperature, but the completion of the formation reaction still requires calcination temperatures from 750 to 1100 °C. This high-temperature calcination will inevitably promote particle agglomeration and particle size growth. The improvement in the solid-state reaction technique may be able to produce solid-state BaTiO$_3$ down to 300 nm at industrial quantity, but it is extremely difficult, if not impossible, to produce BaTiO$_3$ at about a 100 nm range via this method.

3.3.6. Colloidal Assembly Method

Colloidal assembly is a process by which nanometer-sized colloids (nanoparticles) are organized into structures by mixing two or more particle types (differences in sizes and/or chemical nature [271]). Assembly is controlled by either specific or nonspecific interactions between particles. The assembly process is usually performed such that smaller particles assemble around larger ones. Examples include chemical bonding, biological interactions, electrostatic interactions, capillary action, and physical adsorption.

Pileni [272] has reviewed syntheses of nanosized particles that used colloidal assemblies as templates. The chemical mechanisms in nanoparticle production using colloidal assemblies can differ from those usually observed in homogeneous solutions. The colloidal systems mimic nature to control the size and shape of nanomaterials. It is possible to select the size and markedly reduce the particle size distribution by using a surface treatment of the nanoparticles. This favors the formation of mono- and multilayers made of nanoparticles. These particles form crystals organized in a 3-D face-centered cubic superlattice.

An unusual phase diagram is presented by Pileni et al. [273]. It is composed of copper(II) bis(2–ethylhexyl) sulfosuccinate Cu(AOT)2–isooctane–water. Syntheses performed in the various parts of the phase diagram show that the use of colloidal assemblies as templates favors control of the shape of nanoparticles. Cylindrical metallic copper particles having the same size can be obtained in various parts of the phase diagram when the template is made of interconnected cylinders. A small number of cylinders (13% of the amount that could be formed) are formed when the synthesis is performed in cylindrical reverse micelles. When the colloidal self-assembly is a mixture of several phases, various types of shapes can be obtained. In some cases, the polydispersity in size is so low that metallic particles are able to self-assemble in a hexagonal network. Multilayers can be observed, and are arranged in an FCC structure.

Monolayers of nanoparticles have been physically adsorbed onto highly oriented pyrolytic graphite, first by self-assembly, and second by assembly as Langmuir films and subsequent deposition. Nanoparticles have been self-assembled on gold, and immobilized by chemical absorption, using decanedithiol during assembly as a linking molecule. Rolandi et al. [274] have obtained scanning tunneling microscope images of the monolayers of gold nanocrystals, with mean diameter 2.8 nm, coated with an insulating chemically stable self-assembled monolayer of dodecanethiol.

Kurth et al. [275] have demonstrated that self-assembly of CdTe nanoparticles and alkylammonium surfactants gives stable, hydrophobic surfactant-encapsulated CdTe clusters that can be isolated as solid materials which dissolve in common organic solvents, spread at the air–water interface, and show enhanced photochemical stability.

Christophe and Pileni [276] have used colloidal assemblies to synthesize FCC cobalt nanoparticles. The nanocrystals are coated and extracted from micelles. These cobalt metal particles are stable in air, and have a narrow size distribution. After deposition on a graphite support, these nanocrystals form a 2-D hexagonal network. The magnetic properties are compared when they are dispersed in a solvent and organized in 2-D superlattices. Changes in the hysteresis loop and in the blocking temperature are observed, and are attributed to a collective flip of the magnetization of adjacent particles.

Self-assembly of solid colloids into nanoparticles with the assistance of organic molecules, surfactants, and polymerized vesicles has also been inspired by Mother Nature's organizational ability [26, 27, 234, 271, 277–279]. This method could provide a unique way to synthesize stable and unagglomerated nanoparticles at low temperature and in an environmentally friendly way [280, 281].

3.3.7. Selective Leaching of a Single-Phase Solid-Solution Method

This is a top-down approach, but at a molecular scale. In this approach, a precursor powder of normal size (micro or macro) containing the desired elements is synthesized by any conventional method, such as a solid-state method. The unwanted species are then chemically leached away in a suitable liquid, which could be either water or an acid solution. The concomitant change in volume and crystal evolution during leaching leads to the formation of molecular-level fragments, resulting in nanoparticles. Jiang et al. [19] have demonstrated the synthesis of nanosized yttrium-stabilized zirconium by using this method. They have demonstrated this approach using two different precursors, Na_2ZrO_3 and $BaZrO_3$.

For the preparation of yttrium-stabilized $BaZrO_3$, the starting materials $BaCO_3$, ZrO_2, and Y_2O_3 were mixed in the requisite proportion, wet ball milled in alcohol for 24 h, and then dried. For the preparation of $Y–Na_2ZrO_3$, Na_2CO_3 and commercial yttrium-stabilized zirconium (YSZ) powders were mixed, wet milled, and then dried. The ball-milled and dried powders were calcined at various temperatures, and the resulting powders were examined to ensure that completely converted single-phase precursor powders (i.e., $Y–BaZrO_3$ or $Y–Na_2ZrO_3$) had been formed.

Chemical leaching of BaO from $Y–BaZrO_3$ was achieved in dilute aqueous HNO_3 solution. The $Y–BaZrO_3$ was boiled in a dilute HNO_3 solution, filtered, and washed repeatedly until the solution pH no longer changed. The washing process leached Ba^{2+} and left $Y–ZrO_2$ behind:

$$Y–BaZrO_3 + 2HNO_3 \rightarrow Ba(NO_3)_2 + Y–ZrO_2 + H_2O.$$
For the $Y–Na_2ZrO_3$ precursor, repeated boiling in water is sufficient to remove sodium according to

$$Y–Na_2ZrO_3 + 2H_2O \rightarrow 2NaOH + Y–ZrO_2.$$
Chemical analysis of the boiled and washed powders showed only ZrO_2 and Y_2O_3.

XRD patterns of leached and washed powders from both precursors were identical, even though they showed very different XRD patterns before leaching. Both end products showed an XRD pattern similar to commercial $Y–ZrO_2$. The particle size was a few nanometers, and increased to tens of nanometers after thermal treatment at a temperature of 1000 °C.

4. SUMMARY

Here brief review of ceramic nanoparticle syntheses is provided. Nanoparticles can be defined as particles with a size range from 1 nm to a size whose ratio of the number of atoms on the surfaces and at the grain boundaries to the atoms at the center is such that new physical, chemical, and biological properties occur when compared with their corresponding bulk materials. The challenges in manufacturing nanoparticles are: controlling their size, morphology, crystallinity, shape, and properties, and making them with a variety of materials at large volumes and at a reasonable cost. The synthetic methods can be classified by the strategy of the synthesis (top down or bottom up), by the nature of the synthetic process (physical, chemical, or biological), by energy sources (laser, plasma, sputtering, microwave, electron beam, heating, freeze drying, hydrothermal, mechanical milling, combustion, flame, supercritical, etc.), and by the media in which nanoparticles are formed (gas, liquid, and solid). Gas-phase syntheses are actively coupled with liquid dispersion to achieve better deagglomeration. There is an increasing trend of using nonaqueous solvents in liquid-phase syntheses for preparing nanoparticles with less agglomeration. Solid-phase syntheses such as mechanical milling have been increasingly coupled with chemical reactions to broaden their applications in nanoparticle synthesis. The most viable methods for the production of nanoparticles are those that utilize low temperatures since high-temperature treatment always means aggregation and agglomeration. Biomineralization could be one of the future means for synthesizing nanoparticles if the synthesis can be carried out quickly and on a large scale. Selection of the most suitable synthetic methods is usually based on

- the desired attributes of the product, such as particle size and its distribution, crystallinity (amorphous or crystalline), morphology (single particle or agglomerates), and composition (single component versus multiple components)
- media for delivery (in solvents, dry powders, or other deposited forms)
- quantity and cost tolerance (how much is to be produced, and what kind of cost the product can bear)
- production facility considerations (cost, complexity, and operating parameters such as temperature, pressure, and toxicity).

GLOSSARY

Gel Liquid particles/pockets suspended in a continuous solid phase.

Nanoparticles Particles with a size range from 1 nm to the largest nanometer dimension, where the ratio of the number of atoms on surfaces and at grain boundaries to those at the center is such that new physical, chemical, and biological properties occur, compared to bulk materials. A typical nanoparticle most often consists of several small "primary particles." The size of nanoparticles usually refers to the "secondary" particle size. Primary particles agglomerate into these "secondary" particles.

Sol Solid particles suspended in a continuous liquid phase.

Sol–gel process Refers to processing in a liquid medium to obtain solid matter at low temperature, and involves, first, the formation of sol, and then gel.

CONTENTS

1. INTRODUCTION

Ceramic nanopowders have received considerable attention during the last two decades, since they are expected to demonstrate improved or unique characteristics as compared to conventional ceramic materials [1–20]. Ceramic nanopowders can be utilized for various applications concerning mechanical, electronic, ionic, thermal, optical, and catalytic properties. In particular, the combination of a relatively large portion of interfacial or grain boundary atoms along with the interactions of photons, electrons, or dislocations can lead to unusual mechanical and electrical behavior.

The terminology of nanopowders is generally defined as powders having an average particle size of less than 100 nm. The specific advantages of the nanopowders include superior phase homogeneity and lower densification temperature. Beyond achieving nanoscaled particles, the control of other powder characteristics such as particle distribution, phase purity, and morphology are equally important in obtaining promising performance. For example, narrow size distribution and less agglomeration result in reduced microstructural defects in the sintered body by improving powder flow and packing efficiency during pressing. Figure 1 shows a typical example of ceramic nanopowers. The microstructure corresponds to the nanocrystalline powder (∼20 nm of average particle size) of a LiZn ferrite composition, which was prepared by a combustion synthesis method.

The value of achieving nanosized particles is believed to be strongly associated with crystal structure of the given ceramic material, its formation energy, and chemical reaction route if multiple phases are involved. Simple oxide systems that can be synthesized at relatively low temperatures by solid-state reactions have a great potential of producing nanocrystalline powders by chemical processing. The formation of nanocrystalline powder is often difficult when intermediate phases are involved or structural ordering is required prior to the formation of phase-pure ceramics. Intensive energy sources generated by nonconventional techniques such as plasma, laser, and microwave processing have been successfully utilized to suppress unnecessary particle growth but provide sufficient activation energies for nucleation within a relatively short period.

Nanoscaled particles agglomerate easily due to the very strong van der Waals attraction force between small particles. Particle agglomeration leads to in nonuniform packing density and inhomogeneous densification over the sample during firing. It can be minimized by additional processing treatments including chemical modification of particle surface, redispersion in a liquid medium, ultrasonication, or breaking-up in the dry state. Particle aggregation can also be a problem and often occurs after synthesis or subsequent calcination. Particle aggregation refers to a strong agglomeration state where particles form a neck between them by the recrystallization process during powder processing or thermal treatment. The aggregate acts as a single particle and is difficult to be broken up due to its strong bonding force.

There are several potential issues concerning the commercial production of ceramic nanopowders. They include cost efficiency, powder handling and related safety concerns, productivity, and difficulty in control of powder quality. High-reliability methods for the inexpensive production of large quantities of high-quality, multicomponent-capable nanopowders must be preferred for commercial applications to be realized.

This chapter concerning ceramic nanopowders consists of three major sections. The first section deals with chemical
Figure 1. Typical nanocrystalline ceramic powder.

processing methods that have been successful in preparing ceramic nanopowders. The brief introduction and principle of each chemical method will be described based on the classification of two major categories: liquid phase precipitation and gas phase condensation. The second section covers the sintering behavior of ceramic nanopowders and additional processing techniques to improve packing density and homogeneous densification. Finally, various examples of ceramic materials including zirconia, alumina, silicon carbide, silicon nitride, titania, titanates, and ferrites will be described with obtainable powder characteristics and property benefits.

2. CHEMICAL PROCESSING FOR NANOPOWDERS

Production methods of ceramic nanopowders can be classified into two broad categories: liquid phase precipitation and gas phase condensation. Specific methods have evolved that differ only in the means by which thermal or mechanical energy is supplied to the precursor species. While it is virtually impossible to avoid agglomeration in pristine nanopowders, the extent of agglomeration depends on the synthesis technique [16].

In liquid phase synthesis, such as sol–gel or hydrothermal processes, nanopowders can be produced with relatively narrow size distributions. However, such processes often produce nanopowders that contain chemical residues. Gas phase condensation processes can avoid some of the contamination problems but have problems with agglomeration and coalescence associated with the high temperatures involved.

2.1. Liquid Phase Precipitation

The most common and widely used liquid phase chemistry process is sol–gel. Other wet chemistry methods include precipitation from solutions, hydrothermal processing, and microemulsion techniques.

2.1.1. Sol–Gel Processing

The sol–gel process is when chemical methods are used to turn solutions of metal compounds such as organometallics, into gels [42]. It is a low-temperature synthesis technique whereby ceramic particles are produced from a liquid solution or a colloidal suspension of metallic acids, metallic chlorides, colloidal metal oxides, and/or metal alkoxides (general formula of $M(OR)_n$ where R is an alkyl and M is a metal with a valence n).

The sol–gel process can be used to prepare metal oxides via the hydrolysis of reactive metal precursors, usually alkoxides in an alcoholic solution, resulting in the corresponding hydroxide. Usually a catalyst is necessary to make these reactions rapid. Condensation of the hydroxide molecules by elimination of water leads to the formation of a network of metal hydroxide. When all hydroxide species are linked in one network-like structure, gelation is achieved and a dense porous gel is obtained. Removal of the solvents and appropriate drying of the gel results in an ultrafine powder of the metal hydroxide. Mixed oxide nanoparticles are synthesized by combining sols or co-hydrolyzing or co-polymerizing mixtures of alkoxides. Further heat treatment of the hydroxide leads to the corresponding ultrafine powder of the metal oxide. Since the process starts with nanosized units and undergoes reactions on the nanometer scale, it results in nanometer-sized materials [62, 66, 70].

Sol–gel processes have several advantages. These include the production of ultrafine porous powders and the homogeneity of the product as a result of the homogeneous mixing of the starting materials on the molecular level [27].

2.1.2. Hydrodynamic Cavitation

In hydrodynamic cavitation, nanoparticles are generated through creation and release of gas bubbles inside sol–gel solutions. By rapidly pressurizing in a supercritical drying chamber and exposing to cavitational disturbance and high-temperature heating, the sol–gel solution is intimately mixed. The erupted hydrodynamic bubbles are responsible for nucleation, growth, and quenching of the nanoparticles. Particle size can be controlled by adjusting the pressure and the solution retention time in the cavitation chamber [44].

2.1.3. Chemical Precipitation

Nanoscale particles can be synthesized by conventional chemical precipitation techniques. Although these systems can produce large amounts of nanosized powders, the rate of reaction is fast, difficult to control, and the powders tend to agglomerate and require post-treatment that will not produce nanocrystalline grain sizes. The use of homogeneous precipitation can help with these problems, producing <5-nm-size particles [61].

2.1.4. Hydrothermal Processing

Hydrothermal processes can be applied to most oxides. Most materials can be synthesized at temperatures <300 °C and at about 1250 psi. A water solution containing water soluble precursors is heated and pressurized to cause the metal ions to react with oxygen and hydroxide ions from the water. After treatment, the solution is brought back to ambient pressure and the ceramic nanoparticles collected [67].

2.1.5. Solvothermal Processing

Solvothermal synthesis is a similar process to hydrothermal except that the reaction is done in a solvent such as alcohol. Crystalline $BaTiO_3$ nanopowders were produced using a solvothermal process. This process had the advantages that stoichiometric powder can be obtained, the process was run under milder conditions than in an aqueous hydrothermal process, and the nanosized particles had a narrower size distribution and exhibited less agglomeration [35].

2.1.6. Microemulsion Technology

A microemulsion is a thermodynamically stable, optically isotropic, and transparent solution of two immiscible liquids (generally water and oil) stabilized by an interfacial film of surfactant. Water in oil microemulsion (or reverse micelles) can be used as microreactors to synthesize nanosized particles with a narrow particle size distribution. In a water in oil microemulsion, the aqueous phase is dispersed as microdroplets (typically 1–50 nm in size) surrounded by a monolayer of surfactant molecules in the continuous hydrocarbon phase. The key is controlling the growth inside the individual microdroplets. Since the microreactors are steric barriers for inhibiting the polymerization of reacting species among different droplets during the reaction period, the particles synthesized are smaller than 100 nm. It is possible to combine the microemulsion process with hydrothermal synthesis to produce nanoparticles of oxides such as titania. The hydrothermal treatment of the microemulsions enables crystalline nanoparticles to be formed under milder conditions than traditional post-treatment calcination processes [32, 33, 46, 68]. For silica particles, the size distribution correlates well with the size, connectivity, and stability of the microemulsion droplets. The final size distribution is predetermined in the particle's nucleation stage [34, 45].

2.2. Gas Phase Condensation

Gas phase synthesis is one of the best techniques with respect to size monodispersity. This can be achieved by using a combination of rigorous control of nucleation and growth with avoidance of coagulation by diffusion and turbulence. In addition, it is required to have effective collection of nanoparticles and their handling after the particles are formed. The stability of the collected nanoparticle powders against agglomeration, sintering, and composition changes can be ensured by collecting the nanoparticles in a liquid [48]. Gas phase synthesis offers easy control of process parameters including gas composition, pressure, temperature, and gas flows. Reactants can be gaseous, volatile liquids, or solids. Heating sources vary from conventional resistance furnaces, to lasers, plasma, and electron beams.

Advantages of gas condensation methods for preparing nanoparticles directly from supersaturated vapor include versatility, ease of performance and analysis, and generation of high-purity products. Disadvantages include high production cost because of lower yields, difficulty in scaling up, and potential reactions with the heating source [17].

Nanosized particles can be produced from the gas phase either by physical vapor deposition or by chemical vapor deposition. Physical vapor deposition involves vaporizing a material and then quenching the vapor. No chemical reaction takes place. This can be used for some oxides and carbides, but is not suitable for most ceramics that have lower vapor pressures [23, 24].

2.2.1. Physical Vapor Deposition

Physical vapor deposition can be done on a ceramic where it is vaporized, condensed from the vapor, and then solidified into a new form. The process can start with a ceramic source material which is then heated to above its melting point so that a vapor is created. Nanoparticles are formed when supersaturation is achieved above the vapor source. Generally, a high pressure of inert gas is usually needed to achieve supersaturation. When the atoms encounter colder gas atoms, they cool and condense to form solid nanoparticles. These particles are transported to a cooled surface by a convection current or by a forced gas flow. By using a forced gas flow, the particle size can be controlled through coalescence [17].

In the gas evaporation methodology, individual nanosized particles can collide with each other while they are being transported by the flow of the gas. When the collisions occur at temperatures below the particle coalescence temperature, the particles form secondary particles in which multiple particles are sintered together. These particles can aggregate further during the collection process. To collect the nanosized particles, a process is needed that removes the nanosized particles from the generation area and dilutes their concentration such that collisions no longer occur [38].

2.2.2. Chemical Vapor Deposition

Chemical vapor deposition (CVD) is the process where a chemical reaction in the gas phase occurs to form the ceramic composition. The chemical vapor deposition process has the following advantages: agglomeration of the powders produced is suppressed, narrow size distributions can be obtained depending on the reaction conditions, and the atmosphere can be easily controlled thereby allowing the production of nitrides, carbides, and borides which are not easily made by other processes.

Metal chlorides are widely used as starting materials. Particle size can be controlled by the reaction temperature and the composition of the reacting gases. The simplest gas phase reaction process involves passing reactive gases through an externally heated reactor called a hot-walled reactor. Variations on this process include chemical flame processes, plasma processes, and laser processes. The properties of the particles synthesized are dependent on the physiochemical characteristics of the reaction system, the construction of the reactor, the heating method, the temperature gradient, and the method of introducing the gas reactants into the reactor [40].

Nanosized ceramic oxides can be prepared through the oxidation of hydrolysis of volatile metal chlorides or direct oxidation of metal vapor. Hydrolysis of metal chloride vapors proceeds faster than direct oxidation and therefore produces smaller sized particles. The reactions of metal chlorides with ammonia to produce nitrides have large equilibrium constants and nitride powders can be produced at relatively low temperatures. In general, high temperatures

are needed for the formation of carbides because the equilibrium constants are generally small at low temperatures where the reaction rates are also slow [40, 64, 71].

Direct oxidation synthesis of nanosized ceramic oxides is done by heating and evaporating metals and semi-metals in an oxygen-containing atmosphere. Resistance, induction, or arc-discharge heating can be used to heat the metal. Resistance heating and induction heating have difficulties due to potential reactions between the molten metal and the heating device. In the arc-discharge heating, the electrodes themselves are evaporated, alleviating the problem associated with resistance heating.

The arc-discharge process consists of a formation chamber, consumable positive and negative electrodes, DC power supply, a gas supply, and a vacuum pumping system. Evaporated metal atoms from the electrodes are collided with atmospheric gas and cooled and reacted, condensing into nanosized particles. The formed particles are deposited on an inner wall of the formation chamber. Generally the atmospheric gas pressure is controlled between 150 torr and 500 torr and the electric current is controlled between 50 A and 200 A. The nanoparticle size and properties are dependent on the kind of atmospheric gas, electric currents, and the pressures [26].

2.2.3. Flame Processes

Additional gas condensation techniques involve using flames in a combustion type process [19, 49–53, 57, 63]. Chemical precursors are vaporized and then oxidized in a combustion process using a flame powered by a fuel-oxidant mixture such as propane-oxygen or methane-air. The energy from a flame is used to drive chemical reactions that result in the formation of species with low vapor pressures, which then nucleate to form particles. A typical sequence of events occurs over a short distance as products and then clusters form. Figure 2 illustrates the formation of nanoparticles by flame processes. The cluster concentration is very high, leading to collisions among the clusters to form particles. At sufficiently high temperatures and sufficiently small particle sizes, the particles coalesce to form larger units that become the primary particles. Further collisions among these primary particles while the gas is cooling leads to the formation of hard aggregates (collections of primary particles that do not have sufficient time or energy to fuse together). The aggregates can range from a few up to many thousands of primary particles. The size range for primary particles is from a few nanometers to 500 nm. Maximum flame temperatures usually range from 1200 K to 2500 K. The temperatures in flame reactors are lower than in plasma reactors, but usually higher than those found in hot-wall, evaporation-condensation, or laser reactors.

Advantages of flame reactors include the ability to produce simple oxides easily using short residence times, simple and relatively inexpensive systems to build and operate, high purity, and ability to produce a large range of sizes (generally in aggregates). Disadvantages include the formation of hard aggregates under most conditions, broad particle size distribution, difficulty in maintaining a uniform temperature and velocity profile, difficulty in producing easily oxidized materials, and the fact that particle properties are
Figure 2. Typical sequence for flame processes.

affected by mixing of the precursors used [41]. Flame processes are used industrially to produce commercial quantities of ceramic powders because of the lower cost of production [17].

The controlled thermal decomposition of one or more precursors in an atmospheric pressure flame spray gave nanopowders of Al_2O_3, SiO_2, and yttria-stabilized zirconia with sizes ranging from 2 to 100 nm. These powders were collected in liquid to form a colloidal dispersion [18, 19].

The combustion flame–chemical vapor condensation process (CF-CVC) has been used to produce a variety of oxide nanopowders which include SiO_2, TiO_2, Al_2O_3, SnO_2, V_2O_5, and ZrO_2. This process can produce a high rate of production of nanopowders by making use of chemical precursors as the starting material and a low-pressure flat flame to provide the thermal energy required to pyrolyze the precursors. These powders have an average primary particle size in the range 15–25 nm and a secondary particle size of approximately 100 nm. The use of a low-pressure flat flame with a uniform temperature distribution has been shown to reduce the gas phase residence time and alleviate aggregation [17, 32, 60].

2.2.4. Laser Heating

Laser vaporization is achieved by focusing a high-energy pulsed laser onto a metal target. The temperature at the focusing spot is high enough to vaporize the material. The hot metal atoms are then allowed to react with the reactive gas inside the chamber and the nanosized particles of oxides, nitrides, or carbides are collected [17, 65].

Laser light can be used to drive chemical reactions that result in particle formation. There are two types of laser reactors. In the photothermal process, the laser light is absorbed by the reactor or other gaseous species and then energy is transferred to the carrier gas, resulting in the heating of the gas. After this, the reactions are thermally driven. The dynamics are similar to those found in flame reactors and hot-wall reactors. In the photochemical process, shorter wavelengths are used and the reactant molecules absorb the laser light at specific wavelengths, resulting in dissociation to form the condensable species. Temperatures can be near ambient in contrast to the photothermal case where temperatures are near 1000 °C or higher [41]. The advantages of using laser reactors include being able to produce simple oxides and non-oxide ceramics and high-purity powders, and the utilization of low gas temperatures (photochemical). The disadvantages include the need to use expensive reactants, formation of hard agglomerates under most conditions, the complexity of the system, and the generally high cost of the equipment [41].

2.2.5. Laser Ablation

The schematic of the laser ablation process is illustrated in Figure 3. Pulsed lasers with very high energy are used to ablate the precursor material and form nanoparticles. The laser beam is focused on the surface of a target where a large amount of energy is deposited into a small volume of material, causing the material to be vaporized and ionized. As the formed plume expands, it cools, and the species in the plume interact to generate the vapors that eventually condense to form particles. The chief advantage is the formation of nanophase materials [11, 41, 55].

2.2.6. Plasma Processes

Thermal plasma reactors use high-temperature plasmas to provide the energy required to drive the physical and chemical processes that lead to particle formation and growth.
Figure 3. Particle formation by laser ablation.

A plasma is a system with a high energy content in which a significant fraction of the species are ionized and are conductors of electricity. In thermal plasmas, the temperatures of the electrons and ions are equal and the pressures are high. There are many variations dependent on how the reactants are introduced. The reactants can be introduced as powders, solutions, premixed gases, or gaseous reactants added downstream of the plasma. Temperatures are very high and complete vaporization and dissociation of the reactants into their atomic form is normal [41]. The advantages of this technology for preparation of various oxide powders include no hard agglomeration, availability of a wide range of precursors such as carbonates, alkoxides, hydrolytes, etc., ability to make single- or multicomponent powders, convenient and quick collection methods, and high-purity, uncontaminated powders. Figure 4 represents an example of nanoparticle formation by a plasma vaporization process.

The dissociation temperature of the starting elemental powder is an important factor in plasma synthesis. Carbides are much easier than nitrides and some materials may require addition of another material to decrease contamination. Carbides such as SiC, WC, and TaC can be formed with CH_4 whereas TiC and B_4C may need an addition of H_2 with the CH_4. Nitrides such as Si_3N_4 and AlN can be formed using NH_3 whereas TiN, ZrN, TaN, MgN, NbN, VN, and BN can be formed with N_2 with or without the addition of H_2. Oxides are generally formed in a plasma with the appropriate starting material and O_2.

Plasma pyrolysis technology was used to make nanometer-sized ZnO. Spherical, agglomerate-free 20-nm ZnO was produced using a plasma powder of 2500 W, a plasma gas flux of 10.0 m^3/h, and a feed rate of about 7.0 kg/h [36].

In low-temperature plasmas such as glow discharges or microwave plasmas [12], the temperature of the electrons is much greater than that of the ions and the pressures are lower. The plasmas contain un-ionized atoms and molecules, ionized species, and electrons. The advantages of this process include being able to use materials with high melting points, use of inexpensive powder feeds, rapid cooling rates, and controlled production of non-oxide ceramics. The disadvantages include the difficulty in completely vaporizing the solid reactants, complicated and less understood mechanisms, broad particle size distributions, agglomerated and aggregated particles, and the requirement for high energy [41].

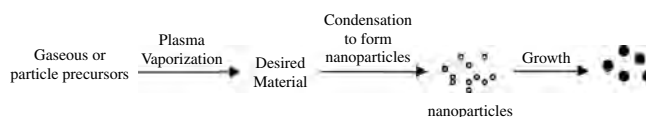
Plasma spray synthesis involves production of nanomaterial by spray pyrolysis in an open atmospheric plasma spray jet. Liquid precursors are atomized and injected into a plasma jet. Nanoparticles are collected as powder in an electrostatic precipitator or directly onto a substrate. Nanoparticles of zirconia powder with sizes varying between 3 and 80 nm were produced this way [56].


Figure 4. Nanoparticle formation by plasma vaporization.

There are a number of plasma torches that can be used. These include direct-current jet torch, radio frequency plasma torch, and hybrids of radio frequency–direct-current coupled plasma torches. Problem areas associated with using plasma torches include (1) lack of uniformity in the injection part of the plasma where there is a steep temperature gradient; (2) control of nucleation and growth processes associated with the quenching of the flow of material; (3) recovery of the materials without sintering and aggregation. Particle size can be controlled by adjusting the amount of injected reactants and by adjusting the cooling speed after reaction. Reactive quenching, in which the injected reactants are reacted and rapidly cooled simultaneously, can be used to effectively control the composition and particle size of the nanoparticles [39].

Carbide, nitride, and oxide powders can be formed in a vapor phase reaction under a high temperature generated by a plasma. Rapid quenching of these gases produces ultra-pure nanoparticles requiring no further milling or grinding. This can be achieved by having the plasma undergo a supersonic expansion into a deposition chamber with a large pressure drop across the nozzle. The nanoparticles are then deposited onto a temperature-controlled substrate [54].

2.3. Other Processes

2.3.1. Spray Pyrolysis

Spray pyrolysis describes all synthesis processes in which a solution is atomized and thermolyzed to attain the requisite phase. The following are all similar in their basic processing: solution aerosol thermolysis, evaporative decomposition of solutions, spray pyrolysis, ultrasonic spray pyrolysis, mist decomposition, spray roasting, chemical reactions with aerosols, aerosol decomposition, and high-temperature aerosol decomposition [14]. Starting materials in the spray pyrolysis process are chemical precursors dissolved in solution or as a colloidal suspension. Aqueous solutions are usually used because of their lower cost, safety, and a wide range of available precursors. The droplets are generated by nebulization or atomization of the starting solution or suspension. The droplets generated undergo evaporation with solute condensation within the droplet, drying, thermolysis of the precipitated particle at higher temperature to form a microporous particle, and finally sintering to form a dense particle. Figure 5 illustrates the process of nanoparticle formation by spray pyrolysis.

Nanoparticles can be directly synthesized from droplets or by liberating the individual crystallites comprising the produced particles after the thermolysis stage. To directly produce powders by spray pyrolysis requires control over droplet formation, coagulation, and evaporation processes as well as precipitation and decomposition processes. The final oxide particle size D_p after sintering can be approximated (assuming the solute concentration is uniform at C_s) by

$$D_p = D_o(C_o \rho_{precursor} W / C_s \rho_{oxide})^{1/3}$$

where D_o is the initial diameter of the solution droplet, C_o is the initial solution concentration, $\rho_{precursor}$ is the precursor theoretical density, ρ_{oxide} is the oxide theoretical density,
Figure 5. Spray pyrolysis nanoparticle formation stages.

and W is the oxide yield of the precursor. Direct production of nanoparticles by spray pyrolysis requires relatively dilute solutions (low C_o/C_s) and small initial droplet size (D_o) [14]. By way of an example, 50-nm ZnO and ZrO$_2$ particles were produced using a nebulizer and impactor [14]. Individual 14-nm MgO nanoparticles were produced by liberating individual crystallites of Mg(CH$_3$CHOO)$_2$ due to the oxidative disintegration of the initially formed particles [15].

Particles produced by spray pyrolysis are more uniform in size and composition than those produced by other techniques because of the microscale reaction within a droplet and the lack of a need for any type of milling. Each droplet contains precursors in the same stoichiometry as desired in the product. This process is very dependent on the aerosol generator. One variation on this process is the use of a filter expansion aerosol generator that was shown to produce ZnO particles less than 20 nm in size [19].

Advantages of spray pyrolysis include lower cost since it is a one step process, production of high-purity materials, the homogeneity of the particles as a result of the homogeneity of the original solution, the fact that each droplet/particle undergoes the same reaction conditions, and the fact that no subsequent milling is required [17]. The use of tubular flow reactors has the advantages of being simple, flexible, able to produce a wide range of sizes, and that they utilize well-understood mechanisms. The disadvantages include requiring precursors with significant vapor pressure, stable precursors below the reaction temperature, potentially expensive precursors, and aggregation at high loadings [41].

Less than 20-nm crystalline ZnO particles were produced using a filter expansion aerosol generator. This process involves spraying liquid through a pneumatic nozzle on to a glass filter surface using a carrier gas. A thin liquid film is formed which is pressed through the filter pores by the carrier gas and expanded into a low-pressure chamber.

2.3.2. Sonochemical and Sonothermal Processing

An acoustic cavitation process can generate a transient localized hot zone with extremely high temperature gradient and pressure. The sudden changes in temperature and pressure destroy the precursor material which enables the formation of nanoparticles [18, 43].

2.3.3. Mechanochemical Processing (High-Energy Ball Milling)

High-energy ball milling is a relatively simple, but normally acceptable method for making nanoparticles. Grinding particles for hours to achieve nanoparticles is considered a relatively dirty process where impurities are introduced through the grinding process, both from the media, from the equipment, and gaseous impurities from the atmosphere. However, the availability of tungsten carbide components and the use of inert atmosphere and/or high vacuum processes can reduce impurities to acceptable levels. Additional disadvantages include low surface area, highly polydispersed size distributions, and the partially amorphous state of the as-prepared powders thereby requiring post-treatment [48].

The intrinsic advantage of mechanochemical processing is that solid-state reactions are triggered by mechanical activation rather than high-temperature calcination. This has special advantages for lead-containing materials since the loss of lead can be avoided by operating at the low temperatures. Lead magnesium niobate particles of sizes ranging between 20 and 30 nm were produced using this method [60].

Nanosized particles can be prepared by starting with precursor powders (usually a salt and a metal oxide), milling the powder to form a nanoscale composite structure that reacts during the milling, and subsequent heating (if necessary) to form a mixture of dispersed nanocrystals of the desired oxide within a soluble salt matrix. The matrix can then be removed by washing or other suitable processes [17, 69]. For example, nanosized ZrO_2 powder was synthesized via the milling and subsequent heat treatment of a mixture of $ZrCL_4$ and CaO powders. The displacement reaction was induced in a steady-state manner forming ZrO_2 nanoparticles within a $CaCl_2$ matrix. Removal of the $CaCl_2$ by washing resulted in nonagglomerated 5-nm ZrO_2 particles [37].

2.3.4. Carbothermal Reduction

Carbothermal reduction is a high-temperature reaction with carbon or boron to produce borides and carbides. Generally, a colloid is mixed with a carbon or boron precursor which is then put into a high-temperature furnace. By adjusting atmosphere, reaction times, and then pressure reduction to vacuum, nanoparticles with sizes less than 100 nm can be obtained. Additional milling may be required [59].

3. SINTERING OF NANOPOWDERS

There have been numerous studies on the sintering behavior of ceramic nanopowders since the performance of ceramic materials depends strongly on their microstructural characteristics such as grain size, porosity, and grain boundary

nature [72–97]. Fine particles must possess a high driving force for sintering (or recrystallization) because sintering rate is inversely proportional to particle size. Usually, sintering temperature can be reduced by a few hundred degrees when nanosized particles are used. Figure 6 gives an example of the effect of nanopowders on densification in the case of nanocrystalline LiZn ferrite (~13 nm). It compares with powders having an average particle size of ~0.3 μm. The densification of nanocrystalline ferrites starts at much lower temperatures of ~400 °C compared to the sintering temperature of ~800 °C for the submicron powder. Generally, nanopowders exhibit much higher fired shrinkage values than conventional ceramic powders at saturated sintering temperatures.

It is very important to have a homogeneous packing density prior to sintering for uniform densification over the entire sample. In most cases, additional high-pressure processes such as hot-pressing, hot-forging, and very-high-pressure sintering have been used to provide better microstructural characteristics. The normal pressing of nanopowders is very difficult to prevent the occurrence of heterogeneously packed regions due mainly to the pre-existence of agglomeration or aggregation. The heterogeneously packed regions have wide variations in pore size and exert different driving forces during densification, leading to abnormal grain growth. Figure 7 shows a typical example of abnormal grain growth in the case of nanocrystalline LiZn ferrite sintered at two different temperatures of 1100 °C and 1200 °C after regular uniaxial pressing at ~80 MPa. Due to the nonuniform packing density resulting from the conventional pressing, highly packed regions (or agglomerated regions) tend to be densified earlier during firing compared to loosely packed regions. It leads to exaggeratedly grown grains with trapped large pores as shown in Figure 7. The grains tend to further grow through the coarsening process with small grains by increasing firing temperature. It is very difficult to eliminate the trapped pores even at very high temperatures.

Table 1 represents several examples of densification studies on the compacts of ceramic nanopowders. In many cases, the high-pressure processes during pressing or sintering were used to achieve a uniform packing density of ceramic nanopowders with a narrow distribution of
Figure 6. Densification behavior of nanocrystalline MnZn ferrite powder.
Figure 7. Microstructures of nanocrystalline LiZn ferrites showing abnormal grain growth. The samples were sintered at (A) 1100 °C for 3 hr and (B) 1200 °C for 3 hr after.

pores. Other sintering techniques such as fast-firing, plasma-assisted sintering, and microwave sintering, which do not require a high-pressure process, have been investigated to obtain nanograined structures. Chemical modification through proper dopants or surface treatment is also known to be effective in helping uniform densification without abnormal grain growth.

Sinter-forging is a processing technique to achieve the dieless compression of a powder compact at elevated temperatures [72, 94]. The compact undergoes simultaneous deformation and densification. It has been successfully documented that high-density materials were obtained without significant grain growth. Hague and Mayo [72] reported that plastic strain was largely responsible for the elimination of small pores in the sinter-forging study of nanocrystalline yttria-stabilized zirconia. They concluded that grain growth depended solely on porosity during the intermediate stage of sintering. Sintering at very high pressures (>1 GPa) can be another way to achieve dense nanocrystalline materials as evidenced in the sintering study of nanocrystalline alumina and titania powders [73, 74]. For example, bulk nanocrystalline titania samples with a grain size of <20 nm were produced when a high pressure (up to 8 GPa) was applied during sintering [74].

Plasma-assisted sintering was conducted to achieve the fast consolidation of nanocrystalline powders. Groza et al.

Table 1. Sintering studies of ceramic nanopowders with the assistance of non-conventional processing.

Nanocrystalline ceramics	Ceramic processing	Ref.
Y_2O_3-ZrO_2 (15 nm)	Sinter-forging after cold isostatic pressing	[72]
γ-Al_2O_3	High-pressure sintering at 1 GPa	[73]
TiO_2 (20 nm)	High-pressure and low-temperature sintering	[74]
ZnO	Pressureless isothermal sintering after hot-pressing	[75]
TiN (70 nm)	Plasma-activated sintering with a pressure under vacuum	[76]
SiC (30 nm)	Fast-firing at >100 °C/min using pulse electric current sintering	[77]
MnZn ferrite (14 nm)	Fast firing at >100 °C/min with chemical dopants of Si and Ca	[78]
Y_2O_3-ZrO_2 (10 nm)	Particle coating with a silicate glass	[79]

[76] reported that nanosized TiN powder of 150–200 nm was obtained at temperatures of 1150–1350 °C and a pressure of 66 MPa as a result of plasma-assisted sintering.

Fast-firing of nanocrystalline compacts can be used to obtain fine-grained microstructures by suppressing unnecessary grain growth [77, 78]. The process is assumed to skip some nondensifying mechanisms such as surface diffusion during firing, which are dominant at the initial sintering stage. Several nanocrystalline materials including Al_2O_3, SiC, $BaTiO_3$, MnZn ferrite were reported to produce better microstructures with fine grains when fast-firing was used with a heating rate of >100 °C/min.

On the other hand, chemical modification of particle surface or through dopants can largely contribute to homogeneous grain growth [78–80]. For example, the addition of Si and Ca to nanocrystalline ferrites via sol–gel processing was proven to be responsible for observed homogeneous grain growth. Figure 8 represents an improved microstructure prepared with the sol–gel additives in the case of nanocrystalline LiZn ferrite sample sintered at 1100 °C for 3 hr.
Figure 8. Microstructure of nanocrystalline LiZn ferrite sample with chemical additives of Si and Ca, sintered at 1100 °C for 3 hr.

The gel additives having a relatively low softening point are thought to penetrate into weak agglomeration and help rearranging nanoparticles at the initial stage of sintering. The additives are further found to inhibit grain growth by segregating at grain boundary and thus exerting a drag force against grain boundary movement. Oxide dopants having low softening points also can improve sintering behavior of nanopowders. Figure 9 demonstrates the effect of Bi_2O_3 addition on microstructure characteristics of nanocrystalline LiZn ferrite fired at 1100 °C for 3 hr. The addition of Bi_2O_3 is believed to contribute significantly to the homogeneous grain growth via liquid phase sintering, but leads to relatively large grain sizes. Further control of heating profiles might be needed to suppress unnecessary grain growth and obtain nanostructured samples after sintering particularly when low softening additives are used.

4. NANOCERAMIC MATERIALS

4.1. ZrO₂

Zirconium oxide (ZrO_2) ceramics have been used for various thermal, mechanical, optical, and electrical applications [79, 98–100]. Their promising chemical and physical properties including excellent chemical resistance, high refractoriness, and ionic conductivity have created a lot of new applications and devices based on the zirconia materials.

ZrO_2 has four polymorphic forms depending on its transition temperature: monoclinic, tetragonal, orthorhombic, and cubic phases. Only the monoclinic form is stable at room temperature. The other polymorphic forms can be generated by quenching from certain high temperatures or by incorporating appropriate additives. Partially or fully stabilized zirconia obtained by adding various dopants such as CaO, Y_2O_3, and CeO_2 is of particular interest for solid electrolytes, fuel cells, coatings, heating elements, and structural and wear components. The partially stabilized zirconia (PSZ) generally consists of two phases (cubic and tetragonal) or single phase (tetragonal).

The well-defined microstructure of dense zirconia determines its final properties and performance. For example, zirconia materials need to be pervious to gases and possess sufficiently high mechanical strength and toughness to
Figure 9. Microstructure of nanocrystalline LiZn ferrite sample with 3 wt% Bi_2O_3, sintered at 1100 °C for 3 hr.

avoid the breakdown of devices at elevated temperatures. To achieve optimal performance, a small grain size is often preferred with a narrow distribution of grain size. Small grain size gives superplastic deformation of ZrO_2, where the deformation rate is proportional to the inverse or the inverse square of the grain size. Highly uniform packing of fine particles leads to low-temperature sintered zirconia with a uniform microstructure.

Many studies have been reported to synthesize nanoscale ZrO_2-based powders and eventually obtain fine grain structures [79, 98–123]. Table 2 summarizes the results of nanocrystalline ZrO_2 obtained from various processing methods such as hydrothermal, combustion, sol-emulsion-gel method, vapor phase hydrolysis, and laser evaporation. Zirconium chloride or nitrate salt has been a popular choice as an inexpensive source for chemical processing of nanocrystalline ZrO_2 powders. Vasylkiv and Sakka [98] reported that the nanosized tetragonal Y_2O_3-doped ZrO_2 powder was produced by hydrothermal precipitation from metal chlorides and urea sol. Ultrasonication after the precipitation was proven to help deagglomerating nanocrystalline ZrO_2 powder. A microwave oven can be another way to improve continuous operation and processing effectiveness in the ZrO_2 hydrothermal synthesis as shown in the study by Bondioli et al. [99]. On the other hand, aqueous solutions of Y and Zr nitrates were used to synthesize nanocrystalline ZrO_2 powder by the combustion process utilizing oxalic dihydrazide as a fuel material [100]. The solution was spray-dried and then the resulting as-dried material was ignited onto a hot plate to produce nanocrystalline ZrO_2 powder.

4.2. Al₂O₃

Nanocrystalline α-alumina (corundum) powder has significant potentials for a wide range of applications including electronic devices and substrates, high-strength materials, and catalysts [124–131]. There have been various chemical processing routes for synthesize fine corundum powders ranging from submicron to nanoscaled particle size. These chemical techniques include sol–gel process, precipitation, vapor phase reaction, flame-spray pyrolysis, and hydrothermal technique. However, many of the methods have difficulty in obtaining nanocrystalline α-alumina phase due to the stability of γ-alumina at low temperatures.

Janbey et al. [124] reported that nanocrystalline corundum phase ($\sim$20 nm average particle size) was successfully prepared by pyrolysis (or combustion) of a complex compound of aluminum with triethanolamine (TEA) and sucrose. The addition of TEA into an aqueous solution of aluminum nitrate forms metal-TEA compounds, while sucrose is used as a fuel for pyrolysis of the polymeric compounds. The amorphous precursor powder transformed into γ-alumina after subsequent firing and then became pure α-alumina with $\sim$20 nm average size at 1150 °C. They found that particle size depends on firing temperature and the amount of sucrose.

Glumac et al. [125] studied a modified chemical vapor condensation process that utilizes a low-pressure flame instead of hot-wall reactor. They used a carrier gas (helium, nitrogen, or ammonia) and aluminum butoxide as a liquid

Table 2. Chemical powder processing of nanocrystalline ZrO_2.

Materials	Powder processing	Precursor	Crystallite size	Comments	Ref.
3 mol% Y_2O_3-ZrO_2	Hydrothermal precipitation	$ZrOCl_2 \cdot 10H_2O$	4–25 nm	Ultrasonication and calcination at 450–900 °C after washing precipitates	[98]
ZrO_2	Microwave-hydrothermal synthesis	$ZrOCl_2 \cdot 8H_2O$	8–23 nm	Washing after microwave-hydrothermal treatment at 200 psi for 2 hr	[99]
4 mol% Y_2O_3-ZrO_2	Combustion synthesis	zirconyl nitrate	8–31 nm	By using oxalic dihydrazide as a combustion source and spray-drying subsequent solution	[100]
ZrO_2	Sol-emulsion-gel method	$ZrO(NO_3)_2 \cdot nH_2O$	<30 nm	Ultrasonication and calcination at <900 °C	[101]
ZrO_2	Alkoxide hydrolysis and condensation	Zr tetra-n-butoxide	<100 nm	Only tetragonal phase after heat treatment at <1000 °C	[101]
ZrO_2	Vapor-phase hydrolysis	$ZrCl_4$	6–70 nm	A vapor mixture of $ZrCl_4$ and water reacts, forms nanocrystalline ZrO_2	[103]
ZrO_2	Laser evaporation and recondensation	ZrO_2 rod or powder	10–50 nm	Use of a CO_2 laser source and carrier gases for recondensation	[104]

precursor. The carrier gas accompanies precursor vapor, which is combined with premixed gas flames. The combustion of the precursors occurs in the preheat zone of the flame, and the particles condense as the flame gases cool upon approach to the substrate (acting as a collector). They reported that 3- to 50-nm-sized alumina (initially pure γ-Al_2O_3) was obtained with a high production rate (<50 g/hour).

On the other hand, a laser ablation technique utilizing a 1-kW Nd:YAG laser was reported to produce spherical nanocrystalline γ-alumina particles [126]. The nanopowder of ~14 nm median diameter was generated by ablation of solid corundum samples with the pulsed radiation of the laser and subsequent condensation of the resulting vapor in a controlled atmosphere.

4.3. SiC

Silicon carbide has been successfully used for thermomechanical, structural, and electronic applications because of its attractive properties such as high strength, stiffness, good wear and corrosion resistance, high thermal conductivity, and low thermal expansion coefficient [132–134]. Especially in electronic devices, SiC can be extensively utilized for various applications requiring high-power, high-frequency, and high-temperature operation. SiC has been generally produced by the well-known Acheson process, which includes a carbothermal reduction of sand by petrol coke at about 2400 °C. The carbothermal reaction of SiO_2 can be described by

$$SiO_2(s) + 3C(s) \rightarrow SiC(s) + 2CO(g)$$
The resultant SiC needs to be processed further for fine powders and purification. There are several chemical processing methods developed for nanocrystalline SiC powder because simple grinding of the SiC powder can not produce nanosized powders. Chemical vapor deposition (CVD)

process, sol–gel process, combustion synthesis using carbothermal reduction, and laser gas phase pyrolysis have been successfully reported in preparing nanocrystalline SiC powder.

Martin et al. [133] studied the synthesis of nanocrystalline SiC powder by the carbothermal reduction of nanosized SiO_2 precursor with the assistance of sugar. A solution of sugar in silica sol was frozen and freeze-dried before pretreatment at 800 °C in argon atmosphere. The pre-treated SiO_2/carbon mixture was converted to nanocrystalline SiC through the carbothermal reduction by heating it at reaction temperatures between 1500 °C and 1800 °C in controlled pressure and atmosphere conditions. The resulting SiC powder was less than 100 nm in average crystallite size with the oxygen content of <0.5 wt%.

CVD has been a useful technique in producing commercial nanocrystalline SiC powders [77, 134, 135]. There can be slightly different chemical vapor reactions to produce nanosized SiC powders depending on precursor and gas system and deposition condition. As an example of the CVD system, Yang and Ding [135] recently reported that the system of SiH_4-C_2H_4-H_2 could be successfully used to produce nanocrystalline SiC powder. A mixture of highly reactive gases such as SiH_4, C_2H_4, and H_2 was introduced into a reaction chamber by high-purity Ar carrier gas. The gas content was controlled by the gas partial pressure and the reaction pressure was adjusted by total flow rates. Resulting powders collected in a sealed flask by using a membrane separation technique showed average particle sizes of less than 30 nm depending on reaction temperature.

Some other efforts were made to improve the properties of nanocrystalline SiC by incorporating beneficial additives or making composites with SiC (e.g., Al_2O_3/SiC and Si_3N_4/SiC). For example, the effects of additives such as AlN, Al_4C_3, and B_4C have been investigated to improve particularly fracture strength, toughness, and electrical properties. Zhang et al. [132] reported that the incorporation of Al and N into SiC was successfully carried out

by making aerogels of SiO_2 and Al_2O_3 from the precursors of aluminum isopropoxide and tetraethylorthosilicate (TEOS), respectively. A carbothermal reaction was conducted at 1550 °C and in nitrogen atmosphere to form nanocrystalline SiC powders with an average crystallite size of <20 nm. On the other hand, Dong et al. [134] demonstrated that the nanocomposite of Si_3N_4/SiC was fabricated by using nanocrystalline Si_3N_4 and SiC powder precursors and a HIP (hot isostatic press) process at 1750 °C and 150 MPa for 1 hr. The resultant microstructure appeared to be dense and homogeneous with an average grain size of 50 nm.

4.4. Si_3N_4

Silicon nitride has been considered as a promising candidate for high-temperature structural applications due to several excellent properties including high mechanical strength, good oxidation resistance, and good wear and thermal shock resistance [141–143]. Silicon nitride is known to have two polymorphic forms: low-temperature α phase and high-temperature β phase. The α to β transformation occurs at 1600–1700 °C, but the reverse transformation has not been observed. The ratio of the two phases is important in determining the final performance of sintered Si_3N_4 and usually influenced by the existence of liquid phases. Various sintering aids generating low melting phases, such as Y_2O_3, Al_2O_3, Yb_2O_3, and ZrO_2, have been added to achieve a high density at low sintering temperatures. In addition, ultrafine SiC powder with proper additives has been strongly motivated by the excellent potential of low-temperature densification and low-temperature superplastic behavior with accompanying favorable influences on the phase transformation.

Several chemical powder synthesis methods including laser-induced chemical vapor deposition, hybrid thermal plasma process, and RF plasma vapor method have been reported to prepare nanocrystalline Si_3N_4 powders [141–148]. The thermal plasma technique is one of the popular methods in producing high-quality Si_3N_4 powders. Gubicza et al. [141] reported that nanocrystalline Si_3N_4 powder (<100 nm) was successfully synthesized by the vapor reaction of silicon tetrachloride and ammonia in a radiofrequency thermal plasma reactor. The collected powder was heat-treated at 400 °C for 1 hr and then 1100 °C for 1 hr to achieve the complete decomposition of by-products. For subsequent crystallization, the powder was re-fired at temperatures of 1250 °C to 1500 °C in nitrogen atmosphere. Similar results on the synthesis of nanocrystalline Si_3N_4 by the RF plasma vapor method were also obtained by the study of Szepvolgyi and Mohai [143]. On the other hand, Li et al. [142] successfully demonstrated that nanocrystalline Si_3N_4 could be prepared by a laser-induced vapor phase induction in the study of crystallization and phase transformation of amorphous silicon nitride. The resulting particle diameter was in the range of 15–20 nm. They found that the crystallization and α/β phase transformation were greatly enhanced by applied high pressure during annealing.

4.5. TiO_2

Titania has been widely used for various commercial applications including pigment, enamels, catalytic support, ceramic membrane, gas sensor, and other electronic devices [149–151]. Titania has three different natural crystalline structures, that is, rutile (tetragonal), anatase (tetragonal), and brookite (orthorhombic). Only rutile is thermodynamically stable, whereas the other two phases of anatase and brookite are metastable at all temperatures. Particularly, the transformation of anatase to rutile has been extensively studied due to its practical importance. The anatase to rutile transformation occurs between 400 and 1000 °C depending on impurity type and content, crystallite size, and reaction atmosphere. Reducing atmosphere or the addition of certain impurity such as CuO, MnO_2, Fe_2O_3, LiF, and Al was reported to promote the transformation rate. The existence of sulfate, chloride, fluoride, nickel, or silicon is known to retard the transformation. Very fine crystallite size was shown to enhance the transformation rate and initial transition temperature.

Commercial titania powders with controlled characteristics have been produced using various chemical methods such as the gas phase oxidation of titanium chloride or sulfate, hydrolysis of titanium chloride, precipitation of titanium hydroxide, sol–gel reactions of titanium alkoxide, and pyrolysis of titanium citrate [149–161]. Titania is a relatively easy material in forming nanosized particles less than 100 nm. Table 3 shows several examples of nanocrystalline titania powders resulting from various chemical routes including sol–gel, precipitation, laser ablation, hydrothermal synthesis, and vapor or aerosol pyrolysis.

Ahonen et al. [149] studied the synthesis of nanocrystalline titania powder by aerosol pyrolysis of titanium in butoxide with variations in synthesis temperature and atmosphere. They observed that subsequent firing after synthesis affected largely particle size distribution and morphology development. Anatase phase was found to start forming from amorphous phase at ∼500 °C depending on synthesis and annealing temperature and firing atmosphere. Firing at nitrogen atmosphere was preferred to obtain pure anatase phase at lower pyrolysis temperatures presumably due to oxygen deficiency and subsequent Ti interstitials.

A laser pyrolysis method using CO_2 laser radiation was investigated in the synthesis of nanocrystalline TiO_2 powder doped with trivalent Al and Ga by Depero et al. [150]. Titanium isopropoxide and ethylene were used as a Ti source and a reaction sensitizer, respectively. Trimethyl-gallium and trimethyl-aluminum were used as dopant precursors. Very fine titania powders (<100 nm) were successfully prepared by the absorption of the CO_2 laser radiation. The incorporation of Ga or Al in the nanopowders was found to inhibit the formation of rutile by hindering the anatase to rutile phase transition.

4.6. Titanates

Various titanate materials that have perovskite structures and relatively high dielectric constants (k) have been extensively used for various electronic, piezoelectric, pyroelectric, and optoelectronic applications. $BaTiO_3$, $SrTiO_3$, $PbTiO_3$, and $Pb(Zr,Ti)O_3$ are representatives pertaining to the high-k ceramic material category. These materials have been important ingredients in manufacturing high capacitive chip devices including multilayer capacitors. Recent tendencies towards device miniaturization, volumetric efficiency, and

Table 3. Chemical powder processing of nanocrystalline TiO_2.

Materials	Powder processing	Precursor	Crystallite size	Comments	Ref.
TiO_2	Aerosol pyrolysis	Ti n-butoxide	30–80 nm	Synthesis atmosphere and temperature affected phase transformation	[149]
TiO_2 with Al and Ga	CO_2 laser pyrolysis	Ti isopropoxide	<100 nm	Incorporation of Al and Ga inhibited the formation of rutile	[150]
TiO_2	Hydrothermal synthesis	Ti n-butoxide	20–65 nm	Crystallite size and powder morphology depend on the type of peptizing agent	[151]
TiO_2	Controlled precipitation	Ti tetra butoxide	<40 nm	Anhydrous acetone was used as solvent and acetic acid as catalyst for hydrolysis reaction	[152]
TiO_2	Sol–gel method	$TiCl_4$	4–12 nm	$Ti(OH)_4$ inorganic gel forms after reactions with ethanol and water	[153]
TiO_2 and TiN	Reactive ion beam evaporation	Ti target	4–45 nm	A high-power-density ion beam is focused on a Ti-target in an oxygen or nitrogen atmosphere (1–10 Torr)	[154]
TiO_2	Vapor hydrolysis	Ti tetra-isopropoxide	5–65 nm	Vapor phase precursor reacts with steam to produce a supersaturated TiO_2 vapor	[155]

cost reduction require thinner layers and the use of inexpensive electrode materials. Utilization of fine powders allows sintering to happen at lower temperatures with possible use of thinner layers and less expensive metallization. The conventional solid-state reaction had a tendency to produce coarse powders with particle agglomeration and compositional inhomogeneity. Therefore, various chemical processing methods such as combustion, sol–gel, co-precipitation, citrate route, and hydrothermal synthesis have been studied to prepare ultrafine, reactive titanate powders [162–178]. Most of earlier studies have focused on the fabrication of submicron-sized powders and control of powder characteristics such as particle distribution and agglomeration.

Table 4 demonstrates several examples of nanocrystalline titanate materials of $BaTiO_3$, $SrTiO_3$, $PbTiO_3$, and Pb $(Zr,Ti)O_3$ (PZT), which were prepared by chemical powder processing or mechanical activation. Chemical synthesis techniques of perovskite $BaTiO_3$ ($k > 1000$) have been extensively studied because barium titanate and its solid solutions with other perovskite materials have been most popular in the capacitor application. The dielectric properties of $BaTiO_3$ depend strongly on Ba/Ti ratio, powder characteristics (i.e., purity, particle size and distribution, and agglomerates), and resultant microstructural characteristics (i.e., grain size and distribution, grain boundary nature, and porosity). Due to the sensitivity of electrical properties to its impurity level and microstructure, very tight control of chemical processing is necessary for reproducibility and consistent performance. Sol–gel, mechanical activation, and combustion processes have been among the successful methods for preparation of nanocrystalline $BaTiO_3$ powders [162–166].

$SrTiO_3$ ($k \sim 320$) has a few advantages over $BaTiO_3$, which include a lower dielectric loss, better temperature dependence of dielectric constant, and better high-frequency

Table 4. Chemical powder processing of nanocrystalline titanates.

Materials	Powder processing	Precursor	Crystallite size	Comments	Ref.
$BaTiO_3$	Combustion synthesis	Ba and Ti nitrates	$\sim$70 nm	Common nitrate solution with alanine as a fuel was spray-dried and then heat-treated	[162]
$BaTiO_3$	Mechanical activation	BaO and TiO_2	10–30 nm	Mechanical activation at room temperature starts to generate nanopowder after 5 hr	[163]
$BaTiO_3$	Sol–gel method	Ba oxyhydrate and Ti n-butoxide	13 nm	Precursor solution became a gel with the assistance of water-diluted ethylene glycol	[165]
$BaTiO_3$	Sol–gel method	Ba alkoxide and Ti n-butoxide	<50 nm	Precursor solution was hydrolyzed via the addition of water and became a gel gradually after cooling	[166]
$SrTiO_3$	Hydrothermal synthesis	Various precursors	<100 nm	Various Sr and Ti precursors were tested. KOH concentration affected particle size	[170]
$SrTiO_3$	Combustion synthesis	Sr and Ti nitrates	<42 nm	Ethylene diamine tetra-acetic acid (EDTA) and NH_4NO_3 were used as a reducing and an oxidizing agent, respectively	[171]
$PbTiO_3$	Mechanochemical synthesis	Oxide mixture	<65 nm	Nanopowders were obtained by a shaker mill operating at 900 rpm for >5 hr	[173]
$Pb(Zr_{0.7}Ti_{0.3})O_3$	Sol–gel synthesis	Pb acetate and Zr and Ti butoxides	$\sim$30 nm	Butyl alcohol was successfully used as a solvent	[175]
$Pb(Zr_{0.5}Ti_{0.5})O_3$	High-energy ball-milling	Oxide mixture	$\sim$20 nm	Oxide mixture was ball-milled at 200 rpm in a tungsten carbide vial with tungsten carbide ball media up to 80 hr	[176]

performance. Solid solutions with $BaTiO_3$ or compositions containing various dopants have been technically important for bulk or thin-film capacitor applications. Several chemical processes including hydrothermal and combustion methods have been successfully used to prepare nanocrystalline $SrTiO_3$ powder [170–171].

4.7. Ferrites

Ferrites have been used mainly as magnetic core materials for inductors and transformers, microwave components, information storage devices, and permanent magnets [179, 180]. Various ferrite materials such as soft and hard ferrites and garnets have been developed to meet requirements depending on each application. For example, soft ferrites generally need to be designed to possess a maximum permeability, a minimum magnetic loss, an adequate saturation magnetization, and good response to temperature and frequency for inductors and transformers covering a wide range of operating frequency. On the other hand, microwave garnet devices have required polycrystalline single-phase materials with a high density and a high degree of chemical homogeneity for narrow line width and minimum low-field loss at microwave frequencies.

Ferrite materials are very sensitive to processing condition and impurity levels because small contents of nonmagnetic impurities change significantly microstructures and resulting magnetic properties by diluting magnetic moments. For example, coercive force tends to increase as grain size decreases due to domain-wall pinning. It results in a higher energy required for switching. Especially for high-power applications, smaller grain size is required to minimize magnetic loss associated with the excitation of spin waves. Saturation magnetization is known to be less dependent on grain size.

Various soft ferrite materials having a spinel structure (e.g., NiZn and MnZn ferrites) have been a popular choice in the development of fine ferrite powders via chemical processing routes due to the ease of forming nano-scaled crystallite powders [78, 181–187]. Hard ferrite (e.g., Ba and Sr hexaferrites) and garnets (e.g., $Y_3Fe_5O_{12}$) are known to be difficult in preparing very fine powders from complex reaction routes involving intermediate phases and subsequent higher firing temperatures [189]. Table 5 demonstrates several examples of nanocrystalline soft ferrites prepared by chemical powder processing routes including hydrothermal,

sol–gel, co-precipitation, and combustion synthesis [181–186]. Inorganic salt-based chlorides, sulfates, and nitrates are usually selected as raw materials for chemical processing. In general, nanocrystalline phase-pure spinel ferrites with 5–50 nm are successfully produced after subsequent firing at less than 500 °C regardless of chemical processing method.

4.8. Other Ceramics

Many other ceramic materials including SiO_2 [190, 191], CeO_2 [192–195], Y_2O_3 [196–199], SnO_2 [200–203], ZnO [204, 205], AlN [206–209], TiN [210, 211], $Pb(Mg_{1/3}Nb_{2/3})O_3$ (PMN) [212, 213], Al_2TiO_5 [214, 215], $LiMn_2O$ [216], Cordierite [217], and YAG [218] have been studied to produce nanopowders by various chemical processing methods. Although applications of each material are different, the concept and advantages of nanopowders are expected to lead to the enhancement of their actual performance. Most of the studies are focusing on the preparation of nanopowders via chemical processing, with less information on improved property characteristics.

Table 6 represents selected nanocrystalline ceramic materials prepared by chemical powder processing, which have been of considerable interest for their technical importance and commercial utilization. Ceria (CeO_2) is one of the important materials for applications of solid electrolytes in solid oxide fuel cells, chemical-mechanical polishing, and catalytic supports. Ceria has a prototypical fluorite structure that is stable from room temperature up to its melting temperature. In particular, hydrothermal synthesis using a cerium nitrate solution was reported to be successful in preparing nanocrystalline ceria powders less than 10 nm [192]. Yttria (Y_2O_3) is one of the traditional refractories and has a wide range of commercial applications including catalyst supports. Many chemical powder processes including combustion, sol–gel, and colloidal processing were found to be effective in preparing nanocrystalline yttria powders [196–199]. ZnO has been very useful in numerous chemical, electronic, cosmetic, and pigment applications [204, 205]. Nanocrystalline ZnO is expected to improve chemical reactivity, sensing performance, and light-absorbing capacity.

Aluminum nitride (AlN) has great potentials for several electronic applications due to its high thermal conductivity and excellent dielectric properties. Several studies on nanopowder processing and sintering behavior have been

Y_2O_3	Gel combustion	Y nitrate	<50 nm	An aqueous solution of Y nitrate and citric acid was used for combustion reactions	[196]
SnO_2	Sol–gel synthesis	$SnCl_4$	~12 nm	A solution of $SnCl_4$ in ethylene glycol was used to form gel at 120 °C	[200]
ZnO	Plasma pyrolysis	$ZnSO_4$	~20 nm	$Zn_5(CO_3)_2(OH)_6$ precursor was synthesized from $ZnSO_4$ and NH_4HCO_3 for plasma pyrolysis	[204]
AlN	Plasma evaporation	Aluminum	<100 nm	A hot gas carrying aluminum vapor was reacted with ammonia to produce powders	[206]
TiN	Direct nitridation	Nanosized Ti oxide	<50 nm	Nanocrystalline TiO_2 was reacted in a NH_3 gas flow to form TiN nanopowders	[209]
$Pb(Mg_{1/3}Nb_{2/3})O_3$	Mechanochemical synthesis	Oxides	20–30 nm	Powder mixture was milled using a shaker-mill at 900 rpm for 20 hr	[212]

reported with great success in achieving translucent, high-density AlN specimens [206–209]. The sintering of AlN often needs to be carried out with the use of rare-earth or alkaline-earth oxide additives to prevent the degradation of thermal conductivity from oxygen-related defects.

5. SUMMARY

The field of ceramic nanopowders (<100 nm) has great potentials for many advanced ceramic applications due to their unique characteristics particularly related to electrical, optical, mechanical, and thermal properties. Production methods of ceramic nanopowders can be classified into two major categories: liquid phase precipitation and gas phase condensation. Sol–gel, hydrothermal, co-precipitation, and microemulsion processes correspond to liquid phase precipitation. Powder processes based on gas phase condensation include physical vapor deposition, chemical vapor deposition, flame processing, laser ablation, and plasma processing. The choice of chemical processing generally depends on type of material, processing and firing condition, availability of raw materials, and safety concerns.

Agglomeration of nanoparticles happens easily due to the strong van der Waals force of attraction and has been responsible for poor microstructural characteristics after sintering. Several sintering techniques including high-pressure processing (e.g., hot-pressing and sinter-forging), high-energy processing (e.g., field-assisted sintering and microwave sintering), and controlled heating profiles have been suggested with successful evidence of improvement in microstructures. Ceramic nanopowders encompass a variety of materials such as oxides, carbides, nitrides, borides, and silicates. Zirconia, alumina, silicon carbide, silicon nitride, titania, titanates, and ferrite have been among the most popular materials for the nanopowder studies due to their scientific and technical significance. The nanopowder formation of the listed ceramic materials by various chemical processes has been successfully demonstrated with information on processing conditions and observed powder characteristics.

GLOSSARY

Agglomerate A Collection of particles where there has been no coalescence and that can be broken into individual particles.

Aggregates A collection of particles that can no longer be broken into individual particles.

Nanopowder Powder having an average particle size of less than 100 nm.

Charge Carrier Dynamics in Nanoparticles

Christian D. Grant, Thaddeus J. Norman, Jr., Jin Z. Zhang

University of California, Santa Cruz, California, USA

CONTENTS

1. INTRODUCTION

Nanoparticles (NPs) have properties that differ from their bulk or atomic counterparts in many different ways. Typically, their equilibrium as well as dynamic properties, such as electronic and optical characteristics and charge carrier recombination rates, vary as a function of size, surface, and shape. For example, spatial confinement and reduced dimensionality often lead to changes in the density of states (DOS) for both electrons and phonons that affect their optical spectroscopy and rates and mechanisms of electron–hole relaxation. Relatively speaking, equilibrium or static properties of nanomaterials have been better studied and understood when compared to dynamic properties. Understanding dynamic characteristics can provide complementary information to static properties that may or may not be studied easily using static experimental techniques.

One way to directly probe the charge carrier dynamics (e.g., rates and mechanisms of electron–hole recombination or relaxation) in nanomaterials is to use time resolved laser spectroscopic techniques, since many of the dynamic processes occur on ultrafast time scales. Direct ultrafast studies of charge carrier dynamics in nanoparticles have emerged as an active area of research in nanoscience in the last decade. These studies have helped gain important fundamental insight into charge carrier properties. For instance, electronic relaxation dynamics sensitively reflects interaction of electrons with phonons, surfaces, and other charge carriers, as well as interparticle interaction. The objective of this chapter is to review some recent advances in the studies of charge carrier dynamics in both semiconductor and metal nanomaterials with examples derived from research from our own lab and others. The first part of this chapter will deal with charge carrier dynamics in semiconductor nanoparticles while the second part of the chapter will cover electronic relaxation in metal nanoparticles.

2. CHARGE CARRIER DYNAMICS IN SEMICONDUCTOR NANOPARTICLES

2.1. Charge Carrier Relaxation and Trapping

Above bandgap photoexcitation of a semiconductor creates an electron in the conduction band (CB) and a hole in the valence band (VB). This process is analogous to a highest occupied molecular orbital to lowest unoccupied molecular orbital transition upon light absorption in molecules. This light absorption in the semiconductor particle creates a nonequilibrium situation. To return to equilibrium, the photogenerated carriers have a myriad of pathways, as illustrated in Figure 1. The simplest is radiative electron–hole recombination, releasing a photon. With above bandgap excitation, the electron and hole usually lose some of their initially acquired energy before they recombine. The electron and hole typically relax energetically to the bottom of the CB and to the top of the VB respectively. Hence, the emitted photon has a lower energy (or is redshifted) than that of the incident photon. For single crystal semiconductors, radiative electron–hole recombination is the dominant mechanism of relaxation and thus the material is highly fluorescent, with quantum yields typically >50%.

If impurities or defects are present in the crystal, new additional electronic states can be introduced within the bandgap and can act to trap the charge carriers. Trapping, then, becomes a major pathway for semiconductors with a high density of trap states.

If surface effects are ignored for the moment, and to first order perturbation, the rate of carrier relaxation (τ) through the emission of phonons is given by Fermi's golden rule [1],

$$\frac{1}{\tau} = \sum_q |\langle f|W|i\rangle|^2 \delta(Ef - Ei + \hbar\omega_q)(n_B(\hbar\omega_q, T) + 1) \quad (1)$$
Figure 1. Schematic illustration of photoexcitation and photolumines-
cence. The curved lines with downward arrows indicate different relax-
ation processes: (1) electronic relaxation within the conduction band
(CB), (2) trapping into shallow trap (ST) and deep trap (DT) states
as well as further trapping from ST to DT, (3) bandedge electron–
hole recombination, (4) trapped electron–hole recombination, and
(5) exciton–exciton annihilation.

where $|i\rangle$ and $|f\rangle$ stand for the initial and final states of
the exciton, respectively, $\mathbf{q}$ is the wave vector of the emitted
phonons, $\hbar\omega$ is the phonon energy, and n_B represents the
Bose–Einstein distribution of phonons in the crystal lattice
at temperature T ($n_B = 0$ when $T = 0$). The electron–
phonon coupling operator, W, is characteristic of the semi-
conductor and depends on the relevant phonon frequencies
and electronic band structure. Changes in phonon distri-
bution and/or frequency or size dependent changes in the
electron–phonon coupling will, therefore, affect the carrier
relaxation time according to Eq. (1). Theoretical investiga-
tions of III–V semiconductor quantum dots indicate that
the electron–phonon scattering rates decrease strongly with
increasing spatial quantization [2].

The nature of the surface is an important factor that influ-
ences the relaxation. However, this is much more difficult to
quantify at the first principles level. Qualitatively, the sur-
face phonon frequencies and distributions are expected to
change relative to bulk. This will affect the overall electron–
phonon interaction [W in Eq. (1)] and thereby the relaxation
time. In addition, the surface introduces a high density of
electronic surface trap states within the bandgap that will
act to trap the charge carriers. This often significantly short-
ens the carrier lifetime and is usually the dominant pathway
of relaxation. Trapped carriers can then further relax radia-
tively or nonradiatively. Trapped electrons and holes sig-
nificantly influence the nanoparticle optical properties and
chemical reactivities. The trapping time scale is typically on
the order of a few hundreds of fs to tens of ps, depending on
the nature of the nanoparticles. Typically, a higher density
of trap states leads to faster trapping. The energy difference
between the trap states and the location of the bandedge
(bottom of the CB for the electron and top of the VB for the
hole) also affects the trapping time. The smaller the energy
difference, the faster the trapping expected, provided that
other factors are similar or the same.

Various trapping time constants have been measured
for various semiconductor nanoparticles. Using transient

absorption techniques trapping times for CdS NPs of
~100 fs have been suggested [3, 4]. However, longer trap-
ping times of 0.5–8 and 30 ps were yielded for CdSe [5]
and CdS [6, 7] NPs using time resolved photon-echo and
trap state emission experiments respectively. Another study
reported a similar 30 ps electron trapping time for CdS
based on the effects of adsorption of viologen derivatives
on the nanoparticle surface [8]. A time resolved photolu-
minescence measurement on CdS reported a hole trapping
time of 1 ps [6]. Sample differences or different data inter-
pretations may be the reason for the discrepancies in the
reported trapping times. However, it is not unreasonable to
conclude that trapping time scales for electrons and holes
occur on the subpicosecond (a few hundred fs) to tens of
picoseconds time scales depending on the nature of the NP
or quality of the sample. It should be noted that trapping
times from bandedge to shallow traps or from shallow traps
to deep traps might differ as well.

Recombination can be either radiative or nonradiative
and can occur before or after electrons or holes have been
trapped. Since the density of trap states is very large in
nanoparticles, recombination usually takes place after trap-
ping. Also due to the high density of traps in NPs, nonra-
diative recombination tends to be the dominant mechanism.
A number of examples will be discussed next to illustrate the
similarities and differences between different nanoparticle
systems in terms of their electronic relaxation dynamics.

2.2. Metal Oxide Nanoparticles

Electronic relaxation dynamics have been studied for sev-
eral metal oxide nanoparticle systems, for example, TiO_2,
ZnO, and Fe_2O_3. For TiO_2 NPs with excitation at 310 nm,
the photoinduced electrons were found to decay following
second-order kinetics with a recombination rate constant of
1.8×10^{-10} cm^3 s^{-1} [9]. The electron trapping was suggested
to occur on the time scale of 180 fs [4]. Similar studies have
been done on ZnO NPs for which the photoinduced electron
decay was also found to follow second-order kinetics with
310 nm excitation [10]. It was also found that the initial elec-
tron trapping and subsequent recombination dynamics were
size dependent. The trapping rate was found to increase with
increasing particle size, which was explained with a trap-to-
trap hopping mechanism. The electron–hole recombination
is faster and occurs to a greater extent in larger particles
because there are two different types of trap states. How-
ever, a different explanation, based on exciton–exciton anni-
hilation upon trap state saturation, has been proposed for
similar excitation intensity dependent and size dependent
relaxation observed in CdS and CdSe NPs [11]. This expla-
nation would also seem to be consistent with the results
observed for TiO_2 [9] and ZnO [10].

A femtosecond electronic relaxation dynamics study was
conducted for both γ and α phased Fe_2O_3 nanoparticles
with 390 nm excitation [12]. The dynamics were found to
be similar between the two types of particles, despite differ-
ences in both their magnetic properties and particle shape.
γ-phased Fe_2O_3 is mostly spherical and paramagnetic, while
the α-phase is spindlelike and diamagnetic [12]. The relax-
ation featured a multiexponential decay with time constants

of 0.36, 4.2, and 67 ps. The overall fast relaxation, in conjunction with very weak emission, indicates highly efficient nonradiative decay processes, most probably related to the intrinsic dense band structure or a large density of trap states. The fast relaxation of the photoinduced electrons is consistent with the low photocurrent efficiency of Fe_2O_3 electrodes. The short lifetime due to rapid electron–hole recombination does not favor charge transport that is necessary for photocurrent generation [12].

2.3. Metal Chalcogenide Nanoparticles

CdS is among the most extensively studied semiconductor nanoparticle systems. Earlier dynamics studies on the picosecond time scale identified a strong transient bleach feature near the excitonic absorption region of the spectrum [13–19]. It was observed that the peak of the bleach feature shifts with time. One explanation proposed was increased screening by charge carriers for the particles [20]. In addition, there was a redshift of the transient absorption features in CdSe, which was explained by some as a result of formation of biexcitons [21, 22]. Later, femtosecond measurements were carried out and a power dependence of the bleach recovery time was found for CdS [23]. The bleach recovery follows a double exponential rise with the fast component increasing with power faster than the slower component.

Work based on transient absorption measurements of CdS found a similar power dependence of the electronic relaxation dynamics featuring a double exponential decay behavior with a fast (2–3 ps) and slow (50 ps) component [3, 11, 24]. The amplitude of the fast decay component increases with excitation intensity faster than that of the slow component. The short component grows nonlinearly (Fig. 2), slightly subquadratically, with excitation intensity.
Figure 2. Excitation intensity dependence of CdS NPs photoinduced electronic relaxation dynamics probed at 780 nm following 390 nm excitation pulse. The 2.5–3.5 ps fast decay component increases nonlinearly with excitation intensity and is absent at low intensity. Reprinted with permission from [3], J. Z. Zhang et al., *J. Phys. Chem.* 98, 3859 (1994). © 1994, American Chemical Society.

This nonlinear fast decay was first attributed to nongeminate electron–hole recombination at high excitation intensities [3]. Subsequent studies using femtosecond transient absorption in conjunction with nanosecond time resolved fluorescence found that the bandedge fluorescence was also power dependent [11]. These results led to the proposal that the fast decay is due to exciton–exciton annihilation upon trap state saturation, as suggested previously [25], and the slow decay is due to trapped charge carrier recombination [11]. Therefore, the transient absorption signal observed has contributions from both bandedge electrons and trapped electrons. At early times, the bandedge electrons contribute significantly to the signal, especially when trap states are saturated at high excitation intensities, while as time progresses the contribution from trapped electrons becomes more dominant. On long time scales (hundreds of picoseconds to nanoseconds), the signal is essentially all from trapped charge carriers. It was believed that this is true of many other colloidal semiconductor nanoparticles [12, 26–29]. A more recent study of the emission lifetime of surface passivated and unpassivated CdS nanoparticles on the nanosecond time scale showed that the passivated sample with a lower density of surface trap states has a lower excitation threshold for observing exciton–exciton annihilation compared to the unpassivated sample [30]. This supports the model of exciton–exciton annihilation upon trap state saturation at high excitation intensities [11].

The charge carrier dynamics in CdSe nanocrystals ranging in size from 2.7 to 7 nm have recently been determined using femtosecond fluorescence upconversion spectroscopy [31]. It has been found that both the rise time and decay of the bandedge emission show a direct correlation to the particle size and the rise time depends on excitation intensity. The long lifetime of the bandedge emission was suggested to originate from a triplet state. The deep trap emission that appears within 2 ps was attributed to relaxation of a surface selenium dangling bond electron to the VB where it recombines radiatively with the initial photogenerated hole. This is also believed to be responsible for the large amplitude, fast (2–6 ps) decay of the bandedge emission. This work seems to indicate that the hole trapping is slower compared to electron trapping. Recent work by Burda et al. and Guyot-Sionnest et al. supports the assertion that hole trapping is slower than electron trapping [32–34].

CdTe has been widely used in optoelectronic devices [e.g., infrared (IR) detectors, solar energy conversion, and light-emitting devices]. In comparason to CdS and CdSe, CdTe has a smaller bandgap ($\sim$1.5 eV) and a larger exciton Bohr radius ($\sim$7.3 nm). Studies on CdTe nanoparticles have been limited due to its high susceptibility to tellurium anion oxidation. Recently, the ultrafast charge carrier dynamics have been measured in CdTe nanocrystals using femtosecond laser spectroscopy [35]. The charge carrier relaxation showed a fast decay (3.37 ps) that is strongly dependent on excitation intensity, followed by a slow decay ($\sim$230 ps) plus an offset of >600 ps. The offset and slow decay are assigned to surface or solvent trapped electron–hole recombination while the intensity dependent short decay is assigned to exciton–exciton annihilation (as discussed previously) or photoionization/Auger recombination.

Another recent study on thiol-capped CdTe showed an unusual power dependence of photoluminescence using nanosecond laser spectroscopy [36]. At high excitation intensities the photoluminescence of CdTe NPs showed an unexpected decrease in emission. Two possible mechanisms were proposed. Photoionization may be occurring during the nanosecond pulse (7 ns duration) that subjects the particles to a stronger repulsive Coulombic force than in the neutral particles. This has the effect of enhancing the Auger effect in the ionized particles. Electron–hole recombination then proceeds by mostly nonradiative pathways leading to the decrease in fluorescence. Alternatively, exciton–exciton annihilation, similar to the CdS case discussed previously, may be the reason for the abnormal excitation intensity dependence. Immediately after excitation, "hot" electrons quickly relax to the bottom of the CB. These bandedge electrons can then relax further by radiative or nonradiative pathways. At high excitation intensities, bandedge electrons can decay through nonradiative pathways such as exciton–exciton annihilation. This nonlinear process becomes increasingly dominant with increasing excitation intensity that in turn causes the unusual decrease in emission.

In comparison to bulk materials, nonlinear properties of nanomaterials are expected to be influenced by two major competing factors: quantum spatial confinement and surface effects. Quantum mechanical confinement, on the one hand, should lead to a lower threshold for nonlinear properties in nanomaterials due to, for example, more efficient exciton–exciton annihilation when compared to bulk materials. In contrast, fast and efficient trapping in nanoparticles due to a high density of trap states should increase the threshold for nonlinear processes. Hence, the higher the density of trap states, the higher the threshold for observing nonlinear properties, as exemplified in the study of passivated and unpassivated CdS samples [30]. Even though quantitative comparisons of nanomaterials and their corresponding bulk counterparts have not been made systematically in terms of nonlinear threshold, it is most likely that the surface effect is dominant in most systems due to the intrinsic high density of surface trap states in nanomaterials. If this conjecture is correct, nanomaterials will have a higher threshold for observing nonlinear properties. This can have important applications in areas such as radiation protection. Nanomaterials would be better than their corresponding bulk counterparts in absorbing high density radiation due to their higher threshold for nonlinearity or saturation.

PbTe nanoparticles of 1.5–3 nm embedded in a glass matrix revealed an interesting oscillatory behavior [37]. The oscillations in the femtosecond transient absorption experiment were assigned to coherent excitation of acoustic phonons similar the case of PbS [38]. It was found that the oscillations had a damping time of 2.1 ps and a frequency of $\sim$0.51 THz at a probe wavelength of 1.5 μm. A longer decay of 175 ps was also present along with an offset and was attributed to radiative/nonradiative recombination and long-lived thermal effects. A probe wavelength dependence (1.4–1.6 μm) of the frequency of oscillation indicated size selectivity since the absorption band is inhomogenously broadened due to polydispersity in the sample. In addition, it was suggested that the damping mechanism was due to

energy loss to the surrounding medium, which is in contrast to colloidal gold nanoparticles where the damping mechanism of the oscillations was attributed to the polydispersity of the colloid [39]. Oscillations in metal nanoparticles will be discussed in more detail below.

Other metal sulfide nanoparticles such as Cu_xS ($x = 1$ or 2) and Ag_2S have also been studied in terms of their charge carrier dynamics. In the dynamics studies of CuS and Cu_2S [40], a dominant fast decay component followed by a slower decay observed for Cu_2S nanoparticles was found to be independent of excitation intensity, probe wavelength, and capping agent. The fast decay (1.1 ps) was assigned to charge carrier trapping at shallow trap sites, while the long decay (80 ps) component was assigned primarily to deep trapping. An interesting power dependence of the dynamics was observed for CuS. Low excitation intensities yielded a transient bleach at first due to ground state absorption followed by a fast recovery (430 fs) due to carrier trapping to shallow traps followed by a long time offset. The long time offset was attributed to relaxation from shallow to deep traps and further relaxation of charge carriers from deep traps. High excitation intensities, however, yielded only a transient absorption signal with a 1.1 ps decay and a slow rise with a lifetime >1 ns. The power dependence of the crystalline CuS could be attributed to trap state saturation [40]. A kinetic model developed to simulate the data for both Cu_2S and CuS led to the proposal of an alternative explanation for a middle-gap state. This was suggested to be either an electron-acceptor or unoccupied state, and the IR absorption band corresponds to a transition from the valance band to this state [40]. Cystine and glutathione caped Ag_2S NPs also displayed an interesting excitation dependence. The dynamics signal contains contributions from both transient absorption as well as transient bleach. At increasing excitation intensity, the transient absorption signal becomes more dominant over the bleach. A kinetic model developed suggested that the difference in dynamics observed between samples is due to different absorption cross sections of deep trap states. Similar to CuS NPs, the observed excitation intensity dependence is attributed to shallow trap state saturation at high intensities [41].

Au_2S is another metal chalcogenide nanoparticle system that has been synthesized and studied via femtosecond transient absorption spectroscopy [42, 43]. Au_2S has been used in photographic sensitization and suggested as a potential ion conductor [44–47]. The electronic relaxation dynamics have been measured with 390 nm excitation and probing at 790 and 850 nm. The transient decay profiles can be fit to a double exponential with time constants of 600 fs and 23 ps. The fast decay can be assigned to trapping of electrons from the conduction band to shallow trap states or from shallow traps to deep traps, while the long decay is assigned to recombination from shallow or deep trap states. Unlike Ag_2S [41] CuS [40], and CdS [11] already discussed, there is no power dependence indicating no trap state saturation and hence the overall fast relaxation can be attributed to a high density of intrinsic or surface trap states. In addition, this fast decay is nonradiative and consistent with a lack of observable luminescence at room temperature. EXAFS measurements were also performed and showed a 20% decrease in the first coordination shell for

nanoparticles relative to bulk, which supports a large number of surface dangling bonds that can contribute to a high density of surface trap states.

2.4. Effect of Nanoparticle Shape on Dynamics

A few studies have been made to study the shape dependence of electronic relaxation in semiconductor nanocrystals. In spherical particles, the bandgap increases as size decreases. However, as particles deviate from a spherical geometry (e.g., CdSe nanorods), it was found that the bandgap depends mainly on the width and, to a lesser degree, on the length of the rods [48]. Deviation from spherical geometry causes splitting of degenerate energy levels due to the lowering of particle symmetry. This effect may have potential consequences for electron–hole relaxation.

Electronic relaxation in CdSe nanorods has been found to be quite different from spherical CdSe particles [49]. Electron–hole kinetics for both CdSe nanodots and nanorods were monitored over the wavelength range of 480–585 nm using 400 nm excitation. In the wavelength range studied, the decay times for the nanorods increased as the energy decreased with ∼300 fs for the 480–515 nm range, a few ps in the 530–575 nm range, and 50 ps for the bandgap state. The long decay for the bandgap state may be attributed to less effective surface trapping in the rods as will be discussed. This is in contrast to the nanodots that displayed a shorter lifetime in the bandgap state (2 and 36 ps) but longer, 2 ps, in the higher energy range (480–515 nm) than the nanorods. The fast carrier dynamics of the rods in the 480–515 nm region was explained by taking into consideration energy level splitting due to particle geometry. As the particles deviate from spherical geometry the energy states associated with the particles split [50, 51]. CdSe nanorods display more absorption bands in the early time bleach spectra than the corresponding nanodots due to the predicted splitting of the degenerate states in the dots. This is agreement with theoretical calculations [49–51]. Higher exciton states, introduced due to the splitting of degenerate states, are populated initially in the nanorods that then decay to lower lying states. Furthermore, nanoparticle geometry seems to play an important role in the formation of defects since surface states depend strongly on the surface curvature or strain. Along the long axis of the rods, charge carrier motion is relatively "free" leading to less effective trapping and thus a long lived bandgap state.

For PbS nanoparticles, attempts have been made to study the surface and shape dependence of electronic relaxation in differently shaped PbS NPs. In contrast to the CdSe nanorod case, when PbS particle shapes are changed from mostly spherical to needle and cube shaped by changing the surface capping polymers, the electronic relaxation dynamics remain about the same for the apparently differently shaped particles [27]. For all cases studied, the electronic relaxation was found to feature a double exponential decay with time constants of 1.2 and 45 ps that are independent of probe wavelength and excitation intensity. The shape independence was attributed to the dominance of the surface effects on the electronic relaxation. While the shapes are different, the different samples may have similar surface properties (e.g.,

high density of trap states). Therefore, if the dynamics are dominated by the surface, change in shape may not affect the electronic relaxation dynamics substantially.

2.5. Doped Nanoparticles

The dynamic properties of doped semiconductor nanoparticles are complex and intriguing, though most experimental results suggest that their optical properties are not significantly different from the corresponding bulk material. The most extensively studied doped nanoparticle system is Mn^{2+} doped ZnS. It was first reported by Bhargava et al. that the Mn emission lifetime in ZnS:Mn was on the ns time scale, significantly shorter than that of bulk [52–54]. They observed a double exponential decay with times constants of 3 and 20 ns. The bulk Mn^{2+} lifetime in ZnS:Mn is 1.8 ms, which is five times slower than in the corresponding nanoparticles. It was proposed that stronger coupling exists between donor (ZnS) and acceptor (Mn^{2+}) due to rehybridization, induced by quantum confinement, of the $s–p$ conduction band in ZnS and the $3d$ states in Mn^{2+} that enhances rapid energy transfer and hence fast radiative decay. A similar explanation was proposed for Mn^{2+} doped two-dimensional (2D) quantum well structures [55].

However, recent work has found that the Mn^{2+} emission lifetime in nanoparticles is essentially the same as that in bulk (1.8 ms). Bol and Meijerink observed nanosecond decay rates for the ZnS host lattice emission but for the Mn^{2+} emission a normal 1.9 ms decay time along with a small amplitude nanosecond decay was measured [56]. Furthermore, in their system the 420 nm host lattice emission band was observed to have a tail that extended into the orange Mn^{2+} region and could be observed with a 2 μs gate. Given this they stated that the fast nanosecond decay was due to ZnS trap state emission and not the Mn^{2+} emission. Unfortunately, the apparatus used in their experiment had limited time resolution. A subsequent study by Murase et al. [57] also suggested that the Mn^{2+} luminescence lifetime in ZnS:Mn^{2+} nanoparticles was similar to that of bulk.

Smith et al. [58] synthesized Mn^{2+} doped ZnS nanoparticles using reverse micelles and measured the emission kinetics on the picosecond, nanosecond, microsecond, and millisecond timescales with adequate time resolution in each time scale. The samples display Mn^{2+} emission in addition to some weak trap state emission from ZnS in the 585 nm region, and the Mn^{2+} emission lifetime in these ZnS nanoparticles is 1.8 ms, very similar to that of bulk. Faster nanosecond and microsecond decays are observed for both doped and undoped particles and attributed to ZnS trap state emission. The main difference between doped and undoped samples is on the millisecond time scales. These conclusions are consistent with those of Bol and Meijerink.

Similar conclusions have been reached in a more recent report by Chung et al. [59], who have further suggested that surface bound Mn^{2+} and lattice bound Mn^{2+} have different emission lifetimes, 0.18 and 2 ms, respectively. The particles were made via standard colloidal methods. An undoped sample was also prepared for reference. The transient absorption decay profile for the undoped sample had a 20 ns component, while the doped sample had no decay on the observed nanosecond time scale. This further confirms

the assignment of the 20 ns emission component observed by Bhargava et al. [52], Bol et al. [56], and Smith et al. [58] to ZnS trap state emission. The doped sample possessed a 700 ps rise component, which is attributed to energy transfer from the ZnS excited state to the Mn^{2+} $^4T_1$ excited state.

The dynamics of Mn^{2+} doped ZnSe nanoparticles have also been studied [60]. The emission lifetime was on the order of 290 μs, which is an order of magnitude smaller than that of the corresponding lattice bound Mn^{2+} in ZnS. This shortened lifetime has been attributed to stronger spin–orbit coupling between the Mn^{2+} and Se^{2-} than Mn^{2+} and S^{2-}. The exchange interaction between Mn^{2+} centers in close proximaty also has an effect on the luminescence lifetime. Higher Mn^{2+} concentrations have shorter lifetimes as a result of these interactions. It has been suggested that Mn^{2+} doping of ZnSe leads to faster electron–hole trapping in bulk and nanocrystalline material [60, 61]. Preliminary transient absorption measurements conducted by Norman et al. [62] support this assertion. They have found that the transient absorption decay profile of undoped ZnSe nanoparticles could be fit to a double exponential with lifetimes of 17 and 143 ps, while a Mn^{2+} doped ZnSe sample had shortened lifetimes of 1.7 and 33 ps.

Bol et al. [63] reported the luminescence lifetime of Pb^{2+} doped ZnS nanoparticles. Two excitation bands, red and white, were observed. The red band originated from 480 nm excitation, while the white band originated from 380 nm excitation. By measuring the temperature dependence of the lifetimes of the two bands the nature of the emission mechanism was determined. As the temperature increased from 4 to 50 K the emission lifetime for the red band decreased exponentially from 3 ms to 0.5 μs. This effect is the consequence of a charge transfer transition of Pb^{2+} on an interior Zn^{2+} lattice site. Above 40 K the white band emission lifetime displayed similar behavior except it possessed a double exponential decay whose components were of the same order of the red bands. Likewise the white band emission was also attributed to a charge transfer emission, but, because the emission peak shifted as a function of temperature, this emission band was assigned to that of Pb^{2+} at or near the surface or defect sites.

2.6. Layered Semiconductor Nanoparticles

Layered semiconductor nanoparticles are of importance due to potential use in photoelectronchemical cells because of high photostablility [64]. They are also of interest due to their strong quantum confinement effect and weak electron–phonon coupling. However, only a few studies have been carried out on the dynamic properties of layered semiconductor nanoparticles. A picosecond transient absorption study of electronic relaxation in MoS_2 NPs has been reported [65] with the relaxation dominated by trap states. The relaxation from shallow traps states to deep traps is fast (40 ps) at room temperature. However, the relaxation slows down to 200 ps at 20 K. This is consistent with the suppression of nonradiative relaxation pathways at low temperatures, which should result in a longer lifetime of charge carriers. Recently, further studies have been performed on MoS_2 [66, 67]. The injection and trapping dynamics were compared between diethylthiodicarbocyanine

iodide (DTDCI) sensitized MoS_2 and bare MoS_2 using a combination of time resolved emission and absorption spectroscopies [67]. Electron and hole trapping times were found to be 275 and 42 ps respectively in the unsensitized case. A hole injection time of 12 ps was found in DTDCI sensiztized MoS_2 NPs. In addition, a decay constant of ~225 ps was observed and assigned to electron trapping and reverse electron transfer. By combining the 225 ps decay time in the sensitized case with the 275 ps decay in the unsensitized case, a reverse electron transfer time of 1.2 ns estimated. It was further found that following electron trapping to deep traps the reverse electron transfer to DTDCI is slow. The electron injection rate and subsequent back transfer may have implications for solar energy conversion in these layered systems.

One study of WS_2 particles using time resolved polarization emission spectroscopy found that electron trapping occurred on the time scale of ~300–500 ps while the hole trapping occurred more rapidly (~30 ps). It was also found that the hole traps were 3000 cm^{-1} above the valence band while the electron traps were only 270 cm^{-1} below the conduction band [68]. However, it was noted that the nature and depth of the trap states are sensitively dependent on nanocluster growth conditions and reagent quality. Another WS_2 nanoparticle study showed that trapping occurred on the 100 ps time scale and varied with trap state density, which is consistent with earlier work already presented. Synthetic conditions were found to dramatically control the density of trap states. For example, WS_2 particles synthesized in or extracted into acetonitrile showed little or no bandedge emission indicating a high density of trap states while those particles extracted or prepared in an octane phase had a lower trap state density and exhibited a long lived bandedge (~1.25 ns) emission [69].

Sengupta et al. have conducted a femtosecond study of charge carrier relaxation dynamics on the layered semiconductor PbI_2 nanoparticles and found the relaxation dominated by surface properties and independent of particle size in the size range (3–100 nm) studied [28]. The early time dynamics showed an interesting oscillation feature with a period varying with solvent (6 ps in acetonitrile and 1.6 ps in alcohol solvents). However, the period did not vary as a function of size. The origin of the oscillation is not clear and such features are rarely observed for colloidal semiconductor nanoparticles. In addition, the relaxation in aqueous PVA solution was found to be much faster than that observed in acetonitrile and alcohol. This was possibly due to aggregation of the nanoparticles as evidenced by a new absorption band in the electronic absorption spectrum and by transmission electron microscopy data [28].

Similar findings have been made for another layered semiconductor nanoparticle system, BiI_3 [70]. The electronic relaxation dynamics were found to be sensitive to solvent, yet insensitive to particle size. The relaxation was also independent of excitation intensity. Oscillations at early times were also observed, with periods changing with solvent (alcohol, 1.3 ps, and acetonitrile, 5 ps) but not with particle size, similar to those found in PbI_2 nanoparticles. The oscillation periods were slightly shorter with the overall relaxation somewhat faster than that in PbI_2. However, the overall decay was much faster in aqueous PVA (9 ps) as

well as in inverse micelles (1.2 and 33 ps) with no oscillations observed. These results suggest that the surface plays a major role in the electronic relaxation process of BiI_3 nanoparticles, similar to PbI_2 nanoparticles. The independence on particle size implies that the relaxation is dominated by surface characteristics that do not vary significantly with size. In addition, the size is much larger than the exciton Bohr radius (0.61 nm for bulk BiI_3) [71] and thereby spatial confinement is not significant in affecting the relaxation process.

A similar study was conducted on another layered semiconductor, Bi_2S_3 [72], in order to test if the observed oscillation in PbI_2 and BiI_3 nanoparticles is unique only to iodide semiconductor particles. Most of the dynamic features observed in Bi_2S_3 are similar to those observed for PbI_2 and BiI_3 (e.g., solvent dependence and size independence). However, no oscillations were observed. One possibility is that the overall electronic relaxation is faster in Bi_2S_3, which makes the observation of the oscillation difficult. On the other hand, the oscillation may simply be absent for Bi_2S_3. If the latter is correct, the results may indicate that the oscillations observed for PbI_2 and BiI_3 are unique to layered, iodide semiconductor nanoparticles. Further study is clearly needed for a more complete explanation.

Recently, luminescent GaSe nanoparticles have been studied via transient emission and absorption spectroscopies by Chikan et al. [73–76]. After excitation by 400 nm light, a multicomponent emission decay was observed consisting of an 80 ps, 400 ps, and a 2.4 ns decay constant. A 270 cm^{-1} shift in the emission maximum was observed during the 80 ps decay and was assigned to a direct to indirect bandedge electron relaxation. The 400 ps decay exhibits a 170 cm^{-1} shift in the emission maximum. This decay was assigned to hole trapping to shallow traps. Finally, the 2.4 ns decay is assigned to further trapping of holes from shallow to deep traps. The assignments were made based on the energetics of bulk GaSe modified by large quantum confinement shifts found in the nanoparticles. Further studies of hole relaxation dynamics in GaSe via transient absorption spectroscopy and carrier quenching experiments were also carried out by Chikan et al. [75]. Following 387.5 nm excitation, a pulse width limited rise followed by a 20 ps rise was observed in the transient absorption with a subsequent decay of 400 ps and 2.4 ns similar to that of the transient emission studies discussed above [73, 76]. The lack of the 80 ps decay as well as the presence of the 400 ps and 2.4 ns decays indicate that the relaxation being probed is hole relaxation. The dynamics changed drastically when the known hole scavenger pyridine is added. The transient absorption is quenched confirming that the further relaxation on the longer time scale (400 ps and 2.4 ns) is due to hole relaxation. The 20 ps component wavelength maximum shifts over time to the blue as the relaxation proceeds indicating the presence of relaxed and unrelaxed hole intraband transition. This is on the same time scale, albeit faster, as electron relaxation in CdSe in the absence of the Auger mechanism.

2.7. Other Semiconductor Nanoparticles

The ultrafast charge carrier dynamics in AgI and core/shell structured AgI/Ag_2S and $ArBr/Ag_2S$ NPs have been studied

[26]. The electronic relaxation of AgI was found to follow a double exponential decay with time constants of 2.5 ps and >0.5 ns, which are independent of excitation intensity at 390 nm. The fast decay was attributed to trapping and nonradiative electron–hole recombination dominated by a high density of trap states. The slow decay was assigned to reaction of deep trapped electrons with silver cations to form silver (Ag) atoms, which is the basis for latent image formation in photography. The slow decay agrees with early nanosecond studies [77]. When the two core/shell systems, AgI/Ag_2S and $AgBr/Ag_2S$, were compared, a new 4 ps rise component with $AgBr/Ag_2S$ was observed which was taken as an indication of electron transfer from Ag_2S to AgBr [26]. However, subsequent experiments conducted on pure Ag_2S nanoparticles capped with cystine and glutathione found similar features to that of the core/shell structured $AgBr/Ag_2S$ [41]. Therefore, the 4 ps rise feature is more likely due to transient bleach, since there is noticeable ground state absorption at the probe wavelength [41].

Copper chloride nanocrystals are interesting due to their promise as nonlinear matierals; it has been observed that they show high optical gain when embedded in a NaCl matrix [78–80]. Dephasing time in CuCl nanocrystals has been measured using femtosecond transient degenerate four-wave mixing (DFWM). For nanocrystals less than 5 nm, a reservoir correlation time of 4.4–8.5 ps, which increases with increasing R, was found based on a stochastic model [81, 82]. This behavior is explained by an increase of exciton–acoustic phonon coupling strength and a change in the acoustic phonon DOS because of acoustic phonon quantum confinement. Exciton dephasing times have also been measured via DFWM and spectral hole burning on CuBr quantum dots embedded in borosilicate glass and were found to be 6.4 ps for the DFWM experiment and 2.3–2.7 ps from the spectral hole burning [83–85]. These represent upper and lower limits for the exciton dephasing times. (See Table 1.)

Carbon nanoparticles have recently been studied in terms of their ultrafast charge carrier properties [86]. Carbon NPs have attracted much interest because they are constituents of many systems including interstellar dust, arc generated soot, and vacuum deposited thin films. The particles ranged in size from 5 to 40 nm, and it was found that the size of the particles decreased with increasing sintering temperature. The ultrafast electronic relaxation followed a biexponential decay yielding a fast and slow component with both time constants varying according to particle size. Smaller C particles exhibited a faster overall decay than did larger particles. The fast decay was assigned to electron–phonon coupling as well as recombination of excited carriers while the long decay was assigned to trapped carriers. It was proposed that quantum size confinement and density of trap states accounted for the difference in dynamics between large and smaller particles [86].

A dynamics study on ion-implanted Si nanocrystals using femtosecond transient absorption identified two photoinduced absorption features. One was attributed to charge carriers in nanocrystal quantized states with higher energy and faster relaxation. The other was assigned to Si/SiO_2 interface states with lower energy and slower relaxation [87]. The observed red emission was shown to be from surface trap

Table 1.

Nanoparticle	Dimension	Decay times	Measurement method	Ref.
Ag_2S	9 nm	750 fs; 4.5 ps; >1 ns	TA/TB	[41]
$AgBr/Ag_2S$	not reported	800 fs; 4 ps rise; >1 ns	TA	
AgI	7 nm	2.5 ps; >0.5 ns	TA	[26]
AgI/Ag_2S	not reported	800 fs; 2.5 ps; >1 ns	TA	
Au_2S	4 nm	600 fs; 23 ps	TA	[42]
Bi_2S_3	20–200 nm	aqueous PVA: 1.4 ps; 18.8 ps	TA	[72]
		aqueous PVP: 4.8 ps; 667 ps		
		aqueous gelatin: 0.9 ps; 5.7 ps		
	1.5–2.5 nm	micelles: 3.3 ps; 87 ps	TA	
BiI_3	2–100 nm	micelles: 1.3 ps; 33 ps	TA	[70]
		alcohol: 9 ps; 50 ps;		
		oscillation period 1.3 ps		
		acetonitrile: 50 ps; 1.3 ns;		
		oscillation period 5 ps		
		PVA: 9 ps		
C	5–40 nm	151–536 fs; 7.5–35 ps	TA	[86]
CdS	various	ps–ns	TRE, TA, TB	[3, 4, 6–8, 11, 13–19, 23, 24]
CdSe	various	ps–ns	TRE, TA, TB, TRPE	[5, 31–34]
CdSe Nanorods	4.2×13.5 nm	~300 fs (480–515 nm);	TB	[49]
		a few ps (530–575 nm); 50 ps (585 nm)		
CdTe	2–3 nm	3.37 ps; 230 ps; >600 ps	TA	[35–36]
CuBr	2.8–12 nm	6.4 ps and 2.3–2.7 ps (exciton dephasing)	SHB and DFWM	[83–85]
CuCl	<5 nm	4.4–8.5 ps (resevoir correlation time)	DFWM	[78–80, 81, 82]
Cu_2S	10 nm	1.1 ps: 80 ps	TA	[40]
CuS	10 nm	low excitation: 430 fs (bleach recovery)	TA/TB	[40]
		+ long time offset (absorption)		
		high excitation: 1.1 ps (absorption); >1 ns (absorption)	TA/TB	
Fe_2O_3	γ-phased 1–2 nm	0.36 ps; 4.2 ps; 67 ps	TA	[12]
	α-phased 1×5 nm	0.36 ps; 4.2 ps; 67 ps	TA	
GaSe	4 nm	80 ps; 400 ps; 2.4 ns	TA/TB/TRE	[73–76]
Ge	4 and 16 nm	230 fs; 1.5 ps	TA/TB	[88, 89]
InP	2.5 and 3.5 nm	300 fs; 200 ps	TB	[90–92]
	<5 nm	240 fs (exciton dephasing)	TRPE	
MoS_2	3.0 and 4.5 nm	40 ps (298 K); 200 ps (20 K)	TRE	[65, 66]
MoS_2 and MoS_2/DTDCI	3.0 nm	42 ps; 225 ps (bare particle); 12 ps (injection to DTDCI); 1.2 ns (reverse electron transfer)	TA/TRE	[67]
PbI_2	~3–100 nm	alcohol: 6 ps; 75 ps; oscillation period 1.6 ps	TA	[28]
		acetonitrile: 75 ps; oscillation period 6 ps	TA	
		PVA: 1 ps; 40 ps; no oscillations observed	TA	
PbS	8–12 nm cubic, needle, and spherical	PVP: 1.2 ps; 45 ps	TA	[27]
	8–12 nm cubic, needle, and spherical	DNA: 1.2 ps; 45 ps	TA	
	4–6 nm spherical	PVA: 1.2 ps: 45 ps	TA	
PbTe	1.5–3 nm	2.1 ps damping; 2.0 ps oscillation period; 175 ps recombination	TA	[37]
Si	2.5–3 nm	1.5 ps; 8 ps	TA	[87]
TiO_2	2 nm	180 fs; 1.8×10^{-10} cm^3 s^{-1}	TA	[4, 9]
WS_2	4–7 nm	30 ps; 300–500 ps	TRE	[68]
		100 ps	TRE	[69]
ZnO	3.2 nm	70 fs (trapping)	TA	[10]
	6.2 nm	<30 fs (trapping)	TA	
$ZnS:Mn^{2+}$	2.7–7.5 nm	3 ns; 20 ns (Mn^{2+} emission)	TRE	[52–54]
	4 nm	1.9 ms (Mn^{2+} emission)	TRE	[56, 57]
	1.2 nm	1–2 ms (Mn^{2+} emission)	TRE	[58]
	6 nm	0.18 ms; 2 ms (Mn^{2+} emission)	TA/TRE	[59]
$ZnS:Pb^{2+}$	4.3 and 5.5 nm	red emission: 3 ms (4 K); 0.5 μs (50 K) white emission: several ms (<40 K); 0.5 μs (>40 K)	TRE	[63]
ZnSe	3.5 nm	17 ps; 143 ps	TA	[62]
$ZnSe:Mn^{2+}$	3–4 nm	290 μs (Mn^{2+} emission)	TRE	[60]
	3.5 nm	1.7 ps; 33 ps	TA	[62]

Note: transient absorption = TA; transient bleach = TB; spectral hole burning =SHB; time resolved emission = TRE; time resolved photon echo = TRPE.

states and not from quantized states. The faster relaxation of the blue emission relative to that of the red emission is similar to that observed for CdS NPs [11].

Two ultrafast studies on carrier dynamics have been performed on Ge nanocrystals evaporated onto an alumina film [88, 89]. Excitation pulses of 1.59, 3.18, and 4.77 eV were used to probe the relaxation processes in 4 and 16 nm Ge particles over a large range of probe wavelengths (1.7–2.8 eV). Using a model based on the band structure of Ge, it was found that the photogenerated electrons scatter rapidly out of the Γ valley part of the Ge band structure and into the X valley with a time constant of 230 fs where they further relax into the L valley on a time scale of about 1.5 ps.

Several time resolved ultrafast studies have been performed on the InP nanoparticle system. Early work utilizing femtosecond transient bleach experiments yielded a rise time of 300 fs followed by a decay that persists longer than 200 ps for both 2.5 and 3.5 nm particles. This long bleaching lifetime was attributed to trapping of charge carriers [90]. Subsequent studies showed that higher energy excitations above the first exciton peak resulted in a loss of relaxation efficiency. It was proposed that the high energy charge carriers are diverted to another channel where they are prevented from relaxing to the bandedge and have the effect of increasing nonradiative recombination [91, 92]. In addition, InP nanocrystal ($R < 5$ nm) dephasing times have also been measured via time resolved photon echo experiments and revealed a dephasing time of ~240 fs. The linewidth in InP nanocrystals at low temperature was found to be smaller than similar sized CdSe due to poorer coupling to LO phonons in InP.

Charge carrier dynamics in semiconductor quantum wires have also been investigated in a few cases, including notably GaAs [93–96]. High luminescence efficiency was found in some cases and the luminescence was found to be completely dominated by radiative electron–hole recombination [93]. A more direct, systematic comparison of electronic relaxation among 2D, 1D, and 0D quantum confined systems should be interesting but is made difficult by practical issues such as sample quality (e.g., surface characteristics, experimental conditions, excitation, wavelength, and intensities) that can significantly influence the measurements. Such studies should be carried out in the future, both experimentally and theoretically.

2.8. Charge Transfer Systems

Photoinduced charge transfer is a very important fundamental process involved in liquid–semiconductor or liquid–metal interfaces. It plays a crucial role in photocatalysis, photodegradation of wastes, photoelectrochemistry, and solar energy conversion [97–102]. Relaxation processes such as trapping and recombination compete with charge transfer. The charge transfer process is desired in many applications. For instance, charge transfer has been extensively studied for dye-sensitized metal oxide nanoparticles (e.g., TiO$_2$ and ZnO) for photovoltaic applications. TiO$_2$ dye sensitization is the most notable example because of its potential use for solar energy conversion [103] and photocatalysis [104]. TiO$_2$ ($E_g = 3.2$ eV) alone does not absorb visible

light; dye sensitization helps to extend the absorption into the visible region.

In dye sensitization, upon absorption of light an electron is promoted to an excited electronic state in the dye. The electron can then undergo charge transfer from the dye molecule to the TiO$_2$ (or other suitable metal oxide) nanoparticle if the dye is attached directly to the surface. There are several requirements for this to work effectively. The excited state of the dye molecule needs to lie above the bottom of the conduction band of the TiO$_2$ nanoparticle in order to provide a driving force (enthalpic as well as entropic) for the electron transfer to occur. Strong binding of the dye onto the TiO$_2$ nanoparticle surface is desired for fast and efficient injection. Back electron transfer to the oxidized dye following injection should be minimal (i.e., electron transfer from the conduction band of the TiO$_2$ to the ground state of the dye molecule). For solar energy conversion applications, the dye molecule must have strong absorption in the visible region preferably closely matching that of the solar spectrum. Many dye molecules have been studied and tested for solar energy conversion applications over the years [105]. The dye molecule that shows the most promise for photovoltaic applications is the ruthenium N3 dye, which showed the highest reported light-to-electricity conversion efficiency of 10% [103, 106]. This work has stimulated strong interest in understanding the mechanism of charge injection and recombination in dye-sensitized nanocrystalline systems.

The rates of electron injection and subsequent back electron transfer in dye sensitization are expected to depend on the nature of the dye molecule and the NPs, most notably the surface characteristics of the NPs. The interaction between dye and NP surface will determine the rates and yields of forward and reverse electron transfer [97, 107]. The shape (facets) and size of the particles may also be important and tend to vary from sample to sample depending on the preparation methods used.

To describe the electron transfer (ET) process from an adsorbed molecule on a nanoparticle surface, one can adopt an approach similar to that of Marcus and co-workers for ET between a discrete electron donor and acceptor level in solution [108–110]. The total ET rate from an adsorbate with discrete states to a semiconductor with a nearly continuum of product states can be expressed as [111]

$$K_{\mathrm{ET}} = \frac{2\pi}{\hbar} \int_0^\infty dE \; \rho(E) |\overline{H}(E)|^2 \frac{1}{\sqrt{4\pi\lambda k_B T}}$$

$$\times \exp\left[-\frac{(\lambda + \Delta G_0 - E)^2}{4\pi\lambda k_B T}\right] \qquad (2)$$

where $\Delta G_0 = E_{\mathrm{CB}} - E_{\mathrm{ox}}$ is the energy difference between conduction bandedge and the redox potential of adsorbate excited state, $\rho(E)$ is the density of states at energy E from the conduction bandedge, which can contain both the bulk states and surface states, $H(E)$ is the average electronic coupling between the adsorbate excited state and different k states in the semiconductor at the same energy E, and λ is the total reorganization energy. Furthermore, since a distribution of adsorbate/semiconductor interactions exists, there should be a distribution of electronic coupling matrix elements, H, and hence injection rates [111]. Ergo, the electron

transfer rate depends on the detailed energetics of both the semiconductor and the adsorbate. In general, a strong electronic coupling, $H(E)$, and large energy difference ($E_{ox} - E_{CB}$) between the adsorbate excited state and the conduction band lead to faster electron transfer. It is often challenging to independently examine experimentally the effects of the different factors since they are often interrelated. However, they can be evaluated separately under certain approximations or special circumstances.

Electron injection rates (forward electron transfer) in dye-sensitized semiconductor metal oxide nanoparticles have generally been found to be extremely fast, $\sim$100 fs. For instance, for the coumarin 343 dye on TiO_2, the electron injection rate was found to be around 200 fs [112]. The first direct femtosecond measurement, for the N3 dye on TiO_2, reported a hot electron injection time of less than 25 fs [113]. However, there has been some debate over possible degradation of the dye sample used [114, 115]. A picosecond infrared study showed an upper limit of 20 ps for electron injection time [116]. Ellingson et al., more recently, reported an injection time of < 50 fs based on transient infrared measurements for N3 on TiO_2 [111, 117]. An electron injection time of anthocyanin dye adsorbed on TiO_2 NPs has been measured and found to be <100 fs [118]. The assignment is made particularly simple in this system since the anthocyanin dye alone has a stimulated emission signal (similar to a transient bleach), while the dye on TiO_2 has a transient absorption signal due to the electron transfer. By carefully performing several control experiments, the transient absorption signal was unambiguously assigned to electrons injected into TiO_2, which has a rise time of <100 fs.

While forward electron transfer has generally been found to be very fast, back electron transfer has been found to occur on a range of time scales, from about 10 ps to μs, depending on the nature of the dye and the nanoparticle [118–120]. For example, both forward and reverse electron transfer have been studied in the case of anthracenecarboxylic acids adsorbed on different types of TiO_2 NPs. The transfer rates were found to be dependent on the molecular structure of the dye and the TiO_2 synthesis method [120].

Electron transfer studies are not confined only to dye-sensitized nanoparticle systems. Recently, a comparison of the electron transfer rate from poly[2-methoxy-5-(2-ethyl-hexyloxy)-(phenylene-vinylene)], a well known conducting polymer, to SnO_2 and TiO_2 semiconductor nanoparticles has been performed [121, 122]. It was found that the electron transfer rate was faster to TiO_2 (<100 fs) than to SnO_2 ($\sim$800 fs). This was explained by the differences in electronic structure of the conduction bands between the two metal oxides even though there is a larger driving force for the polymer SnO_2 system. The SnO_2 conduction band has significant "s" character while TiO_2 is more "d" like, which affects coupling [see Eq. (2)] between nanoparticle and the polymer. However, even though the electron injection is occurring higher in the conduction band for SnO_2 than for TiO_2, the density of states at the injection energy is lower for SnO_2 than for TiO_2. These two factors lead to a higher injection rate for TiO_2 over that of SnO_2.

Electron transfer can also take place from the semiconductor nanoparticle to an electron acceptor near or on the surface of the nanoparticle, otherwise known as photoreduction. This is less studied compared to electron transfer from an adsorbate to the NP. For instance, electron transfer dynamics from CdS and CdSe NPs to electron acceptors (e.g. viologen derivatives) adsorbed on the particle surface have been studied using transient absorption/bleach and time resolved fluorescence [8, 123]. Electron transfer was found to take place on the time scale of 200–300 fs, which competes efficiently with trapping and electron–hole recombination. These results are important to understanding interfacial charge transfer involved in photocatalysis and photoelectrochemistry applications.

3. CHARGE CARRIER DYNAMICS IN METAL NANOPARTICLES

Electronic relaxation in metal nanoparticles occurs on the very short time scale. Direct probe of this relaxation can be monitored via femtosecond laser spectroscopy. Gold [124] and silver [125] nanoparticle electronic relaxation dynamics were first studied by Zhang and co-workers with initial work on Cu [126] performed by Bigot et al. Following these initial studies, many investigations have been performed on a myriad of different metal systems. These include Au [127–133], Ag [133–135], Sn [136], Pt [128, 137], Cu [138, 139], and Ga [140] as representative examples.

An issue of fundamental importance is the size dependence of electronic relaxation. As the size (number of atoms) is reduced from bulk (10^{23}) to the nanoscale (100–1000s) and smaller, how is the relaxation affected? The majority of the relaxation on the very short time scale is dominated by electron–phonon interactions or coupling (i.e., transfer of energy from excited electrons into phonons or vibrational motion). The relaxation time reflects how strongly the excited electrons couple to the phonons. With decreasing size the electron and phonon spectral density of states is expected to decrease as well as the spectral overlap between electrons and phonons. At the same time, the influence of surface becomes more significant with decreasing size. The change in DOS and surface may have competing effects on the electronic relaxation dynamics.

Early work based on transient absorption spectroscopy indicated a possible size dependence of the electronic relaxation in the 1–40 nm range [128]. However, subsequent measurements by Hartland and co-workers, as well as by El-Sayed et al., found no size dependence of the relaxation down to a particle size of 2.5 nm [129, 131–133]. The relaxation time in Au nanoparticles was reported to be the same as that in bulk gold ($\sim$1 ps). One complication in the study of size dependent relaxation in metal nanoparticles is the strong excitation intensity dependence of the dynamics [131, 132]. Another complication is that the relaxation has been found to be solvent dependent [137]. In the early transient absorption work by Zhang et al., the excitation intensities used were likely to have been much higher due to the small signal than those used in the transient bleach measurements by El-Sayed and Hartland. This could be the cause for the difference between the measured lifetimes. Another explanation for the difference is surface or solvent environment.

Measurements by Zhang et al. yielded a 7 ps decay in water and 5 ps in cyclohexane [124, 137]. Surface and solvent influence on relaxation is worthy of further investigation.

However, as particle size becomes smaller than 1 nm the electronic relaxation becomes more molecule-like. Measurements on Au_{13} clusters indicate a very long lifetime $\sim$300 ps [128]. Recently, clusters of 28 gold atoms capped with glutathione molecules have been investigated by femtosecond laser spectroscopy [141]. It was found that the decay was biexponential with a subpicosecond component as well as a longer nanosecond component. The fast component was assigned to relaxation from a higher lying excited state populated by the 400 nm excitation pulse to a lower electronic state. The longer nanosecond component was attributed to the radiative lifetime of the Au_{28} clusters [142]. More recently, preliminary data on electronic relaxation in Au_{11} clusters [143] ($\sim$0.7 nm diameter) reveal a similar long lifetime to Au_{13} and Au_{28}, supporting the possibility that for very small metal clusters (molecule-like) the electronic relaxation becomes much slower due to weak electron–vibration coupling.

The relaxation of hot electrons in a metal nanoparticle can be described by a two-temperature model for energy exchange between electrons and the lattice [144–146],

$$C_e(T_e)\frac{\partial T_e}{\partial t} = -g(T_e - T_l)$$

$$C_l\frac{\partial T_l}{\partial t} = g(T_e - T_l) \qquad (3)$$

where T_e and T_l are the temperatures of the electrons and lattice respectively, $C_e(T_e) = \gamma T_e$ is the temperature dependent electronic heat capacity ($\gamma = 66$ J m^{-3} K^{-2} for Au), C_l is the lattice heat capacity, and g is the electron–phonon coupling constant. Since the electronic heat capacity depends on the temperature of the electron distribution, the effective rate constant for the decay is $g/\gamma T_e$ and decreases as the initial electronic temperature increases. Higher excitation intensities produce higher electronic temperatures, which then yield longer decay times. The coupled differential equations thus describe quite well that higher excitation energies yield longer relaxation times, consistent with experimental observations [147].

A recent interesting discovery was oscillations in the electronic relaxation dynamics of Au, Ag, and bimetallic core/shell particles made of Au, Ag, Pt, and Pb [147–152]. The oscillations have been attributed to a coherent excitation of the radial breathing vibrational modes of the particles. After the initial excitation, electrons transfer their energy into the lattice heating up the particle and causing a rapid expansion. This has the effect of changing the volume of the particle and hence the electron density. This behavior manifests itself as a modulation in the transient signal (see Fig. 3) as the particle vibrates around its new "hot" particle radius. The frequency of the oscillation was found to be strongly dependent on particle size with the frequency increasing linearly with decreasing particle size. Interestingly, this phenomenon can be well described by classical mechanics. In addition, the degree of damping of the vibrational motion depends on the polydispersity of the nanoparticle sample. In a monodisperse (i.e., single sized)
Figure 3. Transient bleach data for 60 nm isolated gold nanoparticles recorded with 400 nm excitation and 550 nm probe pulses. Modulations can be clearly seen due to the coherently excited radial breathing mode. Adapted with permission from [147], J. H. Hodak et al., *J. Phys. Chem. B* 104, 9954 (2000). © 2000, American Chemical Society.

sample of particles, upon excitation all the particles vibrate with the same frequency giving rise to the observed modulation. However, as the size distribution of the sample increases, the different sized particles vibrate with different frequencies that have the effect of washing out or damping the observable oscillations. Hence, the transient absorption/bleach technique can sensitively determine polydispersity of metal nanoparticle samples.

Similar vibrational motion has also been observed in gold nanorods [153], silver ellipsoids [154], and strongly coupled gold nanoparticle aggregates [155]. In the case of the silver ellipsoids embedded in a glass matrix, oscillations along both the long and short axes could be observed using transient optical spectroscopy. Somewhat surprisingly, gold nanorods exhibited an interesting probe wavelength dependence. Due to the polydispersity of the nanorod sample, the longitudinal band is inhomogeneously broadened [156]. Hence, at redder probe wavelengths, the observed period is longer than at bluer probe wavelengths. This is because the bluer probe pulses interrogate nanorods with a shorter length than the redder wavelengths. This technique provides homogeneous linewidth information of the longitudinal plasmon band of the rods. The period of the oscillations was determined to be $2L/c_t$, where L is the length of the rod and c_t is the transverse speed of sound of bulk gold. This is different from the silver ellipsoidal result, which depended on $2d/c_l$ where d is either the length or width of the ellipsoid and c_l longitudinal speed of sound in silver. The discrepancy might be explained as follows. First, the vibrational motion in gold nanorods may be fundamentally different from that of the Ag ellipsoid. Second, the use of bulk materials properties may be inappropriate for small crystallite rods. The elastic properties of a single crystal nanorod may be different from that of a polycrystalline rod.

Aggregates of metal nanoparticles are fundamentally interesting since they provide a means to study interparticle interactions. The interaction can be divided roughly

into the strongly and weak to moderately strong interacting regimes. Weak to moderately strong interactions are found in DNA-linked Au nanoparticles [157–159] and surperlattice structures of Au nanoparticles [160] and manifest themselves as a substantial redshift of the transverse surface plasmon band. Strongly coupled gold nanoparticle aggregates, however, display a broad near-IR absorption band (700–950 nm) in addition to the visible plasmon resonance associated with isolated gold nanoparticles (see Fig. 4) [161–165]. This near-IR band is analogous to the longitudinal plasmon absorption seen in nanorods and arises from strongly interacting particles; it is termed the extended plasmon band (EPB). It is interesting to note that the transverse surface plasmon band in these aggregates does not redshift significantly (no redder than 540 nm) with respect to that of isolated particles.

In the dynamics studies of strongly interacting Au nanoparticle aggregates, the electronic relaxation time was found to be similar to that of isolated particles and bulk [155]. Surprsingly, periodic oscillations were observed despite the fact that aggregates tend to have very large polydispersity in size and shape, which could potentially dampen any possible oscillations [155]. The observation of oscillations in such aggregates strongly suggests that the broad EPB consisted of subbands from different sized and/or structured aggregates. In other words, the EPB is inhomogeneously broadened by aggregates with different sizes and/or structures. This conjecture suggested that different oscillation periods should be observed for different probe wavelengths because each probe wavelength would interrogate a particular size and/or structured aggregate. As the probe wavelength was varied from red to blue (see Fig. 5), the period of the oscillations became longer (37 ps at 720 nm to 55 ps at 850 nm), which is consistent with the previous conjecture.

To further confirm the model, spectral hole burning experiments were conducted and a hole was clearly burned with 810 nm laser excitation clearly supporting the proposal that the EPB is inhomogeneously broadened by different sized and/or structured aggregates. Earlier experimental and theoretical studies of Au nanoparticle aggregates also suggested that the EPB consists of subbands due to different aggregate sizes and/or structures [166–168]. The significance of the observation of oscillations in Au nanoparticle
Figure 5. Ultrafast electronic relaxation dynamics of gold nanoparticle aggregates at varying probe wavelengths (shown at right) with excitation at 390 nm at 8 μJ/pulse. Trend lines (dashed) demonstrate an increase in oscillation period and shift of the first peak toward longer time as probe wavelength is shifted to redder wavelengths. aggregates is that it demonstrates that time resolved fs laser techniques can be used to determine very low frequency vibrational modes of such aggregates, in the <1 cm^{-1} frequency range [155]. There is practically no other experimental means to determine such low vibrational frequencies for such condensed phase systems.

Similar to isolated gold NPs, the vibrational oscillations observed for Au nanoparticle aggregates were assigned to "radial" breathing modes. However, the vibrational behavior is somewhat different from that of purely isolated spherical particles. The Lamb equation predicts rather accurately the vibrational period of isolated spherical metal particles,

$$R = \frac{\eta \tau}{2\pi} c_l \tag{4}$$

where R is the radius of the aggregate or particle, η is the vibrational eigenvalue, τ is the period of the oscillations, and c_l is the longitudinal speed of sound in bulk gold. For the Au nanoparticle aggregates, the observed vibrational period from transient absorption is longer than that predicted based on Eq. (4) using the radius of the aggregates measured from dynamic light scattering. A possible explanation for the discrepancy is that the vibrational motion of the aggregates is "softer" than that of the isolated elastic spherical particles due to a lower speed of sound in the aggregates than in bulk gold. This seems plausible since the aggregates are not solid structures like the elastic nanoparticles [155].

4. CONCLUSION

In summary, charge carrier dynamics in both semiconductor and metal nanomaterials can be directly studied using powerful time resolved optical techniques. These dynamics studies provide complementary information to

Figure 4. Comparative ultraviolet-visible between isolated Au nanoparticles (trace a) and strongly interacting gold nanoparticle aggregates (trace b). The appearance of the near-IR band is attributed to strong particle–particle interaction between gold NPs.

static or equilibrium studies. The intimate interconnections between equilibrium and dynamic properties are illustrated with numerous examples. Dynamics studies are expected to continue to play an important and active role in the study and understanding of properties and functionalities of nanomaterials.

GLOSSARY

Band edge emission Fluorescent emission from electron-hole recombination from conduction band edge to valence band edge.

Exciton–exciton annihilation The process in which one exciton "collides" with another, transfers its energy, and undergoes non-radiative recombination.

Surface plasmon resonance Resonant interaction of conduction band electrons with incident light.

Trap state emission Fluorescent emission from electron-hole recombination from trap states. This emission is red shifted relative to band edge emission due to trap states lying inside the forbidden band-gap region.

Trap states Electronic states that lie energetic ally within the band-gap between the valence and conduction bands. These states act to trap charge-carriers and often affect their lifetimes significantly.

Chemical Derivatization of Carbon Nanotube Tips

Vladimir A. Basiuk, Elena V. Basiuk (Golovataya-Dzhymbeeva)

Universidad Nacional Autónoma de México, México D.F., Mexico

CONTENTS

1. INTRODUCTION

Despite the short history of carbon nanotubes (CNTs), comprising single-walled and multiwalled nanotubes (SWNTs and MWNTs, respectively), this class of materials gained unprecedented attention of scientists in different fields. The reason is that CNTs possess a number of chemical, structural, mechanical, and electronic properties that can hardly be found simultaneously in any other chemical compound or material. In particular, they are characterized by considerable chemical and thermal stability, extremely high tensile strength and elasticity, an extreme aspect ratio (especially for SWNTs), the ability to incorporate other molecules into their interior cavities, the possibility of chemical functionalization, and at the same time metallic and high thermal conductivity [1, 2]. Thus, the versatility of potential applications proposed for CNTs is not surprising. Some of them can be based on the as-grown nanotube materials, without an additional chemical treatment. For other applications, chemical modification might be necessary, such as grafting of moieties that allow assembly of modified SWNTs onto surfaces for electronic applications, moieties that allow reaction with host matrices in composites, and sensing applications that may require the presence of a variety of functional groups

bound to SWNTs [3]. Besides that, almost any technological application requires chemically pure and uniform nanotubes, which can be manipulated and investigated by analytical methods. Unfortunately, this remains a great challenge for chemists and material scientists. In this context, chemical derivatization is an especially attractive goal, since it can improve solubility and processibility of CNTs (SWNTs first of all) and allows their unique properties to be coupled to those of other types of materials [4].

A systematic development of the methods for CNT chemical functionalization started very recently: first results were published in 1998 [5–8]. The studies are focused primarily on SWNTs, which are much easier to handle and characterize due to their simpler, monomolecular structure, higher uniformity and solubility as compared to those of MWNTs. Two recent reviews [3, 4] summarized covalent chemistry of SWNTs (they comprised the data as of 2001; this area has been considerably enriched during the subsequent year). The authors considered all known types of the reactions, which can be divided into two main groups: (a) defect-group functionalization and (b) covalent sidewall functionalization. In this chapter we focus on the former group. Derivatization reactions of this kind are restricted mainly to the nanotube ends and thus are too localized to noticeably change main bulk properties of the materials (contrary to the sidewall functionalization). This is particularly true for their spectroscopic properties, which complicates extremely the product characterization. On the other hand, for some applications this kind of localized chemistry may be desirable and even the only acceptable one, since it does not alter appreciably electronic and mechanical properties of CNTs and generally (in some cases dramatically) improves solubility of SWNTs [3].

2. OXIDIZED NANOTUBES

Pristine CNTs produced by most methods are closed by all-carbon fullerene caps and thus cannot be qualified as functionalized materials. This situation changes if one subjects

the as-prepared nanotubes to an oxidative treatment with nitric acid, its mixture with a sulfuric acid, sulfuric acid–hydrogen peroxide mixture, etc., which are utilized for purification (removal of amorphous carbon, graphite, metals, and their oxides used as catalysts) and cutting of the CNTs [3, 4, 7–9]. The acid treatment methods were adopted from well-explored graphite chemistry [10, 11], where, for example, it is long known that HNO_3–H_2SO_4 mixtures intercalate and exfoliate graphite. The oxidation produces in CNTs terminations and wall defects with a number of oxygenated functionalities, the most important of them being carboxylic groups COOH. This was confirmed by analyzing the samples by vibrational (primarily infrared, IR) [8, 9, 12–14] and near-edge X-ray absorption fine structure (NEXAFS) [14] spectroscopy. In particular, IR spectra of the oxidized SWNTs were reported to exhibit a carboxylic band at 1720–1735 cm^{-1} ($\nu_{C=O}$) [8, 12–14], as well as quinone $\nu_{C=O}$ at 1660 cm^{-1}, a ν_{C-O} band at 1245 cm^{-1}, and ν_{O-H} absorption at 3644 cm^{-1} [13, 14]. In IR spectra of the oxidized MWNTs, the $\nu_{C=O}$ band at 1750 cm^{-1} was observed, along with ν_{O-H} absorption at 3500 cm^{-1} [9]. According to the NEXAFS results [14], both carbonyl (C=O) and ether (C–O–C) functionalities are present in the oxidized SWNTs. The conclusion on ether groups, however, seems rather confusing, since it is difficult to explain how they can survive strong hydrolytic media such as HNO_3–H_2SO_4 and H_2SO_4–H_2O_2 mixtures.

Titration of commercial acid-purified full-length SWNTs with NaOH and NaHCO$_3$ solutions was employed to estimate the total percentage of acidic sites and COOH groups, respectively [15]. Different samples gave fairly consistent results: the SWNT–COOH functionality was about 1–2%, and the total acid functionality was about 1–3%.

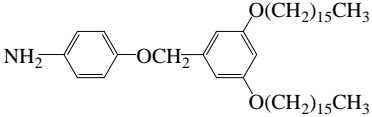
Another frequently employed way to oxidize CNTs is gas-phase ozone treatment [12, 16–18]. This process occurs at a room temperature, at a much lower rate as compared to fullerenes [16]. It is not used for the nanotube purification (as it is unable to remove metal impurities) but helps one to better understand the nature of oxygen-containing functionalities on the CNT tips and wall defects. Room temperature dry ozonation of open- and closed-ended SWNTs, preheated to 800 °C in a vacuum to remove most of the original oxygen-containing functional groups, gave rise to development of several IR bands [17]. The bands at 1739, 1200, and 1040 cm^{-1} are indicative of the production of ester groups. The band at 1650 cm^{-1} was assigned to $\nu_{C=O}$ of quinone groups, while the band at 1581 cm^{-1} was assigned to C=C bonds located near the newly formed oxygenated groups. The esters and quinones can be removed by heating in a vacuum to 600 °C. It is thought that the ozone oxidation is confined to the end caps and the dangling bonds created by the removal of these caps, whereas the structural integrity of the nanotube walls is maintained.

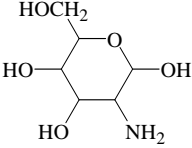
The same research group attempted to quantify the fraction of oxidized carbon sites present in closed-end SWNTs purified by acidic oxidation [12]. This was done by measuring the evolution of CO and CO$_2$ gases on heating to 1000 °C. Following the thermal treatment, the defect sites were titrated repeatedly with O$_3$. According to the results, about 5% of the carbon atoms are localized at defective

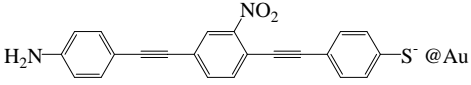
sites, capable of facile oxidation by ozone. In turn, the high defect site density indicates that a significant number of these sites exist on the nanotube walls. At the same time, in neither of the two studies did the authors mention on the formation of COOH groups: the dry ozonation conditions employed are incapable to generate OH-containing moieties.

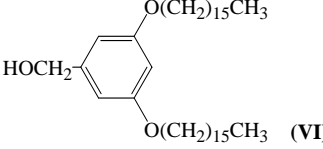
In view of the crucial importance of carboxylic groups for the defect-site covalent chemistry of CNTs, an important development was presented very recently by Cai et al. [18]. The authors modified the ozonation procedure by using simultaneously ultraviolet (UV) irradiation and allowing atmospheric moisture to be present in the reaction system. It was assumed that atmospheric moisture in the presence of UV radiation converts intermediate ozonides into carboxylic acids and other functionalities. The authors observed a $\nu_{C=O}$ peak at 1708 cm^{-1} and a broad hydrogen-bonded band ν_{O-H} at 3410 cm^{-1}, both suggestive of carboxylic acid groups present in the SWNT sample. At the initial oxidation stage, a 1630 cm^{-1} peak of quinone $\nu_{C=O}$ vibrations was observed as well but then became less distinguishable as a shoulder at the $\nu_{C=C}$ background band at 1580 cm^{-1}. The peaks at 1215 and 1055 cm^{-1} were attributed to the vibration modes ν_{C-O-C} of ester or ν_{C-O} of carboxylic acid.

The distribution of the oxygen-containing functionalities within CNTs has not yet been well characterized. As was mentioned above, they are believed to exist primarily at the nanotube ends and at sites along the sidewalls. By use of solution phase mid-IR spectroscopy, Hamon et al. [19] attempted to estimate the ratio of the carbon atoms in the SWNT backbone to the carbon atoms in the end-groups and at defect sites of the octadecylamido functionalized soluble SWNTs (see Section 3.1). Their analysis showed that the weight percentage of the octadecylamido functionality in the derivatized SWNTs is about 50%, which corresponds to a mole fraction of 6%. These high values (consistent with the value of ca. 5% for the oxidized carbon sites measured by the ozone titration [12]) suggested that a large proportion of the COOH-containing defect sites is located on the sidewalls, since the values of 5–6% are roughly one order of magnitude higher than would be indicated by models based solely on end-group functionalization. More detailed considerations on this subject will be presented in Section 4.

3. DERIVATIZATION


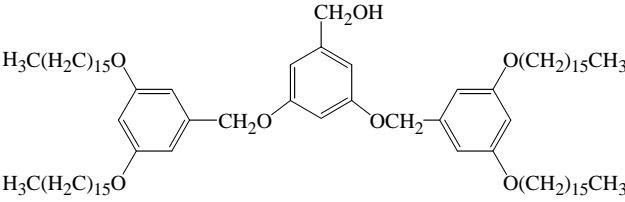


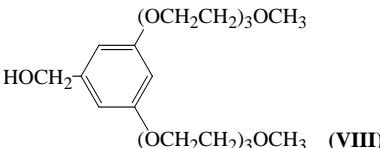




3.1. Amidation

Carboxylic groups can be readily derivatized by a variety of reactions. The easiest and most efficient way is to produce amide derivatives, by linking chemically activated COOH groups at the CNT terminations to amines, according to the general scheme

$$CNT\text{---}COOH + HNR'R'' \rightarrow CNT\text{---}CONR'R'' \quad (1)$$




where R' and R'' are H, aliphatic, or aromatic substituents (Table 1).

Table 1. Amino components, alcohols, and activating agents used to derivatize CNT (SWNT and MWNT) tips through amidation reaction (1) and esterification (3).

Amino component/alcohol	Activating agent and reaction conditions	Nanotubes	Ref.
	Amidation		
NH_2-$(CH_2)_{11}$-SH	$SOCl_2$, RT, toluene	SWNT	[7]
NH_2-$(CH_2)_{17}$-CH_3	$SOCl_2$, amine melt, 90–100 °C, 96 h	SWNT	[8, 19, 21, 22, 24]
		MWNT	[28]
	amine vapor, 170 °C, 2 h	SWNT	[40]
NH_2-$(CH_2)_8$-CH_3	amine vapor, 160–170 °C, 1 h	SWNT	[38]
CH_3-$(CH_2)_4$-NH-$(CH_2)_4$-CH_3	amine vapor, 160–170 °C, 1 h	SWNT	[38]
4-NH_2-C_6H_4-$(CH_2)_{13}$-CH_3	$SOCl_2$, amine melt, 100 °C, 96 h	SWNT	[21]
NH_2—C₆H₄—OCH_2—C₆H₃ with $O(CH_2)_{15}CH_3$ groups	$SOCl_2$, 75 °C, 48 h	SWNT, MWNT	[26]
Glucosamine (pyranose ring: $HOCH_2$, HO, OH, HO, NH_2)	$SOCl_2$, anhydrous THF, reflux, 48 h	SWNT	[34]
NH_2-[-$(CH_2)_2$-O-]$_n$-H	$SOCl_2$, DMF + aqueous NaOH, RT, 12 h	SWNT	[32]
[-$(CH_2)_2$-N(C(=O)C_2H_5)-$(CH_2)_2$-NH-]$_n$ [poly(propionylethylenimine-co-ethylenimine), or PPEI-EI]	$SOCl_2$, polymer melt, 165 °C, 20 min to 2 h	SWNT, MWNT	[27–29, 31]
	EDC, KH_2PO_4 buffer, RT, 2–6 h	MWNT	[30]
	polymer melt, 160–180 °C, 12 h	MWNT	[31]
NH_2-CH_2-C_6H_5	EDC, buffer pH 6.0, RT, 2 h	MWNT	[5]
		SWNT	[6]
NH_2-$(CH_2)_2$-NH_2	EDC, buffer pH 6.0, RT, 2–48 h;	MWNT	[5]
	or EDC, DMF + aqueous buffer, RT, 48 h	SWNT	[6, 33]
NH_2-$(CH_2)_{11}$-S^-@ Au	DCC, DMF, 50–60, °C, 12 h	SWNT	[23]
NH_2-$(CH_2)_2$-SH	DCC, ethanol, RT, 24 h	SWNT	[37]
H_2N—C₆H₄—C≡C—C₆H₃(NO_2)—C≡C—C₆H₄—S^-@Au	DCC (DMF), or EDC (aqueous solution)	SWNT	[18]
NH_2-$(CH_2)_{2n}$-NH_2 (n =1–4)	DCC, DMF + THF, RT, 72 h	MWNT	[25]
Bovine serum albumin	EDC, KH_2PO_4 buffer, RT, 24 h	SWNT, MWNT	[35]

The broad applicability of this coupling reaction to aqueous and nonaqueous chemistry made it especially attractive and widely used for nanotube functionalization [5–8, 18–40]. In one of the very first reports on this subject [7], the derivatization was implemented by converting the carboxylic groups to the corresponding acid chloride by reaction with thionyl chloride SOCl$_2$ at room temperature, with subsequent exposure to an amino alkanethiol NH$_2$–(CH$_2$)$_{11}$–SH in toluene, also at room temperature, that is,

$$\text{SWNT—COOH} \xrightarrow{\text{SOCl}_2} \text{SWNT—COCl}$$
$$\xrightarrow{\text{NH}_2-(\text{CH}_2)_{11}-\text{SH}} \text{SWNT—CONH-(CH}_2)_{11}\text{-SH} \qquad (2)$$
The nanotubes functionalized in this way were bound to 10-nm-diameter gold nanoparticles. Attachment of such strategically designed binding groups is thought to be very useful in directing assembly of CNTs into molecular devices [7].

Varying the structure of hydrocarbon moiety in the amine, one can afford an enhanced affinity to different media or substrates. In particular, the use of octadecylamine NH$_2$-(CH$_2$)$_{17}$-CH$_3$ [8, 19] (Table 1) gives rise to substantial solubility of the shortened (100–300 nm in length) SWNTs in chloroform, dichloromethane, aromatic solvents (benzene, toluene, chlorobenzene, 1,2-dichlorobenzene), tetrahydrofurane, pyridine, and CS$_2$, in sharp contrast to the starting nanotubes [8, 21, 22, 24]. If the reaction is carried out at elevated temperature for a few days, most of the SWNT bundles exfoliate to give individual SWNT macromolecules. SWNTs solubilized in this way can be purified by liquid-chromatographic techniques, offering functionalized material virtually free of contaminants. The nanotubes derivatized with 4-tetradecylaniline, 4-NH$_2$-C$_6$H$_4$-(CH$_2$)$_{13}$-CH$_3$, showed a similar solubility behavior [21] (the authors believed that the product exists primarily as imides, and not amides; in other words, one amine molecule covalently couples to two neighboring COOH groups).

Logically, the more extended the lipophilic moiety in the amino component, the higher the CNT solubility in nonpolar solvents is expected to be. Sun et al. [26] reported on the functionalization of both SWNTs and MWNTs with a dendron-type derivative of 4-aminophenol (Table 1), via the same SOCl$_2$-activated reaction (2). An elevated temperature (typically 75 °C; stirring for 2 days under nitrogen atmosphere) was apparently a requirement for these reactions to proceed efficiently, since the use of lower temperatures (for example, 45 °C) resulted in a significantly less amount of the functionalized nanotubes (on the basis of solution color or visible absorption).

These studies on SWNT functionalization were aimed at solubilization in organic solvents. A much larger range of potential applications would open for water-soluble nanotubes. In particular, biochemical and biomedical applications would require SWNTs in aqueous media. Pompeo and Resasco [34] proposed a very efficient method to increase SWNT solubility in water, by choosing glucosamine as the amino component of high hydrophilicity, to react with the thionyl chloride-activated SWNTs. Aqueous solutions of the resulting functionalized nanotubes were very stable and remained translucent and without precipitation for weeks. When the pH of the solution was lowered to 2 at 80 °C by addition of hydrochloric acid, the SWNTs immediately dropped out of solution: this is apparently due to the hydrolysis of the amide bonds. The hydrolysis was much slower at room temperature.

High molecular weight compounds (polymers) can be used as the amino components as well. The reactive amino groups can be located either on the macromolecule termini, or within the polymer chain. Depending on that, two different types of nanotube–polymer assemblies can form, as is schematically explained in Figure 1. When reactive NH groups are located within the polymer chain, CNTs are bound as a side chain (Fig. 1a). If reactive NH (or NH$_2$) groups are terminal, then CNTs are incorporated into the main chain (Fig. 1b). An example of the latter is the grafting of SWNTs (whose carboxylic groups were activated with thionyl chloride) with monoamine-terminated poly(ethylene oxide) (PEO) [32]. Since amphiphilic PEO is soluble in water (as well as in many organic solvents), the PEO and SWNT segments take expanded and extended
Figure 1. Two general ways of coupling carbon nanotubes with NH-containing polymers through amidation reaction (1): (a) reactive NH groups are located within the polymer chain, and CNTs are bound as a side chain; (b) reactive NH (or NH$_2$) groups are terminal, and CNTs are incorporated into the main chain.

conformations in aqueous medium. When the graft product is dispersed in chloroform, each SWNT segment collapses into a globular aggregate.

In a series of works by Sun et al. [27–29, 31] another possibility was explored (Fig. 1a), that is, to attach CNTs as a side chain to linear polimer poly(propionylethylenimine-*co*-ethylenimine) (PPEI-EI; Table 1). Both SWNTs and MWNTs were employed whose COOH groups were converted to acyl chlorides by treating with SOCl$_2$. The amidation was performed by mixing the reactants and heating at 165 °C for 20 min to 2 h. PPEI-PI is a highly soluble polymer, and the resulting polymer-bound nanotubes are soluble in both organic solvents and water, forming highly colored homogeneous solutions.

Thionyl chloride is not the only reagent which can be used to activate carboxylic groups in amide coupling reactions. Parallel to the works employing SOCl$_2$ to treat COOH groups of CNTs, a number of authors reported on the use of carbodiimide chemistry for the same purpose. Carbodiimides such as dicyclohexylcarbodiimide (commonly known as DCC) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) have some indisputable advantages as compared to thionyl chloride. The direct products of activation with carbodiimides (*O*-acylisoureas) are more stable to moisture (as compared to the acyl chloride intermediates), and the rate of their aminolysis is much higher than that of hydrolysis. This implies a high selectivity of the reaction, as well as allows some flexibility in choosing experimental conditions. Even more important is that some carbodiimides, for example EDC, are soluble in aqueous media (pure water and buffer solutions): this property is absolutely indispensabe when working with biomolecules. And finally, they are not corrosive, contrary to SOCl$_2$ and HCl evolved upon the reaction; this property can be important when working with fine and sensitive devices such as atomic force microscopy (AFM) cantilevers.

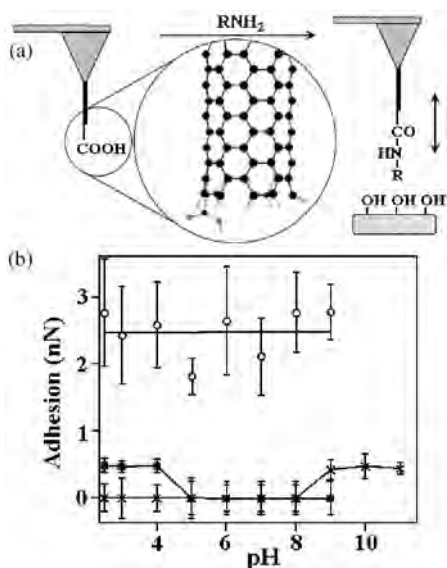
It was the cantilever tip preparation where carbodiimide chemistry was for the first time employed to chemically modify CNT ends by Wong et al. [5]. They derivatized carboxylic MWNT tips with benzylamine and ethylenediamine (Table 1) through EDC-activated amidation in an aqueous buffer solution. The reaction does not require heating and is completed in 2 h. A little later, the same group implemented the above modification strategy with SWNTs [6], in order to achieve the highest lateral resolution in AFM to date. The experiment is schematically explained in Figure 2. The functionality at the SWNT tip ends was determined by measuring the adhesion force between the tip ends and hydroxyl-terminated self-assembled monolayer (SAM) surfaces; the fraction of proton dissociation can be readily monitored in this way. Force titrations made with carboxyl-terminated SWNTs on OH-terminated SAMs exhibited a well-defined drop in adhesion at ca. pH 4.5 (Fig. 2b), which is characteristic of COOH deprotonation. The absolute value of the adhesion force at low pH can vary between tips, and such differences are believed to reflect variations in the number of COOH groups at the ends of different tips. The similarity of the pK_a determined from the SWNT force titrations (4.5) to the bulk solution value for benzoic acid (4.2) indicated that the COOH groups at the SWNT ends are well solvated and hence accessible for reactions. Then SWNT tips were amide-derivatized with benzylamine, which has nonionizable, hydrophobic functionality, to yield the expected pH-independent adhesion forces on OH-terminated SAMs. This covalent modification eliminated the pH-dependent adhesion observed with the unmodified tips. The absolute values of the adhesion forces obtained in aqueous solutions using these phenyl-terminated tips were generally larger than for the COOH-terminated nanotubes and were consistent with the hydrophobic nature of such tips. Furthermore, force titrations with ethylenediamine-derivatized (amine-terminated) SWNT tips showed no measurable adhesion at low pH and finite adhesion above pH 8. This


Figure 2. (a) Schematic illustrating the modification of a SWNT tip by coupling an amine (RNH_2) to a terminal COOH, and the application of this probe to sense specific interactions between the functional group (R) and surface OH groups. pH-dependent behavior correlates with the authors' expectations for exposed amine groups that are neutral at high pH and protonated and charged at low pH. The modified SWNT tips were employed to produce chemically sensitive AFM images with the highest lateral resolution to date and can be used to study binding in biological and chemical systems.

In a similar study by Yang et al. [23], the amidation coupling was used to attach SWNTs to AFM tips, as shown in Figure 3. Commercial Si_3N_4 cantilever tips were coated with 100 nm gold by thermal evaporation onto a 10-nm adhesion layer of titanium. Then the gold-coated tips were immersed in ethanol solution of NH_2-$(CH_2)_{11}$-SH. Due to a high affinity to gold through S^-–Au interactions, the amino alkanethiol formed a densely packed self-assembled monolayer, where the amino groups were available for further coupling with the DCC-activated carboxylic groups. Liu et al. [37] organized SWNTs on gold by linking them through a shorter amino alkanethiol, NH_2-$(CH_2)_2$-SH, by means of DCC-activated amidation.

For the fabrication of SWNT-based molecular devices, conjugated organic molecules with π-orbital overlap are required for charge transport and functional devices. Rigid-rod conjugated oligo(phenylene ethynylene)s, having an array of interesting electronic properties, were used as linking molecules to prepare rigid self-assembled monolayers of wet-ozonated SWNTs on gold [18]. The oligo(phenylene ethynylene)s contained a sulfhydryl group at one end, and one of them had an amino group at the opposite terminus (Table 1). The amidation was performed using either DCC or EDC.

There are several examples of coupling bi- or polyfunctional amino components to carboxylic groups of CNTs in the presence of carbodiimides. The simplest case is chemical modification of shortened MWNTs (<1 μm length) with various straight-chain alkyldiamines, NH_2-$(CH_2)_{2n}$-NH_2 ($n = 1$–4), where DCC was used [25]. The derivatized nanotubes were dispersed in polar solvents such as ethanol, dimethyl sulfoxide (DMSO), and dimethylformamide (DMF) more easily than the starting material. The dispersions (at MWNT concentrations of more than 0.3 mg/ml) were stable without aggregation for more than one month.

EDC was used as an alternative to thionyl chloride in the amidation of MWNTs with high-molecular-weight PPEI-EI (Table 1) [30]. This reaction was found to be significantly improved in both efficiency and yield by sonication under ambient conditions. The enhancement in the reaction yield may be attributed to the sonication-induced activation of the carboxylic acids by EDC, as rationalized for the sonication enhancements in other diimide-activated reactions. It was also found that depending on the duration of sonication, the nanotubes were shortened to different lengths in the functionalization. The authors suggested that this method allows relatively efficient preparation of solubilized CNTs of a potentially selectable average length.

Similarly, SWNTs and MWNTs were functionalized by bovine serum albumin (BSA) via EDC-activated amidation under ambient conditions [35]. The nanotube–BSA conjugates thus obtained were highly water soluble, forming dark-colored aqueous solutions. Results from characterizations using AFM, thermal gravimetric analysis, Raman, and gel electrophoresis showed that the conjugate samples indeed contain both carbon nanotubes and BSA and that the protein species are intimately associated with the nanotubes. Bioactivities of the CNT-bound proteins were evaluated using the total protein microdetermination assay (the modified Lowry procedure). The results showed that the overwhelming majority (~90%) of the protein species in the nanotube–BSA conjugates remain bioactive.

In one of the most recent reports having implications for biosciences, vertically aligned MWNT arrays were fabricated as a nanoelectrode platform for biosensor development and then functionalized with nucleic acids [36]. Prior to chemical functionalization, metal catalyst particles at the nanotube ends were removed and the closed ends are opened, as usual. However, the author concluded that the oxidative treatment for generating COOH groups at the opened ends compromises the mechanical stability of the nanotubes, often leading to total collapse of the aligned MWNTs. To solve this problem, they developed a new approach for filling the gaps between the nanotubes with a spin-on glass (SOG). Nucleic acid attachment was accomplished using EDC along with *N*-hydroxysulfo-succinimide (sulfo-NHS). The EDC-derived ester intermediate rapidly undergoes hydrolysis; however, in the presence of excess sulfo-NHS a more water stable sulfo-succinimidyl intermediate is formed. Subsequently, the succinimidyl intermediate reacted with nucleic acid [DNA or H_2N-$(CH_2)_6$–GCCGATGCACC oligonucleotide], resulting in the formation of desirable amide linkage. It appeared that the reaction was essentially completed after 2 h. Results from the coupling of nucleic acids to the MWNT arrays suggested that the SOG enhances the reactivity by providing structural support to the nanotubes. The SOG also covers the length of the sidewalls of CNTs, leading to a less hydrophobic interface, and thus may aid in improving the chemical reactivity.

Banerjee and Wong [33] synthesized SWNT–nanocrystal heterostructures of possible interest for molecular electronics, photocatalysis, and solar energy conversion and as probes for scanning force microscopy. Oxidized SWNTs were linked to cadmium selenide (CdSe) nanocrystals, capped with mercaptothiol derivatives (*para*-mercaptobenzoic, thioglycolic, and 3-mercaptopropionic acids), as well as to titanium dioxide (TiO_2) nanocrystals, functionalized with 11-aminoundecanoic acid (Table 1). The coupling with acid-terminated CdSe nanocrystals and acid-terminated tubes was facilitated with the aid of intermediary linking agents, such as ethylenediamine and semicarbazide NH_2-$C(=O)$-NH-NH_2, in the EDC-activated amidation; this multistep procedure is schematically explained in Figure 4. Based on electronic absorption spectroscopy, charge transfer is thought to proceed from the nanocrystal to the nanotube in the CdSe-SWNT system, whereas in the TiO_2-SWNT system, charge transfer is expected to occur from the nanotube to the nanocrystal.

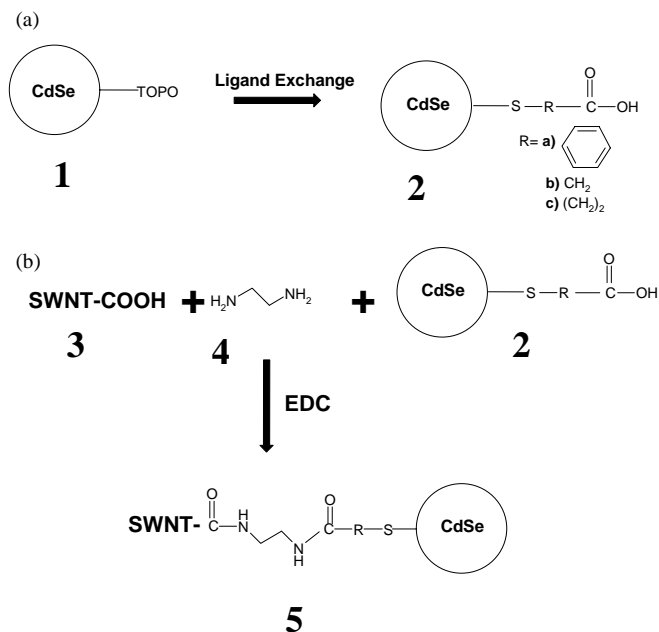
From basic organic chemistry it is known that activation of carboxylic groups can be achieved by using not only chemical reagents like $SOCl_2$ and carbodiimides but also by simple heating. In one of the reports by Sun et al. on the functionalization of CNTs with aminopolymers (see above), the amide coupling was achived by direct heating MWNTs with PPEI-EI at 160–180 °C, that is, in the polymer melt, under nitrogen protection for 12 h [31]. According to the authors' observations, this method seems less efficient in the MWNT dispersion as compared to the $SOCl_2$ activation, because the corresponding solution of the functionalized nanotubes exhibits more scattering in the UV-visible absorption measurements. But, on the other hand, the direct


Figure 4. Schematic of the addition of CdSe nanocrystals to oxidized SWNTs. Trioctylphosphine oxide (TOPO) capped nanocrystals (**1**) were prepared by established methods using organometallic precursors. (a) TOPO capping was substituted by a thiol ligand to form an acid-terminated CdSe nanocrystal (**2**). Substituted thiocarboxylic acids used included *para*-mercaptobenzoic acid, thioglycolic acid, and 3-mercaptopropionic acid, as represented by different R groups shown. (b) (**2**) was linked to SWNTs (**3**) by an ethylenediamine linker (**4**) in the presence of EDC to form the adduct (**5**). The bonds at the interfaces are not drawn to scale. heating apparently produces functionalized MWNT samples of a higher nanotube content.

We used the same strategy for the amidation of oxidized SWNTs with simple amines in the gas phase [38, 40]. This is an extension of the gas-phase derivatization technique originally developed for chemical modification of silica surfaces. Its attractive features are that the formation of amide linkages proceeds smoothly at 150–180 °C and is relatively fast (0.5–1 h), as well as providing high yields of the amide derivatives. Excess vaporous reagent can be removed from the reaction zone under moderate vacuum. In addition, there is no need to use a (organic) solvent medium; this feature is attractive not only from an ecological point of view but also in that it helps to avoid undesirable particle aggregation of the material derivatized. The amino components we employed were nonylamine, dipentylamine, and 1-octadecylamine (Table 1). The resulting SWNT products exhibit solubility properties similar to those of the SWNT derivatized with long-chain amines through thionyl chloride and carbodiimide activation.

An important aspect of CNT reactivity is the existence of different forms of the nanotubes by themselves: zigzag, armchair, and chiral forms [1, 2]. All of these species are apparently present in CNTs grown by most methods. For the particular case of direct (heating-induced) amidation reaction (1), one can expect that the reactivity of carboxylic

groups toward amines might be different depending on whether the nanotubes have an armchair or zigzag structure. Studying the specificity of such a sort can be considered as a possible pathway to selective derivatization of different forms of CNTs and to their further separation: for example, due to different solubility of derivatized and nonderivatized nanotubes. However, this goal seems to be very complicated from the experimental point of view and requires further sophistication of the methods of handling and observing individual CNTs. We tried to give some insight by using the two-level ONIOM (combined quantum mechanics/molecular mechanics) calculations [38, 39]. As model reaction systems, we considered monocarboxylated short fragments of $(10, 0)$ zigzag and $(5, 5)$ armchair SWNTs interacting with the simplest aliphatic amine, methylamine. The models are shown in Figure 5 along with the potential energy surfaces calculated at the B3LYP/6-31G(d) level of theory (energies relative to the level of separated reactants [39]). If one compares the energies of the transition states to those of the reactant level, their values do not differ significantly: 51.1 and 48.8 kcal mol^{-1} for the armchair and zigzag SWNTs, respectively. Much bigger differences can be found for the reaction complexes and products. Energy for the armchair reaction complex (-2.9 kcal mol^{-1}) is 10.5 kcal mol^{-1} higher than that for its zigzag counterpart (-13.4 kcal mol^{-1}). The situation is opposite for the amidation products: the armchair products (-9.0 kcal mol^{-1}) are lower by 7.5 kcal mol^{-1} as compared to the zigzag products (-1.5 kcal mol^{-1}). This shows the direct formation of amides on armchair SWNT tips according to reaction (1) to be much more advantageous, as compared to that on zigzag SWNT tips. Moreover, since for the latter the

reaction complex appears to lie below the products, the amidation as a whole is energetically unfavorable (though it can be facilitated by pumping out water formed, as contemplated in the gas-phase derivatization technique [38]). Another strong argument supporting our conclusion is evident if one compares the transition state energies not to the reactant level but to the level of the reaction complexes. Barrier heights calculated in this way are 54.0 (armchair) and 62.2 kcal mol^{-1} (zigzag), which is a significant difference, of 8.2 kcal mol^{-1}. It is too premature to discuss practical implications of the data obtained (and besides, as any theoretical results, they have to be taken with a certain precaution). Nevertheless, one can envision the use of this or other chemical reactions for selective derivatization of different forms of CNTs (armchair, zigzag, or chiral). In the case of amidation reaction (1) with long-chain amines, the derivatized nanotubes would acquire a higher solubility than underivatized CNTs, which would open a route to their facile separation.

3.2. Salts with Amines

When unactivated carboxylic groups are treated with amines, ammonium salts form. This type of interaction was employed as an alternative [to amidation reaction (1)] approach for the preparation of SWNTs soluble in organic solvents. The nanotubes were heated at 90–130 °C in molten long-chain amines octadecylamine and 4-tetradecylaniline for 4–8 days [21, 41]. Not only shortened but also uncut SWNTs (of lengths of over 1 μm [41]) acquired high solubility in common organic solvents. The authors give a strong preference to this method of CNT derivatization for the following reasons. (1) They found that the ionic functionalization approach generally gave a much higher yield of soluble SWNTs than the covalent functionalization approach. As they believe, the presence of zwitterions can significantly improve the solubility of SWNTs. (2) The acid–base reaction represents the simplest possible route to soluble SWNTs and can be readily scaled up at low cost. (3) Unlike the covalent amide bond, the amine cations formed on the nanotubes can be readily exchanged for other organic and inorganic cations. Thus it will be possible to adjust the solubility properties of the SWNTs and to use soluble SWNTs as versatile building blocks for advanced SWNT-based materials via supramolecular chemistry. Furthermore, such an ionic feature may allow electrostatic interactions between SWNTs and biological molecules and can serve as the basis for developing biocompatible SWNTs.

We would like to point, however, to the following circumstance. As was mentioned above, there are a few examples when the amide coupling was achived by direct heating CNTs with amines. In particular, it was implemented for MWNTs, which were derivatized with molten PPEI-EI polymer by exposing their mixture at 160–180 °C for 12 h [31], as well as for SWNTs, treated with vaporous aliphatic amines at 160–170 °C for 1–2 h [38-40]. Of course, the temperature of 90–130 °C is substantially lower to cause that rapid amide condensation. Nevertheless, this temperature interval goes beyond the boiling point of water, and the equilibrium must be shifted to the amide formation, especially when the whole procedure extends to 4–8 days [21, 41]. Thus one can

Figure 5. (a) Monocarboxyl-substituted fragments of $(5, 5)$ armchair (left) and $(10, 0)$ zigzag (right) SWNTs used for the two-level ONIOM calculations of the model gas-phase reaction with methylamine [39]. The highlighted (dark) atoms and the ones constituting methylamine molecules were treated at the B3LYP/6-31G(d) level of theory; the remaining SWNT atoms were treated with universal force field (UFF) molecular mechanics. (b) Calculated potential energy surfaces for the two SWNT models, including reaction complexes, transition states, and products (water molecules hydrogen-bound to the amide derivatives) with corresponding energies in kcal mol^{-1}.

suspect the presence of a large fraction of the amide derivatives in the SWNTs derivatized ionically.

The true ionic interactions of carboxylic acids with amines were employed to construct hollow spherical cages of nested SWNTs using self-assembly techniques [42]. The process (explained in Figure 6) consisted of the layer-by-layer adsorption of acid-oxidized SWNTs (diameter 1.2 nm) onto template silica gels (spherical particles of 6 μm in average diameter) and stabilization of adsorbed nanotubes. The SWNT dispersion in water was centrifuged at 3500 g, and only the supernatant solution was retained (**I**). Immediately afterward, amine-functionalized silica gel was added to adsorb SWNTs (**II**). After a typical immersion time of 30 min, SWNT-covered amine spheres were forced to sediment by centrifuging at 100 g, and the supernatant solution was decanted (**III**). SWNT spheres were collected on a Teflon filter and dried in oven (**IV**). Once dried, SWNT spheres were extremely stable: SWNTs did not desorb even when the dried SWNT spheres were redispersed in solution. For additional cycles of coating, the dried SWNT spheres were added to the freshly prepared SWNT dispersion, and processes **II** through **IV** were repeated. Silica at any cycle of coating can be etched away by hydrofluoric acid to give spherical cages made of only SWNTs (**V**). Thus, the initial amine–nanotube interactions determine the nested network, and nanotube–nanotube interactions thicken each arm of the nest.

3.3. Esterification

A close remnant of amidation reaction (1) is esterification according to the general scheme

$$CNT{-}COOH + HOR' \rightarrow CNT{-}COOR' \qquad (3)$$
where R' can be an aliphatic or aromatic substituent. Here one water molecule should be eliminated as well, and this can be done by preliminary activation of the carboxylic groups at CNT tips by thionyl chloride [the first step in reaction (2)]. The ester formation, however, is not as common in CNT chemistry as the amidation is, and there are a few reported examples only.

Hamon et al. [43] prepared soluble ester-functionalized SWNTs by reaction with linear octadecylalcohol (Table 1). SWNT–COCl and $C_{18}H_{37}OH$ were heated in pyridine at 117 °C for four days. The ester forms of SWNTs are soluble in common organic solvents (for example, in THF and chloroform) and were found to exist as both individual nanotubes and small bundles (2–5 nanotubes each).

Sun et al. [27, 29] attached CNTs as a side chain to poly(vinyl acetate-*co*-vinyl alcohol) (PVA-VA, a linear polymer with molecular weight $\approx$ 110,000; Table 1). Both SWNTs and MWNTs whose COOH groups were converted to acyl chlorides by treating with SOCl$_2$ were derivatized. The esterificaion was performed by mixing the reactants and heating at 165 °C for 20 min. PVA-VA is a highly soluble polymer, and the resulting polymer-bound nanotubes were soluble in both organic solvents and water, forming intensely colored, stable homogeneous solutions.

Lipophilic (**VI**, **VII**; Table 1) and hydrophilic (**VIII**) dendron species were used to functionalize SWNTs and MWNTs in a similar way [26, 44, 45]. The ester-derivatized nanotubes, depending on the functionalities, were soluble in nonpolar and weakly polar solvents (for **VI** and **VII**), or both organic solvents and water (for **VIII**). When deuterated ethanol-d_6 was used as a co-reactant in the esterification reaction with **VI**, strong attachment of deuterium species (apparently as the corresponding ethanol-d_6 ester groups) was observed [45]. The CNTs prepared can be defunctionalized in homogeneous solutions under base- (sodium hydride in THF) and acid-catalyzed (trifluoroacetic acid) reaction conditions, recovering the starting nanotube materials as dark-colored precipitates [44].

Similarly to the heating-induced direct amidation [31, 38–40], esterification without the use of chemical activating reagents is possible as well. Although this process is not very efficient, there is a possibility to shift the equilibrium by eliminating water from the reaction zone. Unlike the former derivatization technique, the direct esterification of oxidized CNTs has not been reported so far. We attempted to explore this reaction theoretically by using the two-level ONIOM calculations [46]. The SWNT model species (reacting with the simplest alcohol, methanol) considered in this study were in many regards similar to those used for the amidation reaction with methylamine [38, 39]. In particular, the high (quantum mechanics) level included the atoms belonging to methanol molecule and the terminal carboxylic group, together with their adjacent C and H atoms, as shown in Figure 7a. In this way, an important parameter such as the number and nature of high level-treated atoms was kept the
Figure 7. (a) Monocarboxyl-substituted fragments of (10, 10) armchair (left) and (16, 0) zigzag (right) SWNTs used for the two-level ONIOM calculations of the model gas-phase reaction with methanol [46]. The highlighted (dark) atoms and the ones constituting methanol molecules were treated at the B3LYP/6-31G(d) level of theory; the remaining SWNT atoms were treated with UFF molecular mechanics. (b) Calculated potential energy surfaces for the two SWNT models, including reaction complexes, transition states, and products (water molecules hydrogen-bound to the ester derivatives) with corresponding energies in kcal mol^{-1}.

same in the armchair and zigzag models. On the other hand, we rejected the nanotube diameter used previously, that is, (10, 0) for zigzag and (5, 5) for armchair SWNT models, since a detailed inspection revealed that within such narrow cavities, the opposite wall attracts methylamine molecules, making it equilibrate close to the nanotube axis. In turn, this can dramatically influence its position with respect to the carboxylic group, resulting in unrealistically long N–H$\cdots$O separations, which are supposed to be hydrogen bonds, and apparently producing significant errors in energy estimates for the reaction complexes. To avoid this sort of undesirable effect, we chose armchair (10, 10) and zigzag (16, 0) nanotube models, with calculated diameters of ca. 1.3–1.4 nm approaching commonly observed SWNT diameters. The fragment length was also increased, to three complete rows of carbon hexagons (Fig. 7a; compare to Fig. 5a). The potential energy surfaces calculated at the B3LYP/6-31G(d) level of theory (energies relative to the level of separated reactants) are shown in Figure 7b. The energies of the transition states differ insignificantly: 38.7 and 39.3 kcal mol^{-1} for the armchair and zigzag SWNTs, respectively. The differences for the reaction complexes and products are more substantial. Energy for the armchair reaction complex (-3.5 kcal mol^{-1}) is 3.3 kcal mol^{-1} higher than that for its zigzag counterpart (-6.8 kcal mol^{-1}). The situation is quite opposite for the esterification products: the armchair products (-3.3 kcal mol^{-1}) lie lower by 10.7 kcal mol^{-1} as compared to the zigzag products (7.4 kcal mol^{-1}). This has two implications. First, the direct ester formation on armchair SWNT tips according to reaction (3) is much more advantageous as compared to that on zigzag SWNT tips. Second and more important, since for the latter the products appear to lie above the level of separated reactants,

the esterification process is thermodynamically unfavorable at all. From the practical point of view, these results might imply that treating the oxidized CNTs with aliphatic alcohols under the gas-phase high-temperature conditions [38] would derivatize selectively COOH groups at the armchair nanotube tips. If a long-chain alcohol is used for the treatment, the resulting ester-derivatized armchair CNTs would acquire much better solubility in organic solvents than the underivatized zigzag nanotubes have, which in turn opens a facile route to their separation. For a final conclusion, our theoretical results need to be verified experimentally.

3.4. Metal Surfaces

Fabrication of dense arrays of SWNTs aligned normal to substrates is envisioned as an important step in the development of various technologically important devices such as sensors, field emitters, and organic light-emitting diodes, as well as for hydrogen and electrochemical energy storage. Wu et al. [47] proposed a simple technique for the assembly of oxidatively shortened SWNTs on silver surface. This technique is based on the salt formation between COOH groups at the open ends of carbon nanotubes and the surface silver cations. Silver-coated silicon wafers were dipped into colloidal SWNT suspensions in water, ethanol, and other polar solvents. Tapping mode AFM and transmission electron microscopy (TEM) observations of the assemblies formed showed that the SWNTs are perpendicular to the silver surface. TEM studies also revealed that most of the SWNTs (ca. 80%) assembled have a bundle size of 6.5 $\pm$ 0.5 nm, possibly suggesting the selective adsorption (chemisorption would be a more correct term) of SWNTs on silver.

The formation of dense arrays of oxidatively shortened SWNTs using Fe^{3+}-assisted self-assembly from nonaqueous media was reported by Chattopadhyay et al. [48]. An additional feature is that this approach permits growth of successive stacks of SWNTs, one on top of each other, in a layer-by-layer (LBL) assembly format. To ensure a smooth and uniformly charged surface, the substrates [glass, (100) silicon wafers with native oxide and quartz crystal microbalance resonators] were modified with polyelectrolyte films via the LBL method. SWNTs/Fe^{3+} assemblies consisted of sequential dipping in an aqueous solution of FeCl$_3$ (pH 2.2, 15 min) followed by immersion in DMF-dispersed SWNTs (pH 8.5, typically 30 min) and separated by intermediate washing in DMF (pH 12.7). The elevated pH for both DMF wash and SWNTs dispersion causes the surface-immobilized Fe^{3+} layer to transform into its basic hydroxide form, providing the initial driving force (salt formation with the COOH groups of SWNTs) for this assembly to occur. A monolayer of densely packed, needlelike domains was obtained after the first 30-min immersion, with average domain width of 93 $\pm$ 22 nm. Its morphology was reminiscent of aggregated SWNTs, most likely tethered with only one of their ends to the substrate. This geometry is believed to be the result of (i) high concentration of COOH groups on the SWNT tips and hydroxy functionalization of Fe^{3+}-decorated surfaces and (ii) strong hydrophobic interactions between adjacent SWNTs. Polarization Raman studies indicated significant orientation normal to the substrate. Subsequent adsorption of Fe^{3+} ions onto the carboxy-terminated SWNTs at the untethered ends

gave rise to the formation of multilayer Fe^{3+}/SWNT assemblies. Both the average film thickness (measured by spectroscopic ellipsometry) and mass deposition (obtained via quartz crystal microbalance) were in good agreement with the formation of multilayered structures, readily observed by gradual substrate darkening. The linear increase in both average film thickness (ca. 37.7 nm) and mass (ca. 4.1 g/cm^2) corresponded to an average density of 1.1 g/cm^3 for the multilayer Fe^{3+}/SWNTs assemblies.

Ionic interaction of carboxylic groups of oxidized SWNTs with metal ions at surfaces can also be used to improve resolution in scanning tunneling microscopy (STM). Nishino et al. [49] deposited acid-cut SWNTs onto the apexes of gold tips for STM. The affinity of COOH functionalities to gold is relatively weak, and the Au tips were first modified with self-assembled monolayers of 4-mercaptobenzoic acid, strongly adhering to gold surfaces due to the presence of thiol groups. Its carboxylic groups in *para*-position remained free for further derivatization steps and were used to anchor carboxylated SWNTs through Zn^{2+} ion-bridged coordination as follows:

$$SWNT\text{—}COO^-\ Zn^{2+}\ {}^-OOC\text{-}C_6H_4\text{-}S^-@Au \qquad (\textbf{IX})$$

The SWNTs deposited in this way were present on the gold tips as bundles of about 10 nm width. Since oxidatively shortened SWNTs have a broad distribution of their length, and the tunneling current flows only through the foremost part of the probe tip, a high STM resolution was achieved, even if not an individual SWNTs were present at the tip apex.

A very similar approach was employed by Cai et al. [18], who used rigid-rod conjugated oligo(phenylene ethynylenes) **X** and **XI**
X = COOH (**X**), SH (**XI**)

having an array of interesting electronic properties, as linking molecules to prepare rigid self-assembled monolayers of wet-ozonated SWNTs on gold [18]. As the first step, they were deposited onto gold surface, forming self-assembled monolayers. Then, in the case of the carboxylic derivative **X**, the COOH groups were chelated to Fe^{3+} ions; incubation in the oxidized SWNT dispersions produced ion bridges similar to the ones shown in the previous paragraph (**IX**). Likewise, the thiol derivative **XI** on gold was bridged to the SWNTs through Cu^{2+} ions, having high affinity to both COOH and SH functionalities. Aromatic and conjugated organic molecules of this sort, having π-orbital overlap capable of charge transport, are necessary for the fabrication of SWNT-based molecular devices.

3.5. Miscellaneous

CNT materials can be potentially utilized as effective reinforcements in advanced composites (although so far their cost remains prohibitive). In that case, a good chemical bond to the matrix is highly desirable to efficiently transfer mechanical loads from the matrix to the nanotubes and thus take advantage of their outstanding mechanical properties. Organosilanes R–Si–R$_3'$ were proposed as coupling agents to chemically join CNTs and organic polymers [50]. The R group is chosen to be reactive depending on the organic matrix, and the R' group is usually methoxy radical (OCH$_3$), which is easily hydrolyzed to produce silanol Si–OH (in [50], 3-mercaptopropyl trimethoxysilane was used). In turn, the latter can be reacted with hydroxyl groups on the oxidized nanotubes, the authors suggested. One should remember, however, that phenoxy silanes with C–O–Si≡ bonds, and especially pseudo-esters with —C(=O)O–Si≡ linkage, are hydrolytically unstable and cannot serve to reliably join CNTs and the polymers.

Judging from the literature, there has not been much effort in treating carbon nanotubes as chemical reagents in their own right. Attempting to fill this gap, Banerjee and Wong [51, 52] studied complexation between oxidized SWNTs and platinum–metal coordination compounds: Vaska's compound, *trans*-IrCl(CO)(PPh$_3$)$_2$ [51], and Wilkinson's complex, RhCl(PPh$_3$)$_3$ [52]. Both reacted directly with SWNTs dispersed in DMF or DMSO, under inert atmosphere (nitrogen or argon) at 50–60 °C for a period of 0.5–3 days. According to the results of spectral measurements, the electronic structure of the nanotubes was preserved, suggestive of the fact that SWNTs are functionalized through coordinative attachment at the terminal carboxylic groups, as well as possibly hydroxylic (phenolic) and carbonyl groups. A more explicit characterization of the binding pattern was not achieved. The proposed functionalization process not only opens up the area of metal-organic chemistry to carbon nanotubes but also suggests potential applications in catalysis and molecular electronics. An increased solubility of the complex-derivatized SWNTs in DMF should facilitate their chemical manipulation and photophysical analyses.

4. SPECTROSCOPIC CHARACTERIZATION

Difficulties in characterizing the chemical structure of the derivatization products, "inability to declare success or failure in attempted functionalization reactions" [3], constantly hamper further developments in this area. A standard suite of techniques does not yet exist for adequate characterization of chemically modified nanotubes [3]. Solution phase absorption spectroscopy (UV/visible) is considered one of the most accessible techniques that offers some information on the electronic state of CNTs and hence functionalization. However, this can actually be fruitful for sidewall-functionalized but not defect-functionalized CNTs: obviously due to a low contribution of bands corresponding to the terminal derivatizing groups into the entire spectrum. What this technique allows in our case is to confirm the formation of true solutions (and not just dispersions), when the absorption phenomena are linearly dependent on the solution concentration (Lambert–Beer law) [26, 29–31, 35, 44]; to reveal unusual optical properties, such as strong luminescence of the polymer- and dendron-bound nanotubes [26, 27]; or to

conclude that the electronic structure of the CNTs, whose terminal groups were derivatized, is preserved [34, 52].

Raman [8, 21, 22, 24, 30, 41, 43] and near-IR spectra [22, 24, 41, 43, 52] very closely resemble those of the under-ivatized SWNTs. They are sensitive to changes in the electronic structure of CNTs and can detect chemical reactions along the sidewalls. But in our context these methods can only serve to estimate the diameter distribution of nanotubes, since the sidewalls do not undergo any detectable changes in the end-group derivatization.

[1]H and ^{13}C nuclear magnetic resonance (NMR) spectroscopy can show the presence of long aliphatic [8, 21, 26, 44] or polymeric chains [30, 31] and the existence of magnetically different types nanotubes in the samples [8]. As a whole, the proton signals are broadened as compared to the spectra of individual starting organic reagents. For the dendron-derivatized CNTs [26, 44], this was explained in terms of two different mechanisms: the attachment of the monomeric dendrons **VI–VIII** to a "polymer-like" nanotube vs the effect of possible paramagnetic impurities in the solution. The latter is obviously relevant to the CNT-containing samples because of the possibility of residual metal catalysts. In their ^{13}C NMR spectra [26, 44], no signals due to carbons on the nanotubes themselves or the nanotube-bound carbonyl C atoms were detected. This is likely due to the fact that the CNT solution concentrations are too low even when saturated and that the relaxation times of the nanotube carbons are expected to be very long. When deuterated ethanol-d_6 was used as a co-reactant in the esterification reaction with **VI**, ^{2}H NMR measurements allowed one to detect strong attachment of deuterium species (apparently as the corresponding ethanol-d_6 ester groups) [45].

^{31}P NMR was employed to study the binding of Vaska's compound, *trans*-IrCl(CO)(PPh$_3$)$_2$, to oxidized SWNTs [51]. The data were consistent with Ir coordination to oxygen atoms on the SWNTs; the presence of a multitude of peaks suggested the potential of several modes of coordination. Similar conclusions were made in the case of Wilkinson's complex, RhCl(PPh$_3$)$_3$ [52], from ^{31}P, ^{1}H, and ^{13}C NMR measurements.

As in the all modern organic chemistry, a "battle horse" for the characterization of chemically modified carbon nanotubes is mid-IR spectroscopy. This is especially true for CNTs reacted with organic amines [reactions (1) and (2)], whose IR spectra have been measured by many research groups [8, 19, 21, 24, 25, 33, 34, 37, 38, 41]. Unfortunately, the data reported so far do not allow an unambiguous interpretation of the spectral changes observed, since they turn out to be quite contradictory. In particular, after transforming oxidized SWNTs into their octadecylamide derivatives, Chen et al. [8] found two $\nu_{C=O}$ (amide I) bands at 1663 and 1642 cm^{-1} of almost equal intensity, and not one band as one normally expects. In the IR spectrum of octadecylamide SWNTs, presented later, only one $\nu_{C=O}$ band at 1660 cm^{-1} is seen [19]. Comparison of these two spectra makes one suspect that the band at about 1640 cm^{-1} corresponds to ν_{OH} vibrations in adsorbed water molecules (apparently the latter sample was dried better than the former). This feature is quite common for IR spectra of a vast variety of adsorbents, since water is ubiquitous. In the spectra of the amide-bound SWNT–nanocrystal heterostructures based on

titanium dioxide and cadmium selenide [33], whose surfaces are highly polar and always contain adsorbed water under ambient conditions, a band at 1638 cm^{-1} was observed systematically (interpreted by the authors as the amide I band). In the SWNTs amide-derivatized with 4-dodecylaniline [21] two bands at 1655 and 1598 cm^{-1} were assigned to $\nu_{C=O}$ (amide I) and δ_{NH} (amide II) vibrations, respectively. This is a reasonable assignment for the wavenumbers; however, the band intensities have to be taken into account equally. At the same time, in this spectrum the intensity of the δ_{NH} band is several times higher than that of the $\nu_{C=O}$ band [21], whereas in amides the carbonyl band is always more intense (usually by about a factor of two) than the amide II band. According to Liu et al. [37], SWNTs derivatized with cysteamine exhibit a band around 1600 cm^{-1}, which was assigned to amide I vibrations: this interpretation can hardly agree with all the preceding data.

One more alerting circumstance can be noticed in the case of octadecylamide and 4-dodecylanilide SWNTs [8, 19, 21], where the bands appearing after derivatization (Fig. 8) turn out to be much more intense than those typical for oxidized SWNTs (at 1200, 1590, and 1720 cm^{-1}; Fig. 9a). This gives the impression that in the synthesized samples the amine content is higher than the SWNT content.

We monitored IR spectral changes during the gas phase amidation of oxidized SWNTs with nonylamine, dipentylamine, ethylenediamine, and propylenediamine [38]. Of four amines, only nonylamine treatment caused evident changes in the IR spectra (Fig. 9); for the others, the changes were at a noise level. If we admit that all the amines studied form amide bonds with carboxylic groups at SWNT tips (there are no logical reasons to expect otherwise), such spectral behavior is hard to explain: for smaller amine molecules, the efficiency of amide formation should be higher than for longer chain molecules (such as nonylamine), due to a better accessibility to the reacting carboxylic groups of SWNTs.

The IR spectrum of nonylamine-treated SWNTs (Fig. 9b) exhibited several new bands due to nonylamine: at 1358 (C–N stretch.), 1462 (C–H def.), 2856 (sym. C–H stretch.), 2927 (asym. C–H stretch.), and 1586 cm^{-1}. Assignment of the last band is the most important to characterize a
Figure 8. Mid-IR spectrum of SWNT–CONH(CH$_2$)$_{17}$CH$_3$ (thin film on quartz substrate). Reprinted with permission from [19], M. A. Hamon et al., *Chem. Phys. Lett.* 347, 8 (2001). © 2001, Elsevier Science.

due to an overwhelming mass fraction of the adsorbent itself. For CNTs, the same effect should be expected due to their typically large aspect ratios and due to multishell structure in the case of MWNTs. Even SWNTs called "short," prepared by oxidative cutting in strong acids, are on average 100–300 nm in length, at a diameter of ≈1.4 nm. These parameters have crucial implications for band intensities in the IR spectra.

To evaluate the SWNT–nonylamine mass ratio in our gas-phase treated samples [38], we impregnated oxidized SWNTs with the amine from ethanol solution taking two different proportions SWNT:nonylamine of 3:1 and 1:1 by weight (Fig. 9). The gas-phase-treated sample had a closer resemblance to the first of them (3:1). What does it mean in terms of SWNT aspect ratios? Let us consider a $(20, 0)$ zigzag SWNT backbone, containing 1920 carbon atoms (Fig. 10a), of ≈1.55 nm diameter and 10 nm length. Such a SWNT can have about 10 carboxylic groups at each tip (a higher density of COOH groups is unlikely for steric reasons). As a result, it can form amide bonds with 20 nonylamine molecules, and this stoichiometry would correspond to a SWNT:nonylamine mass ratio of 8.4:1. Thus, even if we suppose that oxidized SWNTs are on average 10 nm in length, to obtain the IR-band intensities shown in Figure 9b and c we would have to triplicate the nonylamine content. The sample would have to contain >60% nonylamine in a physically adsorbed form, and correspondingly >60% IR absorption would be due to the chemically unbound fraction. It should be obvious that for 100–300 nm long SWNTs, the amide contribution to the IR absorption will be even lower, by 10–30 times, and such bands are almost impossible to distinguish (especially given the generally poor quality of the CNT spectra). Consequently, the bands visible in most IR spectra of amide-derivatized CNTs correspond to the molecules, strongly physisorbed due to hydrophobic interactions between their hydrocarbon moieties and CNT sidewalls. Recent results afforded by temperature-programmed desorption mass spectrometry supported our conclusion by

chemical state of nonylamine, but obviously its frequency is too low to attribute this band to $\nu_{C=O}$ (amide I) vibrations: it should be assigned to δ_{NH} vibrations in NH$_2$. Along with the above bands, there is one more at 1715 cm^{-1}, having a shoulder at about 1750 cm^{-1}. However, before attempting further interpretation, let us analyze in principle what kind of information on the terminal organic groups can be expected from IR spectra of typical SWNTs.

In some respect carbon nanotubes resemble chemically derivatized inorganic adsorbents (silica, alumina, amorphous carbon, graphite, etc.), where the contribution of surface organic groups to the whole IR spectrum is relatively low,

Figure 10. (a) Schematic representation of a $(20, 0)$ zigzag SWNT, of ≈1.55 nm diameter and 10 nm length, containing 10 carboxylic groups at each tip. Reprinted with permisson from [38], E. V. Basiuk et al., *J. Phys. Chem. B* 106, 1588 (2002). © 2002, American Chemical Society. (b) Schematic end section of $(10, 10)$ SWNT–COOH. Reprinted with permission from [19], M. A. Hamon et al., *Chem. Phys. Lett.* 347, 8 (2001). © 2001, Elsevier Science.

revealing two different forms of nonylamine in the amide-derivatized SWNTs [38].

As we already mentioned, in the IR spectrum of the gas-phase-treated sample (Fig. 9b), one more band was detected at 1715 cm^{-1} with a shoulder at 1750 cm^{-1}. This band (reported in the 1700–1735 cm^{-1} range by different authors) is believed to correspond to the terminal COOH groups [8, 9, 12–14, 21, 37, 41]. A higher frequency absorption was reported as well: in particular, for SWNTs after oxidation with gaseous ozone (i.e., no liquid-phase treatment with strong acids), the band at 1739 cm^{-1} was assigned to ester $\nu_{C=O}$ vibrations [17]. A band at 1750 cm^{-1} was found also for CNTs after boiling in concentrated HNO$_3$ [9]; in this case, however, the existence of ester groups must be excluded: in strong acid media they are hydrolyzed into COOH groups. In our case the shoulder at 1750 cm^{-1} cannot be due to ester absorption for the same reason. One might suggest the formation of anhydrides through thermal condensation of neighboring carboxylic groups; however, carboxy anhydrides are extremely reactive, especially with amines. Besides that, we did not detect this absorption in IR spectra of oxidized SWNTs heated to 150–180 °C in vacuum in the absence of amines.

The above considerations were presented in supposition that most reactive carboxylic groups are located at CNT tips. However, a considerable fraction of COOH functionalities are believed to exist at defect sites along the sidewalls. Can they account for the high IR band intensities? Hamon et al. [19] addressed this issue, determining the weight contribution of octadecylamine (ODA) in the amide-derivatized acid-cut SWNTs (Section 3.1). In their samples (for example, the IR spectrum in Fig. 8), the ODA corresponds to about 50% of the sample by weight. On a molar basis the ODA is incorporated to the extent of about 6%. If each ODA molecule reacts with a single COOH group in the SWNT, then this result corresponds to the number of reactive sites in the SWNTs. Other reported reactive site functionality determinations gave values of ∼5% [12] and 3–4% [41] for the amount of carbon atoms at defect sites in purified SWNTs. While the results are consistent, they are far higher than would appear from the models based solely on end-group functionalization. The model employed for their estimates is shown in Figure 10b. It is an armchair (10, 10) SWNT, in which the ends are cut vertically to the nanotube axis. With these simplifications there are 20 carboxylic acid groups at each nanotube tip. Furthermore, the unit cell of a (10, 10) SWNT contains 40 carbon atoms and the translation repeat distance (a_0) of the unit cell along the one-dimensional lattice is $\sqrt{3}a$, where a is the length of the carbon–carbon bond, and thus $a_0 = 2.46$ Å. A perfect 100-nm-long (10, 10) SWNT–COOH would contain $40 \times (1000/2.46) \approx 16{,}000$ carbon atoms (neglecting oxygen functionality) and 40 carboxylic acid groups. Thus the mole fraction of reactive end-group sites would be about 0.25% in such a perfect 100-nm-long SWNT–COOH. In order to match the experimental values of a few percent, the average length of perfect SWNT–COOH in the samples should be about 5 nm, whereas it is roughly two orders of magnitude longer (according to AFM). If the previous estimates of reactive sites are accepted (3–5% [12, 41]), this would suggest that there is a large concentration of SWNT

defect sites which are able to react with amines. At the same time, the Raman and near-IR spectra of the amide-derivatized SWNTs [8, 19, 21] provide convincing evidence for the preservation of the SWNT electronic band structure.

Thus, Hamon et al. [19] also came to the conclusion that there is a noncovalent interaction between the SWNTs and the ODA. In particular, the ODA molecules could occupy the interior gallery of the SWNTs, and the authors estimated the amount of material that could be accommodated inside the SWNTs. They took an interior van der Waals diameter of 1 nm for the SWNTs, and this allowed them to calculate an interior volume for a unit cell of a (10, 10) SWNT of 1.93×10^{-22} cm^3. By using the density of ODA (0.862 g/cm^3), they obtained a mass of 1.66×10^{-22} g for the ODA that could occupy the interior of a unit cell of a (10, 10) SWNT. Using this value together with the weight of a unit cell of a (10, 10) SWNT (7.98×10^{-22} g), they obtained a weight percentage of the interior ODA of 17%—far less than the 50% they found experimentally. Similar results were obtained for the esterification [reaction (3)] of oxidized SWNTs with octadecylalcohol [43].

To summarize, we believe that some of the existing interpretations of mid-IR spectra of derivatized carbon nanotubes are premature and need further extensive studies. One of the most important points to take into account is that CNTs can behave as typical adsorbents, retaining large amounts of organic reagents (amines, alcohols, etc., and possibly solvents!) due to noncovalent interactions, both in their interiors (adsorption in nanopores) and on the outer walls (surface adsorption). Concentrations of such adsorbed molecules can be a few orders of magnitude higher than those of the covalently bound species: in this case IR spectroscopy is unable to provide information on the derivatization products.

5. PROPERTIES

Due to the large aspect ratios typical for carbon nanotubes (both SWNTs and MWNTs) and, in addition to that, due to multishell structure in the case of MWNTs, the derivatizing organic groups cannot cause visible morphological changes, unless they are high-molecular-weight polymers. Thus, the presence of relatively small functionalities cannot be seen by the commonly used microscopic techniques, such as SEM, TEM, AFM, and STM. On the other hand, when large polymeric chains (PPEI-EI and PVA-VA, molecular weight of 100,000–200,000) were attached to the CNTs, organization of the polymer at the tube tip and in many cases along the tube body was clearly visible by STM [29]. Similarly, the presence of poly(ethylene oxide) grafted to SWNTs was seen in AFM images [32].

The appearance of functional groups at CNT tips changes their affinity to solid surfaces and consequently can be used for the preparation of self-assembled monolayers. In some of them carboxylic groups of the oxidized CNTs are ionically bound to surface metal ions [47, 48], whereas in others the carboxylic groups are covalently linked through different organic groups [18, 23, 33, 37, 49]. In the case of nanotube cantilevers for AFM, the chemical alterations were characterized as changes in the adhesion force in a given pH range [5, 6]. Such chemically modified carbon nanotube tips are

suitable to produce chemically sensitive images with high lateral resolution, as well as to study binding in biological and chemical systems [5, 6, 49].

Increased solubility due to exfoliation of the nanotube bundles is the most important, common, and frequently reported property of the derivatized CNT materials. The amide and ester derivatization dramatically improves their solubility in organic solvents [8, 19, 21, 22, 24, 25, 40, 43–45]; similar solubility properties were obtained for amine zwitterion-functionalized SWNTs [21, 41]. SWNTs and MWNTs derivatized with highly soluble PPEI-EI, PVA-VA, and PEO polymers [27–32], as well as with PEO-derived dendron moieties [26], are soluble not only in organic solvents but also in water. Glucosamine [34] and protein conjugates with CNTs [35] are highly soluble in water as well; this can serve as the basis for developing biocompatible carbon nanotube materials. Attaching transition metal complexes to the nanotubes increases their solubility in dimethylformamide, dimethylsulfoxide, tetrahydrofuran, methanol, chloroform, toluene, etc. [51, 52], opening a new prospect for their applications not only in heterogeneous but also in homogeneous catalysis.

Strong luminescence was reported for the CNTs chemically bound to PPEI-EI, PVA-VA polymers, and PEO-derived dendron moieties [26, 27]. Luminescence quantum yields are substantial, for example 11% for MWNT—PPEI-EI in chloroform at 400 nm excitation [27].

6. CONCLUSIONS

The covalent chemistry at the carbon nanotube tips is not particularly rich. Unlike sidewall chemistry, which in many regards is similar to fullerene chemistry, it is limited to a few relatively simple reactions of terminal carboxylic groups. A very low mass contribution of the terminal functional groups causes only insignificant changes in spectral properties of the bulk material, which makes characterizing the chemical structure of the derivatization products a very complicated (sometimes unfeasible) task.

The present limitations in spectroscopic characterizations of the end-derivatized CNTs might create a pessimistic opinion on further prospects of this exciting and difficult area. Nevertheless, one should remember that the end goal here is not to obtain good-quality spectra, but the preparation of new nanomaterials with given properties, suitable for particular applications. And it is material science aspects where impressive results have been achieved. First, chemical derivatization of the carbon nanotube tips made possible the preparation of SWNTs and MWNTs soluble not only in organic but also in aqueous solvents. In turn, this allows facile purification and fractionation of the carbon nanotubes by liquid-chromatographic techniques, simplifies their handling, as well as solves the problem of their compatibility with biological systems. An especially important point is that this way of derivatization does not alter the sidewall structure and consequently preserves the unique electronic and mechanic properties of CNTs. Second, the chemical modification allows one to change CNT affinity to molecules, ions, and solid surfaces. This is especially important for the deposition of dense arrays of nanotubes aligned normal to substrates, considered as a crucial step in the development of various technologically important devices such as sensors, field emitters, organic light-emitting diodes, etc. One of the goals already achieved is the preparation of carbon nanotube probe tips for atomic force microscopy and chemically sensitive imaging with high lateral resolution. Such probe tips have potential applications in many areas of chemistry and biology for titrating different surface functionalities, imaging patterned samples based on molecular interactions, and measuring the binding force between single protein–ligand pairs. Third, an array of hybrid carbon nanotube structures was prepared by combining them with organic polymers and inorganic microparticulate materials (silica gel, semiconductor nanocrystals of CdSe and TiO_2); these recent studies open new routes to CNT-based supramolecular chemistry and nanoscale assembly. And one more line suggesting potential applications in catalysis and molecular electronics is the combination of CNT materials with transition-metal complexes.

Coming back to the spectroscopic characterization of the end-derivatized carbon nanotubes, which is still very important to fully qualify the CNT chemistry as a branch of modern organic chemistry, a solution to this problem can, in principle, be found even with the typical sensitivity of the existing experimental techniques. Cutting the carbon nanotubes to short pieces of ca. 10 nm in length would substantially increase mass contribution of the end and wall-defect functionalities into the total sample mass, thus improving detectability of the species by 1–2 orders of magnitude. This turns to be an economical rather than a scientific issue, since the present high cost of purified CNTs (for example, more than USD 1000 for 1 g of 95% + SWNTs) and significant losses of the material during the acid cutting makes this approach prohibitive for many academic researchers. How fast the progress in this area will be relies upon the development of inexpensive and efficient methods of CNT production.

GLOSSARY

Carbon nanotubes Fullerene-related structures consisting of graphene cylinders. As-prepared carbon nonotubes are closed at either end with caps containing fused hexagonal and pentagonal rings. Oxidation with strong oxidants (nitric acid, ozone, hydrogen peroxide, etc.) destroys the caps, producing oxygen-containing functional groups at the nanotube tips.

Derivatization Converting functional groups into other groups, having different chemical properties.

Functionalization Chemical attachment of reactive (functional) groups to molecules.

MWNT Multiwalled (or multilayer) carbon nanotube, a carbon nanotube consisting of two or many coaxial graphene cylinders, maintained together by van der Waals forces.

Solubilization Enhancement of solubility of a chemical compound.

SWNT Single-walled (or single-layer) carbon nanotube, a carbon nanotube consisting of one graphene cylinder.

CONTENTS

1. INTRODUCTION

The colloidal metals, particularly gold, generated considerable interest due to their intensive colors which enabled them to be used as pigments for glass or ceramics. Presently, with an increasing understanding of the unique electronic structure and extremely large surface areas of nanosized metal particles, there is a rapid growth in the number of potential technological applications. Generally, isolable particles between 1 and 50 nm size that are prevented from agglomeration by protecting shells are regarded as nanostructured metal colloids. Depending on the nature of the protecting shell, they can be redispersed either in water ("hydrosols") or in organic solvents ("organosols"). As the size of the metal particle decreases to nanometer scale, the mechanical, electronic, optical, magnetic, as well as the thermodynamic properties are significantly altered from those of either the bulk or the single molecule. The object of this chapter is to provide a synopsis of the wet chemical method syntheses of colloidal nanoparticles exercised to date with a discussion on their potential applications. A brief discussion on their physical properties and some spectral characterizations are provided.

A wealth of knowledge has been acquired about these colloidal materials in the last few decades through the work of leading scientists in the field [1–12]. Mono- and bimetallic colloids in their dispersed forms can be used as precursors for a new type of catalyst that is applicable both in the homogeneous and heterogeneous phases [13–16]. Recent studies show the potential of nanostructured metal colloids as fuel cell catalysts apart from the obvious applications in chemical catalysis [17–20]. Though presently there are no major industrial applications of nanostructured materials known, current developments are inching closer to it than ever before.

2. WET CHEMICAL SYNTHESIS

Production of nanostructured metal colloids is brought about by two methods. The "top-down method" involves chopping down the bulk metal by mechanical means, and the resulting colloidal particles are subsequently stabilized by colloidal protecting agents [21, 22]. Application of metal vapor techniques [23–26], which work on this principle, provides chemists with a very versatile route for the production of a wide range of nanostructured metal colloids on a preparative laboratory scale [27, 28]. However, this method has a few drawbacks in that it is difficult to obtain a narrow particle size distribution, and installation of metal vapor machines is highly demanding. On the other hand, "bottom-up methods" of wet chemical nanoparticle preparation basically rely on the chemical reduction of metal salts, electrochemical pathways, or the controlled decomposition of metastable organometallic compounds in solution. Control over the growth of the primarily formed nanoclusters and their agglomeration is effected by the use of a variety of stabilizers, in the form of donor ligands, polymers, and surfactants. Faraday, in 1857, was the first to report chemical reduction of transition-metal salts in the presence of stabilizing agents to generate zerovalent metal colloids in aqueous or organic media [29]. This reliable approach has become the most common and powerful synthetic method in this field [10, 11, 30]. Nearly a century later, Turkevich [1–3] established the first reproducible standard recipe for the preparation of 20-nm gold metal colloids by the reduction of $[AuCl_4]^-$ using sodium citrate. Additionally, he proposed a mechanism for the stepwise formation of nanoclusters based on nucleation, growth, and agglomeration [1] which in essence is still valid. With the help of better analytical techniques and data from more recent thermodynamic and kinetic results [31–41], this model has been refined as illustrated in Figure 1.
Figure 1. Formation of nanostructured metal colloids via the "salt reduction" method. Adapted with permission from [36], M. Maase, Ph.D. Thesis, Verlag Mainz, Aachen, 1999.

During the embryonic stage of nucleation [31], the metal salt is reduced to give zerovalent metal atoms. Collisions of these in solution with other metal ions, metal atoms, or clusters result in an irreversible "seed" of stable metal nuclei. The diameter of these seeds can be well below 1 nm depending on the strength of the metal-metal bonds and the difference in redox potentials of the metal salt and the reducing agent used.

The mechanism of colloidal metal formation has been carefully followed by a healthy combination of chemical reactions, NMR, ASAXS (anomalous small angle X-ray scattering), XAS (X-ray absorption spectroscopy), DFT (density functional theory) computations, and electron microscopy [37]. It has been exemplified in the reduction of Pt(acac)$_2$ (acac = acetylacetonate) by trimethylaluminum yielding an intermediate having a four-membered ring containing alternate aluminum and platinum atoms with the remaining valencies of these atoms satisfied by methyl groups. From this complex (**3**), monodisperse platinum nanoparticles with a mean diameter of 1.2 nm are obtained. Formation of redispersible Pt-colloid of nearly 1.2 nm size from the reaction of the complex with excess of trialkylaluminum is an interesting observation. Figure 2 depicts the formation of the proposed platinum seed.

The central concept of seeds serving as nucleation centers has been evidenced by the wet chemical synthesis of gold nanoparticles via reduction of a gold salt. Examination of the effect of 12-nm gold seed concentration (obtained by citrate reduction of gold salt solution) in the solution phase preparation of gold nanoparticles for varied concentrations of different reducing agents and conditions [38, 39] led to
Figure 2. Schematic representation of the platinum seed formation through the intermediate complex (**3**). Adapted with permission from [37], K. Angermund et al., *Angew. Chem. Int. Ed.* 41, 4041 (2002). © 2002, VCH.

the observation that presence of seeds causes additional nucleation.

Size of nanoparticle products gets affected by two important parameters, namely, seed concentration and the rate of addition of the reducing agent. With increased addition rate of reducing agents, the presence of seeds promotes the formation of more seeds instead of growth of a particular seed. If the addition of the reducing agent is slow, there is growth of the seeds but this is compensated by uniform size distribution of the resulting colloids. On similar lines, Buhro and co-workers have reported results on a seeded growth mechanism in which 1.5-nm Au seeds are used to grow Bi, Sn, and In nanoparticles [40]. Seeding growth for size control of 5- to 40-nm diameter gold nanoparticles has also been studied [41].

For silver nanoparticle synthesis [31], it has been experimentally verified that stronger reducing agents produce smaller nuclei in the "seed." During the "ripening" process, these nuclei grow to yield colloidal metal particles in the size range of 1–50 nm, having a narrow size distribution. It was assumed that the mechanism for the particle formation is an agglomeration of zerovalent nuclei in the "seed" or, alternately, collisions of already formed nuclei with reduced metal atoms. Stepwise reductive formation of Ag_3^+ and Ag_4^+ clusters by spectroscopic methods has been carefully followed by Henglein and co-workers [32]. An autocatalytic pathway was strongly suggested in which metal ions are adsorbed and successively reduced at the zerovalent cluster surface. In addition to the aforesaid results on nucleation, formation of colloidal Cu protected by cationic surfactants (NR_4^+) was investigated by *in-situ* X-ray absorption spectroscopy showing the formation of an intermediate Cu^+ state prior to the nucleation of the particles [35]. Although the processes during nucleation and particle growth cannot be analyzed separately, it is now generally accepted that the size of the resulting metal colloid is determined by the relative rates of nucleation and particle growth.

2.1. Particle Stabilization

Protective agents play a crucial role in stabilizing the nanostructured colloidal metals from agglomeration. Two basic modes of stabilization have been distinguished [30] though, in principle, a combination of these two effects, use of solvents or ligands for stabilization, can be regarded as a different mode of stabilization.

Electrostatic stabilization is caused by the Coulombic repulsion between particles, caused by the electrical double layer formed by ions adsorbed at the particle surface (e.g., sodium citrate) and the corresponding counter ions. The reduction of $[AuCl_4]^-$ with sodium citrate to produce gold sols is an example [1–3].

Steric stabilization is achieved because of the coordination of sterically demanding organic molecules that act as protective shields on the metallic surface. The nanometallic cores are separated from each other, preventing agglomeration. Polymers [42–46] and block copolymers; P, N, S-donors (e.g., phosphines, amines, thioethers) [6, 63–90]; solvents such as THF [6, 91], THF/MeOH [92], or propylene carbonate [93]; long chain alcohols [47–62, 94]; surfactants [6, 7, 9, 15, 16, 95–106], and organometallics [107–110] are the main classes of protective groups used. While lipophilic protective agents give metal colloids that are soluble in organic media ("organosols"), hydrophilic agents yield water soluble colloids ("hydrosols"). In Pd organosols stabilized by tetraalkylammonium halides, the metal core is protected by a surfactant monolayer [111]. A pictorial representation of tetraalkylammonium halide supporting a metal colloid is depicted (see Fig. 4). In contrast, metal hydrosols that are stabilized by zwitterionic surfactants capable of self-aggregation are enclosed in organic double layers. TEM micrographs (Fig. 3) show that the colloidal Pt particles (average size 2.8 nm) are surrounded by a double layer zone of the zwitterionic carboxybetaine (3–5 nm) after the application of contrasting agent in uranylacetate. The charged metal surface interacts with the hydrophilic head group of the betaine. The lipophilic tail is associated with the tail of a
Figure 3. (a) TEM micrographs of colloidal Pt particles (single and aggregated, average core size = 2.8 nm) stabilized by carboxybetaine 12. (b) Schematic model of the hydrosol stabilization by a double layer of the zwitterionic carboxybetaine 12. Adapted with permission from [112], A. Schulze Tilling, Ph.D. Thesis, RWTH Aachen, 1996.

second surfactant molecule. As a result, a hydrophilic outer sphere is formed [112].

Pt or Pt/Au particles can be hosted in the hydrophobic holes of nonionic surfactants, for example, polyethylene monolaurate [113, 114]. High-resolution small-angle X-ray scattering and X-ray photon correlation spectroscopy have been used to find the structure and diffusive dynamics of a colloidal palladium aggregate sol under dilute and semidilute conditions. The sizes of the aggregates determined in the static structure and the one derived from diffusive dynamics at low concentration are found consistent with each other.

The aggregates tend to overlap at high concentration. While the system remains in a liquid-like state, the apparent diffusion constant decreases. The structural features obtained by comparison of static and dynamic data are not accessible solely by one technique [115].

2.2. Reducing Agents and Reduction Methods

2.2.1. Metal Salt Reduction

This is one of the most used wet chemical methods of nanoparticle synthesis. The major advantage of the salt reduction method is that it allows colloidal nanoparticles to be prepared with reproducibility in multigram amounts having a narrow size distribution. The classical Faraday route of reducing $[AuCl_4]^-$ by sodium citrate is still used to prepare standard 20-nm gold sols for histological staining applications [1, 116]. An array of chemical reducing agents and methods have successfully been applied to obtain nanostructured colloidal metals.

Diborane-as-reductant route was established by Schmid and co-workers for the synthesis of $Au_{55}(PPh_3)_{12}Cl_6$ (1.4 nm), a full shell ("magic number") nanocluster stabilized by phosphine ligands [63–78]. Careful introduction of B_2H_6 into a Au^{III} ion solution essentially yielded uniform Au_{55} clusters. The "diborane route" for $M_{55}L_{12}Cl_n$ nanoclusters was reviewed by Aiken and Finke [11]. Bimetallic nanoclusters that were made accessible by this method [63–78] have been thoroughly characterized. The phosphine ligands may be exchanged in the Au_{55} nanoclusters quantitatively using silsesquioxanes which causes important changes in the physical and chemical behavior of the gold clusters [77, 78]. The synthesis and general chemistry of nanosized silica coated metal particles have been elaborated by Mulvaney and co-workers [78].

The "alcohol reduction process" by Hirai and Toshima [10, 42–45, 117, 118] is widely applicable for the preparation of colloidal precious metals stabilized by organic polymers such as poly(vinylpyrrolidone) (PVP), poly(vinyl alcohol) (PVA), and poly(methylvinyl ether). During salt reduction, alcohols having α-hydrogen atoms are oxidized to the corresponding carbonyl compound. Thus methanol gets converted to formaldehyde. The method for preparing bimetallic nanoparticles via the co-reduction of mixed ions has been evaluated in a recent review [10]. Using ethylene glycol as a solvent and reducing agent, PVP stabilized Ag nanoprisms and nanorods [119], Au, Pt, Pd, Ir [120], Ru and Pt-Mn [120–122] are obtained by what is now termed as poly-ol synthesis. Nanometer-size platinum colloid, FePt nanoparticle

alloy, $(Fe_{49}Pt_{51})_{88}Ag_{12}$ nanoclusters are obtained by using ethylene glycol, glycerol, and other long chain polyols [88, 123–125]. While ethanol in aqueous medium has been used for generating Pd nanoparticles with varying particle sizes [126, 127], pure ethanol and in some instances methanol has been used to prepare Ag, Au, Pd, Cu, Ag-Pd, and Cu-Pd nanoparticles and alloys [128–130]. Reduction of a mixture of Pt and Ru salts on a support with atomic ratios of the metals in 1:1 and 7:3 respectively using a modified alcohol reduction procedure has been performed to good effect [131].

Hydrogen is an efficient reducing agent for the preparation of electrostatically stabilized metal sols and of polymer-stabilized hydrosols of Pd, Pt, Rh, and Ir [132–136]. Moiseev's giant palladium cluster [79–84] and Finke's polyoxoanion- and tetrabutylammonium-stabilized transition-metal nanoclusters [11, 34, 137–141] are all made by the hydrogen reduction method.

The characterization of Moiseev's "giant" cationic palladium clusters [79–84] [idealized formula $Pd_{\approx561}L_{\approx60}$ · $(OAc)_{\approx180}$ (L = phenanthroline, bipyridine)] and their catalytic properties have also been reviewed by Aiken and Finke [11]. The "giant Pd cluster" is synthesized in two steps: reduction of palladium(II) acetate in acetic acid by hydrogen gas in the presence of either 1,10-phenanthroline (phen) or 2,2′-bipyridine (bipy) yields an intermediate product $[Pd_4phen(OAC)_2H_4]_{n\approx100}$ of 2-nm size, Eq. (1):

$$4Pd_3(OCOCH_3)_6 + 3phen + 15H_2$$
$$\longrightarrow 3Pd_4phen(OCOCH_3)_2H_4 + 18CH_3COOH \quad (1)$$
In acetic acid solution, $[Pd_4phen(OAC)_2H_4]_{n\approx100}$ takes up to 5 Mol of O_2 per gram-atom of palladium over about 20 minutes to give air-stable and water-soluble "giant Pd cluster" in 85% yield. Finke's system [11, 34, 137–141] is synthesized via hydrogen reduction under completely air- and water-free conditions using a polyoxoanion-supported Ir(I) organometallic complex $[(n\text{-}C_4H_9)_4N]_5Na_3[(1.5\text{-}COD)Ir \cdot P_2W_{15}Nb_3O_{62}]$ as the molecular precursor (Eq. (2)):

$$300[(1.5\text{-}COD)Ir \cdot P_2W_{15}Nb_3O_{62}]^{8-} + 750H_2$$
$$\longrightarrow 300cyclooctane + 1Ir(0)_{\sim300}$$
$$+ 300P_2W_{15}Nb_3O_{62}^{9-} + 300H^+ \quad (2)$$
This represents a new subclass of transition-metal nanoclusters. A zerovalent transition-metal core, for example, Ir(0) [11, 34, 137, 138] or Rh(0) [139–141], is doubly stabilized by a cationic surfactant (e.g., NR_4^+) and by a polyoxoanion (e.g., $P_2W_{15}Nb_3O_{62}^{9-}$). Treatment of this precursor with H_2 in acetone and excess cyclohexene results in the formation of nearly monodisperse [i.e., ±15% size dispersion 2 ± 0.3 nm $Ir(0)_{\approx300}$] nanoclusters. In the absence of cyclohexene, the same procedure yields larger $Ir(0)_{\approx900}$ nanoclusters (3 ± 0.4 nm). The results of a combination of modern instrumental analysis methods applied to Finke's nanoclusters have been carefully discussed [11]. It was clear that the Ir(0) core is uncharged, and that the particles have an "extremely clean, exposed, chemically reactive surface." These experiments were done on a few milligram scales. Very recently, nearly a gram scale synthesis of polyoxoanion and tetrabutylammonium protected $Ir(0)_{\sim2000}$ with a mean

particle size of 3.8 ± 0.6 nm and its activity before and after storage have been reported [142].

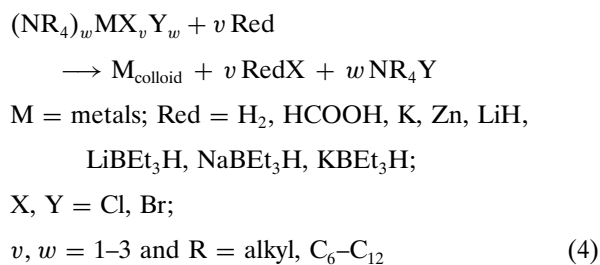
Shape-selective preparation of oxalate-stabilized Pt nanoparticles with a mean diameter of 6.5, 3.5, and 7.9 nm starting from $K_2[Pt(C_2O_4)]_2$, K_2PtCl_6, and K_2PtCl_4, respectively, using hydrogen as a reducing agent has been a recent development [143]. Production of Pt-Au bimetallic catalyst by surface redox reactions has been performed by direct redox reaction and refilling method [144], in which parent platinum metal adsorbed with hydrogen reduces the $AuCl_4^-$ species by contact with the Pt-H interface at low temperatures. Using hydrogen as a reducing agent, platinum nanoparticles have been synthesized along with polyacrylic acid as capping material on alumina [145], or in the presence of N-propylacrylamide [146, 147].

Colloidal Pt in water [2, 148] is obtained using CO, formic acid, or sodium formate, formaldehyde, and benzaldehyde as reductants [149]. Silanes are found to be effective for the reductive preparation of Pt sols [150, 151]. Duff, Johnson, and Baiker and their co-workers have successfully introduced tetrakis(hydroxymethyl)phosphoniumchloride (THPC) as a reducing agent, which allows the size- and morphology-selective synthesis of Ag, Cu, Pt, and Au nanoparticles from the corresponding metal salts [152–157]. Further, hydrazine [158–160], hydroxylamine [41, 161, 162], and electrons trapped in, for example, $K^+[(crown)_2K]^-$ [163], were applied as reductants. In spite of its disadvantage in the formation of transition-metal borides during the synthesis, BH_4^- is a powerful and valuable reagent for the salt reduction [46, 164–169]. Borate reduction followed by octa(3-aminopropyl)silsesquioxane (NSi_8) stabilization of silver nanoparticles on poly(styrenesulphonate)/silica has been prepared [170] and aqueous reduction using $NaBH_4$ is being used extensively [166, 167, 171–173]. Very recently, solvent-stabilized platinum and its alloy with Ru, Mo, W, and Ni with an average diameter of 1.7 nm has been reported. In an application oriented synthesis of platinum- based electrocatalysts, the reduction of platinum and the combining metal halides was performed using $LiBH_4$ as a reducing agent. The resulting nanoparticles were found dispersed in THF, being stabilized by the solvent. Evaporation of THF and further treatment with ethanol gave the desired product. This residue was then taken into benzene by sonication and then in water before checking their catalytic activity. Though this method gives relief to many synthetic chemists because of its simplicity and the quoted electrocatalytic activity, the redispersibility of the obtained nanoparticles and their solubility as naked metals in higher concentration in THF are questionable [188]. Cubic platinum nanoparticles are generated by $NaBH_4$ reduction of K_2PtCl_4 in an aqueous medium. Under the effect of phase transfer inducer HCl, Pt nanoparticles were transferred to a toluene solution containing dodecanethiol, forming a toluene organosol of cubic Pt nanoparticles protected by dodecanethiol which upon supporting on carbon resulted in a self-assembled nanoparticle [174]. Hydrotriorganoborates having tetraalkylammonium cations [6, 7, 9, 15, 95–97] offer a wide range of applications in the wet chemical reduction of transition-metal salts. In this case, the reductant $[BEt_3H^-]$ is combined with the stabilizing agent, NR_4^+. The surface active NR_4^+ salts are formed

immediately at the reduction center in high local concentration and act as powerful protecting agents for the metal particles and prevent particle aggregation. This resulting colloid can be isolated in solid form and redissolved in various solvents. Another advantage is that trialkylboron is recovered unchanged from the reaction and no borides contaminate the products. It has been recently shown in the case of tetrabutylammonium- and tetraoctylammonium-stabilized Pd colloids [175] by various advanced physical methods that negatively charged chloride is present on the inner side of the protecting shell and is located between palladium core and N(alkyl)$_4$ groups forming the protecting shell. Moreover, results also suggest a dependence of the equilibrium position of the chloride between the metal core and the alkyl chain length of the protecting shell. This picture (Fig. 4b) is in contrast to the previously presumed model as depicted (Fig. 4a):

$$MX_\nu + NR_4(BEt_3H)$$
$$\longrightarrow M_{colloid} + \nu NR_4X + \nu BEt_3 + \nu/2H_2\uparrow$$

M = metals of the groups 6–11; X = Cl, Br;

$\nu = 1, 2, 3$; and R = alkyl, C_6–C_{20} (3)
From this method of colloidal synthesis, the NR_4^+-stabilized metal "raw" colloids typically contain 6–12 wt % of metal. "Purified" transition-metal colloids containing ca. 70–85 wt % of metal are obtained by the workup with ethanol or ether and subsequent reprecipitation by a solvent of different polarity [6]. The pre-preparation of [$NR_4^+BEt_3H^-$] can be avoided when NR_4X is coupled to the metal salt prior to the reduction step. NR_4^+-stabilized transition-metal nanoparticles can also be obtained from NR_4X-transition-metal double salts. Since the local concentration of the protecting group is sufficiently high, a number of conventional reducing agents may be applied to get the protected colloidal metal (Eq. (4)) [7, 15]:


$$(NR_4)_w MX_v Y_w + v\,Red$$
$$\longrightarrow M_{colloid} + v\,RedX + w\,NR_4Y$$

M = metals; Red = H_2, HCOOH, K, Zn, LiH,

    $LiBEt_3H$, $NaBEt_3H$, $KBEt_3H$;

X, Y = Cl, Br;

$v, w = 1$–3 and R = alkyl, C_6–C_{12} (4)

In a recent review [11], the scope and limitations of this method have been evaluated. Isolable colloids of the zerovalent early transition metals which are stabilized only with THF have been prepared via the [BEt_3H^-] reduction of the preformed THF adducts of $TiBr_4$ (Eq. (5)), $ZrBr_4$, VBr_3, $NbCl_4$, and $MnBr_2$:

$$x \cdot [TiBr_4 \cdot 2THF + x \cdot 4K[BEt_3H]$$
$$\xrightarrow{THF,\,2\,h,\,20\,°C} [Ti \cdot 0.5THF]_x + x \cdot 4BEt_3$$
$$+ x \cdot 4KBr\downarrow + x \cdot 4H_2\uparrow \quad (5)$$
Detailed studies of [Ti · 0.5 THF] [91] show that it consists of Ti_{13} clusters in the zerovalent state, stabilized by six THF molecules (Fig. 5). By analogy, [Mn · 0.3 THF] particles (1–2.5 nm) were prepared [177] and the physical properties have been studied [108]. THF in Eq. (5) has been successfully replaced by tetrahydrothiophene (THT) in the case of Mn, Pd, and Pt organosols; but attempts to stabilize Ti and V this way led to decomposition [15] (Fig. 6).

Figure 7 gives a survey of the [BEt_3H^-] method. The advantages of the method (Fig. 7) may be summarized as follows:

- The method is generally applicable to salts of metals in groups 4–11 in the periodic table.
- It yields extraordinary stable metal colloids that are easy to isolate as dry powders.
- The particle size distribution is nearly monodisperse.
- Bi- and plurimetallic colloids are easily accessible by co-reduction of different metal salts.
- The synthesis is suitable for multigram preparations and easy to scale up.
- The method is reproducible.

Although there is a drawback to this method in that the particle size of the resulting sols cannot be varied by altering the reaction conditions, this method has been conveniently used by other research groups in generating efficient electrocatalyst precursors [179–181]. Triethylhydroborate has also been used for the preparation of acicular iron particles and

granular particles, without using acicular starting materials during the reduction of FeCl$_3$ [176].

Highly water-soluble hydrosols, particularly those of zerovalent precious metals, were made accessible using betaines instead of NR$_4^+$ salts as the protecting group (Eq. (3)). As shown in Eq. (4), a broad variety of hydrophilic surfactants may be used [7, 15, 96]. A new method for the size- and morphology-selective preparation of metal colloids using tetraalkylammonium carboxylates of the type NR$_4^+$R′CO$_2^-$ (R = octyl, R′ = alkyl, aryl, H) both as the reducing agent and the stabilizer (Eq. (6)) was reported by Reetz and Maase [36, 183, 184]:

$$M^+ + R_4N^+R'CO_2^-$$
$$\xrightarrow{50-90\,°C} M^0(R_4NR'CO_2)_x + CO_2 + R'\text{-}R'$$
$$R = \text{octyl},\ R' = \text{alkyl, aryl, H} \tag{6}$$
The resulting particle sizes were found to correlate with the electronic nature of the R′ group in the carboxylate. Electron donors produce small nanoclusters while electron-withdrawing substituents R′, in contrast, yield larger particles. For example, Pd particles of 2.2 nm size are found when Pd(NO$_3$)$_2$ is treated with an excess of tetra(*n*-octyl)ammonium-carboxylate bearing R′ = (CH$_3$)$_3$CCO$_2^-$

as the substituent. With R′ = Cl$_2$CHCO$_2^-$ (an electron-withdrawing substituent) the particle size was found to be 5.4 nm. The following bimetallic colloids were obtained with tetra(*n*-octyl) ammonium formate as the reductant: Pd/Pt (2.2 nm), Pd/Sn (4.4 nm), Pd/Au (3.3 nm), Pd/Rh (1.8 nm), Pt/Ru (1.7 nm), and Pd/Cu (2.2 nm). The shape of the particles also depends on the reductant: With tetra(*n*-octyl) ammonium glycolate Pd(NO$_3$)$_2$ a significant amount of trigonal particles in the resulting Pd colloid was detected.

Organoaluminum compounds have been used for the reductive stabilization of mono- and bimetallic nanoparticles (see Eq. (7)) [107, 108]:
M = metals of groups 6–11 PSE
X = halogene, acetylacetonate $n = 2$–4
R = C$_1$–C$_8$-Alkyl
Particle sizes 1–12 nm $\tag{7}$

From Eq. (7), it is clear that colloids of zerovalent elements of groups 6–11 of the periodic table (and also of tin) can be prepared in the form of stable, isolable organosols. This method is now shown to be a reliable approach for the production of a wide range of small zerovalent transition-metal particles that can be redispersed in organic solvents such as toluene or THF. The key feature of this synthesis is the formation of an organometallic colloidal protecting shell around the particles. In other words, highly reactive aluminum alkyl groups (e.g., al-C$_2$H$_5$ or al-CH$_3$) are present as protective agents for the colloids. Formation of alkyl aluminum protecting shell over platinum nanocluster was confirmed by quantitative protonolysis experiments, by using spacer molecules (bifunctional), and also modifiers (monofunctional). The mechanistic aspect has already been stated before. In the case of protonolytic reaction with diols, because of the presence of a second OH group in the molecule, an interconnection of particles is brought about. As the particles are statistically covered with reactive Al-CH$_3$ groups, this reaction leads to the formation of a three-dimensional (3D) cross-linked nanoparticle network having vitrious structure in contrast to modification that yields redispersible colloids (Eq. (8)):
Modifiers: alcohols, carbonic acids, silanols, sugars, poly-alcohols, polyvinylpyrrolidone, surfactants, silica, alumina, etc. $\tag{8}$

This "modification" (Eq. (8)) of the organoaluminum protecting shell can be used to tailor the dispersion characteristics of the original organosols. A vast spectrum of dissolubilities of the colloidal metals in hydrophobic and hydrophilic media (including water) has been achieved this way. Inorganic surfaces bearing -OH groups reacting with the active Al-C bonds in the colloidal protecting shell opens new ways in the heterogeneous catalyst preparation. The modification process does not alter the particle size of the metal core (see Fig. 8) [185].

Using a very similar route, a wet chemical method for the production of β-NiAl using alkylaluminum as a reducing agent has been developed [186]. The method involves reaction between $Ni(COD)_2$ and trialkylaluminum in toluene. Hydrogen under high pressure is used to saturate the COD and ethylene. Through analysis and comparable literature data, an intermediate depicted in Figure 9 has been proposed.

The product is found in the form of a black powder which upon purification procedures is found in aggregates of 100–500 nm, comprising smaller particles (5–7 nm). In these reactions, aluminum organic acts not as a reducing agent but rather as a reaction partner for the Ni(0) complex. The reaction can be summarized as shown in Eq. (9). Alloys of Ni and Al have been prepared in various stoichiometries by using appropriate ratios of the starting materials. The resulting product is then leached off aluminum in order to obtain skeletal nickel catalyst [187], to be compared with Raney nickel-type catalysts. The advent of this not only gives a versatile access to new bottom-up alloys between transition and main-group metals but also allows one to synthesize trimetallic or multimetal component nanoparticles:

$$Ni(COD)_2 + xAlEt_3 \xrightarrow[\text{Toluene}]{H_2} NiAl_x + cyclooctane + ethane$$

$$\xrightarrow[\text{16 h, 130 °C}]{H_2} NiAl_x \qquad (9)$$
Apart from these, a novel synthesis of anisotropic silver nanoparticles based on the use of N, N-dimethyl formamide as a solvent and as a reducing agent in the presence of polymer PVP has been performed recently [119]. The chemical reaction is presented in Eq. (10):

$$HCONMe_2 + 2Ag^+ + H_2O \longrightarrow 2Ag^0 + Me_2NCOOH + 2H^+ \qquad (10)$$

This modification follows the preparation of silver nanoparticles by direct reduction using DMF [189]. Presence of different additives was shown to induce the formation of core-shell structures such as Ag on SiO_2 and Ag on TiO_2 [190, 191]. Preparation of PVP-protected gold and silver nanoparticles having low concentration of metal in the solution of DMF has been dealt with in great detail [192]. Another example of solvent acting as a reducing agent is the case of DMSO [193].

Preparation of gold nanoparticles protected by alkanethiol capping agents, performed by Brust et al., is probably the most popular preparation method for the synthesis of gold nanoparticles. This has been modified by other researchers and these methods are discussed later [182]. Alfalfa plants are shown to produce gold and silver nanoparticles when the plants are germinated in corresponding metal salt in either solid media or media solution. The analysis by extended X-ray absorption fine structure (EXAFS) clearly indicates the presence of zerovalent metal atoms [194, 195]. There are a few reports on biological systems producing nanoparticles. Magnetostatic bacteria have demonstrated the ability to synthesize magnetic nanoparticles and *verticillium* isolated from the Taxus plants have shown the capability of reducing silver ions from aqueous solutions intercellularly to corresponding nanoparticles [196, 197]. These have opened up new avenues of recovering precious metals from mining wastes and a new alternative to produce nanoparticles.

Digestive ripening process has been applied to obtain polydisperse colloidal gold in toluene using a series of alkyl thiols [198] and in generating monodisperse metal nanoparticles by the solvated metal atom dispersion method [199]. Other synthetic developments include production of thiol-stabilized CdTe nanocrystals via an alternate to organometallic synthetic route [200], core-shell nanoparticles of Au-Ag [201], and that of chalcogenides [202, 203]. Electroless deposition methods which describe three fundamentally different plating mechanisms including autocatalytic, substrate catalyzed, and galvanic displacements (immersion) processes, are on the rise in preparing metal on metal, metal on semiconductors, and metal on insulators [208–210]. Noble metal nanoparticle films on germanium surfaces have been done by controlled electroless deposition by the immersion of germanium substrate into dilute $AuCl_4^-$, $PdCl_4^{2-}$, and $PtCl_4^{2-}$ aqueous solutions. Electroless

deposition of Cu on catalytically active Pd linked through a dendrimer to HOPG are also known [205].

2.2.2. Electrochemical Synthesis

Preparation route for nanostructured mono- and bimetallic colloids using this very versatile method has been further developed by Reetz and his group since 1994 [8, 98, 99]. The overall process of electrochemical synthesis (Eq. (11)) can be divided into six elemental steps:

$$
\begin{aligned}
\text{Anode:} \quad & M_{bulk} \longrightarrow M^{n+} + ne^- \\
\text{Cathode:} \quad & M^{n+} + ne^- + \text{stabilizer} \longrightarrow M_{coll}/\text{stabilizer} \\
\hline
\text{Sum} \quad & M_{bulk} + \text{stabilizer} \longrightarrow M_{coll}/\text{stabilizer}
\end{aligned} \quad (11)
$$
1. oxidative dissolution of the sacrificial Met_{bulk} anode
2. migration of Met^{n+} ions to the cathode
3. reductive formation of zerovalent metal atoms at the cathode
4. formation of metal particles by nucleation and growth
5. arrest of the growth process and stabilization of particles by colloidal protecting agents, for example, tetraalkylammonium ions
6. precipitation of the nanostructured metal colloids.

Advantages of the electrochemical pathway are that contamination with byproducts resulting from chemical reduction agents are avoided, and that the products are easy to isolate from the precipitate. A size-selective particle formation is an added advantage of the method. Experiments using Pd as the sacrificial anode in the electrochemical cell to give $(C_8H_{17})_4N^+Br$-stabilized $Pd^{(0)}$ particles indicate that the particle size depends on the current density applied: While having high current densities produced small Pd particles (1.4 nm), low current densities, in contrast, gave larger particles (4.8 nm) [98]. As was seen in a careful analysis of tetraalkylammonium-stabilized Pd and Ni with a combination of TEM and SAX, the control of the particle size does not have a single cause. It can be brought about by adjusting the following parameters:

• distance between the electrodes
• reaction time and temperature
• polarity of the solvent.

The electrochemical synthesis yields almost monodisperse Pd(0) particles with sizes between 1 and 6 nm according to the parameters above. It was also shown that the size of NR_4^+-stabilized Ni(0) particles [100] can be adjusted at will. The electrochemical method [98–105] (Eq. (11)) has been successfully applied to prepare a number of monometallic organosols and hydrosols, for example, of Pd, Ni, Co, Fe, Ti, Ag, and Au on a scale of several hundred milligrams (yields >95%). Solvent-stabilized (propylene carbonate) palladium particles (8–10 nm) have also been obtained using electrochemical pathway [93]. Bimetallic nanocolloids (Pd/Ni, Fe/Co, Fe/Ni) are accessible [103] if two sacrificial Met_{bulk} anodes are used in a single electrolysis cell. In case of Pt, Rh, Ru, and Mo, which are anodically less readily soluble, the corresponding metal salts were electrochemically reduced at the cathode.

In a Kolbe electrolysis at the anode, tetraalkylammonium acetate was used both as the supporting electrolyte and the stabilizer (see Eq. (12)) [104]:

$$
\begin{aligned}
\text{Cathode:} \quad & Pt^{2+} + 2e^- \longrightarrow Pt^0 \\
\text{Anode:} \quad & 2CH_3CO_2^- \longrightarrow 2CH_3CO_2 + 2e^-
\end{aligned} \quad (12)
$$
Bimetallic nanocolloids can be prepared by combining the electrochemical methods described in Eqs. (11) and (12) [104].

In addition, the synthesis of layered bimetallic nanocolloids (e.g., Pt/Pd) has been achieved by modifying the electrochemical method [100, 105]. A preformed $(Oct)_4NBr$-stabilized Pt colloid core (size: 3.8 nm) was electrolyzed in 0.1 M $(Oct)_4NBr$/THF solution with Pd as sacrificial anode (Fig. 10). The preformed Pt core may be regarded as a "living-metal polymer" on which the Pd atoms are deposited to give "onion-type" bimetallic nanoparticles (5 nm). A combination of various analytical methods was used to elucidate the structure.

Layer-by-layer self-assembly of hexanethiol-stabilized gold nanoclusters has been synthesized by a series of alkanedithiol coupling agents $[HS(CH_2)_nSH, n = 6, 8, 9, 12]$ onto SiO_2/Si substrates with micron- and nanometer-scale. Gold clusters are initially generated by sodium borohydride reduction of the auric salt followed by stabilization through alkylthiol. This stabilized gold cluster in combination with alkanedithiol coupling agents are used in self-assembling on silica using Au electrodes. (See Fig. 11.)

The chemistry of both single- and multiple-layer films of gold nanoclusters formed on insulating substrate has been nicely described [178]. Using anodic alumina membrane as masks, gold nanorods and nanowires are being synthesized by various groups [204, 205] and by template synthesis by Mallouk and co-workers [206].

Finely dispersed sandwich composite nanoparticles of Cu-Ni-Cu in the region of 31 nm and with an average length
Figure 10. Modified electrolysis cell for the preparation of layered bimetallic Pt/Pd nanocolloids. Adapted with permission from [100], M. A. Winter, Ph.D. Thesis, Verlag Mainz, Aachen, 1998.
of 33 nm have been prepared by a novel method combining electrodeposition of Ni-Cu nanowires onto a template followed by template removal and ultrasonic treatment method [207].

2.2.3. Decomposition of Low-Valent Transition-Metal Complexes

Low-valent organometallic complexes and several organic derivatives of the transition metals decompose under the action of heat, light, or ultrasound to give short-lived nucleation particles of zerovalent metals in solution which may be stabilized by colloidal protecting agents. For example, thermolysis [211–216] leads to the rapid decomposition of cobalt carbonyls to give colloidal cobalt in organic solutions [212]. Colloidal Pd, Pt, and bimetallic Pd/Cu nanoparticles were obtained by thermolysis of labile precious metal salts in the absence of stabilizers [213]. The resulting particles showed a broad size distribution. These results were much improved when the thermolysis was performed in the presence of stabilizing polymers, such as PVP [214]. A review by Gonsalves et al. outlines the application of different methodologies for the production of nanostructured metals (Fe, Co, Ni) and metal alloys (Fe-Co, Pt-Pd, M50 steel) from their corresponding organometallics [217]. Recently, microwave heating in a simple household oven was chosen as a mode for preparing nanosized metal particles and colloids [215, 216, 218]. A modification to that is microwave assisted polyol reduction of PVP-supported platinum and silver salts to their corresponding nanoparticles [219]. The electromagnetic waves can heat the substrate uniformly, leading to a more homogeneous nucleation and a shorter aggregation time. It is instructive to compare the particle size of polymer-stabilized Pt colloids (spheres, 2–4 nm, narrow size distribution) prepared using dielectrical microwave heating with samples made by conventional heating under identical conditions.

The energy induced in the sonochemical decomposition of metal salts and organometallic complexes [220–225] is produced by the formation, growth, and implosive collapse of bubbles in a liquid. Suslick et al. [220] and Gedanken

and co-workers [221–223] have successfully developed this method. Fe, Mo_2C, Ni, Pd, and Ag nanoparticles in various stabilizing environments have been prepared. Within certain limits, the sonochemical decomposition also allows size control which has been observed in the case of Pd nanoparticles immobilized on alumina [224]. The growth of very clean colloidal metals has been achieved by the photolysis of organometallics and metal salts [113, 114, 225]. Henglein et al. [226–234, 236] and Belloni et al. [235] have studied the γ-radiolytic decomposition of metal ions to give nanostructured metal colloids. Short pulses of high-energy photons are applied to metal ions in solution. This allows the reduction process in the whole reaction medium to be "turned on" instantaneously. The process of nucleation and growth of the metal particles in solution can be monitored by spectroscopic methods. In the case of silver, the detailed mechanism of nucleation has been compared with the photographic process [227]. Nanostructured Cd colloids [231] and even bimetallic systems [230–232] have also been studied. In the case of gold, the particle size has been controlled at will. Bimetallic $Au_{core}Pt_{shell}$ and $Pt_{core}Au_{shell}$ colloids have also been obtained [236]. Using laser ablation, the size-selective formation of silver colloids has been reported [237, 238]. The limitation of photo-, γ-radiolysis, and laser irradiation methods lies in the restriction to low metal concentrations in solution. Consequently, they are not suitable to prepare nanostructured metal colloids on a preparative scale. Sonochemical process and conventional method reduction of $[Pd(NH_3)_4]^{2+}$ complexes on Y-zeolite in an aqueous solution has been reported recently. The radicals formed from 2-propanol sonolysis reduces the Pd complex to yield zerovalent Pd [239].

Reduction of neutral molecular precursors of platinum and ruthenium with core composition of $PtRu_5$ and Pt_2Ru_4 yielding corresponding nanoparticles through reduction by hydrogen at elevated temperatures has been performed [240, 241]. Isolable yields of product in multigram amounts can be prepared by the controlled chemical decomposition of zerovalent transition-metal complexes on the addition of CO or H_2 in the presence of appropriate stabilizers [85–88, 242–250]. The growth of metallic Ru particles from Ru(COT)(COD) (COT = cyclooctatetraene, COD = cycloocta-1,5-diene) with low-pressure dihydrogen was initially reported by Pertuci and Vituli, and Ciardelli's group [242, 252]. Bradley and Chaudret and co-workers [85–88, 243–251, 253–255, 257–259] have demonstrated the use of low-valent transition-metal olefin complexes as a very clean source for the preparation of nanostructured mono- and bimetallic colloids. In one of their communications, they showed the decomposition of organometallic complexes of the type [M(dba)$_2$] (dba = dibenzylidene acetone, M = Pt, Pd) under low carbon monoxide pressure in the presence of polyvinylpyrrolidone (PVP) to give nanosized colloidal Pt or Pd particles having a fcc structure. Remarkably, the surface of the resulting particles undergoes no measurable interaction with the stabilizing polymer or with the solvent. Composition-induced structural changes in the bimetallic ruthenium platinum nanoparticles resulting from the relative concentration of the two complexes in the initial solution has been reported by the reaction of Pt(dba)$_2$

with Ru(COD)(COT) in various proportions under dihydrogen in the presence of PVP. The progressive incorporation of ruthenium into the platinum matrix leads to structural changes from face-centered cubic (fcc) for high platinum contents to hexagonal close packed (hcp) for high ruthenium contents. For the composition Pt_1Ru_3 a contraction of the size of the particles (about 1.1 nm) and of the size distribution indicates the presence of a new phase consisting of monodisperse particles for which a model of truncated twinned octahedrons of 79 atoms was proposed [251].

Nanoparticles of Ru, Au, and Cu were obtained analogously from Ru(COT)(COD), (THT)AuCl (THT = tetrahydrothiophene), and $(C_5H_5)Cu(Bu^tNC)$. Colloidal molybdenum, silver, and bimetallic Cu/Pd colloids were also reported where a polymer matrix of PVP (polyvinylpyrrolidone), PPO (dimethylphenylene-oxide), or NC (nitrocellulose) was used as the stabilizing agent [85, 243–246]. Platinum and palladium nanoparticles stabilized by donor ligands such as carbonyl and phosphines have been described by Chaudret and Bradley. The structure of the particles is influenced by the ligands [86–88]. The cleavage of the complexed olefins from the coordination sphere of the metals and the simultaneous formation of nanosized colloidal particles occurs very smoothly and the hydrogenolysis of zerovalent organometallic olefin complexes has been established in the literature as a very clean and elegant method, for example, for the manufacture of monometallic colloids via the decomposition of $Fe(COT)_2$, Ru(COT)(COD), $Co(C_8H_{13})(COD)$ ($C_8H_{13} = \eta^3$-cyclooctenyl), and $Ni(COD)_2$ under H_2. The hydrogenolysis method has been used to obtain a number of nanostructured Au, Pd, Pt colloids, and of bimetallic systems (Pt/Ru, Pt/Co, and Cu/Pd) in a polymer matrix [247–249]. Ultrafine cobalt particles have been obtained by the hydrogenolytic decomposition of $Co(\eta^3$-$C_8H_{13})(\eta^4C_8H_{12})$ in the presence of polyphenylphenylenoxide to give particles of 4.2 nm size; when the same procedure was carried out with polyvinylpyrrolidone, the size of the resulting particles was 1.4 nm. It is clear from these results that a close relationship exists between the synthesis conditions and the structure of the resulting particles [250]. The reaction of $Co(\eta^3$-$C_8H_{13})(\eta^4C_8H_{12})$ and $Pt_2(dba)_3$ (dba = bis-dibenzylidene acetone) under dihydrogen leads in the presence of poly(vinylpyrrolidone) to nanometric bimetallic particles Co_xPt_{1-x}. The initial ratio of the two organometallic precursors determines the composition of the material [260]. Mo, W, Cu nanoparticles (5–50 nm) have been synthesized very recently from reactions employing metal complex and an organopolysilane oligomer either in hexane solution or in a sealed tube. The metal complexes are reduced due to the energetically favored reaction route by the oxo- and chlorophilicities of the silyl groups. Proper mixing of the reactants in vapor and solution phases allows the association and growth of molecules into small clusters, then into nanosized metal particles [261]. Recently it has been shown that Korantine peptisized monodisperse Co nanoparticles with a particle size of 10 ± 1 nm can be prepared by thermal decomposition of $Co_2(CO)_8$ in presence of trialkylaluminum. Another finding was that chain length in the aluminum organic has a direct influence on the particle size of the resulting nanoparticle [262–265]. Weakly ferromagnetic cobalt

nanoparticles were allowed to self-assemble into bracelet-like rings with discrete particle counts when dispersed by C-undecyl calix(4)resorcinarene. Herein, Co particles were prepared by the thermal decomposition of $Co_2(CO)_8$ in hot toluene solutions containing resorcinarene tetraphosphonite. Another example of Co nanoparticle bracelet was the report by Alivisatos and co-workers [266, 267]. Redox transmetallation reactions between $Co_2(CO)_8$ and $Pt(hfac)_2$ (hfac = hexafluoroacetalacetonate) is found to result in "solid solution" type alloy (e.g., $CoPt_3$) while addition of Co nanoparticles with $Pt(hfac)_2$ in solution results in "$Co_{core} \cdot Pt_{shell}$" type nanoalloys. The advantage of this method is the reaction does not need any additional reducing agents [268]. Using bis(hexyl(methyl)dithio-/-diselenocarbamato)-cadmium(II)/zinc(II) compounds as a single source precursor, nanoparticles of CdSe/CdS, CdSe/ZnS, CdSe/ZnSe core/shell, and CdSe/CdS alloys have been prepared [207]. Similarly with block co-polymer of PS_{25300}-b-$PMMA_{25900}$ (poly(styrene-b-methyl methacrylate)), three-dimensional, patterned, anisotropic nanoparticular self-assembly of cobalt has been evidenced [269]. Mixed metal clusters of ruthenium in association with either platinum or tin have been deposited onto multiwall carbon nanotubes (MWNTs) using metal complexes with dichloromethane-isopropanol (1:1 v/v). The size distribution of the resulting particles in the case of platinum ruthenium was found to be narrow with the average particle size of 1.8 ± 0.5 nm [270]. There are many such reports of nanoparticles decorating the exterior of a carbon nanotube [271–278] and an evidence for bimetallic particles formed inside nanotubes via a template method [279]. Thermal decomposition of manganese carbonyl on the polyol reduced platinum results in Mn-Pt nanoparticles which have ferromagnetic nanoparticles with a property totally different from its bulk. Thermal decomposition (673 K) of $PtRu_5C(CO)_{16}$ under hydrogen resulting in Pt:Ru ratio of 1:5 with a mean particle size of 1.5 nm has been evidenced [280]. On the other hand, by subsequent reduction of platinum and iron, platinum-meghamite core-shell nanoparticles are obtained. Herein, platinum is initially reduced from its acetylacetonate precursor, yielding platinum nanoparticles. Iron oxide is then deposited on them by decomposing iron pentacarbonyl which undergoes oxidation under the reaction conditions to give Fe_2O_3 [281]. From a mixed metal acetate precursor, Ni and Ni-Co alloy nanoparticles have been generated [282].

2.2.4. Preparation in Micelles, Reverse Micelles, and Encapsulation

Colloidal assemblies have widely been used as templates in order to "preform" the size, shape, and polydispersity of nanosized metal particles [47–62]. Surfactant micelles may enclose metal ions to form amphiphilic "microreactors." Water-in-oil reverse micelles or larger vesicles may function in similar ways. On the addition of reducing agents, nanosized metal particles are formed. The size and the shape of the products appear to be "imprinted" by the constrained environments in which they are grown. Surfactants play a crucial role in the compartmentalization of nanoparticles during their formation. A reverse micellar preparation of Cu_2S in aqueous micellar hosts reveals that different surfactants mediate the nanoparticle formation process and yield

different products, though it involves the same principle [283].

Tanori and Pileni [47] were first to grow cobalt rods with a length of 300–1500 nm and a diameter of between 10 and 30 nm in colloidal micelles. Cylindrical copper metal particles having identical sizes and shapes can be prepared in a template made of interconnected cylinders [49]. These form monolayers organized in a hexagonal network over very large domains of particles. Small or large aggregates can be produced at will, depending on the preformed template used. The particles are highly organized and form pseudo-crystals with a face-centered cubic structure. Colloidal metals have also been grown in reverse micelles. A series of articles by Pileni describes the micellar synthesis of metal nanoparticles, their fabrication into a three-dimensional array or domains and superlattices, followed by examination of their magnetic properties [284, 285]. These reports are apart from the micellar synthesis of copper nanoparticles [286–288] nanocrystal islands [289]. Micelles and inverse micelle synthesis techniques are used to prepare nanoparticles of platinum, palladium [290], Pt/Ru alloy [291], triangular CdS [292], and solid solution of $Cd_{1-y}Mn_yS$ [293].

Micellar formation of stable gold nanoparticles of different size and shape has been reported via UV photoactivation of $HAuCl_4$ in variable concentration of TX100 [TX100 = poly(oxyethylene) isooctylphenyl ether], which apparently acts as a reducing agent [294].

Platinum nanoparticles deposited on alumina support synthesized in water-in-oil microemulsions have been tested for the CO oxidation by oxygen. One of the two modes followed for the preparation and support involve platinum nanoparticles obtained by reducing the platinum complex $PtCl_6^{2-}$ in a mixture of oil (cyclohexene or n-heptane) and 15 wt % surfactant ($C_{12}E_4$ or AOT) followed by reduction with hydrazine monohydrate. The other method involves addition of the alumina support to the particle suspension and the microemulsion subsequently destabilized by addition of tetrahydrofuran whereby the particles are deposited on alumina support. A detailed discussion on the particle size with the variation in surfactants and pH is depicted in detail [295]. Dodecanethiol-capped cadmium sulfide nanoparticles have been synthesized and characterized in a Winsor II microemulsion of diethyl ether/AOT/water [AOT = bis(2-ethyl-hexyl)-sulfosuccinate]. This follows a similar synthesis involving capped silver and gold nanoparticles [296–299]. Other important water-in-oil microemulsion syntheses include preparation of palladium nanoparticles [300], Pt-Ru [301], and Pd-Pt [302] nanoparticles.

Synthesis of silver and copper nanoparticles in water/CO_2 microemulsions has been demonstrated. Sodium cyanoborohydride and N,N,N,N-tetramethyl-p-phenylenediamine were used as effective reducing agents for preparing the metal nanoparticles in the microemulsions [303]. In a similar environment, using hydrogen as reducing agent, metallic palladium was produced and *in-situ* hydrogenation of olefins was performed using this catalyst [304]. Dendrimers have been used to explore the method of immobilizing Pd nanoparticles on atomically flat surfaces. PAMAM dendrimers are the ones which are extensively used as templates for nanoparticle preparation. Cu, Pd, Pt, Au, Ag, and ceramic materials have

been successfully encapsulated inside these dendrimers [305–312]. These dendrimers are, however, pH sensitive. Recently, silver [313] and Pd nanoparticles [201] have been prepared by encapsulation methods using dendrimers.

Amphiphilic block copolymers for the "preformation" of the microreactors have been designed and used by Antonietti [52]. Micellar and ordered continuous topologies are adopted by self-assembly. The block lengths govern the size and topology of the resulting colloidal structures. The stability of these templates allows well-defined polymer/nanometal hybrid materials to be prepared. Noble metal colloids can be formed in block copolymer micro domains. Because of their enhanced stability, such colloids may be used directly as efficient catalysts. Besides controlling the particle growth, the self-assembly of the macromolecules allows the nanoparticles to take up well-defined arrangements on substrates, in thin films, or in bulk samples. Monodisperse noble metal particles, for example, gold, silver, palladium, have been applied to prepare thin polymer films. The strategies for the organization of nanoparticles into aggregate structures have been summarized in recent reviews in which the most successful approaches to form two- and three-dimensional arrays of nanoparticles having diameters between 1 and 20 nm are described [55, 56]. Additions to this synthetic method of using copolymer encapsulation are the preparation of aggregation stable gold nanoparticles using star-block copolymers [314] and addition-fragmentation chain transfer polymerization [315], reported recently. The encapsulation of small metal particles (Pd, Pd/Au) in solid organic [56] and inorganic matrices has also been achieved and used for applications in heterogeneous catalysis (discussed later). Gold nanoclusters have been encapsulated in a silica matrix, silica glass via a sol–gel procedure, and the optical properties of the product have been examined [59, 316]. Size-dependent silica-encapsulated gold nanoparticles with a special observation of having size-dependent melting points are also known [317]. In a silica sol–gel entrapment method, inclusion of metallic palladium and a rhodium(I) complex catalyst has been performed and its catalytic properties verified [318]. A novel two-step Pt nanoparticle encapsulation in mesoporous silica (SBA-15) has been done recently. In the first step, aqueous phase reduction of K_2PtCl_4 was carried out with the help of hydrogen and by using tri-block poly(ethyleneoxide)-poly(propyleneoxide)-poly(ethylene oxide) copolymer as capping material. In the next step, this supported nanoparticle was encapsulated into microporous silica synthesized using the same copolymer as template from tetraethyl orthosilicate by hydrolysis [319].

Nickel nanoparticles encapsulated in an amorphous carbon matrix have been synthesized by sonication of $Ni(COD)_2$, and further heated at 773 K under an Ar atmosphere. Both as-prepared and heated samples have been fully characterized using high-resolution transmission electron microscopy (HRTEM), electron loss spectroscopy (EELS), and energy-filtered TEM (EFTEM). The EELS and EFTEM analyses show that the nickel nanocrystallites are surrounded by amorphous carbon which acts as a "protecting agent" and protects the nickel surface from oxidation [225].

2.2.5. Colloidal Nanostructured Metal Oxides

Preparation of nanometals is difficult in certain cases. Nanosized (i.e., 3–5 nm) colloidal $Fe^{(0)}$, $Co^{(0)}$, and $Ni^{(0)}$ particles cannot be redispersed after exposure to air because they are immediately oxidized both in solution and in powder form. When the addition of oxygen is precisely controlled, for example, by using stoichiometric amounts of O_2 diluted in large excess of argon, an organic solution of a 3-nm iron$^{(0)}$-sol stabilized by $N(octyl)_4^+Br^-$ is transformed to a rusty-brown solution of colloidal Fe^{3+} oxide which is redispersible in THF [7]. $N(octyl)_4^+Br^-$-stabilized $Co^{(0)}$ particles were oxidized in air to give colloidal CoO nanoparticles characterized by HRTEM [320]. The process was followed by UV-visible spectra and magnetic susceptibility measurements. The resulting CoO particles were supported on alumina. Small CoO and Co_3O_4 particles have been obtained in a polymer matrix dispersion by solid-state oxidation of 1.6-nm $Co^{(0)}$ particles. The structural changes which occur during the oxidation process were monitored using physical analytic methods and it was shown that air oxidation at room temperature leads to surface passivation. The resulting particles have a metallic core which is surrounded by an oxide surface layer [321]. The particle size of nanosized Pt dispersed on γ-Al_2O_3 is markedly influenced during the oxidation by O_2 [322]. A new process was recently reported for the manufacture of a water-soluble PtO_2 colloid which is applicable as a water-soluble "Adams catalyst" (see Eq. (13)) [323, 324]:

$$PtCl_4 \xrightarrow[\text{Stabilizer}]{H_2O/\text{base}} PtO_2 \text{ colloid} \qquad (13)$$

$$\text{Stabilizer: } C_{12}H_{25}(CH_3)_2N^+(CH_2)_nCO_2^-$$
$$C_{12}H_{25}(CH_3)_2N^+(CH_2)_3SO_3^-$$
$$n = 1, 3$$

Using the simple hydrolysis/condensation of metal salts under basic aqueous conditions in the presence of carbo- or sulfobetaines, respectively, colloidal PtO_2 was obtained, the analytical data of which correspond to pure α-PtO_2 and to commercial samples of Adams catalyst. Bi- and trimetallic colloidal metal oxides as precursors for fuel cell catalysts, for example, colloidal Pt/RuO_x and $Pt/Ru/WO_x$, have also been prepared this way [325]. Magnetite particles below 20 nm size have been synthesized by high-temperature reaction of iron(III) acetylacetonate, in phenyl ether in the presence of alcohol, oleic acid, and oleylamine and the resulting particle was found to be monodisperse [326]. Organic soluble maghemite γ-Fe_2O_3 nanoparticles with monodispersity have been obtained by the reduction of $FeCl_3$ by glycol with n-octylamine serving as capping agent [327]. Another example of organic soluble titania is dodecylbenzenesulfonate capped nanoparticles [328]. A simple route for the synthesis of Ti, W, and V oxide nanoparticles using benzylalcohol under thermal conditions is a recent advancement [329].

2.2.6. Particle Size Control

Metal colloid sols where the particle size deviates less than 15% from the average value are generally addressed as "monodisperse." Histograms with a standard deviation from the mean particle size of approximately 20% are described as showing a "narrow size distribution." The kinetics of the particle nucleation from atomic units and of the subsequent growth process cannot be observed directly by physical methods. The tools of the preparative chemist to control the particle size in practice are size-selective separation [49, 330, 331], and size-selective synthesis [36, 47–62, 98, 127, 183, 184, 332–348].

The so-called *size-selective precipitation* (SPP) was predominantly developed by Pileni [49, 349]. Monodisperse silver particles (2.3 nm, $\sigma = 15\%$) are precipitated from a polydisperse silver colloid solution in hexane by the addition of pyridine in three iterative steps. Followed by this, Schmid et al. [330] reported the two-dimensional "crystallization" of truly monodisperse Au_{55} clusters. Schmid has also shown that the size of nanoparticles can be limited by steric restrictions imposed by a 3D polymer network [350]. Chromatographic separation methods proved unsuccessful because the colloid decomposed after the colloidal protecting shell had been stripped off [36]. The size-selective ultracentrifuge separation of Pt colloids has been developed by Cölfen and Pauck [331]. However, although this elegant separation method gives true monodisperse metal colloids, it still provides only milligram samples. The first size-selective colloid synthesis was described by Turkevich [1, 2]. Using the salt reduction method, he was able to vary the particle size of colloidal Pd between 0.55 and 4.5 nm. The crucial parameters were the amount of the reducing agent applied, and the pH value. According to the literature on the process of nucleation and particle growth, the essential factors which control the particle size are the strength of the metal-metal bond [45], the molar ratio of metal salt, colloidal stabilizer, and reduction agent [1, 118, 127, 149, 156, 256, 332–348, 351], the extent of conversion or the reaction time [149], temperature applied [1, 333, 345], and the pressure [333]. The preparation of near monodisperse nanostructured metal colloids using the salt reduction pathway is well documented in literature. In practice, however, the "control," that is, the variation of particle sizes (and shapes), in wet chemical colloid synthesis is left to the intuition of the chemist. There are two kinds of methods used to control the morphology of the metal nanoparticles. The growth-directed preparation is performed by selecting a suitable metal precursor, protective agent, and the reduction method. On the other hand, template-directed preparation involves reducing metal ions or complexes that grow in a template. The shape and size of the resulting product is controlled by the template [352]. Pileni also has demonstrated that control of particle size and composition can be achieved using oil-in-water micelles [353].

At present, the electrochemical synthesis by Reetz and co-workers offers the most rational method for selecting the particle size (see Section 2.2.2). Using variable current densities and by suitable adjustment of further essential parameters, the authors have obtained at will, a monodisperse product in colloidal Pd and Ni between 1 and 6 nm [98–105]. In the thermal decomposition method, the resulting particle size depends on the heat source [216]. Size control has also been reported for the sonochemical decomposition method [237] and γ-radiolysis [238]. Size-dependent alloy formation of silver-coated gold nanoparticles (2.5–20 nm diameter) in

aqueous solution using radiolytic wet techniques at ambient temperature was observed [354]. Silver nanoparticles incorporated into SiO$_2$ matrix with a proper control over the particle size has been performed by the sol–gel method. The process involves complexation of the silicon alkoxide with AgNO$_3$ in an appropriate ratio, to be followed by hydrolysis, polycondensation, and subsequent thermal treatment of the resulting powder [355].

The control on shape of the metal particle via pre-formation of size and morphology of the products in nanoreaction chambers is the domain of preparation methods using constrained environments [47–62], such as the controlled temperature-induced size and shape manipulation of 2- to 6-nm gold particles which are encapsulated in alkanethiolate monolayers [60]. An enormous increase in the size of thiol-passivated gold particles up to ca. 200 nm has been induced by near-IR laser light [60]. A new medium-energy ion scattering (MEIS) simulation program has successfully been applied to the composition and average particle size analysis of Pt-Rh/α-Al$_2$O$_3$ [61].

Synthesis of colloidal cobalt nanoparticles with controlled sizes and shapes has been performed. Rapid pyrolysis of cobalt carbonyl in an inert atmosphere was employed to produce monodispersed, stabilized, defect-free ε-cobalt nanocrystals with spherical shapes and sizes ranging from 3 to 17 nm [356]. Seeding growth was used for getting palladium nanoparticles [357], and with improved size control for polymer-stabilized Pd nanoparticles [358]. Laser light has been of great importance since it is possible to change the particles' size and shape after their preparation [359–370]. Schiffrin and co-workers' seminal work on the two-phase synthesis has led to the controlled particle size nanoparticles. The interesting part here is that by altering the ratio of the metal to octanethiol (capping agent), different particle size gold particles are obtained which show characteristically different colors. Octane thiol linked to gold atoms 1.6 (black), 2.1 (red), 2.8 (blue), 3.8 (dark violet), and 4.0 nm (cyan) are prepared and their properties studied [371].

Before going on to the further studies of these nanoparticles, it is appropriate to list the important methods available in literature on the synthesis of protected nanoparticles. Table 1 lists these.

3. SPECTRAL CHARACTERIZATION OF NANOPARTICLES

The whole exercise of characterization of nanoparticles lies in the determination of the particle size, overall composition, and seldom, the formidable, surface compositions. In case of stabilized particles, the interaction with the stabilizers, chelates, and adsorbates forms an interesting part of the characterization process. Various spectroscopic methods like ultraviolet-visible spectroscopy (UV-Vis), infrared (IR) and raman spectroscopy, nuclear magnetic resonance spectroscopy (NMR), and X-ray absorption spectroscopy (XAS, which includes EXAFS and XANES) have been adequately used in literature for the characterization purposes. However, for the understanding of the physical properties of the nanoparticles, the techniques of greatest utility are TEM and in instances where the particles are crystalline, X-ray

diffraction studies. Here, we highlight some of the spectroscopic methods which are conveniently used for the purpose of characterizing nanoparticles.

UV-Vis spectroscopy is very useful in characterizing semiconductor-type nanoparticles or metal particles whose plasmon resonance lies in the visible range as in the case of organic substrate linked Ag, Cu, and Au nanoparticles. UV-Vis spectra are also used for determining both particle size and the degree of cluster aggregation in the sample. With an increasing interest in the self-assembling of these semiconductor nanoparticles for varied applications, efforts on the characterization of such organized structures through this method are also on the rise (see also Section 6).

Tetraoctylammonium-stabilized transition-metal nanoparticles have been studied for their particle size determination by UV-Vis spectra. Characterization upon synthesis of Pd nanoparticles with diameters of 1.4, 2.3, and 4.1 nm is an example of this kind of a study [8]. Correlation between UV-Vis spectra on the nanoparticle size has been established by Chestnoy and co-workers in one of their premier works [372]. This was complemented by the study undertaken by Wilcoxon and co-workers on the shift in λ_{max} depending on the size, shape, amount of aggregation, and the presence of adsorbates on the nanoparticles [373, 374]. In a recent development, gold nanorods with controlled aspect ratios dictated by the added silver ions in solution as seed have been studied. The gold nanorods formed in the absence of silver ions form gold nanoparticles and exhibit a characteristic absorption band at 530 nm, which is drastically changed upon addition of silver ions to a transversal surface plasma peak at 520 nm and an additional, longitudinal peak between 600 and 800 nm [375]. This study also describes how the presence of silver ions regulates the gold particle growth during the photochemical synthesis. Changes in the absorption maxima of programmed assembling in solution of mixed metal nanocrystal aggregates of silver and gold, forming new absorption bands corresponding to inter-crystal plasmon resonance bands [376], synthesis of silver nanoparticles and nanorods in presence of PVP (polyvinyl pyrrolidone) [377, 378], BSA (bovine serum albumin) [377], interaction of gold nanoparticles with lithium ions [379], dendrimer protection of nanoparticles [305, 309, 380–382], their pH dependence [313], incorporation of TiO$_2$ as an additive to WO$_3$ nanoparticles [383], have all been studied.

In an application-directed study, interaction of pyrene methylamine (a fluorophore) onto gold nanoparticles has been examined. Interaction of this species is shown to alter the electron density of the gold nanoparticles on the metal surface, thereby directly affecting the absorption of the surface bound organic moiety as well as surface plasmon absorption band. Pyrene methylamine chromophore exhibits characteristic absorption bands at 313, 327.5, and 343.5 nm and upon addition of the gold nanoparticles, the absorption bands shift to 354, 361, 373, and 382 nm with a concomitant decrease in the absorption for the chromophore. This gives a direct measure of the alteration in the electronic properties of the chromophore as it binds to the gold nanoparticle. The presence of isobestic points at 319, 331, 338, and 347 nm for different concentrations of gold nanoparticles confirms the presence of both bound and free forms of pyrene methylamine [384]. There is a plethora of

Table 1. Major synthetic methods for the preparation of metal nanoparticles and nanoclusters.

Method/reducing agent	Nanoparticle metal/alloy systems	Metal stabilizers (protecting/capping/supporting)	Particle size (nm)	Ref.
diborane reduction	$Au_{55}(PPh_3)_{12}Cl_6$ and other $M_{55}L_{16}Cl_8$ systems; also '$Pt_{309}Phen_{36}O_{30\pm10}$' and '$Pd_{561}Phen_{36}O_{190-200}$'	phosphine ligands	1.4 nm	[4, 63–77, 416, 552, 555, 615, 617]
alcohol (polyol) reduction	A wide range of precious transition metals	PVP, PVA, PMVE	Variable (1–100 nm)	[10, 42–45, 117, 118]
	Ag, Pt, FePt, $(Fe_{49}Pt_{51})_{88}Ag_{12}$, Pd, Cu, Ag-Pd, Cu-Pd, Pt-Ru	PVP, ion conducting polymers, hydrophilic stabilizers	Variable particle size	[89, 123, 124–131]
	Pt	polymer	2–4 nm	[219]
hydrogen reduction	Pd, Pt, Rh, Ir	polymers	3–4 nm	[132–136]
	Pd giant clusters	acetate		[79–84]
	Various transition metals	tetrabutylammonium	2–3 nm	[34, 137–141]
	Au, Pd, Pt, Pt/Ru, Pt/Co, Cu/Pd	polymer	—	[247–249]
carboxylate reduction	Au	citrate	12–20 nm	[1–3, 38, 39, 116, 340]
	Au	ascorbate	>10 nm	[698]
	Pt	oxalate	6.5 nm	[143]
	Pd		2.2, 5.4 nm	
	Pd/Pt		2.2 nm	
	Pd/Sn	tetraalkylammonium	4.4 nm	[46, 183, 184]
	Pd/Au	carboxylates	3.3 nm	
	Pd/Ru		1.8 nm	
	Pd/Rh		1.7 nm	
	Pd/Cu		2.2 nm	
borate reduction	Au	alkanethiol	1–3 nm	[182]
	Au	other stabilizers	1–5 nm	[305, 188]
	Pt-Ru, Pt-Mo, Pt-W, Pt-Ni	THF solvent-stabilized	1.7 nm	[174]
	Pt	dodecanethiol	—	
	Ni, Cu, Ru, Rh, Pd, Ag, Ir, Pt, Ru/Fe, Ru/Co, Ru/Ni, Pt/Co, Pt/Cu, Ru/Rh, Ru/Ir, Ru/Pt, Rh/Ir, Rh/Pt, Pd/Pt, Pd/Ag, Ir/Pt	SB12	All <10 nm	[7, 15, 96]
tetraalkylammoniumborohydride method (organosol)	Group 4–11 metals of the periodic table, also tin. Bi- and pluri-metallic combinations	tetraalkylammonium	See Figure 7 for particle size of monometal particles	[6, 7, 9, 15, 95–97, 175]
electrochemical method	Pd	tetraalkylammonium	1.4, 3.1, 4.8 nm 1–6 nm	[98]
	Ni	tetraalkylammonium	<10 nm	[100]
	Co, Fe, Ti, Ag and Au	hydrosols and organosols organosols and hydrosols	8–10 nm	[100–105]
	Pd	propylene carbonate tetraoctylammonium	<10 nm	[93]
	Pd/Ni, Fe/Co, Fe/Ni, Pd/Pt	polymer	3.8 nm	[100, 105]
	Pt-Pd onion-type colloid Cu-Ni-Cu	organic template	5 nm 31–33 nm	[207]
trialkylaluminum method	Pt	organoaluminum	1.2 nm	[37]
	Co	organoaluminum	5–10 nm	[262–265]
	Pt/Ru	organoaluminum	1–3 nm	[594]
	Bi and plurimetals from group 6–11 of periodic table	organoaluminum	<5 nm	
	Ni-Al	aluminum organic	100–150 nm	[186, 187]

Table 1. Continued

Method/reducing agent	Nanoparticle metal/alloy systems	Metal stabilizers (protecting/capping/supporting)	Particle size (nm)	Ref.
oxoanion	Ir(0) ∼ 300 and Rh	Polyoxoanion	2–3 nm	[11, 34, 137–142]
	Ir(0) ∼ 900 and Rh		3.8–4.5 nm	
decomposition of metal complexes	Mo, W, Cu	organopolysilane oligomer polyphenyloxide	5–50 nm	[261]
	Co	PVP	4.2 nm	[250]
	Co		1.4 nm	[250]

UV-Vis spectra for colloidal metals [384–386]. For colloidal particles which have an absorption band in the visible region, the absorption maxima are dependent on the size and shape of the particles, as well as how close the particles are relative to each other [386]. This implies, not only can a particle's size be determined by UV-Vis spectroscopy, but phenomena such as aggregation can also be verified [386]. The ability to tune the optical properties of a system by changing particle size, degree of aggregation, or surface composition holds potential for many applications [386–392]. Selective colorimetric detection of polynucleotides based on the distance-dependent optical properties of 13-nm-sized mercaptoalkyl derivatized gold nanoparticles studied by Mirkin and co-workers is an example of this [390]. The fascination of nanoparticles combined to biomolecules and their characterization, in part, by UV-Vis analysis can be obtained from the review of Niemeyer [393].

Infrared spectroscopy has been used as a surface probe in nanocluster systems, commonly done for surface adsorption of CO. The strong dipole associated with C-O makes this molecule a particularly easy one, but the metal-carbon bond which falls in frequency limits of 200 and 450 cm^{-1} is difficult to study. Carbon monoxide is an ideal ligand because it readily adsorbs to metal surfaces, and has characteristic vibrational frequencies around 1800–2100 cm^{-1} [5, 394]. The C-O stretch frequency is an excellent indicator for the way CO is bound to the substrate. Linearly adsorbed CO absorbs at frequencies between 2000 and 2130 cm^{-1}, twofold CO between 1880 and 2000 cm^{-1}, threefold CO between 1800 and 1880 cm^{-1}, and a fourfold bonded CO at wave numbers below 1800 cm^{-1} [395].

Some of the early studies on CO adsorption on metal include adsorption on silica-supported Pt-Ag alloys [396], Ni-Cu/SiO$_2$, Pd-Au/SiO$_2$, and the more interesting one, displacement of CO from a twofold adsorption site on palladium to a single adsorption site when NO was co-adsorbed [397]. Lewis and Lewis provided an early report of CO adsorbed to suspended metal particles, showing linear and doubly bridging CO on 2.3-nm Pt particles in methylene chloride [150]. Bradley's most comprehensive work in this area reports numerous IR studies of CO adsorbed onto colloidal and nanocluster metal surfaces [87, 214, 243, 244, 398–401]. The message here is that the infrared spectra of metal-bound CO change drastically as the size of the metal particle changes [87, 214, 243, 244, 398–401]. For instance, from a systematic IR study it was shown that as the Pd particle size increased, the ratio of terminal CO to bridging CO decreased for saturated CO adsorption of

poly(vinylpyrrolidone)-stabilized Pd clusters with diameters of 2.5, 4.0, and 6.0 nm in methanol [243]. Moreover, the largest particles showed only bridging CO on the metal surface [243]. Bradley has also used CO as a probe to study metal-surface enrichment in bimetallic Cu/Pd nanoclusters [214]; he finds that CO binds to both Cu and Pd, indicating that both metals are at the surface of the nanoparticles. Others have studied the effect of pH on nanocluster surface-bound CO [402], finding that increasing the pH leads to reduced CO coverage on Pt nanoparticles. Grazing-angle IR spectroscopy has been used to characterize the self-assembled monolayers on gold and further treatment of it in combination with cyclic voltammetry [403]. There are few other examples where infrared spectroscopy is used as a powerful tool in the characterization process [404–407].

To a lesser extent, surface enhanced raman spectroscopy (SERS) has been used to probe the surfaces of small metal particles, often involving metals like gold and silver [408, 409]. For example, the raman intensity of molecules adsorbed on electrochemically roughened silver electrodes is enhanced by factors of up to 10^5 [410]. The magnitude of this enhancement is related to the roughness of the surface, that is to say, the state of division of the adsorbing surface. In the study of pyridine adsorbed on gold and silver hydrosols, Creighton and co-workers demonstrated that these same metals exhibit this effect. The initial yellow color of the sol, due to the plasma resonance at 380 nm, changed to red and then blue-gray as the particles agglomerated due to the presence of pyridine and thus showed enhanced raman scattering [411]. Multiplexed detection of oligonucleotide targets has been performed with gold nanoparticle probes labeled with oligonucleotides and raman-active dyes [408]. Raman spectroscopy has been recently used for the electroless addition of Pt to SnO$_2$ nanopowders, and CdS incorporation into MCM-41 and SBA 15 systems [412, 413]. For the reduction of silver(I) salt by Fe(II) using citrate, SERS has also been a very useful method of analysis to detect the adsorbates on the surface [414]. There is limited application of SERS because it should involve metals which have a well-defined plasmon band [5] needed to provide the required signal enhancement.

Mass spectrometry (also FAB-MS and TOF-MS) and Mössbauer spectroscopy are used in some cases.

Nuclear magnetic resonance (NMR) is a powerful method for characterizing the nanoparticulates associated with ligands and for probing the intermetallic interactions, the simplest one being ^{1}H NMR that could be conveniently used for characterizing organic ligands in the nanoparticle-bound

ligand complex [376]. Characterization of $Rh_{55}(PPh_3)_{12}Cl_6$ nanocluster by proton decoupled ^{31}P NMR was performed by Günter Schmid and co-workers. Spectral results obtained having a singlet with no ^{31}P-^{103}Rh coupling under different solvents at room temperature, no appearance of additional peaks upon addition of phosphine, but rather resulting in an upfield shift of the signals, led to the conclusion that there is a fast exchange between the free and nanocluster-bound phosphine ligands with a calculated time of 3 ± 0.5 μs. In addition, the ^{31}P study in pyridine as solvent regenerates free phosphine displacing the ligated phosphine from the surface of the metal. However, this is one of the earlier studies which indicates the amount of information one can obtain by an NMR study [415, 416]. In one of the most important developments that took place in the recent past, EC NMR (electrochemical NMR), it is possible to investigate in detail metal/liquid interfaces by solid-state NMR under external potentiostatic control, in the presence of an electrolyte [417–419]. The multiple advantages of this are, it permits the determination of electronic properties of electrodes and of adsorbates as well as the study of the surface diffusion of adsorbates. This method also provides useful information on the dispersion of platinum-based fuel cell catalysts, on electrochemically generated sintering effects, and on the electronic effects caused by the presence of different surface adatoms. In general, EC NMR provides information on local frontier orbitals of the metal surface, adsorbate structure/bonding details, and even bond lengths, rates, and activation energies for surface diffusion and also, electrode potential effects on the electronic properties of the electrochemical interface, as seen by both metal and ligand NMR. A detailed review on this subject has been recently published by Wieckowski and co-workers based on their collective work performed on Pt-based fuel cell catalysts [417].

A classic example of using NMR for characterization of intermediates during nanoparticles synthesis is the one described very recently for preparation of platinum nanoparticles by trialkylaluminum reduction of platinum acetyl acetonate. The most revealing finding was the information obtained from the *in-situ* ^1H NMR studies on the solution after 30 min from the addition of reactants to isolate the intermediate complex (compound **3** of Fig. 2). In this initial measurement, a signal was observed at $\delta = 0.51$ ppm that was assigned to methyl groups in an intermediate platinum complex on account of the coupling with ^{195}Pt (I = 1/2, 33.8% natural abundance), which increased in intensity over the next few hours. Through a series of convincing assignments, the methyl group not being located at the bridges between platinum atoms but instead as a terminal group was established. Additionally, long-range coupling (COSY; correlation spectroscopy) between the hydrogen atoms on the methyl carbons linked to platinum and aluminum established the bridging group of the complex, giving almost all the information needed for characterizing this intermediate. However, additional information from EXAFS (extended X-ray absorption fine structure), XANES (X-ray absorption near edge surfaces), and *in-situ* ASAXS (anomalous small-angle X-ray scattering) measurements helped in confirming the structure. From the EXAFS it was seen that Pt absorber atom is directly surrounded by a light backscatterer in either

C atom at a distance of 2.11 ± 0.02 Å or O atom at a distance of 2.09 ± 0.04 Å and an Al atom at a distance of 2.45 ± 0.02 Å, but surprisingly no backscattering from Pt, indicating no Pt-Pt bond in the complex [37]. EXAFS is a spectroscopic technique that probes the local coordination environment of an atom that corresponds well to the event of metal-metal interactions and the number of coordination shells that might be formed in a cluster of 1–2 nm range. The basis of this spectroscopic measurement involves the analysis of the absorption coefficient of a metal atom in a cluster from about 40 eV to about 1500 eV past the absorption edge. The oscillatory behavior of the absorption coefficient in this region can be thought of as being caused by an interference that occurs between the outgoing and incoming photoelectron waves, and given the formal scattering lengths associated with this effect, the interference signal contains information about the average atomic environment of an absorbing atom. There is a great deal of information on the use of EXAFS to investigate the geometric and electronic structures of supported metal particles [420–432]. Most of the recent structural elucidations involve one of these XAS measurements for the surface determination of metal nanoparticles. A recent review by Frenkel et al. describes the structural dynamics of supported Pt nanoscale particles [420]. For detailed information on the origin of X-ray absorption spectroscopy and the validity and use of these techniques for characterization of the nanoparticle colloids, see [433]. XAS study of Pt-Ru supported on carbon [240, 434] and giant Pd clusters [435] are some of the other recent major studies. There are mentions of the use of spectroscopic methods for characterization of nanoparticles in other sections of this chapter, where appropriate.

4. PHYSICAL PROPERTIES OF NANOPARTICLES

Physical properties of nanoparticles and nanoclusters are a subject of intense contemporary interest. As the size decreases to the nanometer scale, many of the mechanical, electronic, optical, magnetic, as well as the thermodynamic properties are significantly altered from those of either the bulk or the single molecule. An analogy in cyclohexane, benzene (C_6), and adamantine (C_{14}) which represent the molecular states, with C_{60} or C_{70} fullerenes (as clusters) with that of diamond and graphite (representing bulk) with differences in their chemical and physical properties is worth mentioning [5]. The properties of nanoparticles depend on the following, individually or in combination [217]:

(a) the grain size and size distribution,
(b) the chemical composition of the constituent phases,
(c) the presence of interfaces, more specifically grain boundaries, heterophase interfaces, or the free surface, and
(d) the interactions between the constituent atoms.

Production of inorganic clusters is a thermodynamically unfavorable condition for the energy that is stored in such high surface particles. The stability is also decided by the complicated interplay of surface energy, surface tension, and surface stress [436]. If two smaller-sized metal particles

are allowed to come together, they spontaneously club to become a single entity because of the exothermic coalescence, in order to have reduced total surface area. If two naked metal particles are separated by protecting shells or even have an impurity, then coalescence can be minimized, but the particles will then undergo aggregation wherein the two protected nanoparticles come together without a direct contact between the metal particles. The minimization of these two principles is possible if the nanoparticles are immediately stabilized by deposition on a support, a concept well known in literature as a "precursor method." A detailed description of the properties related to particle aggregation and means of minimizing such effects are discussed [433].

Nanostructured materials bridge the gap between the molecular level and the solid (bulk) state and therefore display distinct physicochemical properties because of which many new technological applications can be found [437–440]. A simple case is Günter Schmid's illustration (Fig. 1 of [69]) of the electronic states in a metal particle with bulk properties and its typical band structure (overlapped), a cluster of cubic close packing of atoms with small bandgap and a simple triatomic unit (representing a molecular status) with completely separated bonding and antibonding molecular orbitals [69]. Another important aspect of interest is that as the particle size gets lower and lower, there are more atoms at the surface that are coordinatively highly unsaturated. The electronic structures and thus properties of these metal atoms are different from those of the metals in the core of a cluster. Such effects are pronounced if the surface atoms are ligated. The other important issue is that a cluster of 1.5 nm was found to have some bulk metal characteristics and that the formation of metallic state is mainly determined by the cluster nucleus and not the surface atoms. This has been in some cases experimentally verified in that, a SQUID measurement on $Pd_{\sim 561}$ shows that the inner core has bulk metal-like magnetic susceptibility while the outer layer does not [69]. It is universally accepted now that as the cluster size increases, some physical properties converge to the crystalline value more rapidly than others. The changes in the melting points is one such. Initial attempts at theoretical understanding of the melting of small particles were made within a macroscopic framework [441–444]. Theoretical phenomenological considerations, based on the classical Kelvin equations, led to the development of a quantitative relationship between the melting temperature and the particle size [441]. When computational resources became available, the melting of specific clusters was treated microscopically using molecular dynamics simulations. Using this, of late, metal clusters of sodium [445], copper [446], gold [447, 448], beryllium [449], lead [450], and nickel [451] have been studied. These simulations reveal that some features of cluster melting are qualitatively different from bulk melting, such as a difference between the melting and freezing points and the coexistence of solid and liquid clusters.

Gold metal melts at 1064 °C whereas a 1.5-nm gold nanoparticle melts between 500 and 600 °C. This trend of depression in the melting point for nanosized materials is not only restricted to metals but encompasses semiconductors, and even molecular organic crystals. This led to the suspicion that the surface plays important roles [452–459], which has now been confirmed [460]. These include structural demonstrations of liquid-skin formation on flat surfaces below the melting temperature of the interior crystal [461–463] and, in the case of some mono- and bimetallic nanoparticles [464–468], are readily studied by TEM. On the contrary, by exposing gold nanorods in solution to femtosecond and nanosecond laser irradiations, structural rearrangement of the gold atoms has been observed that starts at the interior of the rods by the creation of point and line defects which then evolve into planar defects on the spherical nanoparticles [468]. This is explained by the conversion of {110} facets into the more stable {100} and {111} facets and hence minimization of their surface energy. These observations suggest that short laser pulsed photothermal melting begins with the creation of defects inside the nanorods followed by surface reconstruction and diffusion, in contrast with the thermal melting on the rods or the bulk material, where the melting starts on the surface. Similarly, using laser irradiation, induced interdiffusion of Au-Ag core-shell nanoparticles has been evidenced indicating a reduced temperature for the melting of bimetallic nanoparticles [206]. The size-dependent melting and surface melting of Pb nanocrystals is demonstrated by X-ray powder diffraction in ultra high vacuum. Measurements indicate that the melting temperature varies inversely with the crystallite size and quantitatively favors the liquid-skin melting model over the homogeneous melting model. Surface melting is also demonstrated via the reversible growth of a 0.5-nm liquid skin on 50-nm crystallites just below the size-dependent melting temperature [469]. Molecular-dynamics simulations using the Sutton–Chen body potential function, and the melting characteristics of nickel core and copper shell of $Cu_{0.25}Ni_{0.75}$ and $Cu_{0.5}Ni_{0.5}$ were examined. The melting characteristics determined on the basis of the variations of potential energy and heat capacity with temperature showed this bimetallic system to melt in two stages [470]. A similar study on the melting behavior of narrow-dispersity alkanethiol-functionalized Au and Pt nanoclusters in inverse micellar solutions has been performed [471].

There are, however, some anomalies to the observation that metal nanoparticles melt at a lower temperature than the bulk. A tin nanocluster melts at a higher melting point than that of the bulk, indicating a different structural arrangement in the nanocrystal than in the bulk. It is demonstrated that cluster ions of tin between 10 and 30 atoms remain solid at ∼50 K above the melting point of bulk tin. A similar trend is expected of silicon and germanium owing to their heavily restructured geometries [472]. Investigations on the structural and dynamic properties of gold nanocrystallites with Au_{75}, Au_{146}, and Au_{459} were performed using molecular-dynamics simulations employing embedded-atom interactions. Diffusionless solid-to-solid structural transformations from the low-temperature optimal structures to icosahedral structures have been seen. These structural transformations were found to be precursors to the melting transition that occurs below the bulk melting temperature [473].

At the size of a few nanometers, metallic particles might become liquid, possibly labeled as droplets, even if their bulk metal temperatures are hundreds of degrees higher. This implies that even if composite particles are originally constructed as core-shell structures, they may spontaneously

alloy at relatively low temperatures and over relatively short periods of time. This has already been stated in the case of Au-Ag core-shell bimetallics [206]. The situation could be similar while considering the co-reduced bimetallics and their easy alloying at lower temperatures [317, 474].

Similar to melting, the changes in the structure upon incorporation of metals have been seen in the case of incorporation of ruthenium into platinum nanoparticles. The progressive incorporation of ruthenium into platinum matrix leads to structural changes from face-centered cubic (fcc) for high platinum contents to hexagonal close-packed (hcp) for high ruthenium contents [251]. Preparation of FePt monodisperse nanoparticles (3–10 nm) and further thermal annealing converts the internal particle structure from a chemically disordered face-centered cubic phase to the chemically ordered face-centered tetragonal phase and transforms the nanoparticles superlattices into ferromagnetic nanocrystal assemblies [89]. There have been some reports on the effect of additives on the thermal ordering of sputtered films of either CoPt or FePt alloys. Addition of Sn, Pb, Sb, Bi, or Ag into sputtered CoPt films is found to promote the disordered fcc to ordered tetragonal transformations, resulting in significant reductions in the temperature required for ordering [475, 476]. Similarly, reduction in the ordering temperature for FePt sputtered films by addition of Cu was seen [477]. Addition of Ag was found to promote the fcc to tetragonal phase transition, thereby reducing the temperature required for this transition by some 100 to 150 °C compared with pure FePt nanoparticles [125].

Nanoparticles, especially of the alkali metal and noble metals copper, silver, and gold, have a broad absorption band in the visible region of the electromagnetic spectrum. Solutions of these metal nanoparticles show very intense colors which are absent for the bulk material as well as for the atoms [467]. Their origin is attributed to the collective oscillation of the free conduction electrons induced by an interacting electromagnetic field. This has made them to be detected by spectral methods which have been discussed earlier. These resonances are also designated as surface plasmons. There have been many attempts to prepare Au-Ag systems using various reducing agents, obtaining different sized nanoparticles [478–483]. It is generally seen that when the reduced Au and Ag exist as separate entities, they possess two plasmon bands corresponding to each metal based on the Mie theory [484] which is widely applicable to explain the experimental results. These distinct bands get changed to a single absorption band upon alloying [478, 485, 486], which happens rapidly under reaction conditions.

An effective method for manipulating the semiconductor nanoparticles is impurity doping. Addition of, for example, Mn^{2+} to bulk semiconductors imparts unusual giant Zeeman, Faraday rotation, and magnetic polaron effects that characterize this class of materials [487]. Nanostructured magnetic materials also have received considerable attention for their fascinating applications in both mechanical and biomedical sciences. When magnetic nanoparticles are agglomerated in dense systems as granular films, the magnetic properties largely differ from those of both the individual particles and the bulk material. Thus, in order to understand the collective behavior of the two-dimensional and three-dimensional assemblies of magnetic nanocrystals,

models have been developed [285]. It has been quite clearly demonstrated that nanocrystals having a low size distribution are able to self-organize in a very-large-scale hexagonal network. On increasing these nanocrystal concentrations, 3D superlattices are obtained. Clarity over this issue can be had from the work which envisages control over the melting and optical properties of gold nanoparticle linked to DNA which has been studied in great detail by Mirkin, Schatz, and co-workers [488, 489].

Understanding the properties of protected colloids is not easy, as the protective groups change the electronic states of those metal atoms which are linked with the protective molecules. The protected nanoparticles will therefore not have the same properties as those without protection. This has been evidenced clearly in a few instances [65, 490–493]. The electronic behavior of Au_{55} clusters stabilized by $[P(C_6H_5)_3]_{12}Cl_6$ was analyzed by scanning tunneling microscopy. The arene rings of the ligand molecules could be imaged at 7 K. During spectral investigations, the discrete energy levels with an average spacing of 170 emV were attributed to Au_{55} core [494]. Aromaticity of Au_5Zn^+ clusters involving only σ orbitals has been demonstrated. The contention here is aromaticity is not restricted to organic compounds even M_4^{2-} (Al, Ga, and In) has two delocalized π electrons satisfying the $4n + 2$ electron counting rule. Of the three low-energy confirmers, a triangular structure with Zn atom located on a side of the triangle was the best fit. The formation of Au_5Zn^+ was evidenced by cationic photofragmentation mass spectroscopy [495]. The determination of particle size, and compositional studies by XRD for crystallites are the subject matter of all the scientific study done on nanoparticle synthesis and can be had from any of the references listed at the end of this chapter.

5. APPLICATIONS IN CATALYSIS

5.1. "Quasi-Homogeneous" Reactions

Lipophilic or hydrophilic nanostructured metal colloids dissolved in the form of organosols or hydrosols can serve as catalysts either in organic solution or in the aqueous phase. Schmid [70] has called these quasi-homogeneous catalytic reactions, which include solvated metal atom dispersions (SMAD) [26] "heterogeneous catalysis in solution." Rhodium hydrosols dissolved in water were proved to be effective as hydrogenation catalysts in two-phase systems where the olefin is in the organic phase [496]. Solutions of Moiseev's giant Pd colloids [79–84] were shown to catalyze a number of reactions in the "quasi-homogeneous" phase, namely oxidative acetoxylation reactions [79], the oxidative carbonylation of phenol to diphenyl carbonate [84], the hydrogen-transfer reduction of multiple bonds by formic acid [497], the reduction of nitriles and nitroarenes, and the acetal formation [498] with high turnover frequencies and significant lifetimes (see [11]). Anion ligands-preserved cationic giant Pd clusters were prepared and used for catalyzing oxidative acetoxylation of toluene in the presence of molecular oxygen [499]. Finke has reported remarkable catalytic lifetimes for the polyoxoanion- and tetrabutylammonium-stabilized transition-metal nanoclusters [137–141]. For example, in the

catalytic hydrogenation of cyclohexene, a common test for structure-insensitive reactions, the Ir(0) nanocluster [34] showed up to 18,000 total turnovers with turnover frequencies of 3200 h^{-1} [500]. As many as 190,000 turnovers were reported in the case of the Rh(0) analogue reported recently [501]. These results are quite unprecedented. Obviously, the polyoxoanion component prevents the precious metal nanoparticles from aggregating so that the active metals exhibit a high surface area [501]. A review [7] compares this new approach with the catalytic properties of other nanometallic systems active in "quasi-homogeneous" phase. The formation of olefins from aldehydes and ketones via McMurry-type coupling reactions were reported when nanostructured Ti colloids (3 nm) stabilized by Bu$_4$NBr were used [502]. THF-protected Ti$_{13}$ nanoclusters [91] were found to hydrogenate Ti and Zr sponges in the "quasi-homogeneous" phase [503, 504]. The enantioselective hydrogenation of ethylpyruvate in HOAc/MeOH solution was performed using cinchonidine-stabilized Pt colloids [344]. Heck and Suzuki C-C–bond coupling reactions were catalyzed with NR$_4^+$X$^-$-stabilized Pd and Pd/Ni colloids in dimethylacetamide. The same reactions have been observed when solvent-stabilized Pd particles in propylene carbonate were applied as the catalyst [93, 505, 506]. Nanosized Pd colloids generated *in-situ* by reduction of Pd(II) to Pd(0) are involved in the catalysis of phosphine-free Heck and Suzuki reactions [507]. Hexagonal or quasi-two-dimensional Pd nanoparticles (hcp structure, 53 nm) encapsulated in graphite have also been tested as catalysts for the Heck reaction. Microphotographs confirmed that the nanoparticles are located between the spacing layers of graphite. The catalyst is very stable: Although no strong interaction is present between the nanoparticles and the carbon lattice, the particles cannot be washed out and they are still found inside the carbon lattice after the Heck reaction [508]. The [3 + 2] cycloaddition of methylenecyclopropane to methylacrylate is effectively catalyzed by nanostructured nickel colloids (2.5 nm) in solution [509]. The liquid-phase hydrogenation of isomeric undecenoic acids has been demonstrated to be catalyzed selectively by Pt colloids encapsulated in polymerized micelles [510]. Metal colloids stabilized by amphiphilic block copolymers were used as efficient catalysts in the "quasi-homogeneous" phase [511–514]. A generally applicable synthesis of metal colloids in microemulsions, in particular, of nanostructured noble metals in amphiphilic block copolymers, has been worked out by Antonietti and co-workers [511, 512]. Micelles in which nanosized metals are incorporated are very stable; they undergo no significant change of the colloidal properties such as size and polydispersity and consequently are effective hydrogenation catalysts. The morphology of the metal core can be varied between a "cherry" type and a "raspberry" type architecture depending on the strength of the reducing agent. Block copolymer-stabilized Pd-"raspberry" colloids have an extraordinary high metal surface and no additional support is needed for catalytic applications in solution. This type of colloid catalyst combines the advantages of homogeneous and heterogeneous catalysis; that is, the high selectivity and reactivity of homogeneous hydrogenation catalysts are coupled with the long-term stability of the heterogeneous systems. Nanostructured metal colloids stabilized with

synthetic polymers [515–519] may be regarded as artificial enzyme models. The interaction between the "polymeric fields" and the reactive substrates determines the selectivity of the colloidal nanometal catalysts. Coordinating polymers such as poly(N-vinyl-2-pyrrolidone) have been shown to protect nanostructured metal particles that have an average diameter of ca. 1–3 nm and a narrow size distribution. The resulting materials are effective catalysts for olefin hydrogenation [516], nitrile hydration [517], photoinduced electron transfer [518], and Suzuki reactions [126]. The application of dendrimer-encapsulated Pd nanoparticles to fluorous phase-soluble catalysts has been described recently [519]. The scope of ligand-stabilized transition-metal nanoparticles in catalysis was recently summarized by Schmid et al. [74, 520]. A very recent review on the catalytic activity of various soluble transition-metal nanoclusters as arene hydrogenation catalysts has been critically reviewed [521]. This work on the hydrogenation catalysts describes comprehensively 18 prominent catalyst systems from the literature, highlighting their synthesis and catalytic application.

5.2. Heterogeneous Reactions

Heterogeneous catalysts are readily obtained when preprepared nanometal colloids are deposited on supports [2]. The so-called "precursor concept" for manufacture of heterogeneous metal colloid catalysts was developed on this basis in the 1990s [6, 7, 9, 15, 95–97]. As a result, so-called *egg-shell* catalysts were obtained which contain the active metal particles as a thin layer (<250 nm) on the surface of the support. Metal colloid catalysts of this type have successfully been applied to hydrogenate C,C double bonds, organic carbonyl groups, unsaturated C,N bonds, and to reduce N,O bonds [522]. An obvious advantage of the precursor concept over the conventional salt-impregnation method is that both the size and the composition of the colloidal metal precursors may be tailored independently of the support. Further, the metal particle surface may be modified by lipophilic or hydrophilic protective shells and coated by intermediate layers, for example, of oxide. The modification of the precursor by dopants is also possible. The catalyst is manufactured by dipping the supports into organic or aqueous media containing the dispersed precursor at ambient temperature to adsorb the pre-prepared particles. This has been demonstrated for supports such as charcoal, various oxidic support materials, and even low-surface materials such as quartz, sapphire, and highly oriented pyrolitic graphite (HOPG). No subsequent calcination is required (see Fig. 12). The feasibility of preparing catalysts in this way for industrial purposes has been demonstrated by Degussa.

A combination of AFM, STM, and XPS [523, 524] has revealed the interaction of platinum hydrosols with oxide (sapphire, quartz) and graphite single-crystal substrates. The metal core is immediately adsorbed onto the support surface when dipped into aqueous Pt colloid solutions at 20 °C. The carpet-like coat formed over the particles by the protecting shell and the support surface cannot be removed from the particle surface even by intense washing with solvent. The organic protecting shell decomposes on annealing at 280 °C and above in UHV. The thermal degradation can be monitored by XPS up to 800 °C and by STM. It was shown

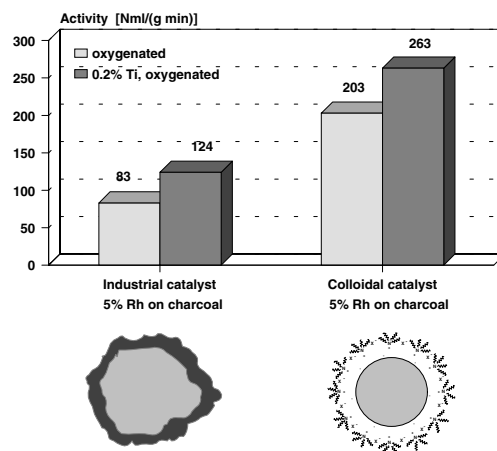
that the Pt particles remain virtually unchanged at up to ca. 800 °C. Sintering processes are observed only above this temperature. Reetz et al. have used $N(octyl)_4Br$-stabilized Pd colloids (typical size, e.g., 3 nm) as precursors to form so-called "cortex catalyst," where the active metal forms an extremely fine shell of less than 10 nm on the supports (e.g., Al_2O_3) [525]. Within the first 1–4 s, the impregnation of Al_2O_3 pellets by dispersed nanostructured metal colloids leads to the time-dependent penetration of the support which is complete after 10 s.

"Cortex catalysts" were reported to show a threefold higher activity in olefin hydrogenation than conventionally prepared catalysts of the same metal loading (5% Pd on Al_2O_3). Schmid [70] has described phosphine-stabilized Rh_{55} nanoclusters, namely $Rh_{55}[P(t\text{-Bu})_3]_{12}Cl_{20}$ and $Rh_{55}[PPh_3]_{12}Cl_{20}$, deposited on TiO_2. These systems were used to catalyze the heterogeneous hydroformylation of propene with high turnover numbers giving equal amounts of *n*- and *i*-butanal. The observed turnover frequencies are higher than seen with homogeneous complex catalysts but the selectivity was found to be too low for practical applications. In the butyronitrile hydrogenation test, the activity of surfactant-stabilized colloidal rhodium (5 wt % on charcoal) was found to surpass that of conventional salt impregnation catalysts of the same metal loading. The addition of 0.2% of colloidal Ti(0) to the supported noble metal [89] resulted in a significant enhancement in activity [7] (see Fig. 13).

The "dopants" are not restricted only to transition metals. The hydrogenation of acrylic acid can be promoted significantly by the addition of neodymium ions onto the palladium particles [526]. The selective transformation of 3,4-dichloronitrobenzene to the corresponding aniline has been selected to test pre-prepared Pt hydrosols as heterogeneous catalyst precursors (see Fig. 14) [527].

In batch and continuous tests, the performance of the colloidal catalyst system was evaluated and compared to conventional Pt/C systems. In summary, the potential of the colloidal heterogeneous catalyst lies in the possibility of tailoring the properties for specific applications by the addition of special dopants or "poisons" (such as sulfur). Further "fine tuning" of the complex process shown in Figure 14 has been achieved by using the synergistic effect of bimetallic precursors (e.g., Pt/Cu). The influence of metal ions on the hydrogenation of o-chloronitrobenzene


over platinum colloids, and the effect of metal complexes on the catalytic performance of metal clusters have also been investigated [528–530]. It was found that the catalytic properties of platinum clusters for the hydrogenation of o-chloronitrobenzene to o-chloroaniline are very sensitive to the metallic cations added. When Ni^{2+} ions were used as the modifier, the activity and selectivity were enhanced. The selectivity for o-chloroaniline jumped from 44.7% to 66.3% while the activity of the catalyst was nearly doubled. The maximum activity and selectivity (82.9%) to o-chloroaniline was obtained at a molar ratio of Ni^{2+} to Pt of 8:1 [528]. The "doping effect" of additional metal complexes on the activity and selectivity of platinum clusters in the homogeneous liquid-phase hydrogenation of cinnamaldehyde was studied by the same authors [530]. The conversion was promoted from 65.5% to 78.0% using Na_3FeF_6 as the additive, while the selective formation of cinnamic alcohol increased from 17.7% to 75.0%. The addition of $Ni(bipy)_3Cl_2$ to the
Figure 14. Reaction scheme for the hydrogenation of 3,4-dichloronitrobenzene.

colloidal platinum catalyst raised the conversion to 82.1%, while the selectivity towards hydrocinnamaldehyde was as high as 97.3%. In the hydrogenation of cinnamic acid to cinnamic alcohol, the selectivity can be varied by doping Rh colloid catalysts with Sn. A selectivity of 86% is achieved with a colloidal Rh/Sn (Rh:Sn = 1.5:1) catalyst on carbon [15]. Copper-catalyzed Suzuki cross-coupling reactions using mixed nanocluster catalysts have been studied recently. Copper-based catalysts were shown to be effective as reagents which can present an inexpensive and environmentally friendly alternate to noble metal catalysts. Remarkably, the stabilizing surfactant was shown to modify the colloidal metal surface and hence the catalytic properties [527]. Hanaoka et al. [531] have reported the selective photocatalytic transfer of hydrogen to 1,5-cyclooctadiene with a light transition-metal modified rhodium colloid catalyst. Bulk industrial processes often rely on alloy-like bimetallic catalysts [532–535]. Here, nanostructured bimetallic colloid catalysts have opened the possibility of differential studies on the mutual influence of two different metals on the catalytic properties. The controlled co-reduction of two different metal ions has made bimetallic colloids readily accessible [6, 7, 15, 42–45, 76, 98–105, 535]. The structural characterization and some catalytic aspects of bimetallic colloids have been reviewed recently [10]. The successive reduction of mixed metal ions allows the homogeneous structure of bimetallic particles to be altered to colloidal particles having composition gradients from the core to the shell [516, 536–539]. Truly layered particles consisting of, for example, a gold core plated by palladium or vice versa [76], have also been synthesized. Bimetallic particles having a gradient metal distribution or a layered structure are most interesting for catalytic applications. In the catalytic hydrogenation of crotonic acid to butanoic acid, a clear synergistic effect of Pt and Rh [6] was observed when bimetallic colloidal precursors ($Pt_{20}Rh_{80}$) have a gradient core/shell structure with an increase in the Rh concentration from the core towards the surface of the particle [536] (see Fig. 15). Toshima has discussed a similar effect in the partial hydrogenation of 1,3-cyclooctadiene with $Pt_{80}Pd_{20}$ and $Pd_{80}Au_{20}$ colloid catalysts [10].

Brijoux, in "Advanced Catalysts and Nanostructured Materials" (W. Moser, Ed.), Chap. 7, p. 165. Academic Press, San Diego, 1996. © 1996, Elsevier Science.

The difference between the electronegativities of Pd and Au together with the combination of the partially filled d band of Pd and the completely filled d band of Au result in a novel electronic structure. This may be the reason for the catalytic behavior of gold-palladium alloys [540–549]. Fascinating prospects for the design of new catalysts have been opened up using bimetallic particles with layered structures. First principles-based density functional methods and theoretical models have been used to investigate the reactivity of different RhCu alloys towards molecular hydrogen dissociation [550]. Schmid and Peschel [76] have applied the classical seed growth method [551] to synthesize layered bimetallic Au/Pd and Pd/Au colloids in the size range of 20 to 56 nm. The sequential reduction of gold salts and palladium salts with sodium citrate allows the gold core to be coated with Pd. The layered bimetallic colloid is stabilized by trisulfonated triphenylphosphane and sodium sulfanilate. More than 90% metal can be isolated in the solid state. The redispersion in water is possible in high concentration. Au/Pd and Pd/Au systems on a TiO_2 support have been used in stabilized and nonstabilized forms as heterogeneous catalysts for the hydrogenation of hex-2-yne to cis-hex-2-ene. Both the palladium-plated gold seeds and the gold-plated palladium particles showed considerably increased activities compared with the pure metals. The protecting ligand shell enhances the lifetime of the ligand-stabilized colloid catalysts considerably. The influence of the electronegativity difference between Au and Pd on the activity and selectivity of the hydrosilylation reaction [552] on colloidal Pt surfaces [150, 151] was carefully investigated. In essence, the results demonstrate that the activity, selectivity, and the lifetime of metal colloid catalysts may be optimized by a defined variation of the core/shell composition in bimetallic precursor.

Residues of the stabilizing agents which are still present at the surface of the colloidal metal precursors (1 and 5 wt % metal loading on charcoal, glassy carbon, zeolites, TiO_2, Al_2O_3, $CaCO_3$, SiO_2, single-crystal oxides, or HOPG) may act as effective catalyst modifiers which control the selectivity and durability of heterogeneous colloid catalysts. Ligands such as phosphines or phenanthrolines [75], surfactants of various types [7, 15] or organic "envelopes" such as polymers [510, 553, 554] were found to control the regio- and enantioselectivity of heterogeneous metal colloid catalysts. In case of the semi-hydrogenation of hex-2-yne to cis-hex-2-ene, Schmid has found that even subtle changes in the chain length of the substituents of the alkyl-substituted phenanthrolines used as colloid stabilizers alter the regioselectivity significantly [555]. Seven- and eight-shell palladium clusters on TiO_2, protected by phenanthroline, catalyze the semi-hydrogenation of hex-2-yne to cis-hex-2-ene with 93% cis-hex-2-ene selectivity. With the 3-n-decyl phenanthroline as the stabilizer, a similar selectivity resulted.

On substitution of the phenanthroline with n-butyl or n-heptyl groups, however, the activity drops dramatically and the consecutive isomerization or total hydrogenation of the cis-hex-2-ene is completely suppressed. Geometric, that is, steric, reasons were claimed to explain the strong influence on the selectivity and this has been illustrated by further

examples. A surfactant was found to control the selectivity in the cis-selective partial hydrogenation of 3-hexyn-1-ol, giving leaf alcohol, which is a valuable fragrance (Eq. (14)) [556]:

$$HO \equiv\!\!\!\!\!/\!\!\!\!\!/ \xrightarrow[\text{Pd}]{\text{H}_2} HO \diagdown\!\!=\!\!\diagup + \left(HO \diagdown\!\!=\!\!\diagup + HO \diagup\!\!\diagdown\!\!\diagup \right) \quad (14)$$
The performance in this reaction (Eq. (14)) of heterogeneous Pd colloid catalysts on $CaCO_3$ modified by a number of surfactants was compared with conventional Pd/C and Lindlar catalysts under optimized reaction conditions. The selectivity was found to depend on the support and various promoters. The highest activity and the best selectivity (98.1%) towards the desired cis-3-hexen-1-ol was found when employing a lead-acetate-promoted palladium colloid on $CaCO_3$ modified by the zwitterionic surfactant sulfobetaine-12 (N,N-dimethyl-dodecylammoniopropanesulfonate). Chemisorption measurements have shown that residual amounts of the surfactant are still present on the surface of the immobilized particles. This colloid catalyst was twice as active as a conventional Lindlar catalyst, and surpassed its selectivity by 0.5%. The contact of heterogenized metal colloid surfaces with substrates in aqueous media is improved when hydrophilic protecting shells are present. For example, a hydrophilic ruthenium colloid catalyst on lanthanium oxide was shown to convert benzene into cyclohexene with 59% selectivity at 50% benzene conversion when suspended in an aqueous solution of sodium hydroxide [557]. Chiral molecules on the surface of the metal colloid can induce enantioselectivity control. Following this concept, a new type of enantioselective platinum sol catalyst stabilized by the alkaloid dihydrocinchonidine was designed (see Fig. 16) [344, 558].

The colloidal catalysts have been prepared in different particle sizes by the reduction of platinum tetrachloride with formic acid in the presence of different amounts of alkaloid. Optical yields of 75–80% *ee* were obtained in the hydrogenation of ethyl pyruvate with chirally modified Pt sols (Eq. (15)). The catalysts were demonstrated to be

Figure 16. Enantioselective hydrogenation of ethyl pyruvate using dihydrocinchonidine-stabilized Pt colloids. Adapted with permission from [15], H. Bönnemann and W. Brijoux, in "Advanced Catalysts and Nanostructured Materials" (W. Moser, Ed.), Chap. 7, p. 165. Academic Press, San Diego, 1996. © 1996, Elsevier Science.

structure insensitive since turnover frequencies (ca. 1 sec^{-1}) and enantiomeric excess are independent of the particle size:

$$\text{(15)}$$

R-ethyl lactate
In order to evaluate the catalytic characteristics of colloidal platinum, the efficiency of Pt nanoparticles in the "quasi-homogeneous" reaction shown in Eq. (15) was compared with that of supported colloids of the same charge and of a conventional heterogeneous platinum catalyst. The "quasi-homogeneous" colloidal system surpassed the conventional catalyst in turnover frequency by a factor of 3 [558]. Köhler and Bradley [559, 560] and Liu and co-workers [561, 562] have studied the enantioselectivity of the reaction (Eq. (15)) in the presence of polyvinylpyrrolidone as the stabilizer. In addition, Köhler and Bradley [559] have observed that the presence of HCl in as-prepared Pt sols modified by cinchona alkaloids has a marked effect on rate and reproducibility. The performance of the catalysts was improved in both reproducibility and rate by the removal of HCl by dialysis. These "purified" colloidal catalysts can be used as reliable test systems to screen chiral modifiers alternative to cinchona alkaloids and for precise rate studies. In addition, a systematic variation of the reaction parameters relevant to the catalyst performance is possible without unwanted side effects. It was shown that an excess of polyvinylpyrrolidone present on the colloidal Pt catalyst is irrelevant to the access of modifier molecules to the colloidal metal surface. However, the polymer may adsorb at the metal surface, reducing the number of modified surface sites available for the enantioselective hydrogenation [560]. Nanostructured metal colloids can be used for the stereoselective and enantioselective transformation of specific prochiral substrates into valuable fine chemicals. The application of a rational ligand-control based on molecular modelling which has been successful in homogeneous metal complex catalysis promises similar results in heterogeneous metal colloid catalysis.

Superior lifetimes should be also achieved since it is reasonable to assume on the basis of the chemisorption results that the "coating" on catalytically active nanometal particles which is permeable for small molecules such as H_2 or O_2 effectively prevents the contact of the metal surface with poisons. In fact, the lifetime of the colloid catalysts is considerably longer than of conventional precipitation catalysts. For example, the activity of a conventional Pd/C catalyst expires completely in the hydrogenation of cyclooctene to cyclooctane after 38×10^3 catalytic cycles per Pd atom, but the Pd colloid/C catalyst still shows a residual activity after 96×10^3 catalytic turnovers [563] (Fig. 17).

Superior catalytic oxidation catalysts were obtained when surfactant-stabilized Pd-Pt precursors were supported on charcoal and promoted by bismuth. By comparison with industrial heterogeneous Pd/Pt catalysts, charcoal-supported Pd_{88}/Pt_{12}-$(Oct)_4NCl$ alloy particles (1.5 to 3 nm) show an

Figure 17. Durability of colloidal Pd/C catalysts in the cyclooctene hydrogenation test compared with a conventional Pd/C system. Adapted with permission from [15], H. Bönnemann and W. Brijoux, in "Advanced Catalysts and Nanostructured Materials" (W. Moser, Ed.), Chap. 7, p. 165. Academic Press, San Diego, 1996. © 1996, Elsevier Science.

excellent activity combined with high selectivity in the glucose oxidation to gluconic acid by molecular oxygen (see Eq. (16)) [564]:

$$\text{(16)}$$

The greater durability of the colloidal Pd/C catalysts was also observed in this case. The catalytic activity was found to have declined much less than a conventionally manufactured Pd/C catalyst after recycling both catalysts 25 times under similar conditions. Obviously, the lipophilic $(Oct)_4NCl$ surfactant layer prevents the colloid particles from coagulating and being poisoned in the alkaline aqueous reaction medium. Shape-selective hydrocarbon oxidation catalysts have been described where active Pt colloid particles are present exclusively in the pores of ultramicroscopic tungsten heteropoly compounds [565]. Phosphine-free Suzuki and Heck reactions involving iodo-, bromo-, or activated chloroatoms were performed catalytically with ammonium salt- or poly(vinylpyrrolidone)-stabilized palladium or palladium nickel colloids (Eq. (17)) [221, 565]:

$$\text{(17)}$$

(E)-stilbene was the exclusive product of the Pd colloid-catalyzed Heck arylation of styrene with chlorobenzene. Recently, a polymer-mediated self-assembly of functionalized Pd and SiO_2 nanoparticles has been found to be a highly active catalyst for hydrogenation and Heck coupling reactions [566]. This type of C-C linkage is valuable for the production of pharmaceutical intermediates and fine chemicals. Turnover frequencies (TOF) of more than 80,000 have been achieved in the coupling of p-bromobenzaldehyde with butyl acrylate using poly(vinylpyrrolidone)-stabilized palladium as the catalyst [567]. Reetz has applied colloidal,

water-soluble PtO_2 (i.e., a colloidal "Adams catalyst") in the immobilized form for the reductive amination of benzaldehyde by n-propylamine (Eq. (18)) [323, 324]:

$$\text{(18)}$$

The selectivity in favor of the desired monobenzylated product was found to be >99% and the immobilized PtO_2 was found to be 4–5 times more active than the commercial Adams catalysts. In solution or in immobilized form, the PtO_2 colloid is effective in the hydrogenation of carbonyl compounds or of olefins. Recently, the heterogeneous catalytic amination of aryl bromides by immobilized Pd(0) particles has been reported [565]. Secondary amines such as piperidine and diethyl amine are used in the amination of aryl bromides and the reaction proceeds with good turnover numbers and regio-control. The catalysts can be reused repeatedly without loss of activity or selectivity after filtration from the reaction mixture.

Noble metals nanoparticles have been used as catalysts for olefin hydrogenation, in C-C coupling reactions including Heck and Suzuki coupling reactions. Co nanoparticles are also being used as heterogenous Pauson–Khand catalysts. Fabrication of hollow spheres composed of paladium nanoparticles and their application to heterogenous Suzuki reactions have been recently performed [568–570].

A new class of heterogeneous catalyst has emerged from the incorporation of mono- and bimetallic nanocolloids in the mesopores of MCM-41 or via the entrapment of pre-prepared colloidal metal in sol–gel materials [571–573]. Noble metal nanoparticles containing Mex-MCM-41 were synthesized using surfactant-stabilized palladium, iridium, and rhodium nanoparticles in the synthesis gel. The materials were characterized by a number of physical methods which showed that the nanoparticles were present inside the pores of MCM-41. They were found to be active catalysts in the hydrogenation of cyclic olefins such as cyclohexene, cyclooctene, cyclododecene, and norbornene [574]. Pre-prepared Pd colloids stabilized via phenanthroline by the Schmid method [63–78] have successfully been embedded in MCM-41 mesopores (some are deposited on the external surface) to give CO oxidation catalysts [571].

A strategy for the entrapment of monodisperse nanometal colloids, for example, NR_4X-stabilized Pd particles, has been developed by Reetz [572]. The nanosized particles (2 to 3.5 nm) are pre-prepared by electrochemical synthesis [98–105, 572]. The entrapment in hydrophobic sol–gel materials occurs via the fluoride-catalyzed hydrolysis of mixtures of $CH_3Si(OCH_3)$ and $Mg(OC_2H_5)_2$. Finally, the stabilizer is extracted and the "naked" nanometallic particles are left trapped in the pores. Ultramicrotomic techniques in combination with shadow casting TEM has confirmed that the Pd particles are embedded in the oxide matrix and not fixed on the outer surface. Reetz and Dugal [572] have investigated the catalytic properties of the new material. By adjusting the relative amounts of the $CH_3Si(OCH_3)_3$ and $Mg(OC_2H_5)_2$ in the gel, they were able to control the hydrophobicity of the matrix. The catalytic activity and selectivity were tested by the partial hydrogenation of COD to give cyclooctene;

it was found that the activity of the new systems is governed by the specific pore volume and the hydrophobic properties of the wall. The selectivity for cyclooctene was 93%. The most active of these sol–gel-entrapped Pd catalysts had a considerably higher activity than the commercially available Pd/Al_2O_3 samples. The preparation of a fully alloyed Pd-Au colloid of 3.0 nm particle size, by a modified sol–gel procedure using THF as the solvent, from the co-reduction of Pd and Au salts with tetraalkyl-ammonium-triethylhydroborate [6] and its embedding in a silica has been described [573]. The integrity of the incorporated Pd-Au alloy particles remained virtually untouched. After the removal of the protecting surfactant, a mesoporous texture with a comparatively narrow pore distribution remained. According to the physical characterization by a combination of techniques, the SiO_2-embedded Pd-Au colloid preserves the size and the structural characteristics of the colloidal metal precursor. Tetraalkyl-substituted Ru in either silica or zirconia sol–gel matrix has been used for hydrogenolysis [575]. In a similar fashion, colloidal palladium supported on silica gel has been conclusively proved to be involved in the direct reaction of H_2 and O_2 to give H_2O_2 [576]. The material exhibits excellent catalytic properties in selective hydrogenation test reactions. These few examples show that colloidal bimetallic precursors—embedded in matrices or deposited on various supports, and promoted by additives if necessary—may become of practical importance in heterogeneous catalysis. A recent review describes various synthetic strategies applied for the synthesis of metal nanoparticles which can be used as reusable catalysts with almost all kinds of reactions studied so far. They include hydrosilylation, oxidation, C-C coupling reactions such as carbonylation, Heck and Suzuki reactions, hydrogenation, chemoselective, regioselective, stereo-, and enantioselective reactions [577].

5.3. Fuel Cell Catalysts

"Fuel cell technology" allows the direct conversion of chemical energy into electricity [578]. The fuel cell is an electrochemical reactor where the catalyst systems are an important component. Among the wide-ranging applications, fuel cells are best suited for low-emission transport systems, stationary power stations, and combined heat and power sources. The classical studies were carried out in the early 1900s and major innovations and improvements have been achieved over the last few years. The first "new electric cars" are expected to roll on the markets around the year 2010, but further developments are still needed, notably in the catalyst sector. Hydrogen fuel cell catalysts rely on pure Pt, whereas Pt-alloy electrocatalysts are applied for the conversion of reformer gas or methanol into electricity. The active components in the latter cases are small Pt-containing bi- or trimetallic particles of 1–3 nm size which scatter X-rays as nearly perfect "single crystals." These systems offer improved efficiency and tolerance against certain contaminations, especially CO in the anode feed [579–584]. It was clear from patents filed in the early 1970s that finely particulated colloidal platinum sols should be the ideal precursors for the manufacture of fuel cell electrodes [579].

This survey focuses on recent developments in catalysts for phosphoric acid fuel cells (PAFC), proton exchange membrane fuel cells (PEMFC), and the direct methanol fuel cell (DMFC). There are six main types of fuel cell described in literature [585–589]. In PAFC, operating at 160–220 °C, orthophosphoric acid is used as the electrolyte, the anode catalyst is Pt, and the cathode can be, for example, Pt/Cr/Co [585–589]. For this application, a trimetallic colloidal precursor of the composition $Pt_{50}Co_{30}Cr_{20}$ (size 3.8 nm) was prepared by the co-reduction of the corresponding metal salts [590–592]. From XRD analysis, the trimetallic particles were found alloyed in an ordered fct structure. The electro-catalytic performance in a standard half-cell was compared with an industrial standard catalyst (trimetallic crystallites of 5.7 nm size) manufactured by co-precipitation and subsequent annealing to 900 °C. The advantage of the trimetallic colloid catalyst lies in its improved durability, which is essential for PAFC applications. After 22 h it was found that the potential had decayed by less than 10 mV [593].

PEM fuel cells use a solid proton-conducting polymer as the electrolyte at 50–125 °C. The cathode catalyst is based on Pt alone, but because of the required tolerance to CO, a combination of Pt and Ru is preferred for the anode [579–584]. Colloidal Pt/Ru catalysts are currently under widespread investigation for low-temperature (80 °C) polymer membrane fuel cells [593–595]. These have also been proposed for use in the DMFC or in PEMFC which are fed with CO-contaminated hydrogen produced in on-board methanol reformers. The ultimate dispersion state of the metals is essential for CO-tolerant PEMFC, and truly alloyed Pt/Ru colloid particles of less than 2 nm size seem to fulfill these requirements [17, 18, 20, 579, 581, 596–603]. Alternatively, bimetallic Pt/Ru PEM catalysts have been developed for the same purpose, where nonalloyed Pt nanoparticles <2 nm and Ru particles <1 nm are dispersed on the carbon support [581]. From the results it can be concluded that a Pt/Ru interface is essential for the CO tolerance of the catalyst regardless of whether the precious metals are alloyed. For the manufacture of DMFC catalysts, in contrast, Pt/Ru nanopowders of 3–5 nm size or thin films are used as the precursors [582–584]. For the electrocatalytic methanol oxidation, a Pt metal or a Pt metal alloy catalyst has been developed where a Ru phthalocyanine complex is added as a dopant to reinforce the catalytic effect substantially [592]. For comparison, the electrocatalytic activity was compared to that of a bimetallic Pt_{50}/Ru_{50}-$N(Oct_4)Cl$ colloid prepared by the salt co-reduction method [6, 95–97] toward the oxidation of CO and a CO/H_2 gas mixture (simulated reformer gas) [17]. According to high-resolution transmission electron microscopy, the mean particle diameter was 1.7 nm. Alloyed state of the particles was verified by point-resolved energy-dispersive X-ray (EDX) analysis. CO tolerance and direct methanol oxidation on Pt_3Mo/C have been investigated in PEM fuel cell conditions. This catalyst has shown threefold enhancement for the CO tolerance, while for methanol oxidation no such enhancement was seen. It is also emphasized that the mechanism involved in CO oxidation is different from the conventional Pt-Ru catalysts. While ruthenium gets converted into its oxide that helps in the oxidation of CO, Mo oxide surface shows no

affinity for CO providing a pathway of easy oxidation at lower overpotentials [601].

Glassy carbon-supported Pt_{50}/Ru_{50}-N(Oct$_4$)Cl colloids were examined by CO-stripping voltammetry and the data were found to be essentially identical with those found in well-characterized bulk alloy electrodes. In a rotating disk electrode, the activity of the colloid toward the continuous oxidation of 2% CO in H_2 was determined at 25 °C in 0.5 M H_2SO_4, and the results led to the conclusion that these Pt/Ru colloids are very suitable precursors for high-surface-area fuel cell catalysts [20]. Structural information on the precursor was obtained by *in-situ* XRD via Debye function analysis. In addition, the XANES data support the bimetallic character of the particles. *In-situ* XRD has revealed the catalytic function of the alloyed Ru in the CO oxidation: surface oxide species are formed on the Ru surface at 280 °C which slowly coalesce to RuO_2 particles. After re-reduction the catalyst shows a pure hcp ruthenium phase and larger platinum-enriched alloy particles [604]. Scanning probe microscopy (SPM) has been applied in order to characterize the real-space morphology of the electrode surfaces of supported nanostructured metal colloids on the nanometer scale [605]. Colloidal Pt_{50}/Ru_{50} precursors (<2 nm) raise the tolerance to CO, allowing higher CO concentrations in the H_2 feed of a PEMFC without a significant drop in performance [18–20]. A selective Pt/Mo oxidation catalyst for the oxidation of H_2 in the presence of CO in fuel cells comprises Pt_xMo_y particles, where x is 0.5–0.9 and y is 0.5–0.1 [606]. The colloid method was found to be a highly suitable exploratory approach to finding improved formulations for binary and ternary anode electrocatalysts. The metals used include Pt, Ru, W, Mo, and Sn [19]. The combinatorial screening method has successfully been applied to electrocatalysts [607], and it is an obvious step to include colloids in these experiments. As an alternative to the reductive metal colloid synthesis, the so-called "metal oxide concept" was developed which allows the fabrication of binary and ternary colloidal metal oxides as electrocatalyst precursors (Eq. (19)) [323–325]:

$$PtCl_4 + RuCl_3 \xrightarrow[\text{stabilizer}]{\text{H}_2\text{O/base}} PtRuO_x \text{ colloid} \qquad (19)$$
There are many recent reports of Pt-Ru being prepared by different methods and supported on different carbon supports to check their catalytic activity [608–613]. Colloidal Pt/RuO_x (1.5 ± 0.4 nm) stabilized by a surfactant was prepared by co-hydrolysis of $PtCl_4$ and $RuCl_3$ under basic conditions. The Pt:Ru ratio in the colloids can be varied between 1:4 and 4:1 by variation of the stoichiometry of the transition-metal salts. The corresponding zerovalent metal colloids are obtained by the subsequent application of H_2 to the colloidal Pt/Ru oxides (optionally in the immobilized form). Additional metals have been included in the "metal oxide concept" (Eq. (17)) in order to prepare binary and ternary mixed metal oxides in the colloidal form. $Pt/Ru/WO_x$ is regarded as a good precatalyst especially for the application in DMFCs. Main group elements such as Al have been included in multimetallic alloy systems in order to improve the durability of fuel cell catalysts. $Pt_3AlC_{0.5}$ alloyed with Cr, Mo, or W particles of 4–7 nm size has been prepared

by sequential precipitation on conductant carbon supports such as highly disperse Vulcan XC72® [614]. Alternatively, colloidal precursors composed of Pt/Ru/Al allow the manufacture of multimetallic fuel cell catalysts (1–2 nm) having a metal loading of >20%.

The colloidal Pt/Ru/Al precursor is pre-prepared via the organoaluminum route. In the absence of stabilizers, the co-reduction of organic Pt and Ru salts using $Al(CH_3)_3$ gives halogen-free, multimetallic Pt colloids, for example, $Pt_{50}Ru_{50}/Al$ (size 1.2 ± 0.3 nm). When the stoichiometric ratio of the metal salts is changed, the ratio of Pt to the second metal in the colloid can be adjusted. The addition of alcohols or suitable surfactants allows the dispersivity of the colloidal precursor in organic media or water to be tailored without affecting the particle size. In the second step, the Pt/Ru/Al colloid is adsorbed on high-surface-area carbon by treatment at 40 °C for 24 h. In the third step (conditioning), the dried Pt/Ru/Al Vulcan catalyst powders are exposed to O_2 and H_2 for 30 minutes each at 250–300 °C to remove the surfactants completely. The particle size of the Pt/Ru/Al colloid adsorbed on the support was found to be virtually untouched (1.3 ± 0.4 nm) and after the thermal treatment only a moderate growth was determined (1.5 ± 0.4 nm). The aluminum was found to be present on the Pt/Ru surface in an oxidized form. This accounts for the size-stabilization observed in the Pt/Ru particles and for the improved durability of the resulting electrocatalysts. Recently, a fuel cell for generating electric power from a liquid organic fuel ("synfuel") was described. It comprises a solid electrolyte membrane directly supporting the anode and cathode layers which contain 7–10% Pt and Ru, 70–80% of perfluorovinyl ether sulfonic acid, and 15–20% polytetrafluoroethylene [599]. In conclusion, nanostructured metal colloids are very promising precursors for manufacturing multimetallic fuel cell catalysts that are truly nanosized (i.e., <2 nm) and have high metal loadings (20 wt % of metal).

6. APPLICATIONS IN MATERIALS SCIENCE

Metal nanoparticles and their assemblies are expected to have numerous applications in materials science. They should exhibit a range of physical and chemical properties that are promising for potential application in a new generation of optical, electronic, chemical, and biological devices. Quantum size effects are related to the "dimensionality" of a system in the nanometer range. "Zero-dimensional" metal particles might still comprise hundreds of atoms. The differences between the material properties of nanosized particle structures and the bulk material stem from the loss of characteristic magnetic domain size, and from the particle sizes relative to the scattering length of conduction electrons and the de Broglie wavelength of the electron. Size reduction may even cause changes in the melting point. One-dimensional nanoparticle arrangements (cluster wires) are of potential practical interest as semiconducting nanopaths for applications in nanoelectronics. One-dimensional particle arrangements may be induced through host templates. Using vacuum or electrophoretic methods Schmid and co-workers [615–617] were able to fill the parallel channels of nanoporous alumina membranes with chains/rows

of 1.4-nm gold particles giving one-dimensional "quantum wires" consisting of insulated 20–100 Au_{55} clusters in a helical array. The diameter of the nanowire could be controlled by varying the pore size. Interestingly, 1.4-nm Au particles were found to arrange themselves into a linear row when attached to single stranded DNA oligonucleotide [618]. Driven by the technological significance associated with such architectures, the fabrication of ordered two-dimensional nanoparticle arrays has successfully been achieved by several research groups. Their work was recently reviewed [619, 620]. Planar arrays of uniform metal nanoparticles would allow the design of new "supercomputers" having a superior data storage capacity. Langmuir–Blodgett films of nanometal systems have frequently been studied in this respect. Starting with nanoparticles of defined nuclearity, 2D lattices of thiolized Au_{55}, Pd_{561}, and Pd_{1415} have been made [619]. Recently, the first successful preparation of 2D hexagonal and cubic lattices of Au_{55} nanoparticles by self-assembly on polymer films was reported. Simply dipping polyethylenimine-modified surfaces into aqueous solutions of acid-functionalized Au_{55} cluster was shown to generate Au_{55} monolayers [330]. A report on the molecular organization with special emphasis on the Langmuir–Blodgett and molecular self-assembly emphasizes the need for heterogenizing the homogeneous catalysts in achieving activity, selectivity, and recovery and recycling ability [621].

The interactions between the nanoparticles and the surface are obviously strong enough to prevent mechanical removal. Whereas the hexagonal form shown is normal for an ordered monolayer, the cubic orientation is unprecedented. Most of the work published on organized nanometal structures centers on gold particles and sulfur-containing groups in various ligands [622–627]. Water-soluble gold particles functionalized with a monolayer of 11-thioacetate-undecanol-derivatized neoglycoconjugates of two biologically significant oligosaccharides have been prepared [628], following a general method of *in-situ* functionalization synthesis of nanoparticles and monolayer-protected gold colloids [629].

Schiffrin and co-workers have achieved the self-organization of nanosized gold particles using $NR_4^+X^-$ surfactants [630]. Ramos et al. have recently reported surfactant-mediated two-dimensional crystallization of colloidal crystals [631]. The use of attractive Coulombic interaction between colloidal structures and surfactant structures offers a potential new route to self-assembly of ordered colloidal structures. Nanostructured palladium clusters, stabilized by a monomolecular coat of tetraalkylammonium halide surfactants, self-assemble on carbon surfaces in an ordered manner resulting in a hcp structure [632].

The self-organization of magnetic nanosized cobalt particles was studied by the group of Pileni [633, 634]. A comparison of the magnetic properties of deposited cobalt nanoparticles with those dispersed in a solvent indicates a collective flip of magnetization of adjacent particles when they are self-assembled. Additionally, Pileni and co-workers have recently published a number of articles concerning the self-assembly of nanoparticles and have developed numerous methods for the manipulation of these systems [635–637]. Marzan and Mulvaney have described in a recent review two-dimensional and three-dimensional assemblies of

metal-core-silica-shell nanoparticles [638]. A feature article by Balazs et al. [639] outlines how solid additives can be used to tailor the morphology of binary mixtures containing nanoscopic particles and thereby control the macroscopic properties (e.g., the mechanical integrity) of composites. In addition, computer-aided design has been employed to establish how self-assembled nanostructures can be induced to form arbitrary functional designs on surfaces [640]. Bifunctional spacer molecules such as diamines have been tried to link nanoparticles three-dimensionally [641]. The multilayer deposition of particle arrays on gold has been successfully achieved via the sequential adsorption of dithiol and near monodisperse nanometal or CdS particles [370].

Several monometal-, bimetal-, and plurimetal-semiconductor superlattices have been prepared by dipping a gold substrate into the respective solutions with intermediate steps involving washing and drying [642]. The stepwise three-dimensional assembly of layered gold nanoparticles in porous silica matrices has also been reported [643]. There are a few important developments in the self-assembling of gold and silver nanoparticles with varied applications foreseen [140, 644–658]. The Pileni description on the self-assemblies, their fabrication, and collective properties is one of the recent reviews in connection with Co nanoparticles [647]. In one of the most recent developments, an ambitious goal in the nanobiosciences has been realized in combining functionality and stability of inorganic nanostructured solids and the structural variety and self-organizing abilities of the biochemical molecules. Au nanoparticles with a mean diameter 2.2 nm was functionalized and built up to achieve a stable and specific conjugation with biotin linked to Avidin [659].

The ability of serotonin-labeled CdSe nanocrystals to interact with antidepressant-sensitive, human, and Drosophila serotonin transporters (hSERT, dSERT) expressed in HeLa and HEK-293 cells has been observed. These findings support further consideration of using ligand-conjugated nanocrystals as versatile probes for membrane proteins in living cells [660]. Refractive index sensors have been developed by the fabrication of a metal-coated three-dimensionally ordered macroporous film [661]. A different field of technological interest stems from the high spin density of nanostructured magnetic metals of the Fe, Co, Ni series [662, 663]. Magneto switchable bioelectrocatalysis has been performed by suitably derivatizing magnetite [664]. THF-stabilized Mn(0) particles which exhibit superparamagnetism below 20 K were described as the first example of an antiferromagnetic metal colloid [665]. The superparamagnetic properties of nanostructured Ni particles have also been investigated [666]. Cobalt nanoparticles stabilized in block copolymer micelles can be used as magnetic fluids [667]. Chaudret and co-workers have established the chemistry of ligand-free ultrafine cobalt particles in a polymer surrounding and studied their magnetic properties [668–670]. Magnetic cobalt nanoparticles—besides their potential applications in magneto-optical data storage and fluid magnetic lubricants—are of special interest in medicine. Three keywords here are "magnetic separation," "magnetic drug carriers," and "magnetic hyperthermia" [671–672]. The targeted transport of drugs by a magnetic field and the biological aspects of magnetic fluid technology have been reviewed

from the medical viewpoint [673, 674], and superparamagnetic nanoparticles have even been considered for the treatment of AIDS [675]. The growth of cobalt nanoparticles using wet chemical [6, 247] or electrochemical methods [676–678] is well established in the literature. An important prerequisite for all medical or biological applications, however, is the long-term protection of the nanosized magnetic material against water and air. In a first attempt to protect tetraalkylammonium-stabilized cobalt particles (3 nm) from corrosion by gold coating their surfaces, a toluene dispersion was treated with $AuCl_3$ which slowly dissolves and undergoes a redox reaction at the cobalt(0) surface according to Eq. (20):

$$12Co(0) + 2AuCl_3 \longrightarrow Co_9Au_2 + 3CoCl_2 \qquad (20)$$

Comparative magnetic susceptibility measurements with the naked and the gold-plated cobalt particles show that the magnetic stability of the naked cobalt (50 hr) is increased to 300 hr after the redox plating of the surface with gold. However, only an incomplete gold coverage of the cobalt surface is achieved by this simple method (Eq. (20)). Protection of the magnetic material is much improved by treating the cobalt particles with gold halides in the presence of excess borohydride and an enhanced magnetic stability of more than 1000 hr is observed. Similarly, using the aforementioned trialkylaluminum method of colloids, Co particles with considerable stability against oxidation is achieved. This property is going to be used in preparing magnetic fluids with special properties [263–265]. Information on the ferrofluids with their potential application has been elaborated [679].

New strategies utilizing DNA as a construction material for the generation of biometallic nanostructures have made it possible to develop larger "nanotechnology devices" (<100 nm) for microelectronic photolithographic applications. DNA is regarded as a promising construction material for the selective positioning of molecular devices because of its recognition capabilities, physicochemical stability, and mechanical rigidity. Seeman was the first to propose DNA for the precise spatial arrangement of 3D networks [680, 681]. Assemblies of DNA-derivatized gold colloids were recently prepared via the DNA hybridization-based self-organization pathway and the resulting defined arrangements of nanometal particles have actual applications in laser technology [682–692]. As already mentioned, Alivisatos et al. [618] have obtained defined monoadducts from commercially available 1.4-nm gold clusters where one reactive maleimido group is attached to every particle. These were coupled with thiolated 18-mer oligonucleotides in order to add an individual "codon" sequence. When a single-stranded DNA template containing complementary codons is added, a self-assembly of molecules is observed [683, 693] (Fig. 18). This work has been the subject of recent reviews [393, 693–695].

Niemeyer [393, 694] has reported the coupling of metal particles bearing a biotin substituent with the DNA-streptavidin hybrid. The growth of a 12 μm-long, 100-nm-wide conductive silver wire has been achieved using a DNA molecule stretched between two gold electrodes as
Figure 18. Self-organization of conjugates from gold particles (shaded spheres) and oligonucleotide codons to supramolecular assemblies by the addition of a template strand. The derivatization of the oligonucleotides in 3′- or 5′-position allows to control the mode of head-to-head (a) or head-to-tail (b) homodimers. The trimer (c) is formed using the complementary sequence in triplicate. Adapted with permission from [693], C. M. Niemeyer, *Angew. Chem. Int. Ed. Engl.* 36, 585 (1997). © 1997, VCH.

a template [696]. A recent inclusion in his study is deriving nanomechanical devices based on DNA [697]. See also [698].

7. CONCLUSION

We have reported the synthetic methods used for the synthesis of nanoparticles and highlighted their potential applications. It can now be said that during the last few decades an array of synthetic methodology for the wet chemical preparation of nanoparticles has been established. Powerful techniques for the detailed analysis of the geometrical and electronic structures of these materials have also been developed. It now remains to be seen how practical applications of these materials, namely, in the fields of catalysis and materials science, will grow from these seeds over the next few years.

GLOSSARY

Fuel cell An electrochemical cell that convert the chemical energy of a fuel and an oxidant to electrical energy.

Hydrosols and organosols Hydrosols are isolable, protected colloidal particles that can be readily redispersed in water. If the protecting shell is lipophilic (eg., tetraalkylammonium), such colloidal particles can be readily redispersable in organic solvents and are termed organosols.

Nanostructured metal colloids Isolable metal particles in the range of 1–50 nm that are prevented from agglomeration by protecting shells.

Precursor method A very efficient method for the preparation of active catalyst on a support in an *egg-shell* form via their precursor. The protected colloidal metal is loaded onto a support and the protecting shell is subsequently leached. Uniform coating of the metal catalyst on the support prevents its agglomeration.

Reductive stabilization A process in which the reductant is used in combination with the stabilizing agent. Protective shells for the reduced metals are formed immediately at the reduction centre in high local concentration and prevent their aggregation.

Chemically Prepared Magnetic Nanoparticles

M. A. Willard, L. K. Kurihara, E. E. Carpenter, S. Calvin, V. G. Harris

Naval Research Laboratory, Washington, DC, USA

CONTENTS

1. INTRODUCTION

Interest in nanoparticle science and technology in the United States and abroad has experienced resurgence over the last 10 years largely spurred by the Presidential Nanoscience Initiative that was sponsored by both the Clinton and Bush administrations and their increased utility in a broad range of application.

Nanoparticles are typically defined as being less than 100 nm in all three dimensions. More often, they are particles made to be spherical having diameters on the order of 10 nm or less. At these length scales, a large fraction of the particle's atoms are at or near the surface providing them with unique properties. In the case of magnetic nanoparticles, crystal symmetry breaking at the surface has profound ramifications. For example, in metallic alloys the surface atoms oxidize quickly, forming oxides that are typically ferrimagnetic or in some cases antiferromagnetic. If the metallic alloy is not prone to oxidation, then there typically exists a magnetic "dead" layer at the surface of the particle. Atoms in the dead layer do not have enough magnetic neighbors in their first and second coordination sphere to support long-range ferromagnetism. Alternatively, the surfaces of magnetic oxide particles often experience bond bending through surface relaxation. The magnetism in oxide systems stems from double-exchange and/or superexchange interactions, both of which are very sensitive to the bond angles that form between cation-anion-cation arrangements. Surface bond-bending in these cases leads to profound changes in the magnetic interactions, in some instances changing its behavior from ferromagnetism to antiferromagnetism or to a spin glass-like behavior. This surface relaxation has been linked to surface spin canting and spin disorder [1] which cause anomalously large magnetic anisotropy that requires very large fields to attain magnetic saturation.

In order to design magnetic nanoparticles for specific applications, one is challenged by the need to understand the atomic structure of the particle, surface structure, and its magnetic structure or spin dynamics. Specifically, for metallic nanoparticles, this includes understanding atomic symmetry and chemistry of the interior atoms and surface atoms, as well as the dynamics of both interior and surface spins. In addition, for the case of oxide nanoparticles, the surface energy and synthesis methodology may also lead to the stabilization of defects. All of these issues become more difficult to ascertain as the particle diameter is reduced, whereupon traditional characterization tools like X-ray diffraction and electron microscopy have only limited utility.

The goal of the present work is to provide a broad review of magnetic nanoparticle research that has been carried out during the past decade. We focus on chemical synthesis methods for producing magnetic nanoparticles, methods of effectively characterizing said particles, and finally a review of the magnetic nature of these nanoparticles.

2. APPLICATIONS

Magnetic nanoparticles have a wide range of uses in many diverse applications. These applications make use of magnetic nanoparticles in a variety of forms; for example, in solution as ferrofluids for audio speakers; as surface functionalized particles for biosensing applications [2]; as particle arrays in magnetic storage media [3]; as powder compacts for power generation, conditioning and conversion; in medical applications including magnetic-targeted drug delivery, contrasting agents in magnetic resonance imaging, and alternatives to radioactive materials as tracers.

2.1. Ferrofluids

A ferrofluid consists of surfactant-coated magnetic nanoparticles in a liquid host that forms a stable colloidal suspension. A typical ferrofluid has only 5 volume percent of magnetic particles, 10 volume percent surfactant, and the balance is the carrier liquid. The particles are coated with a surfactant that disperses the particles and prevents agglomeration by overcoming the local magnetic fields and van der Waals forces that exist between particles. As a result, when the ferrofluid is not in the presence of an external magnetic field it has no net magnetization. However, when a magnetic field is applied to the solution, the particles spontaneously orient with respect to and along the magnetic flux lines. When the field is removed, the particles again disperse randomizing their orientation and establishing a state of no net magnetization. Since the ferrofluid is sensitive to external fields, the particles can be positioned and controlled by fields with the forces holding the particles in place proportional to the applied field strength and the magnetization of the particles. These unique properties make ferrofluids useful in seals, bearings, dampers, stepping motors, loudspeakers, and sensors [4].

2.2. Magnetic Recording Media

It has recently been shown that surfactant-coated magnetic nanoparticles can self-assemble into periodic arrays. The equal spacing of the particles allow them to be considered for next generation magnetic storage materials as individually addressable bits. One example of this new material is the array of FePt nanoparticles created by researchers at IBM [3]. In this case, FePt monodispersed nanoparticles were processed by reduction of platinum acetylacetonate and decomposition of iron pentacarbonyl in the presence of oleic acid and oleyl amine stabilizers. The particles self-assemble into a disordered FCC particle lattice, whereas a heat treatment provides a chemically ordered tetragonal lattice of particles. The crucial properties for media applications is that the particles be monodispersed with a very tight size distribution of <10% and a high magnetocrystalline anisotropy. IBM is considering this form of media that may hold 100 times more data that today's products [5].

2.3. Power Generation, Conversion, and Conditioning

High frequency (*i.e.*, $f > 1MHz$) electronic components, including switch mode power supplies, filters for power conditioning, and power converters, typically use ferrite cores. Ferrites are desirable since they are insulating magnetic oxides with high electrical resistance that minimizes conduction-related losses. These cores are made by compaction of ferrite particles. Typically, these particles have diameters on the order of microns and are processed using chemical reduction methods followed by mixing, firing, compaction, and sintering. Recently, nanoparticle ferrites have been considered for these applications. Benefits of using nanoparticles include lower heat treatment temperatures, fewer processing steps, and in some instances, improved performance. Difficulties in the use of nanoparticle ferrites include understanding cation disorder and the role of processing and surfaces. In addition, the compaction of nanoparticles to near their theoretical densities is very difficult and remains one of the major obstacles that are limiting the wide scale acceptance of nanoparticle ferrites.

2.4. Targeted Drug Delivery

It is well known that chemotherapy is an effective treatment to fight cancer cells, but since it is delivered as a full body dose, the side effects of its toxicity are often severe and devastating to the patient. One proposed use of magnetic nanoparticles that is particularly exciting is for targeted drug delivery. In this application, the magnetic particle is coated with activated carbon and serves to deliver pharmaceuticals to specific sites. In practice, the administered drug is absorbed to the particle and is localized to a specific site in the body by an external magnet field. The physical force created by the external magnetic field acts to transport the particles through the vascular wall, thus positioning and retaining the drugs in close proximity to the cancer cells. This allows for more concentrated doses of the anti-cancer drugs to be delivered to the cancer and keep them on site for longer periods of time. This targeted drug therapy was in phase I and II trials as of June 2000 [6].

Magnetic nanoparticle for targeted drug delivery must be tailor-made for *in vivo* applications. In order to prevent dangerous agglomeration of the particles in the blood stream, the particles must be of a small size relative to dimensions of the capillaries, spherical in shape, and have a size distribution (*i.e.*, standard deviation) or less than 15%. In addition, the particles must have a high magnetic moment and switch their magnetization quickly and at low fields [7].

In this chapter, we discuss the chemical synthesis methods that are used in processing monodispersed magnetic nanoparticles (Section 3), characterization tools that allow one to determine the structure and phase of the nanoparticles (Section 4), and finally the magnetic nature of fine particles (Section 5). We limit our scope to 1990 to the present and make reference to other reviews predating this period where appropriate.

3. CHEMICAL SYNTHESES

Three approaches are most often used to produce magnetic nanoparticles. These include physical vapor deposition, mechanical attrition, and chemical routes from solution. In both the vapor phase and solution routes, the particles are assembled from individual atoms to form nanoparticles. Alternatively, mechanical attrition involves the fracturing of larger coarse-grained materials to form nanostructures.

In this section, an overview of the chemical synthesis and processing of nanostructured particles is presented. Chemical routes often provide the best method for production of nanoparticles. Solution chemistry techniques offer the advantages of enhanced homogeneity due to molecular level design of the materials and, in many cases, cost-effective bulk quantity production. Solution chemical routes also allow control of particle size and size distribution, morphology, and agglomerate size through the manipulation of the

parameters that determine nucleation, growth, and coalescence. Surface modification of the particles during synthesis or post-synthesis is easily accomplished, providing additional functionality to the nanoparticles.

The synthesis of particles in a solution occurs by chemical reactions forming stable nuclei with subsequent particle growth. This phenomenon of precipitation of solids in solution has been well-studied [8, 9]. Upon the addition of precipitating, reducing, or oxidizing reagents to the solution containing the reactants, chemical reactions occur and the solution becomes supersaturated. Supersaturation drives the chemical system far past the minimum free-energy configuration for the precipitating species in solution. The thermodynamically equilibrated state is restored by condensation of nuclei of the reaction product.

Kinetic factors control the dynamics of approach to the thermodynamic equilibrium of the system in the growth process [10, 11]. These factors include reaction rates, transport rates of reactants, removal and redistribution of matter. The reaction and transport rates are affected by the temperature, pH, and mixing of the solution, as well as the concentration of reactants and the order in which the reagents are added to the solution. Reaction rates and impurities can influence the structure and crystallinity of the particle. The particle morphology is influenced by factors such as supersaturation, colloidal stability, nucleation and growth rates, recrystallization, and aging times. Generally, supersaturation has a dominant role in determining the morphology of precipitates. At low supersaturation, the particles are small with shape depending on crystal structure, composition, and surface energies. As the level of supersaturation is increased, larger, dendritic particles form. Finally, at high supersaturation levels, smaller but compacted, agglomerated particles form [10].

In a supersaturated solution when the nuclei form at nearly the same time, subsequent growth of these nuclei results in formation of particles with a very narrow size distribution [12]. This narrow size distribution can be maintained as long as agglomeration, Ostwald ripening, and secondary nucleation do not occur. The growth in solution is interface-controlled when the particle is small; after reaching a critical size, it becomes diffusion-controlled [12]. The formation of stable colloids and dispersion of agglomerated particles have been extensively investigated [13].

As a result of attractive van der Waals force, and the tendency of the system to minimize the total surface or interfacial energy, nanostructured particles often form agglomerates. Agglomeration of particles can occur during any of the following stages: synthesis, drying, handling, and/or post processing. For applications where dispersed particles or stabilized dispersions are required, agglomeration must be prevented at each processing step. To produce monodispersed particles without agglomeration, surfactants can be used to control the dispersion during chemical synthesis. Surfactants can also be used to disperse as-synthesized agglomerated fine particles.

A surfactant (an acronym for "surface-active agent") is any substance that affects the surface or interfacial tension of the medium in which it is dissolved. As such, surfactants need not be completely soluble and may decrease or

increase surface tension by spreading over a surface or interface. Surfactants are used during nanoparticle synthesis in order to reduce interparticle interaction through an increase in repulsive forces. Surfactants are used to control particle size and distribution in most chemical synthesis routes.

In the following section, selected examples of various chemical routes used to prepare magnetic nanoparticles are given, highlighting some aspects of each route. Figure 1 gives an extensive overview of the types of nanoparticles that have been prepared using these methods.

3.1. Precipitation

One of the oldest techniques for the synthesis of nanoparticles is the precipitation of products from bulk solutions. In precipitation reactions, the metal precursors are dissolved in a common solvent (such as water) and a precipitating agent is added to form an insoluble solid. In most cases, a further reduction step is required, either in solution after synthesis (such as borohydride reduction) or to the collected precipitate (*i.e.*, heat treatment in hydrogen gas). Many magnetic nanoparticles can be synthesized using these classical aqueous precipitation reactions to yield nanoparticles that have broad size distribution and irregular morphology. These reactions can generate a wide range of magnetic materials including spinel ferrites, perovskites, metals, and alloys.

The major advantage of precipitation reactions is that large quantities of particles can be synthesized. However, it is difficult to tailor the particle size as only kinetic factors are available to control growth. Chelating agents (or ligands

Figure 1. Transmission electron micrographs (TEMs) depicting antiferromagnetic KMnF$_3$ nanoparticles synthesized by reverse micelle reactions. (a) Polyhedral 13 nm average particle size synthesized by quenching the reaction after a short reaction time; (b) Spherical 39 nm particles formed after reacting for two hours [405, 406].

with multiple binding sites) may be used to help control the particle size, decomposing as the precursor is heated. The chelate-modified precipitation yields magnetic nanoparticles that often have very well-defined crystallinity but lack controlled morphologies. This method is used in precipitation of many ferrites such as barium and strontium hexaferrite.

The size and morphology of precipitated nanoparticles can be tailored with limited success through the tight control of synthesis parameters such as pH, metal cation concentration, and the type of the precipitating agent. These parameters allow for the formation of nanoparticles that have a large size distribution (greater than 30%) [14] and are roughly spherical. The concentration of the metal species present in the initial reaction mixture has the largest effect on the overall nanoparticle size [15]. Unfortunately, low concentrations result in limited particle growth, although the resultant particles are generally more uniform in size. As the metal concentration is increased, there is increased particle growth with a subsequent loss of size uniformity. The precipitating agent has a pronounced effect not only on the overall particle size but also on the phase purity of the particle formed. This is especially true in the case of mixed metal spinels. Numerous precipitating agents have been employed in the past including, citric acid [16–18], and oxalic acid [19]. In each case, there is a chelating effect that helps to facilitate complete precipitation. The precipitating agent is then evaporated through subsequent heating cycles. However, subjecting the metal solutions to alkaline media facilitates the precipitation of metal hydroxides that result in a product with less agglomeration.

The first controlled synthesis of magnetic nanoparticles utilizing this alkaline precipitation technique was performed by Massart [14]. In this synthesis, Fe_3O_4 nanoparticles were precipitated from $FeCl_3$ and $FeCl_2$ at a slightly basic pH of 8.2. These particles were roughly spherical, 10 nm in diameter with greater than 50% size distribution. Through size selection titration, the size distribution can be reduced to less than 5% [20]. Size selection titration is a technique that disperses nanoparticles in a solvent to form a stable colloidal suspension. The solution is then titrated with an electrolyte solution or a nonsolvent that disrupts the stable colloid causing larger nanoparticles to precipitate out, leaving the particles suspended in the supernatant nearly monodispersed. Temperature reduction has the same result. The precipitate can be collected using centrifugation or filtration. This can reduce the size distribution to less than 5%, generating a monodispersed colloidal solution [21]. Massart later expanded the synthesis of alkaline precipitation to include mixed ferrites (MFe_2O_4, where M = Co [22–24], Mn [22, 23], MnZn [25], and NiZn [26]). These mixed ferrites result in additional difficulties due to the varying solubilities of the metal hydroxides. In the case of $(Mn,Zn)Fe_2O_4$, $Fe(OH)_3$ starts to precipitate early at pH 2.6, while $Mn(OH)_2$ precipitates at a much higher pH of 9.4. Zn^{2+} is amphoteric and precipitates as $Zn(OH)_2$ at pH 7.6 but starts to redissolve at pH 9 forming $Zn(OH)_4^{2-}$ [27]. Therefore, to create a uniform metal precipitate, the pH must be carefully controlled at a pH of 8.6. The synthesis is further complicated by the propensity of Fe to oxidize, forming the γ-Fe_2O_3. The Fe^{3+} cation undergoes oxidation at pH >9, producing this common impurity phase resulting in poor magnetic properties.

Titration of the metal by the base increases pH to the target value more slowly than does a titration of the base by the metal. A slow titration tends to cause additional problems due to inhomogenity. As the pH is slowly increased, the Fe^{3+} will be precipitated first and nearly completely before the Zn and finally the Mn. This results in a central core, which oxidizes to form γ-Fe_2O_3, coated by a shell of iron-deficient ferrite.

3.2. Borohydride Reduction

The reduction of metal salts using sodium borohydride can form very uniform spherical nanoparticles. Although the chemistry of the reduction can be very complex, the reduction of iron [28], cobalt [29], and nickel [30] have been explained in detail by Glave et al. Although boride formation is a side reaction, it can be eliminated with careful control of atmosphere and water content in the reaction. For this reason, the reactions are typically carried out in nonaqueous media (dimethylglyoxime, tetrahydrofuran, etc.) to obtain a pure phase material. Mixing metal salts to form one reaction before reduction can form alloys [31–33]. FeNiCu (Cu-Invar) is one example presented by Stolk and Manthiram [34]. In this case, the particles reduced by borohydride are spherical, 10–20 nm in diameter, and of predominantly Invar phase with some impurities of Cu_2O and $Fe(BO_2)_2$ present. This material can be heated where it undergoes a conversion to pure phase Cu-Invar, but the particle size increases to 200 nm.

3.3. Hydrothermal

Hydrothermal reactions are aqueous reactions carried out using autoclaves or high-pressure reactors where the pressure can be over 2000 psi at temperatures over 200 °C. At these supercritical conditions, water acts as a reactant, accelerating the kinetics of the hydrolysis reactions. At increased temperatures, the solubility of most ionic species increases and, with the lower viscosity of water, exhibits greater mobility. The increase mobility allows Ostwald ripening to continue at a faster rate increasing the uniformity of the precipitates.

Size and morphological control in hydrothermal reactions is achieved by controlling the conditions of time and temperature. The reactant conditions of precursor material and pH have an impact on phase purity of the nanoparticles. There are two main routes for the formation of ferrites via hydrothermal conditions: hydrolysis and oxidation, and neutralization of mixed metal hydroxides. Some lesser routes involve the hydrothermal treatment of mixed metal oxides [35, 36], or the use of other solvents such as ethylene glycol at supercritical conditions [37, 38]. Hydrolysis and oxidation reactions are very similar to neutralization reactions, except ferrous salts are used instead of ferric salts.

Rozman and Drofenik [39] gave a detailed account of the synthesis of MnZn ferrite nanoparticles using neutralization of the mixed metal hydroxides. The hydrothermal parameters of temperature and time were the first variables tested with 11 nm nanoparticles synthesized at both 95 °C for 50 h and 140 °C for 0.5 h. The shorter reaction time resulted in a nanoparticle surface with a greater amount

of hydroxide groups, while reduced temperatures allowed additional water to be incorporated in the crystal structure which caused increased lattice distortions. Differential thermal analysis showed that the water is actually incorporated into the lattice with final dehydration at temperatures in excess of 700 °C. This distortion and poor surface quality deteriorates magnetic properties. Rozman also noted that the spinel phase starts to crystallize at 90 °C and continues through to 200 °C. At temperatures greater than 200 °C, the spinel phase can recrystallize as γ-Fe_2O_3. The nanoparticle grains grow via Ostwald ripening to a maximum value. Longer times under hydrothermal conditions result in improved crystallinity but not larger grains.

Strontium [40] and barium [41] hexaferrites are more difficult to form due to the less thermodynamically favored magnetoplumbite structure. Initial reactants have a greater impact on the final size, morphology, and phase of the hexaferrites than in other mixed metal ferrites. As with other ferrite preparations, temperature and reaction time influence size, as does the ratio of Fe/Ba. The choice of precipitating reagent has a pronounced effect on nanoparticle crystallinity. The larger the spectator ion of the precipitating agent, the poorer the crystallinity. This phenomenon is presumably due to a change in the electrostatic potential of the metal hydroxides. The lower the electrostatic potential of the metal solution, the greater the likelihood that the metal sols coagulate. This coagulation tends to facilitate the formation of γ-Fe_2O_3 [42]. Since coagulation favors side reactions, stirring is often used. Stirring the hydrothermal solution has resulted in improved nanoparticle uniformity and phase purity.

3.4. Micelle Routes

Surfactant molecules may spontaneously form spherical aggregates called micelles or microemulsions. The difference between microemulsions and micelles is more than simple semantics, although recently, these terms have been used interchangeably. The difference lies in the size of the aggregate, with micelles being 1 to 10 nm in diameter, while microemulsions contain aggregates that are 10 to 100 nm in diameter [43].

Direct micelles have the hydrophilic portion of the surfactant on the outside of the aggregate, while reverse or inverse micelles have the hydrophobic portion on the outside. Micelles can form in the presence or absence of water. In the case of reverse micelles formed in hydrocarbon, water can be readily solubilized forming a "water pool," where size is characterized by a water-to-surfactant ratio. In this fashion, the water pools within micelles impose kinetic and thermodynamic constraints on particle formation resulting in restricted "nano-reactors".

Aerosol OT or AOT (sodium dioctylsulfosuccinate) was the first and most characterized surfactant system used in the synthesis of magnetic nanoparticles [44, 45]. Other systems, such as cetyltrimethylammonium bromide (CTAB) [46], sodium dodecylsulfate (SDS) [47], and polyethoxylates (Igepal, Brij, Tween, $C_{12}E_5$) [48] have been used, and more are being developed to optimize morphology and chemical parameters. Many of the reactions carried out in micelles are very similar to those performed in bulk aqueous reactions but with the added morphological controls afforded by the surfactant system.

The first magnetic nanoparticles formed in micelles were from the oxidation of Fe^{2+} salts to form Fe_3O_4 and γ-Fe_2O_3 [49]. This reaction was carried out in an AOT/isooctane system and formed spherical nanoparticles with surprisingly tight size distributions of less than 10%. Later, other reactions, using hydrogen peroxide, were used to form $MnFe_2O_4$. The initial reaction conditions not only controlled the particle size, but also the cation occupancy [50].

An interesting phenomenon seen with iron reductions is the influence of the surfactant on the iron crystal structure. If anionic surfactants (such as AOT) are used α-Fe is formed with the expected body-centered cubic (BCC) crystal structure [51]. Conversely, if a nonionic surfactant is used (for instance, nonyl phenol polyethoxylate), a face-centered cubic (FCC) crystal structure forms [52]. The process for the formation of metals can be expanded to form metal alloys. Instead of using a single metal salt, mixed metal salts are used and reduced simultaneously [53]. It is essential that the reduction is carried out simultaneously or mixed phase products will be formed.

The precipitation of precursors that are subsequently fired to produce the end product is an important synthetic process. This has been used in the synthesis of many different ferrite materials: $(Mn,Zn)Fe_2O_4$, $(Ni,Zn)Fe_2O_4$, $ZnFe_2O_4$ [54], and $BaFe_{12}O_{19}$ [55]. In these cases, the particles were formed with sizes between 5 and 50 nm. The particles had spheroidal morphology with typical size variations of 10%, although higher conversion temperatures generally widen the size distribution to 10–20%.

Transmission electron microscopy (TEM) images of antiferromagnetic $KMnF_3$ nanoparticles synthesized using reverse micelles are shown in Figure 1. The reaction time of the metathesis reaction controlled the morphology and size of the particles for this reaction. Particles synthesized by quenching the reaction after short reaction times developed polyhedral morphology and 13 nm average particle size (Fig. 1a). Similar reactions carried out for 2 h resulted in particles with spherical morphology and 39 nm average grain diameters (Fig. 1b) [405, 406].

Although there are many examples of inverse micelles used as micro-reactors, there are only a few examples of the use of direct micelles. Sodium dodecylsulfate is the principle surfactant used in these reactions due to the morphology of the aggregate. The most striking example of direct micelle synthesis was presented by Liu et al. with the synthesis of $CoFe_2O_4$ [56]. In this example, Liu et al. created a chemometric model for predicting the size of a ferrite from the synthesis conditions of surfactant concentration, metal concentration, base concentration, and temperature. The synthesis was later expanded to include the mixed ferrites of $MnFe_2O_4$ and $MgFe_2O_4$ [57].

In order to control side reactions and precipitation common to aqueous systems, micelles are formed using alcohol as the polar phase. Fang et al. [58] utilized ethanol-based micelles to form $SrFe_{12}O_{19}$. In this case, $Sr(OH)_2$ has such a high solubility in water that inhomogeneous and Sr-deficient precipitates are formed. Although the particles formed

display a large size distribution, they also display a plate-like morphology with an average particle size of 100 nm.

Heating causes an increase in crystallinity, which in turn greatly affects the magnetic and electronic properties [59]. The heat treatment, however, can be carried too far resulting in increased grain growth. Excessive grain growth adversely affects the magnetic and electronic properties (*e.g.*, magnetic domain formation). Microwave heating typically increases crystallinity with significant grain growth. The annealing temperature at which significant grain growth occurs has been shown to be half the melting point of the material [60]. It is important to note that nanoparticles generally possess reduced melting temperatures, primarily due to the large surface-to-volume ratio.

3.5. Thermolysis, Photolysis, and Sonolysis Methods

One of the simplest methods to prepare nanoparticles is the decomposition of organometallic precursors. This decomposition may be driven by heat (thermolysis), light (photolysis), or sound (sonolysis). Advantages of using organometallic compounds are that precursors can be decomposed at relatively low temperatures to form the final product. By controlling the decomposition temperature, the growth of the nanoparticles can be controlled. Since size and morphology have an effect on the properties of the nanoparticles, control of these properties is a primary goal. In many cases, polymers, organic capping agents, or structural hosts are used to limit the size of the nanoparticle growth [61–72]. If these restraints interact with the particle surface, then the magnetic properties may be altered. Polymers and capping agents are generally used to stearically protect the particles so that they do not coalesce. The biggest disadvantage of this approach is that most of the reactions involve air-sensitive reactants as well as the final precursor; therefore, glove box or schlenck line techniques must be used. Because of the air-sensitive nature of some of reactants, greater care must also be taken in preparation of solvents and the choice of atmospheres used. The particles synthesized are often agglomerated and have a large size distribution ($<15\%$), and if they are stabilized with surfactants or other organics to prevent agglomeration, they can interact with the surface, changing the magnetic properties. It has been shown that the magnetic properties of nickel are effected by the presence of surface moieties [72–74].

There has been a renewed interest in the synthesis of magnetic nanoclusters with unique properties such as enhanced magnetization [75]. One polymer—polyvinylpyrrolidone (PVP)—has been shown to interact minimally with the surface of Co [61, 62]. It is suggested that the polymer matrix determines the cluster size and efficiently protects the particles. Cobalt nanoclusters were prepared by reduction of organometallic compounds of $Co(\eta^3\text{-}C_8H_{13})(\eta^4\text{-}C_8H_{12})$ in hydrogen and in the presence of PVP [61]. Dried colloids were noninteracting, superparamagnetic particles with enhanced magnetization relative to that of the bulk. By varying the decomposition temperature, the size of particles could be controlled. Organometallic precursors were also used to prepare other colloidal metal with a variation of size and structure.

In most cases, when carbonyls are decomposed in the presence of stabilizing polymers, spherical nanoparticles are formed. However, Dinega and Puntes et al. have shown that Co nanorods could be prepared by modifying the thermal decomposition of cobalt carbonyl in the presence of oleic acid and trioctylphospheneoxide (TOPO) [63–65]. They rapidly injected the organometallic precursor into a hot surfactant mixture. This rapid injection of the precursor allowed for a "size distribution focusing" [64–65] by separating nucleation from growth. The decomposition of the precursor and nucleation occurs immediately upon injection and metal nuclei are coated with the coordinating ligands. When a surfactant mixture is used, such as oleic acid and TOPO, and quenched shortly after injection, nanoparticles (4 nm $\times$ 25 nm) of hcp Co are formed. This indicates that the surfactants absorb to different crystal faces with different strengths [64, 65]. If the reaction is allowed to proceed, the rods transform to monodispersed spherical ε-Co nanoparticles. This ε-Co crystal structure has been reported for Co nanoparticles prepared by a variety of solution techniques [63–66].

When the organometallic precursor, nickel bis-cycloocta-1,5-diene ($Ni(COD)_2$) undergoes thermolysis in the presence of hexadecylamine (HAD) or TOPO, nanorods, spheres, or tear-shaped nanorods are formed, the shape being related to the concentration of the organic species [76]. Varying the organic stabilizing agents used could result in other shapes. Bracelet arrays of 27 nm Co are formed in the presence of resorcinarene tetraphosphonate [77] and tetrahedral structures [78] are found when cobalt nanoclusters are reacted with NaAOT/toluene at 130 °C.

CoPt alloys and Co with a Pt shell have been prepared using transmetallation and CO decomposition [79]. Alloys are prepared by the addition of $Co_2(CO)_8$ to a hot solution of an organic solvent containing a platinum organometallic compound and oleic acid. As the carbonyl decomposes to form Co nuclei, it also undergoes a transmetallation reaction with the platinum organometallic compound. To prepare a core/shell material, cobalt colloids are first formed by the decomposition of the carbonyl and then they are refluxed with the platinum organometallic compound with dodecane isocyanide as a stabilizer. The decomposition process may also be applied to form magnetic oxides [80]. This can be done by either oxidizing the metal particles or through an oxidative decomposition. In the first case, an iron oleate precursor is formed from the decomposition of iron carbonyl in the presence of octyl ether and oleic acid at 100 °C. This solution is cooled to room temperature and the mild oxidizing agent, $(CH_3)_3NO$, is added and the solution refluxed. This results in 11 nm Fe_2O_3 particles that will also form a two-dimensional hexagonal, close-packed lattice. When the solution is refluxed, the iron oleate complex breaks down and iron particles are formed and then oxidized by $(CH_3)_3NO$. Changing the amount of reactants could vary the particle size and adding already prepared 11 nm nanoparticles into a fresh solution and reheating could form larger particles. Oxidative decomposition occurs when the oxidizing agent and surfactant are added to the original solution. If a bimetallic organometallic precursor is used, such as $(\eta^5\text{-}C_5H_5)CoFe_2(CO)_9$, $CoFe_2O_4$ nanoparticles with sizes of 4–9 nm are formed [81].

In sonolysis or sonochemistry, ultrasound or acoustic waves are used to decompose the organometallic precursors. The formation, growth, and collapse of bubbles in a liquid drive high-energy, sonochemical reactions, without any molecular coupling of the ultrasound with the chemical species. This acoustic cavitation involves a localized hot spot of temperature of about 5000 K, a pressure of $\sim$1800 atm and a subsequent cooling rate of about 10^9 K/sec, due to implosive collapse of a bubble in the liquid [82–92]. Generally, volatile precursors in low vapor pressure solvents are used to optimize the yield. Ultrasonic irradiation is carried out with an ultrasound probe, such as a titanium horn operating at 20 kHz.

Nanostructured particles are easily produced by sonochemically treating volatile organometallic precursors [82–100]. The powders formed are usually amorphous, agglomerated, and porous. To get the crystalline phases, these powders must be further annealed; however, this annealing temperature is lower than that needed to do the solid state conversion.

When organic solvents with high boiling points are used for sonolysis, highly porous amorphous powders are formed. For example, an amorphous iron powder was produced by the sonocation of iron carbonyl in decalin [82–84]. This powder was comprised of small crystallites (5 Å) and had a surface area of 120 $m^2 g^{-1}$. Annealing this powder at 350 °C under nitrogen resulted in α-Fe that was 50 nm in diameter. FeCo [85, 86], FeNi [87], and CoNi [93] alloys have been prepared by this method. The as-synthesized powders are amorphous. Annealing these powders in argon at 450 °C for 5 h yields crystalline material. The FeCo is comprised of BCC Fe and a mixture of FCC and cobalt. The (Fe,Ni) and (Co,Ni) alloys possess a single set of FCC peaks.

If stabilizers or polymers are added postsonication or during sonication, then metal colloids result [84, 85, 88, 94]. These stabilizers could be alkyl thiols [86, 89, 94], PVP [84], oleic acid [84], octadecyltrichlorosilane (OTS) [94], sodium dodecylsulfate (SDS) [71]. Gedanken et al. [87, 88, 95] have also used sonochemical routes to prepare nanoparticles of Fe, Fe_3O_4, Fe_2O_3, cobalt ferrite and copper ferrite. If the sonication is done in the presence of oxygen, then oxides are formed [95, 96]. In the case of Fe_2O_3, when the coating solution was present during sonolysis, amorphous powder resulted that was then converted to γ-Fe_2O_3 upon annealing at 300 °C for 3 h under an argon atmosphere. If the powder is first converted to γ-Fe_2O_3, the OTS does not coat the powder. In general, nanoparticles with dimensions less than 10 nm will self-assemble to the lowest thermodynamically stable form. By pressing the nanoparticle solution on a substrate or interface, careful removal of the solvent will result in self-assembled monolayers (SAMs). The size of the SAM-coated nanoparticles is determined by the surfactant concentration in the coating solution. Oxide formation (Fe_3O_4, Co_3O_4) was also seen if the sonication was done in aqueous conditions and with noncarbonyl precursors; however, the resulting powders are crystalline [96–99].

If the sonolysis is done in the presence of a support or porous host, then colloidal metal particles are formed. These powders have a surface area, over 100 times greater than powders commercially available. For example, 3–8 nm amorphous iron particles on silica support were synthesized at 20 °C from iron pentacarbonyl ($Fe(CO)_5$), decane, and silica gel [85]. These materials are generally considered for catalytic reactions and not for magnetic applications.

3.6. Sol–Gel Methods

Sol–gel processing can be used to prepare a variety of materials, including glass, powders, films, fibers, and monoliths. Traditionally, the sol–gel process generally involves hydrolysis and condensation of a metal alkoxides. Metal alkoxides are good precursors because they readily undergo hydrolysis; that is, the hydrolysis step replaces an alkoxide with a hydroxide group from water and free alcohol is formed. Once hydrolysis has occurred, the sol can react further and condensation (polymerization) occurs.

Factors that need to be considered in a sol–gel process are solvent, temperature, precursors, catalysts, pH, additives, and mechanical agitation. These factors can influence the kinetics, growth reactions, and hydrolysis and condensation reactions [101]. The solvent influences the kinetics and conformation of the precursors, and the pH affects the hydrolysis and condensation reactions. Acidic conditions favor hydrolysis, which means that fully or nearly full hydrolyzed species are formed before condensation begins. Under acidic conditions, there is a low cross-link density that yields a denser final product when the gel collapses. Basic conditions favor condensation reactions; therefore, condensation begins before hydrolysis is complete. The pH also affects the isoelectric point and the stability of the sol. These, in turn, affect the aggregation and particle size. By varying the factors that influence the reaction rates of hydrolysis and condensation, the structure and properties of the gel can be tailored. Because these reactions are done at room temperature, further heat treatments need to be done to get to the final crystalline state. Because the as-synthesized particles are amorphous or metastable, annealing and sintering can be done at lower temperatures rather than at conventional solid-state reactions.

Sol–gel routes can be used to prepare pure, stoichiometric, dense, equiaxed, and monodispersed particles of TiO_2 and SiO_2 [101]. But this control has not been extended to the metal ferrites. Generally, the particles produced are agglomerated. Ultrafine powders of $CoFe_2O_4$ ($\sim$30 nm) [102] and $NiFe_2O_4$ (5–30 nm) [103] after being fired at 450 °C and 400 °C, respectively. Most of the ferrite sol–gel synthesis focus has been on cobalt ferrite doping studies with Mn [104], Cr [105], Bi [106], Y, La [107], Gd, Nd [108], and Zn [109].

Sol–gel routes have been attractive for the preparation of hexagonal ferrites. For example, the M-type hexagonal ferrite, $Ba_{1-x}Sr_xFe_{12}O_{19}$, formed 80–85 nm hexagonal platelets after a 950 °C calcination for 6 h [110]. Nanospheres of the W-type ferrite, $BaZn_{2-x}Co_xFe_{16}O_{27}$, resulted after calcination in air for 4 h at 650 °C [111]. The particle size ranged from 10 nm to 500 nm (650 °C–1250 °C) and increased with increasing calcination temperatures. U-type hexagonal ferrite was also prepared, with 10–25 nm spherical particles formed at 750 °C [112]. The grain size could be changed by increasing the calcination temperature. These calcined powders had an amorphous layer on them. Yttrium iron garnets with particle sizes from 45–450 nm have also been prepared

[113]. Mathur and Shen [114] have prepared the manganite perovskite, $La_{0.67}Ca_{0.33}MnO_3$, by dissolving the metal precursors in an acidic ethanolic solution. Drying the solution at 120 °C and calcining at 300–400 °C leads to preceramic foam, which forms nanocrystalline $La_{0.67}Ca_{0.33}MnO_3$ (40 nm) after a heat treatment at 650 °C.

It should be noted that the sol–gel process is particularly attractive for the synthesis of multicomponent particles with binary or ternary compositions, using double alkoxides (two metals in one molecule) or mixed alkoxides (with mixed metaloxane bonds between two metals). Atomic homogeneity is not easily achieved by coprecipitating colloidal hydroxides from a mixture of salt solutions, since it is difficult to construct double metaloxane bonds from metal salt [101].

Hybrid materials such as metal oxide-organic nanocomposites can be prepared using the sol–gel approach. For example, controlled nanoheterogeneity can be achieved in metal/ceramic nanocomposites [101]. Reduction of metal oxide particles in hydrogen provided the metal-ceramic nanocomposite powders such as Fe in silica [115], Fe_2O_3 [116], and $NiFe_2O_4$ [117]. The metal particles, a few nanometers in size with a very narrow size distribution even for high metal loading, were statistically distributed in the oxide matrix without any agglomeration, as a result of anchoring the metal complexes to the oxide matrix. The narrow particle size distribution could not be achieved if the sol–gel processing was performed without complexation of metal ions.

3.7. Polyol

The polyol method, in which the polyol acts as a solvent as well as the reducing agent and a surfactant, is a suitable method for preparing nanophase- and micron-size particles with well-defined shapes and controlled particle sizes [118–151]. By this method, precursor compounds such as oxides, nitrates, and acetates are either dissolved or suspended in a diol, such as ethylene glycol or diethylene glycol. The reaction mixture is then heated to reflux between 180 °C and 199 °C. During the reaction, the metal precursors become solubilized in the diol, form an intermediate, and are then reduced to form metal nuclei that will then nucleate and form metal particles. Submicron-sized particles can be synthesized by increasing the reaction temperature or inducing heterogeneous nucleation via adding foreign nuclei or forming foreign nuclei *in-situ*. Nanocrystalline powders such as Fe, Co, Ni, Cu, Ru, Rh, Pd, Ag, Sn, Re, W, Pt, Au, Fe-Cu, Co-Cu, Co-Ni, and Ni-Cu were also synthesized using different salt precursors by this method [118–146]. In many cases, use of nucleating agents to assist formation of nanoparticles was not required. For example, nanostructured powders of Co_xCu_{100-x} ($4 \leq x \leq 49$ at. %) [118, 119] were synthesized by reacting cobalt acetate tetrahydrate and copper acetate hydrate in various proportions in ethylene glycol. The mixtures were refluxed at 180–190 °C for 2 h, the powders precipitated out of solution, and were subsequently collected and dried. Since Cu was more reducible than Co, nucleation of Cu occurred first, and Co subsequently nucleated on Cu crystallites. X-ray diffraction, often conventionally used to study alloy formation, showed some evidence to suggest that metastable alloy could have formed. Diffraction peaks due to FCC Cu were detected in all samples with different

copper concentrations, but Co diffraction peaks were not detected until $x = 19$ atomic percent. To confirm the structure of powders, studies of local atomic environment were performed using extended X-ray absorption fine structure (EXAFS) spectroscopy and solid-state nuclear magnetic resonance (NMR). The results from these investigations and vibrating sample magnetometry (VSM) ruled out the formation of metastable alloys, but confirmed the synthesis of nanocomposites of Co-Cu.

The polyol method has also been shown as a useful preparative technique for the synthesis of nanocrystalline alloys and bimetallic clusters. Fievet et al. have extensively studied the ferromagnetic system of Co-Ni, Fe-Co, Fe-Co-Ni [123–132]. The Co-Ni alloy particles had densities and saturation magnetization close to the bulk values, and showed a shift to higher resonance frequencies as the Co/Ni increased. This was also observed in the Fe-Co-Ni particles that were 50–150 nm in size. An example of the morphology of alloy nanoparticles formed by the polyol technique is shown in Figure 2. The particles depicted by the scanning electron microscope (SEM) image consist of $Fe_{48}Co_{52}$ [143].

Nanocrystalline $Fe_{10}Co_{90}$ powders with a grain size of 20 nm were prepared by reducing iron chloride and cobalt hydroxide in ethylene glycol without nucleating agents [133]. Nickel clusters were prepared using Pt or Pd as nucleation agents [134]. The nucleating agent was added 10 min after the nickel-hydroxide-PVP-ethylene glycol solution began refluxing. The Ni particle size was reduced from about 140 nm to 30 nm when nucleating agent was used. Reduction of particle size was also obtained by decreasing the nickel hydroxide concentration and by the use of PVP. Nickel prepared without nucleating agents had an oxidation temperature of 370 °C. Smaller nickel particles synthesized with nucleating aids oxidized at a lower temperature of 260 °C, as expected from the higher surface area of finer particles. Desorption studies showed the adsorbed surface species were CO moieties and H_2O, and nitrogen-containing species were not observed. This indicated that ethylene glycol, not the polymer, was adsorbed on the surface of particles. The ethylene glycol had only half monolayer coverage. When this protective glycol was completely removed from the surface, oxidation occurred. It was suggested that the Ni-Pd and Ni-Pt particles had a 7–9 nm Pd nucleus and a 6–8 nm Pt

Figure 2. Scanning electron microscope (SEM) image of $Fe_{48}Co_{52}$ nanoparticles prepared by a polyol method [143].

nucleus, respectively. Oxidation studies showed that some alloying of Ni with Pt occurred. Cobalt nickel alloys of 210 to 260 nm particle sizes were also prepared using either Ag or Fe as nucleating agents [135].

Polymer-protected bimetallic clusters were also formed using a modified polyol process [135]. The modification included addition of other solvents and sodium hydroxide. In the synthesis of Co-Ni with average diameters between 150–500 nm, PVP and ethylene glycol were mixed with either cobalt or nickel acetate with PVP. The glycol and organic solvents were removed from the solution by acetone or filtration. The PVP-covered particles were stable in the air for extended periods of time (*i.e.*, months).

Compared to aqueous methods, the polyol approach resulted in the synthesis of metallic nanoparticles protected by surface-adsorbed glycol, thus minimizing the oxidation problem. The use of nonaqueous solvent, such as polyol, also further reduced the problem of hydrolysis of fine metal particles as did often occur in the aqueous case.

By modifying the polyol method with the addition of water to act more like a sol–gel reaction (forced hydrolysis), oxides can be prepared [136–139]. For example, 5.5 nm $CoFe_2O_4$ was prepared by the reaction of ferric chloride and cobalt acetate in 1.2-propanediol with the addition of water and sodium acetate.

Other heating sources for the polyol method have been reported [150–153] besides the conventional heating mantle. An alternative heating source includes a 2.45 GHz microwave gyrotron [150] and millimeter wave beam sources [151]. One technique, the laser-liquid method, uses a laser to heat the solution [152, 153]. This has been used to prepare submicron nickel particles.

3.8. Electrochemical/Electrodeposition

Electrochemical and electrodeposition routes are generally used to prepare nanocrystalline coatings, and are not the focus of this article. However, electrodeposition has been used to prepare wires of magnetic materials [154–164] and recently it has been used to prepare particles [165–173]. In electrodeposition, nucleation occurs by either the formation of new nuclei or the build-up of existing nuclei in solution. These two processes are in competition with each other. Grain growth is favored at low overpotentials and high surface diffusion rates, and nuclei formation is favored at high overpotentials and low diffusion rates. These conditions are experimentally achieved when using pulsed modes. Under pulsed conditions, the peak current density can be considerably higher than the limiting current density attained for the same electrolyte during direct current plating. It has been shown that nanostructured materials will result when the deposition variables (*i.e.*, bath composition, pH, temperature, current density, overpotential, and additives) are chosen so that nucleation is favored with reduced grain growth.

Recently, Penner et al. [165] has done a detailed study and modeling of the parameters that effect this nucleation and growth in electrodeposited nanoparticles and wires. He has tried to follow the LaMer [11] model to explain the formation of electrodeposited nanoparticles (Pt) on graphite electrodes, and found that when instantaneous nucleation and diffusion-controlled growth conditions were satisfied to

produce monodispersed particles, the particles formed were 7.2 nm with a standard deviation of 3.2 nm [174]. It was reasoned that there are two factors causing this particle size broadening. In electrodeposition, the nuclei are distributed on the electrode surface in a "pseudo-random" process. On the terraces, the nucleation process is random, yet while on the step edges, the nucleation process is aligned. The growth step is dependent on the number and proximity of the neighboring nuclei. Penner points out that these interparticle diffusion coupling (IDC) are the most important mechanisms for broadening of randomly nucleated particles. This condition also exists in solutions, but instead of being attached to a surface, the particles in solution collide and react and move on. Experimentally, to overcome IDC, the slow growth method [165, 166, 174, 175] or H_2 coevolution method were used. In the slow growth method, a high overpotential is applied to nucleate the electrode. A second low overpotential pulse is then applied to promote the growth step. Nickel nanoparticles were synthesized using this slow growth method [167]. In H_2 coevolution, convective mixing equalizes the growth rate of the nanoparticles. The formation of gas bubbles and their release and movement through the solution causes convective mixing. By varying the deposition time and potential, nickel nanoparticles from 2–250 nm were synthesized [165, 166].

Another electrochemical method that has been used to prepare nanoparticles involves the use of a sacrificial anode [167–169, 176]. Based on a method developed by Reetz [177], Pascal et al. [169] have prepared 3–8 nm maghemite from a sacrificial iron electrode in an aqueous solution of dimethylformamide (DMF) and cationic surfactants. Adjusting the current density controls the particle size. The as-prepared nanoparticles showed a broad scattering peak by X-ray diffraction consistent with an amorphous phase. Raman and selected area electron diffraction determined the magnetite phase. Hemplemann has used a similar strategy to prepare other metal oxides [167]. This technique is coined electrochemical deposition under oxidizing conditions (EDOCs). Here the anode is oxidized to produce Mn+ species in solution, which are then reduced by electrons generated by the cathode in the presence of stabilizers. These stabilized metal species are then oxidized by oxygen that is bubbled into the system [167]. Electrochemical deposition under oxidizing conditions has been used to prepare nanoparticles Fe_2O_3, Fe_3O_4, Co_3O_4, NiO, and $CoFe_2O_4$ [154]. The difference between Pascal's method and EDOC, is that in EDOC, oxygen is bubbled in, whereas in Pascal's synthesis, oxygen is produced from the electrochemical breakdown of water. Mixed oxides of Sr-Fe oxides [170] and Mn-Zn-Fe oxides [171] have also been prepared using sacrificial electrodes.

Nanowires are easily formed in porous templates by electrodeposition. In precipitation methods and chemical vapor deposition, care must be taken so as not to plug the pores during wire formation. In templated electrodeposition, material growth is from the base and there is not the problem of plugging the pores. This technique has been used to prepare nanowires of Co [155–159, 177], Ni [156–160, 168, 172], FePt [161], FeCo [162], FeNi [154], CoPt [161]. Common templates are polycarbonate [178], anodized alumina [155, 160], and mica [154].

3.9. Multi-Synthesis Processing Methods

The IBM nanoparticle synthesis route [3] is a combination and variation of the polyol method and the Alivisatos thermal decomposition routes [64, 66]. This synthesis involves a high temperature organic- or solution-phase synthesis followed by a size selective separation technique to get relatively monodispersed (<5%) nanoparticles. More specifically, by rapidly injecting the organometallic precursor into a hot solution containing the stabilizing agents, allows for the formation nuclei immediately upon injection. Because the capping agents/surfactants are present, the size and shape of the nanoparticles are controlled. By adjusting the reaction conditions such as time temperature, precursor concentration, and surfactant type and concentration, size and morphology can be controlled.

Sun and Murray et al. [3] have prepared monodispersed FePt nanoparticles and superlattices by the high temperature reduction of platinum acetylacetonate and the thermal decomposition of iron carbonyl in the presence of stabilizing agents. In the case of FePt, both reactions were carried out together in the presence of oleic acid and oleyl amine. The composition was controlled by the ratio of the iron precursor to that of the platinum precursor. The nanoparticles were produced with sizes tunable in the range of 3–10 nm. A colloidal solution of the nanoparticles was prepared by flocculating the particles and redispersing them in a nonpolar solvent. This solution was put on a substrate and the solvent allowed to evaporate. This led to the self-assembly of the nanoparticles. A hcp three-dimensional superlattice was formed by the self-assembly of 6 nm $Fe_{50}Pt_{50}$ with the stabilizers oleic acid and oleyl amine. Changing the alkyl group on the stabilizers can change the interparticle distance. By changing the alkyl group from dodecyl to hexyl leads to a particle spacing of 1 nm, and a superlattice that is cubic close-packed. This hcp to cubic transition was also seen above with ε-Co. The superlattices show no aggregation at temperatures up to 600 °C.

The as-synthesized 4 nm $Fe_{52}Pt_{48}$ had a fcc structure and annealing at 560 °C for 30 min lead to particles with a fct internal structure. Superlattices of these particles exhibit a similar trend. The as-synthesized assembly has a chemically disordered fcc structure and annealing results in the Fe and Pt atom rearranging into the chemically ordered fct structure. The amount of ordering can be controlled by temperature and annealing time. Since the initial paper on FePt synthesis [3] there has been an explosion of research on FePt prepared by this method [179–186] or variations on this method [187, 188] or other magnetic materials (i.e., CoPt [189], FePd [189], and SmCo [178]).

One of the greatest advantages of chemical routes is that they are done in solution. This allows for a great deal of versatility and compatibility. Since many of the chemical routes use similar or the same solvent systems, they may be interchanged for one another or done concurrently. Therefore, combining one or more techniques is relatively simple. Micellar techniques are often used to regulate the size of the nanoparticles in sol–gel synthesis. The versatility also comes from the fact that a broader spectrum of materials can be prepared by combining techniques. And because this is a solution technique, additives, capping agents, functionalities are easily added to the reaction. These additives can be added presynthesis, in-situ, or post-synthesis. It is also possible to prepare nuclei or cores by one technique and injecting them into the solution of a second, and either forming particles or core/shell structures.

4. STRUCTURAL CHARACTERIZATION

The magnetic properties of nanoparticles are determined by their physical structure: the size and shape of the particles, their microstructure, the chemical phase or phases that are present, the defects, and differences between the crystal structure of nanoscale phases and their bulk counterparts. Although individual structural probes are sometimes capable of providing definitive information about some aspect of the particles, in many cases the results of a single probe are ambiguous, inconclusive, or difficult to interpret. This may be true even when the technique is reliable for bulk measurements. Consider, for example, an X-ray diffractogram of nanoparticles believed to consist of a single phase (see Fig. 3). Compared to a bulk standard, the peaks will be broadened. In the case of subnanometer particles, structural relaxation may change the lattice constant measurably. Surface effects, negligible in a bulk crystal, may play a significant role. These effects will result in differences between the nanoparticle diffractogram and the diffractogram of a standard bulk material, reducing the utility of diffraction as a "fingerprinting" technique.

Accordingly, a suite of complementary tools generally determines the physical characteristics of nanoparticles. Self-consistency between these techniques increases the certainty of a given characteristic's accuracy. In some cases, the use of parameters from one technique can be used to refine

Figure 3. Diffraction patterns for a sample of (a) manganese zinc ferrite nanoparticles (12 nm in diameter) and (b) bulk manganese zinc ferrite sample. Although the diffraction patterns look similar, EXAFS analysis of these samples indicated that the particles were multi-phase. The broad peaks of the manganese zinc ferrite largely mask the iron oxide impurity phase.

parameters by another technique, thereby providing a better picture of the particle assembly. This is especially true of diffraction techniques (XRD and TEM) aiding Mössbauer effect or synchrotron radiation analyses.

The advent of increasingly sophisticated synchrotron radiation analyses have been important in this regard. Concurrent with the rapid increase in the intensity of ultraviolet and X-ray beamlines available to the scientific community has been the development of increasingly powerful experimental and analytical techniques for structural determinations.

The first portion of this section will discuss conventional tools for determining the structure of magnetic nanoparticles; a discussion of applying synchrotron radiation to the problem follows. A subjective summary of the relative applicability of the various probes discussed here is given in Table 1 [190].

4.1. Conventional Techniques

4.1.1. Size and Morphology Determinations

The defining characteristic of nanoparticles is, of course, their size. In principle, most structural probes are sensitive in one way or another to the size of the particles. In practice, however, nanoparticle "size" is an ambiguous concept. An assembly of nanoparticles generally consists of some distribution of sizes, approximating a log normal distribution. Often this distribution is significant. For magnetic nanoparticles, the superparamagnetic blocking temperature is strongly dependent on the size and size distribution of the particles. A different value will be obtained depending on whether a technique is sensitive to the median size or the mean size, and whether that median and mean is number-weighted or volume-weighted (the former case will yield smaller sizes than the latter). In addition, nanoparticles are not always single crystals. Many techniques yield a crystallite size; others give the size of the aggregate particles.

One of the most powerful tools for determining particle size and morphology is TEM. Transmission electron microscopy will generally report the total particle size (as well as crystallite size) and has the virtue of providing details of the size distribution. In many cases, aggregates of smaller particles can be discerned. If the nanoparticles consist of more than one phase and the phases provide enough contrast, then the individual phases may also be visible (Fig. 4). For further discussion of the capabilities of electron microscopy for investigating the physical and magnetic structure of nanostructured materials, see the review article by Thomas and Hütten [191]; imaging of small metallic nanoparticles is discussed by Ascencio et al. [192]. A few

representative examples of the application of TEM imaging to magnetic nanoparticles are given in the references [169, 193–199]. Dynamic light scattering [200] (DLS), also known as photon correlation spectroscopy (PCS) or quasi-elastic light scattering (QELS), is an important supplemental technique for determining the sizes of particles in solution, particularly when the size distribution is approximately log normal. Because of the ability to size particles in solution (including aerosols), DLS shows promise for *in-situ* studies of nanoparticle synthesis [201]. Dynamic light scattering is sensitive to total particle size, and yields information that is weighted by the square of the particle volume, although results are generally converted to volume- or number-weighting prior to publication.

For determinations of crystallite size, Scherrer analysis of XRD is commonly used [39, 202, 203]. This technique relies on the broadening of diffraction peaks due to the finite number of diffracting planes. Because other factors, such as strain, can broaden XRD peaks, Scherrer analysis generally provides a lower limit on mean crystallite size.

4.1.2. Phase Identification

Although XRD is often considered the gold standard for determination of crystal structure, it does possess significant limitations. As discussed in the introduction to this section, differences between nanoparticle and bulk crystal structures in combination with peak broadening and multiple phases may make XRD results less than conclusive. Sometimes, it yields almost no information: very small particles less than a nanometer across, core/shell structures with shells a few monolayers thick, and amorphous phases are all difficult to discern using conventional XRD. Certainly, XRD is still the method of choice for confirming the presence of a single expected phase with crystallite size greater than about 10 nanometers. But the nature of magnetic nanoparticles often yields samples that do not meet those criteria.

In some cases, the high intensities and small spot sizes of electron beams may make electron diffraction useful [195, 199, 204, 205]. Selected area electron diffraction (SAED or SAD) sometimes allows discrimination of phases as small as 1–2 nanometers in size, but at this scale, double diffraction, calibration issues, and the close proximity of diffraction spots arising from different phases often prevents an unambiguous identification [191].

4.1.3. Site Occupancy

Magnetic materials with the same nominal chemical composition, even when very high phase purity, often differ markedly from one another due to a different distribution of

Table 1. Applicability of structural probes to magnetic nanoparticles. One check indicates a technique which provides uncertain or incomplete information for a wide range of materials, or is only applicable in especially favorable situations. Three checks indicates a technique which is widely (but not universally) applicable and often gives fairly reliable information. Two checks is, of course, intermediate.

Figure 4. TEM of nanoparticles comprising an iron oxide shell on an iron core. The difference in contrast between the oxide and the metal allows the shells to be clearly visible.

species (atoms, ions, or vacancies) among the available crystallographic sites. This is especially true for ferrimagnetic materials containing multiple sublattices. Spinel ferrites, for example, have two sublattices with parallel coupling of the magnetic moments within each sublattice and antiparallel coupling between them. The result is that the magnetization of the material arises from the difference in magnetization of the sublattices. Often, different species reside on each sublattice. If vacancies are found preferentially on one sublattice, or if some of the atoms on one sublattice are switched with those on the other, the magnetization may be altered substantially [206]. It is thus very important to determine site occupancy in these materials.

If the material possesses atomic ordering, then diffraction techniques are often applicable. Even if the occupancy is random or quasi-random in nature, diffraction can often be used to obtain the average structure. For example, XRD can reveal the percentage of sites in the octahedral sublattice of a spinel compound that are vacant [207]. X-ray diffractograms cannot, however, conclusively reveal the local distortions caused by these vacancies, nor the tendency of vacancies to cluster or disperse. In the case of one atom substituting for another, however, XRD is only useful if the substituted atom differs substantially in its atomic scattering factor from the one being substituted for. The atomic scattering factor for a given scattering angle is, in turn, primarily a function of the number of electrons in the atom. Since in ferrimagnetic oxide materials, the substitution is often one first-row transition metal for another (particularly manganese, iron, cobalt, nickel, and zinc), this prevents XRD from being used to find average site occupancy in many cases. The same restrictions apply to electron diffraction.

Neutrons, on the other hand, are uncharged, and thus interact predominantly with the nucleus of atoms rather than the surrounding electrons. Since the coherent scattering

cross-section of nuclei is not correlated with atomic number, elements with very similar atomic scattering factors for X-rays may have very different scattering cross-sections for neutrons. For example, iron (with its isotopes present in their natural abundance) has about six times the cross-section for coherent scattering of thermal neutrons as does manganese, and more than 14 times that of cobalt. The atomic scattering factors for X-rays for these three elements, in contrast, are within a few percents of each other. In some cases, therefore, neutron diffraction (ND) can be useful for probing differences in site occupancy to which XRD is not sensitive [208, 209]. Since this is a diffraction technique, only the average structure can be obtained. In addition, neutrons possess a magnetic dipole moment, and thus are sensitive to magnetic ordering (for some examples of this use, see [210, 211]). Unfortunately, due to the small number of neutrons available for experimentation, relatively large sample sizes are necessary for this technique. This is sometimes difficult for nanoparticles synthesized by chemical means.

Mössbauer spectroscopy depends on the ability of Fe^{57} nuclei embedded in a crystal to emit "recoil-free" gamma radiation (*i.e.*, momentum is conserved by recoil of a macroscopic number of atoms, rather than an individual nucleus). Because essentially, no energy is lost to recoil, the energy distribution of the gamma rays is extremely narrow, and is dependent on the chemical and magnetic environment of the Fe^{57} nuclei. To create a spectrum, the source of the photons is vibrated, imparting a time-dependent Doppler shift to the photons. These photons can then undergo the inverse process in a sample, in which those of the appropriate energy are absorbed by Fe^{57} nuclei ("resonant absorption"). Thus, information is conveyed regarding the local environment of Fe^{57} in the sample, generally including coordination number and oxidation state. The dependence on the coordination number implies a dependence on *domain size* as well; it is possible to use this method to yield an estimate of domain size, even when the domain size cannot be extracted from magnetic parameters such as the superparamagnetic blocking temperature [212]. Because Mössbauer spectroscopy also depends on the magnetic environment, it is an important tool for investigating iron-containing nanoparticles [198, 203, 213–219].

Remarkably, thermal analysis techniques such as thermogravimetric analysis (TGA), differential thermal analysis (DTA), and differential scanning calorimetry (DSC) have been used to determine site occupancies. Each technique measures the value of a physical parameter as the temperature is changed in a controlled fashion. For TGA, the parameter is the mass of the sample (outgassing or oxidation accounts for the mass changes); for DSC, the parameter is the power required to keep the sample at the same temperature as a reference material; for DTA, the temperature of the sample relative to a reference material is measured. Some site occupancies in magnetic nanoparticles have been deduced from DSC and TGA [220], since the temperature at which ions oxidize (*e.g.*, Fe^{2+} going to Fe^{3+}) is dependent on the local environment of the ion [221]. Depending on the synthesis technique and particle size, however, this effect may be obscured by the effects of materials adsorbed onto the surface of the nanoparticles.

4.2. Synchrotron-Based Techniques

The suite of techniques discussed above can provide considerable structural information about many types of magnetic nanoparticles. There are, however, significant gaps. Diffraction, for example, can provide only very limited information about amorphous phases. Likewise, the structure of nanoparticle materials consisting of multiple chemical phases may resist solution via the above techniques. Fortunately, techniques that utilize synchrotron radiation are well suited to both of these scenarios.

About 40 dedicated "light-source" synchrotrons on four (soon to be five) continents are currently available to the scientific community. Although each facility has different capabilities, they generally provide broad-spectrum ultraviolet and X-ray radiation that is more than six orders of magnitude brighter than a conventional X-ray tube. These characteristics allow high-resolution spectroscopy to be conducted in a reasonably short time-frame, sometimes even allowing the kinetics of a synthesis to be observed *in-situ*. Although there are a variety of modes in which this spectroscopy can be conducted, many of which will be discussed later, the essential feature of these spectra is that they provide information about electronic structure and/or local environment that is completely element-specific. Because the information is inherently local, amorphous materials can be investigated; because the information is element-specific, the structures of materials consisting of multiple phases, or of those exhibiting point defects, can often be clarified.

4.2.1. Modes of Data Collection

X-ray absorption spectroscopy (XAS) experiments filter the photons emerging from the synchrotron with a monochromator so that only a narrow band of energies impinge on the sample at any given time; this energy is then varied to produce the spectrum. The intensity of transmitted photons, yield of fluorescent photons, total electron yield, may be measured independently. Total electron yield is surface-sensitive, with most of the signal coming from the first few nanometers of material (depending on the material and the energies involved). Fluorescence is less surface-sensitive, typically probing to a depth on the order of 10 microns, and is suitable for extremely dilute samples or those that are too thick for transmission. Transmission is sensitive to the entire thickness of the sample, but requires the sample to be on the order of several microns thick.

In emission techniques, a monochromator is still used, but the energy is left fixed. Instead, the distribution of kinetic energies produced by the emitted electrons is recorded, providing information about the electronic structure of the material. This is known as X-ray or ultraviolet photoelectron spectroscopy (XPS, UPS), or sometimes as electron spectroscopy for chemical analysis (ESCA).

Energy-dispersive X-ray absorption spectroscopy [222, 223] (EDXAS or DXAS) utilizes a curved polychromator to send photons through the sample with a range of energies corresponding to different diffracted angles, so that an entire spectrum can be collected simultaneously with a linear or areal detector. Energy-dispersive XAS holds promise for investigating the kinetic and mechanisms of reactions on the subsecond time scale [224–228]. The high intensity and selectable energy of synchrotron radiation can also be used advantageously in XRD; this can be combined with XAS in a number of ways. For example, in diffraction anomalous fine structure [229–230] (DAFS) experiments, the angle of diffraction is varied simultaneously with the incident photon energy in such a way that the same Bragg peak is being sampled at different energies. The result is an element-specific spectrum that is sampling only atoms in sublattices that obey the Bragg condition for that peak. In this way, the local environment of an element in a particular phase, or under favorable conditions, a particular type of lattice site [231–234], can be probed. A comparison of DAFS and XAS analyses of nanoparticulate metals is given by Bazin et al. [235].

In DAFS, many energies are sampled at one Bragg peak. In anomalous diffraction, entire diffractograms are sampled at a small number of energies. This technique has recently been used to determine the site occupancy not only by element, but by valence as well [236].

4.2.2. Data Interpretation and Analysis

The interpretation of synchrotron-based X-ray absorption spectra is often not straightforward. For example, a portion of the X-ray absorption spectrum for iron is shown in Figure 5. The binding energy of the K electrons in iron is 7112 eV; therefore, the absorption shows a large jump (the "edge") as the energy of the incident photon exceeds that energy. This binding energy will increase by a few eV if the iron is oxidized and the edge will shift accordingly; thus, the position of the edge can be used to estimate the oxidation state. The detailed structure within about 30 eV of the edge, known as X-ray absorption near-edge structure (XANES), is generally interpreted in terms of core electron transitions to available energy states (either above or below the Fermi level); XANES, therefore, yield information on bonding and the local symmetry of the atoms surrounding the absorber.

Extended X-ray absorption fine structure (EXAFS), the quasi-oscillatory features above 30 eV, are due to coherent scattering of atoms in the local environment up to a distance of several Ångstroms from the absorbing atom.

Figure 5. XAS of an iron foil near the K edge. Dotted line divides XANES from EXAFS region.

Depending on the sample, type, and region of spectrum, and desired information, several techniques are used to analyze this information (references immediately after the technique name are to applications of the technique to magnetic nanoparticles):

(a) *Fingerprinting* [237]. The simplest method of analysis is to compare the spectrum with a known reference compound (the "empirical standard"). Of course, if the material is crystalline and sufficiently similar to the reference, XRD can perform this task without the need for a synchrotron. On the other hand, nanoparticle materials are often similar on a local scale to a bulk analogue, but lacking (or different) in long-range order. If the XANES (or the XPS) of the material is similar to the reference, it suggests that the immediate environment of the atoms is similar; if the EXAFS are similar, then the local environment may be similar out to several Ångstroms.

(b) *Comparison to theory* [219, 238, 239]. This may represent either qualitative assignments of particular spectral features to particular causes (*e.g.*, a particular electronic transition or backscattering from a particular coordination shell) or comparison to an *ab-initio* calculation [240, 241] of a spectrum (a "theoretical standard").

(c) *Curve-fitting to a theoretical standard* [242–243]. This technique is used most often to analyze EXAFS, including the oscillatory portion of DAFS [244]. In this technique, a model of the material, with several parameters left free, is hypothesized. For example, a sample may be hypothesized to consist of nanoparticles composed of bcc iron mixed with Fe_2O_3. Free parameters might include the size of the particles and the fraction of each phase present. A theoretical standard is then calculated for reasonable values of the free parameters; theoretical expressions can be used to compute how the spectrum changes for different values of the parameters. Subsequently, the values of the free parameters are optimized by a least-squares fit of the modified theoretical standard to the data. A poor fit indicates that the model is poor; a good fit indicates that the model *may* be good. If the model is good, then the values of the free parameters that produce the fit are expected to reflect the actual structure of the material.

When used judiciously, this technique is among the most powerful and can be used profitably even when the material is made up of multiple phases. It is, however, prone to misinterpretation if used carelessly, partly because more than one model may correspond to the same spectrum or similar spectra (the model that does not correspond to the material is often termed a "false minimum"). For this reason, an EXAFS fit of a single coordination shell of a single sample under a single set of conditions is difficult to interpret uniquely. There are, however, several methods of reducing the likelihood of false minima. For example, the probability of a good fit being achieved with a poor model is considerably reduced if more than one absorption edge is refined simultaneously. Likewise, fitting more than one coordination shell simultaneously is advisable, at least for crystalline phases, because this will reduce the correlation between parameters (a single-shell fit, for example, cannot distinguish the coordination number from the EXAFS quantum efficiency S_o^2) and because it will act as a powerful constraint on valid models. Of course, it is helpful if the number of free parameters can be reduced by using the results of other probes. Stoichiometry, for example, can be determined reliably by methods such as inductively coupled plasma-atomic emission spectroscopy (ICP-AES). The stoichiometry, in turn, can be used to constrain site occupancies of materials exhibiting substitutional disorder. It is also worth noting that analyses of EXAFS by the curve-fitting method are almost always dominated by systematic error; this error may stem from limitations of the *ab-initio* calculation, the choice of free parameters, the values chosen for fixed parameters, the method used to extract the EXAFS oscillations from the raw data, or the way in which the samples were prepared for measurement. Fortunately, these sources of systematic error do not vary much for a set of samples prepared and analyzed in the same way. Thus, if a series of measurements and fits are performed on a sample while varying some extrinsic parameters (*e.g.*, temperature, pressure) or measurements are performed on a series of samples differing in some way (*e.g.*, nanoparticle size, amount of dopant), the differences between the values of the parameters as determined by the fits are much more reliable than the values themselves. This is a particularly valuable strategy if one of the samples has been well-characterized by another method (*i.e.*, it is an empirical standard), since the degree of systematic error can then be ascertained.

(d) *Principal component analysis* [245] (*PCA*): This technique requires a family of samples presumed to have differing (but unknown) proportions of chemical phases present, some (or all) of which may be unknown. For example, a sequence of core/shell nanoparticles could be prepared in such a way that the ratio of shell volume to core volume varies. As another example, an aging study could be performed on metallic nanoparticles: the ratio of oxide to metal could be expected to increase over time. If all the phases are unknown, PCA will yield only the number of phases present. If the identity of all of the phases are known and empirical or theoretical standards are available, then PCA reveals the fraction of each phase that is present. Finally, if the structures of some phases are known and others unknown, PCA may be combined with curve-fitting to a theoretical standard; this combination is sometimes called residual phase analysis (RPA). Principal component analysis has recently been used to analyze EXAFS [245–247], XANES [226, 228, 248, 249], and XPS [250, 251].

4.3. Future Trends

As the synthesis of magnetic nanoparticles has become more sophisticated, moving from ball-milling methods which generate a broad size distribution of disordered single-phase particles to wet chemical techniques which show promise for producing nearly monodisperse particles with a high degree of structural order, so have the techniques used to characterize them. Increasingly, synchrotron radiation has played a role, with both experimental and analytical techniques rapidly advancing and proliferating. High-intensity sources, for example, have stimulated the development of DAFS, enhancing the element-specificity of XAS with the ability, in many cases, to probe individual phases. Energy-dispersive XAS is now allowing the progress of synthesis reactions to be monitored at a scale of seconds or below; this technique as yet has been little-used with magnetic nanoparticles, but is likely to change as researchers broaden their focus from the end product of a synthesis to its mechanism and kinetics. Curve-fitting to theoretical standards is becoming increasingly sophisticated, with simultaneous multiedge refinements [243, 252] and models that account for the size and shape of nanoparticles [253–255] beginning to appear. Finally, PCA promises to yield significant structural information from materials that had previously resisted characterization.

5. MAGNETIC PROPERTIES OF NANOPARTICLES

This section emphasizes the magnetic characteristics important to nanoparticles. The following sections provide a general overview of the relevant parameters, behavior, and experimental tools used to examine magnetic properties. Additionally, select examples from recent literature have been included as examples of the types of research being conducted and to emphasize the strengths of the characterization techniques.

5.1. Magnetism of Fine Particles

The magnetic behavior of nanocrystals is largely dependent on the physical characteristics of individual particles (including particle morphology, intrinsic materials parameters, surfaces/interfaces, and size) and their environments (such as interparticle distance, temperature, and applied magnetic fields). When the particles are isolated and sufficiently small, magnetic responses similar to bulk magnetic materials fail to describe their conduct. However, their magnetic behavior is sufficiently similar to bulk materials as to warrant discussion in the following sections.

When the critical length scales for physical properties are similar in size to the structural length scales of the material, interesting physical phenomena arise. In the case of exchange-coupled magnetic materials, this length is called the exchange correlation length and is on the order of 1–100 nm. This naturally leads to the consideration of nanoparticulate materials for interesting magnetic phenomenon. Control of the processing of nanoparticle materials will yield a host of applications in the burgeoning fields of nanoelectronics and bioelectronics. Size, shape, composition, and distributions of these qualities about the particle mean will determine the success of these materials for application.

In recent years, new processing techniques and novel use of proven characterization techniques have advanced our knowledge of magnetic nanoparticles. However, the recent technological attention simply adds to over half a century of basic research in this field. A number of excellent reviews have been published over the years that encompass many of the aspects of the topics contained herein [256–258].

5.1.1. Magnetism Terms and Units

Units of measurement for magnetic applications suffer from unusual definition conventions, making it difficult to easily convert between systems. This article will solely use SI magnetic units for clarity. This section provides definitions for some of the salient terms necessary for understanding the magnetics of nanoparticles. More in-depth descriptions of these terms and their uses are found elsewhere [259, 260].

Intrinsic magnetic characteristics of materials include Curie temperature, saturation magnetization, exchange stiffness, and magnetocrystalline anisotropy. These characteristics are generally invariant with respect to microstructure of the material. However, this is not necessarily the case for nanoparticles, where the large amount of surface area tends to affect these properties due to surface relaxation and truncation. As might be expected, the deviations from the bulk intrinsic properties grow as the particle size is reduced.

Each of the intrinsic magnetic properties mentioned above are described here as an introduction to their meaning. The phase transformation temperature from ferromagnetic (or ferrimagnetic) behavior to paramagnetic behavior occurs at the Curie temperature (T_c). The saturation magnetization (M_s) is the magnetic moment per unit volume of the material (amperes per meter) when a sufficiently large magnetic field is applied. The exchange stiffness (A) is a measure of the strength with which adjacent magnetic moments remain aligned with units of joules per meter. The magnetocrystalline anisotropy (K) is the internal energy density dependent on the direction of the magnetic moment, with respect to the crystalline lattice and has units of joules per cubic meter. Magnetic anisotropy will be discussed in more detail due to its strong influence on the magnetic properties of nanoparticles.

The extrinsic magnetic properties include coercivity, remanent magnetization, and magnetic susceptibility. These parameters depend upon the microstructure of the material and are naturally affected by the size of the particles. The coercivity (H_c) or coercive field is the applied magnetic field required for reduction of a saturated magnetic material to zero magnetization (amperes per meter). The remanent magnetization (M_r) is the magnetization that remains after an applied field has been removed (amperes per meter). The magnetic susceptibility (χ) is the magnetization normalized by the applied magnetic field (with proper normalization, it is unitless). The magnetic susceptibility acts as a technological figure of merit for magnetic nanoparticles, since it links the particles (through their magnetization) with a readily applied field.

5.1.2. Paramagnetism

Paramagnetic materials possess unfilled electronic shells giving them a permanent magnetic moment. This moment consists of contributions from the spin and orbital momentum of the atom's electrons. Paramagnets differ from the more technologically useful ferromagnetic materials due to the fact that their magnetic moments do not interact strongly with each other. The magnetic moments tend to align with an applied magnetic field in a stochastic manner, yielding a slightly positive magnetic susceptibility ($\sim 10^{-6}$). The temperature dependence of the susceptibility for many paramagnetic materials follows the well-known Curie law ($\chi = C/T$, where C is the Curie constant).

5.1.3. Ferromagnetism/Ferrimagnetism

More complex (and interesting) magnetic phenomena are found when the magnetic moments on adjacent atoms interact. Ferromagnetic materials have interactions causing the alignment of the magnetic moments. These materials have high susceptibility and net magnetic moments even in the absence of an applied field.

Still more complex, yet equally interesting from a technological standpoint, are ferrimagnetic materials. These materials consist of anti-parallel arrangements of the magnetic moments, yet the material maintains a net magnetization. This is due to either the numbers of moments being different in each direction, or the size of the magnetic moments in alternating directions being different (or both). Ferrimagnets have high susceptibility (up to 10^6) and net magnetic moments even in the absence of an applied field, much the same as ferromagnets. At sufficiently high temperatures, the magnetic ordering of both ferromagnetic and ferrimagnetic materials is disturbed causing a change to paramagnetic behavior (at the Curie temperature).

The most important technological materials in the bulk come from the classes of ferrimagnetic and ferromagnetic materials due to their high susceptibility and net magnetization. Common examples of technologically important ferromagnetic materials include Fe, Co, Ni, and their alloys and rare earth intermetallics (i.e., $Nd_2Fe_{14}B$ and Sm_2Co_{17}). Prevalent ferrimagnetic materials include Fe-based oxide materials with the inverse spinel crystal structure (called ferrites) and rare earth/iron-based oxides (called garnets).

5.2. Ideal Particle Systems

The magnetic behavior of nanoparticles is diverse and complicated. The characteristics of particles and their environments will be discussed in the simplest manner in this section. This means a discussion of spherical, monodisperse particles without magnetic interactions between adjacent particles or agglomerations. Some complications of real nanoparticle systems will be discussed in the succeeding section.

5.2.1. Single-Domain Particles

As in the case of their bulk counterparts, a feature of primary interest for magnetic nanoparticles is magnetization reversal. In bulk magnetic materials, the nucleation and motion of domain walls through the material control the

reversal. The ease with which the domain walls move through the material when a magnetic field is applied determines the application for which the material is best suited. Pinning of domain walls on grain boundaries, voids, or nonmagnetic inclusions cause an increase in the field necessary for magnetization reversal by hindering the motion of domain walls. The nucleation of magnetic domains arises to minimize the magnetostatic energy. As the size of a bulk ferromagnet is reduced, the nucleation of reverse domains becomes more difficult because of the large magnetostatic energy.

Bulk ferromagnetic materials are generally polycrystalline with each grain consisting of thousands of magnetic domains separated by boundaries called domain walls. In the simplest case, the magnetization in adjacent domains continuously changes direction by $180°$ over the width of the domain wall. The domain wall is a defect in the material that requires energy to form. As mentioned previously, the multiple domains form in a grain to alleviate the magnetostatic field exiting the grain. The first panel of Figure 6 shows a multidomain particle with $90°$ domain walls.

For a small ferromagnetic particle made up of a single spherical grain, the magnetostatic energy has the form $(\pi\mu_0 M_s^2 r^2 w)/9$ and the domain wall energy $(2\pi\rho^3\gamma)/w$, where r is the particle radius, γ is the domain wall energy per unit area, and w is the domain width. Minimizing the total energy with respect to the particle radius yields a relation for the critical radius under which a domain wall will not form in terms of materials parameters $((18(AK)^{1/2}/(\mu_0 M_s^2))$ [261]. In a practical sense, particles below this limit consist of a single domain that thermodynamically cannot support the formation of a domain wall, and therefore have magnetization reversal by rotation of the spins into the applied field direction (as indicated by the second panel of Fig. 6).

The preferred direction of the magnetization for a ferromagnetic material is determined by magnetic anisotropies, which arise from many causes, including the shape of the magnet, the crystalline structure and chemistry of the material, and the strain in the material. Their origins are quite different and affect the characteristics of magnets of all sizes, particles and bulk alike. Generally, many types of anisotropy should be combined to fully describe the nanoparticles [262].

Shape anisotropy arises from the field formed by the magnetization of the material (a consequence of the Maxwell

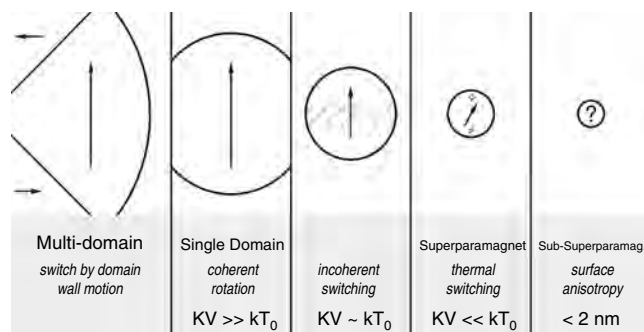

Figure 6. Noninteracting particles (compositionally invariant and single phase) as a function of the particle size, indicating the magnetization reversal mechanism regimes at an isothermal temperature, T_0.

equations) [263, 264]. It is described analytically for ellipsoids of revolution, with a uniaxial form for prolate ellipsoids (*i.e.*, acicular particles): $E = 1/2M_s^2(N_b - N_a)\text{Sin}[\theta]^2$, where θ is the angle between the magnetization and the applied field, M_s is the saturation magnetization and N_b and N_a are the demagnetizing factors for the long and short axes of the spheroid, respectively. Slight aspheric distortions of near-spherical particles yield inconsequential differences in the shape anisotropy until the length of the aspheric axis exceeds approximately 30% of the sphere radius.

The magnetocrystalline anisotropy forms due to the spin-orbital coupling of the material and is linked with the symmetry of the crystal structure for the magnetic material. Uniaxial anisotropy for tetragonal, rhombohedral, and hexagonal crystal structured materials have the form: $E = K_1 \text{Sin}[\theta]^2 + K_2 \text{Sin}[\theta]^4$, while cubic materials follow: $E = K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2) + K_2(\alpha_1^2\alpha_2^2\alpha_3^2)$, where α_i are the direction cosines for the magnetization. The strain derivative of the magnetocrystalline anisotropy provides additional anisotropic response through the magnetostriction coefficient (λ_s). For a single axis of stress, this term is uniaxial, with the form: $E = 3/2\lambda_s\sigma\text{Sin}[\theta]^2$, where σ is the stress on the material.

A simple, elegant model of the hysteretic behavior of single-domain particles was developed in the late 1940's. This Stoner–Wohlfarth (S-W) model [265, 266] considers the energy due to the magnetocrystalline anisotropy, shape anisotropy, and magnetostatic interactions of the particle as a function of a magnetic field applied at a fixed angle from the magnetic easy axis. As the applied field is increased, the magnetization is coherently rotated into the field direction.

Calculations based on the S-W model are presented in Figure 7. The ideal cases of isolated, monodisperse, noninteracting nanoparticles, both single domain and superparamagnetic, are shown. For an assembly of noninteracting particles with aligned magnetization, a square hysteresis loop with high coercivity and remanent magnetization is found (Fig. 7(a)). An assembly of randomly oriented particles, on the other hand, exhibits lower remanence and coercivity (Fig. 7(b)). The S-W model works well for single-domain particles; however, as the particle size is reduced further, the magnetostatic and anisotropic magnetic energies are no longer the only two of consequence—thermal energy plays an increasing role. As demonstrated in Figure 7(c) and discussed in the next subsection, this superparamagnetic behavior exhibits no remanent magnetization and no coercivity.

5.2.2. Superparamagnetism

Superparamagnetism is a magnetization reversal mechanism for fine particles driven by thermal energy [267]. At large particle sizes, the magnetization is confined to specific directions determined by the shape, crystal structure, lattice strain, etc. As the particle size is reduced, stochastic thermal fluctuations exceed the energy barrier, keeping the magnetization in its energy well. Similar to a ferromagnetic material, the magnetic moments of adjacent atoms remain aligned and acting as one large magnetic moment for the whole particle (*i.e.*, exchange coupled); however, their direction is not fixed. An assembly of these particles with "super moments" acts like a paramagnetic material—hence, the term superparamagnetism.

The thermal activation over the magnetic anisotropy energy barrier takes the form: $f = f_0 \text{Exp}[-E_b/kT]$ with E_b as the energy barrier (equal to KV for no applied field), f_0 is an attempt frequency on the order of 10^9 Hz, and kT is the Boltzmann energy term. When the time for activation over the energy barrier is long, the superparamagnetic particles are "blocked." The blocking of superparamagnetic particles occurs below a temperature aptly named the blocking temperature. However, the blocking temperature is dependent on the time of measurement, applied magnetic field, and particle size distribution, making it an ill-defined parameter.

The size scale in-between superparamagnetism and single-domain particles is best described by its magnetization reversal behavior. The constant fluctuation of the superparamagnetic particles is not entirely present; however, magnetic relaxation does occur. The coherent rotation mechanism of the single-domain particles does not describe the particles, although they maintain hysteretic behavior. This size range for nanoparticles can best be described by incoherent rotation of the magnetization, one example of which is the magnetization curling mechanism (see the center panel of Fig. 6) [268].

5.2.3. Isolated Particles

The magnetization of an assembly of superparamagnetic particles has the same dependence on applied magnetic field as a paramagentic material, with the replacement of the atomic magnetic moment of the paramagnet with the particle magnetic moment of the superparamagnet. The Langevin function describes this behavior $L[b] = \text{Coth}[b] - 1/b$, where $b = \mu H/kT$ and $\mu = M_s V$. This function reveals two of the characteristic features of the superparamagnet response to a magnetic field, namely, no coercivity and no remanent magnetization.

Figure 7. Hysteresis loops for an assembly of: (a) aligned single domain particles; (b) randomly oriented single domain particles; (c) superparamagnetic particles.

Since superparamagnetism is a stochastic phenomenon, the direction of the particle's magnetic moment fluctuates with time. Any specific particle will change its direction of magnetization during the time of magnetization measurement. Now the magnitude of the magnetic moment of an individual particle is a strong function of particle radius (or volume), and therefore, the magnetic properties of the nanoparticles will be dependent on the measurement time of the experiment. For example, measurement by SQUID magnetometry has a measurement time of roughly 10^2 s, yielding a blocking temperature defined by $25 = KV/kT_b$, whereas Mössbauer spectroscopy has a measurement time of 10^{-8} s, providing a blocking temperature of $2.7 = KV/kT_b$. In other words, when the measurement times are much greater than the relaxation time, thermal activation will provide a statistical average of the magnetization (for temperatures above a particle's blocking temperature).

As illustrated in the schematic Figure 8, the perceived blocking temperature can be manipulated by changing the measurement time (τ) or the applied field (H) for a given set of nanoparticles (possessing constant magnetic anisotropy, K). Increasing the measurement time increases the blocking temperature when the particle assembly and magnetic fields are kept constant. This is illustrated by the comparison in the previous paragraph between SQUID magnetometry and Mössbauer spectroscopy. When the magnetic field is increased (for a single measurement time and particle assembly), the blocking temperature is reduced. This is due to the stabilizing effect of the magnetic field on the particle assembly.

The smallest nanoparticle materials, with sizes below 1–2 nm, behave in manners that are difficult to relate to their bulk counterparts. Superparamagnetic materials have enough particle volume to remain bulk-like in the case of magnetocrystalline anisotropy and magnetization. However, when the fraction of surface atoms becomes too great, these intrinsic material properties are highly influenced by surface relaxation effects, thereby modifying their values. This, in turn, makes comparisons to the models for superparamagnetism difficult. This has been indicated in Figure 6 by the final panel with the title, "sub-superparamagnetic" particles for lack of a better term.
5.3. Mechanisms for Complicating Magnetic Behavior

Up to this point, the magnetic properties have been simplified to a large degree to avoid confusing issues. These ideal particle systems have avoided the effects of oxidation, organic ligands bound to the particle surface, particle shape, agglomeration, multiphase materials, etc. All of these contribute to the difficulty of characterization and analysis of the magnetic characteristics of nanoparticles. The magnetic behavior of the nanoparticles is sensitive to the physical characteristics of individual particles (including morphology, intrinsic materials parameters, and size) and their environments (such as interparticle interactions, material at the particle surfaces, temperature, and applied magnetic fields). Therefore, a complete characterization of the particles and their surroundings should accompany any magnetic study. Failure to provide these prerequisites makes meaningful determination of the intrinsic magnetic properties of the nanoparticles difficult.

5.3.1. Interparticle Interactions

Interparticle interactions cause a host of complications in the magnetic properties of nanoparticle assemblies. The magnetostatic field generated by the particles can promote chaining of particles and agglomeration if the particles are free to move. As schematically shown in Figure 9, interparticle interactions play an increasing role as the distance between particles decreases. Particles are considered to be isolated when they have a sufficiently small interaction, as the magnetic field generated by adjacent particles is generally the longest range interaction; this limit is determined by some small arbitrary field generated by the particles in the assembly. The particles shown in Figure 6 are considered isolated; this is indicated on Figure 9 by a dashed line.

At large separation distances (d_{12}), the simple cases of superparamagnetic and single-domain particles are found. The hazy region between the two indicates the region where incoherent reversal modes make significant contributions to the magnetization reversal.

When the particles touch each other, short-range exchange interactions are possible. Depending on the amount of

Figure 8. Diagram for the blocking temperature as a function of the particle diameter at constant measurement time, where up-arrows indicate the variation of τ or H.

Figure 9. Schematic phase diagram for interparticle interactions as a function of the particle size.

interface, this might be considered a polycrystalline ferromagnetic material at this point (assuming a large fraction of particle surface is represented by interparticle interfaces). This is the desirable case for using nanoparticles as precursors for bulk compacted material, although the difficulties in achieving this goal are immense.

5.3.2. Intraparticle Effects

Other forms of anisotropy may form when a copious surface area is available. Anisotropy due to surface termination of the particle, exchange coupling to antiferromagnetic oxides, or bonding to surfactants alter the magnetic behavior and, in some cases, the anisotropy of the material directly.

In many cases, a desirable passivating coating has been applied to protect metallic nanoparticles, either from oxidation or as a means of making them compatible with specific environments (biological or chemical). The addition of shells to nanoparticles adds new dimensionality to the complexity of the magnetic response. As demonstrated in Figure 10, the simplest form of a core/shell nanoparticle is represented schematically. Six regions are enumerated for their potential to affect the magnetic properties of the composite material. It is noteworthy that the interface of some of these regions may be coherent and therefore difficult to ascertain. The shell surface has been shown to modify the "magnetic volume" of the particle, making it differ from that of the structural volume (as found by TEM, for instance). This might be due to the direct bonding of ligands to the surface or the missing bonds at the interface.

Depending upon the thickness of the shell, there may be a region with near bulk properties for the shell material. However, that region is sandwiched between a surface dominated region and an interphase, interfacial region near the

Figure 10. Schematic diagram of a metallic nanoparticle with oxidation at the surface, indicating various structural regions: 1) shell exterior surface; 2) shell relaxation region; 3) shell material; 4) shell interphase interface region; 5) core interphase interface; 6) core material.

core material. The shell material within a few unit cells of the surface of the particle presumably has a relaxation of the bonds due to the missing bonds at the surface, which can significantly change the magnetization, especially in magnetic oxides. The interdiffusion of material from the core into the shell material has significant feasibility, depending on how the particles were passivated. This region may also have significant strain produced during the formation of the shell and the interphase interface. Similarly, the diffusion of oxygen into the core material is possible with the same consequences as for the shell material. Finally, presuming that the particles due not fully oxidize, a metallic core with magnetic properties similar to the bulk resides at the center.

5.4. Measurement Techniques

Due to the stochastic nature of many magnetic nanoparticle effects, the magnetic properties obtained by different measurement techniques are dependent on the time scales of measurement, the measurement temperature, and the applied magnetic field strength. Complications arise when the effects of surface atoms, particle size distributions, and interparticle interactions are considered.

5.4.1. Direct Current Susceptibility

Direct current (DC) susceptibility measurement is a common method of determining the superparamagnetic blocking temperature. This is accomplished by examining a particle system assembly under zero-field cooled (ZFC) and field-cooled (FC) experimental conditions. The ZFC experiment requires cooling the sample to a low temperature with subsequent application of a small, applied magnetic field. The temperature is then raised at a constant rate and susceptibility data are collected. The susceptibility reaches a maximum at a temperature near the blocking temperature, with superparamagnetic decay of the susceptibility above the blocking temperature. The FC experiment provides more certainty in the temperature at which superparamagnetic behavior sets in. This experiment requires cooling the sample in a small magnetic field of the same strength as the ZFC experiment, again collecting susceptibility data as the temperature increased. The measurement time for these experiments is near 10 s.

Sun and Murray show that ZFC experiments on monodisperse self-assembled nanoparticles can be used for examination of interparticle interactions [269]. The magnetostatic fields generated by the nearby nanoparticles in the array shift the peak in the ZFC curve to lower temperatures in addition to sharpening the peak. It should be noted that these experiments were supported by evidence from X-ray diffraction, TEM, and inductively coupled plasma experiments, all of which added to the analysis of the magnetic properties.

The work of Puntes and Krishnan show interparticle dipolar interactions through the use of ZFC/FC experimentation [270]. The experiments on ε-Co self-assembled nanoparticles showed a broad peak in the ZFC susceptibility characteristic of dipolar interactions. They also observed a strong increase in the FC susceptibility at low temperatures, presumably due to Brownian motion of the particles

in the viscous oleic acid when the field was applied at high temperature.

5.4.2. Direct Current Hysteresis

Lack of coercivity in a particulate sample is a hallmark of superparamagnetic samples. The hysteretic behavior of a magnetic material can be probed by cycling a large magnetic field between opposite directions relative to the sample. The theoretical hysteresis curves shown in Figure 7 compare the ideal cases of isolated, monodisperse, noninteracting nanoparticles, either single domain, or superparamagnetic. More generally, a particle size distribution, where some of the particles are large enough to be blocked while others remain superparamagnetic, is necessary to describe a real material. As first demonstrated by Bean in 1955 [271], a weighted average of contributions from the superparamagnetic (Langevin function) and blocked particles (S-W model) describe the hysteretic behavior, barring interparticle interactions. Realistic models of this behavior have been developed in recent years to describe the variety of measured loop shapes [272, 273].

A basic type of hysteresis loop study for nanoparticle materials entails the measurement of loops above and below the blocking temperature of the material. This is illustrated by Chen and Zhang for $MgFe_2O_4$ spinel ferrites [274]. They show the increased susceptibility for large-sized superparamagnetic particles at high temperatures and the coercivity dependence on particle size for blocked particles.

Sun et al. used a SQUID magnetometer to examine the phase transformations via hysteresis loops of monodisperse self-assembled FePt nanoparticles [180]. Their hysteresis results identify annealing conditions and composition ranges that were optimized for large coercivity.

SQUID magnetometry studies of the surface effects on the magnetization of nanoparticles were performed by Toneguzzo et al. [130, 145]. These experiments showed a common effect in nanoparticle systems, namely, that the saturation magnetization is inversely proportional to the particle diameter (or proportional to the surface area divided by the volume). This has been explained by pinning of magnetization at the surface of the nanoparticles, the introduction of a "dead" layer at the surface [275], and the formation of surface oxides during various studies. Toneguzzo et al. use a metallo-organic and oxide phase shell model to analyze their data.

A similar study of yttrium-iron garnet ($Y_3Fe_5O_{12}$) by Sanchez et al. showed the saturation magnetization is inversely proportional to the particle diameter [113]. In this case, the oxide particles have a decreased magnetization presumably due to either a nonmagnetic surface layer or noncollinear spin arrangement. Shafi et al. have examined the surface effects of various surfactants on the surfaces of amorphous Fe_2O_3 nanoparticles [96]. They attribute low magnetization found in hysteresis loops for particles coated with octyl phosphonic acid as an indication of antiferromagnetic coupling to the nanoparticles.

5.4.3. Temporal Remanent Magnetization

The switching and relaxation behavior of nanoparticles can be examined by a number of different temporal remanent magnetization techniques. Thermoremanent magnetization

(TMR) studies provide relaxation information about particles that have been field cooled below the blocking temperature with ensuing removal of the magnetic field at the measurement temperature. Isothermal remanent magnetization (IMR) experiments require zero field cooling to the measurement temperature with subsequent application and removal of a magnetic field. Finally, similar to the IMR curves, DC demagnetization curves involve zero field cooling of the sample; however, a large magnetic field is applied to the sample and then a field is applied in the opposite direction from which it is finally removed. The combination of DC demagnetization and IMR experiments can provide interparticle interaction information through the calculation of the δM parameter [276, 277]. Since superparamagnetic particles do not have remanent magnetization, the magnetic remanence will come from the blocked magnetic particles at a given temperature.

The experiments of Zeng et al. have shown the interparticle interactions of FePt nanoparticles by use of δM curves [278]. The particles in this case are annealed, and thereby aggregate showing a trend of negative δM values indicating dipolar interactions for low annealing temperatures and large positive δM indicating exchange coupling at high annealing temperatures.

5.4.4. Alternating Current Susceptibility

Alternating current (AC) susceptibility measurements are a valuable source of magnetic characterization with measurement frequencies from 10 to 10 kHz. This technique gives information about the dynamic behavior of the nanoparticles with the capability for initial susceptibility measurements at very small fields. Experiments show the real part of the susceptibility (χ') is frequency independent at high temperatures due to thermal equilibrium of the superparamagnetic particles. When some of the superparamagnetic particles are blocked as the temperature is reduced, increased frequencies cause an increase in the temperature at which χ' peaks and a decrease in its magnitude.

These attributes are clearly shown by the work of Dormann et al. on γ-Fe_2O_3 nanoparticles [279]. Nanoparticles in varying sizes and degrees of interaction were examined by AC susceptibility. Particle samples (7.1 nm diameter) were examined as chains of particles and as entangled chain agglomerates. The particles with a chain-like environment possessed larger susceptibility for all measurement frequencies than the agglomerated sample. Additionally, the chained particle sample exhibited lower peak temperatures for χ', indicating lower stability of the particles to thermal fluctuations than the agglomerated sample that possesses more near neighbors (thus higher magnetostatic interparticle interactions).

The effect of dilution on relaxation times of amorphous $Fe_{0.78}C_{0.22}$ particles as a function of temperature were examined by Djurberg et al. [280]. The more dilute sample showed much smaller relaxation times for a given temperature. This reflects the significance of interparticle interactions, where higher degrees of magnetostatic interaction provide stability to the system of particles.

5.4.5. Ferromagnetic Resonance

Ferromagnetic resonance (FMR) experiments provide information about the anisotropy, the distribution of particle easy axis orientations, and surface effects of magnetic nanoparticles. The experiment uses a strong magnetic field to align the magnetic moments of the particles and a transverse high frequency field to produce a precession of the magnetic moment about the strong applied field. These experiments are generally accomplished by fixing the high frequency field component and measuring the magnetic susceptibility as a function of the direction and magnitude of the large applied field. The many GHz frequency range of the high frequency field component gives a measurement time of greater than 10^{-9} s.

Studies carried out by Diehl et al. show the general trends of line sharpening for smaller particle size and higher measurement temperatures for ε-Co and twinned face centered cubic Co samples [281]. These effects are due to the thermal relaxation of the nanoparticles, yielding a single sharp resonance peak. The peak shape changes were accompanied by shifts in the resonance lines due to changes in the presence or magnitude of the particle anisotropy.

5.4.6. Mössbauer Spectroscopy

Mössbauer spectroscopic measurements use the absorption and emission of gamma rays to examine the local hyperfine fields at atomic nuclei. Generally, gamma rays with frequencies in the range 10^{18} to 10^{19} Hz are used for these experiments to excite the ^{57}Fe isotope within the sample. This technique can be used to reveal information about the crystal structure and magnetic characteristics of the nanoparticles with roughly a 10^{-8} s measurement time. Modeled Mössbauer spectra can be superimposed to incorporate many crystalline and amorphous phases, including separate contributions from surface atoms when relaxation effects are not significant. Due to thermal activation, superparamagnetic particles exhibit fluctuations in the hyperfine field parameters as a function of time. The effects of large surface area were examined by Bodker et al. by Mössbauer experiments on metallic Fe nanoparticles [282]. The anisotropy of the particles was determined *in-situ* as a function of grain size from the observed hyperfine field. The results indicted an increase in the anisotropy as the particle size

decreased, which was mainly attributed to magnetocrystalline anisotropy of the particles.

6. CONCLUSIONS

The goals of this chapter are to describe the chemical synthesis options available for the processing of magnetic nanoparticles, provide a review of useful and novel characterization methodologies to better understand the structure and chemistry of these particles, and to broadly review the magnetic properties of these particles in terms of their intrinsic magnetism as well as cooperative effects. We have limited our review to the time period beginning in 1990 and extending through 2002. Where appropriate, we direct the reader to other reviews and articles that provide the needed background to understand the outstanding issues addressing magnetic nanoparticles.

Table 2 summarizes different magnetic nanoparticles. Our scope has focused on the chemical methodologies that have been used to synthesize magnetic nanoparticles. Since these techniques use similar solvent systems, they offer the widest versatility and flexibility in processing. Combining one or more of these techniques is relatively simple and allows for the synthesis of many types of oxides and alloys. Of particular interest is the use of surfactant-mediated synthesis, including micellar, sol–gels, and polyol techniques. These techniques offer the ability to control particle size to less than 10% and allow for a wide range of materials and morphologies. Notwithstanding these powerful processing methods, gaining insight into the particles composition, phase, and structure remain elusive. To address this challenge, we propose the use of synchrotron radiation techniques to supplement the more routine laboratory characterization tools. Extended X-ray absorption fine structure has recently been used to analyze magnetic nanoparticles to determine element-specific phase purity, cation disorder, and particle size. This powerful tool can address many of the difficulties that exist in determining the nature of nanoparticles. Finally, we review the intrinsic and extrinsic magnetic properties of nanoparticles. Since the magnetism of these materials depend not only on particle chemistry and phase, but also on the particle size and environment, we explore the roles of interparticle interaction and surface functionalization in determining the magnetic properties of the system.

GLOSSARY

Absorption edge   A large jump in X-ray absorption as a function of energy associated with the ejection of a core electron from a particular element (e.g. the "Fe K edge").

Blocking temperature   Time upon heating. Magnetic moment is frozen into place upon cooling. This parameter is sensitive to applied magnetic field strength, characteristic time of measurement, and particle volume.

Capping agent   Anything that is added to a reaction solution to modify or control the chemical, physical and/or surface properties of nanoparticles. This agent is usually an organic moiety and help to prevent particle growth (e.g. polyvinylpyrrolidone (PVP)).

Chelating ligand   A ligand that can form one or more bonds with a central metal ion (e.g. oxalic acid).

Coercivity   The extrinsic magnetic property defined by the magnetic field required to reduce the magnetization of a ferromagnetic or ferrimagnetic material to zero. SI Units of A/m.

Condensation   The combination of hydrolyzed or partially hydrolyzed reactants that lead to gel formation.

Curie temperature   The phase transformation temperature at which a ferromagnetic material becomes paramagnetic thereby losing its spontaneous magnetization.

Differential scanning calorimetry (DSC)   A thermal analysis technique in which the power required to keep the sample at the same temperature as a reference is the physical parameter.

Differential thermal analysis (DTA)   A thermal analysis technique in which the temperature of the sample relative to the temperature of a reference material is measured.

Diffraction anomalous fine structure (DAFS)   The variation in a Bragg X-ray diffraction peak as a function of energy near an absorption edge.

Disproportionation   A reaction in which a species undergoes both oxidation and reduction simultaneously.

Dynamic light scattering (DLS)   A technique for estimating nanoparticle sizes by measuring fluctuations in light scattered by the sample. Also known as photon correlation spectroscopy or quasi-elastic light scattering.

Electrodeposition   The deposition of a metallic species from an electrolyte solution on a cathode where an external current is applied to the plating system.

Electron spectroscopy for chemical analysis (ESCA)   A term encompassing X-ray photoelectron spectroscopy and ultraviolet photoelectron spectroscopy.

Energy dispersive X-ray absorption spectroscopy (EDXAS or DXAS)   A fast variation of X-ray absorption spectroscopy, in which broad spectrum X-ray radiation is diffracted by the sample, allowing an entire energy spectrum to be collected simultaneously.

Exchange stiffness   The strength of interaction between adjacent magnetic moments. The origin of exchange stiffness is a parameterization of the exchange interaction. The origin of exchange interaction, being quantum mechanical in nature, is the basis for ferromagnetic behavior. SI Units of J/m.

Extended X-ray absorption fine structure (EXAFS)   The variation in X-ray absorption as a function of energy more than 30 eV above an absorption edge.

Ferrimagnetism   The phenomenon exhibited by materials possessing spontaneous magnetization due to either unequal numbers of antiparallel atomic moments or antiparallel atomic moments of differing magnitudes (or both).

Ferromagnetic resonance (FMR)   A magnetic characterization technique performed to examine the anisotropy and distribution of easy axes for assemblies of magnetic nanoparticles. This is accomplished by applying a large, saturating field simultaneously with a small oscillating magnetic field perpendicular to the saturating field, thereby producing a precession of the magnetic moments in the sample. Dynamic susceptibility as a function of field strength and orientation are generally measured.

Ferromagnetism   The phenomenon exhibited by materials possessing spontaneous magnetization due to parallel alignment of atomic moments.

Hydrolysis   The replacement of a ligand with a hydroxide group from water (i.e. alkoxide replacement in sol–gels).

Hydrophilic   "Water attractive," a molecule or compound that dissolves or is miscible in water. In a surfactant, the polar head group is hydrophilic.

Hydrophobic   "Water repulsive," a molecule or compound that does not mix or is immiscible in water (e.g. oil) the hydrophobic end of a surfactant is the hydrocarbon tail.

Hydrothermal reaction   A reaction where an aqueous solution is heated above the boiling point of water in an autoclave or high pressure reactors (pressure can reach over 2000 psi and temperature over 200 °C).

Hysteresis loop   A plot of the variation of the magnetization as an applied magnetic field is swept through a complete cycle $(+/- H_{max})$.

Inverse/reverse micelle   A system in which the surfactant molecules entrap solubilized water pools in a hydrocarbon solvent (also known as water-in-oil microemulsions).

Isoelectric point   The pH where the particle has no net surface charge.

Ligand   A chemical molecule or anion that is directly bonded to a metal ion.

Magnetic domain   A portion of a magnetically ordered material that possesses magnetic moments aligned in the same direction (region over which the spontaneous magnetization is aligned).

Magnetic susceptibility   The ratio of magnetization to magnetic field, in general it is unitless, however it may be normalized by mass, volume, or moles for comparison between materials. The susceptibility may be determined by the application of alternating current or direct current magnetic fields.

Magnetocrystalline anisotropy   The intrinsic magnetic property describing the strength of interaction between the crystalline lattice and magnetic moment. Generally, this is represented as a (low energy state) and any other axis (high energy state) in the material. It is described by materials constants (K_1, K_2, etc.), which in conjunction with angular dependent terms in reference to the easy axis, describe the

anisotropic energy for any other axis in the crystal. SI Units of J/m^3.

Magnetostriction   The strain dependent part of the magnetocrystalline anisotropy. Generally associated with a change in shape of a magnetic material as the magnetization is changed.

Micelle   An aggregate of surfactant molecules in which the oil droplets are stabilized in an aqueous environment.

Mössbauer spectroscopy   A spectroscopic technique utilizing the nearly recoilless emission of gamma rays, most often by ^{57}Fe nuclei, to probe the chemical and magnetic environment of the nuclei.

Multisynthesis processing   The combination of two or more chemical reactions to produce the desired product, for example: FePt formed by the thermal decomposition of iron carbonyl and the reduction of platinum acetylacetonate in a polyol.

Number-weighted mean   An average which counts each nanoparticle in a sample equally.

Organometallic compound   A compound in which the organic species is directly bonded to the metal through a metal-carbon bond (e.g. nickel carbonyl ($Ni(CO)_4$)).

Ostwald ripening   The growth of large particles at the expense of smaller particles driven by the reduction of total surface energy for the assembly of particles as described by the Gibbs-Thomson effect.

Oxidation   A reaction where the oxidation number increases or the oxidized species loses electrons.

Oxidation agent   A reactant that accepts electrons from another reactant (e.g. hydrogen peroxide (H_2O_2)).

Paramagnetism   The phenomenon exhibited by materials that are slightly attracted to magnetic fields however they possess no spontaneous magnetization. These materials have positive, low field, susceptibilities generally less than 10^{-3} in magnitude. The origin of the slightly positive susceptibility is thermal activation of atomic moments in materials with no exchange interaction.

Photolysis   A chemical reaction in which the reaction is driven by light.

Photon correlation spectroscopy (PCS)   See dynamic light scattering.

Polyol   Any alcohol that contains 2 or more hydroxyl groups, commonly 2 hydroxide groups. Diols are a subgroup, which contain exactly 2 hydroxyl groups and are commonly used in polyol reactions (e.g. ethylene glycol).

Polyol reaction   A chemical reaction in which the solvent and reducing agent is a polyol.

Precipitation   A reaction where an insoluble solid is formed when two or more solutions are mixed.

Principle component analysis (PCA)   An analysis technique which decomposes a series of related spectra into orthogonal "components."

Quasi-elastic light scattering (QELS)   See dynamic light scattering.

Reducing agent   A reactant that donates electrons to another reactant (e.g. borohydride (BH_4^-)).

Reduction   A reaction where the oxidation number decreases or the reduced species gains electrons.

Remanent magnetization   The remaining magnetization of a ferromagnetic or ferrimagnetic material after a saturating has been applied and removed. SI Units of A/m.

Saturation magnetization   An intrinsic property of ferromagnetic and ferrimagnetic materials, indicating the magnetic moment per unit volume when sufficiently large magnetic fields are applied to align all magnetic moments in a specimen. SI Units of A/m.

Scherrer analysis   A commonly used technique for estimating particle size from the broadening of peaks in an X-ray diffractogram.

Selected area electron diffraction (SAED or SAD)   Diffraction of an electron beam focused on to a small area.

Self-assembly   The spontaneous reorganization of molecules or particles to into an ordered arrangement. In the case of particles, this is generally accomplished by evaporation of the solvent from a mixture of particles suspended in that solvent.

Shape anisotropy   A bias of the magnetization direction due to the magnetostatic self energy. The magnetostatic self energy is dependent on the shape of the sample and is a equations.

Sol–gel process   Traditionally, the hydrolysis and condensation of metal alkoxides.

Sonolysis   A chemical reaction in which the reaction is driven by sound, i.e. using ultasonics or acoustic waves (also known as sonochemistry).

Spontaneous magnetization   The effect of the quantum mechanical exchange interaction whereby the magnetic moments in a ferromagnetic (or ferrimagnetic) material are aligned without the application of a magnetic field.

Superconducting quantum interference device (SQUID) magnetometer   A magnetic measurement device that uses a Josephson junction to conduct very sensitive magnetic moment measurements (typically near 10^{-8} emu sensitivity).

Superparamagnetism   The phenomenon where the magnetization reversal of an exchange coupled volume of magnetic material is changed by thermal activation (generally for finely divided ferromagnetic or ferrimagnetic materials). Characteristics of superparamagnetic materials include a lack of coercivity and the formation of a universal curve for the magnetization plotted against magnetic field normalized by temperature.

Surfactant   An acronym for "surface active agent," is any substance that affects the surface or interfacial tension of the medium in which it is dissolved. A surfactant is composed of a hydrophilic head and a hydrophobic tail. A surfactant lowers the surface or interfacial tension of the medium in which it is dissolved.

Synchrotron radiation   High-flux broad-spectrum radiation generated by high-speed electrons orbiting in storage rings.

Temporal remanent magnetization   A set of techniques that examine the switching and relaxation behavior of nanoparticles, including thermoremanent magnetization (TMR) and isothermal remanent magnetization (IMR) measurements.

Thermogravimetric analysis (TGA)   A thermal analysis technique with mass as the physical parameter.

Thermolysis A chemical reaction in which the reaction is driven by heat (e.g. the thermal decomposition of an organometallic precursor).

Ultraviolet photoelectron spectroscopy (UPS) A characterization technique in which ultraviolet photons of a fixed energy are absorbed by a sample, and the kinetic energy distribution of the resulting photoelectrons is measured.

Vibrating sample magnetometer (VSM) A magnetic measurement device used to measure magnetization of small samples which are vibrated in a magnetic field, inducing currents in sensing coils.

Volume-weighted mean An average which counts each atom in a sample equally.

Chemistry of Carbon Nanotubes

V. N. Khabashesku, J. L. Margrave

Rice University, Houston, Texas, USA

CONTENTS

1. INTRODUCTION

Carbon nanotubes (tubular fullerenes or buckytubes) are structurally built from rolled graphene sheets closed at the ends by the fullerene caps. Single-walled nanotubes (SWNTs) consist of a single graphitic cylinder, while multiwalled nanotubes (MWNTs) are made of concentric graphitic layers surrounding the central tubule. The diameters of SWNTs can range from 0.4 to 4 nm and those of MWNTs from 1.4 to 100 nm. Since the discovery of MWNTs by Ijima in 1991 [1] and preparation of SWNTs in 1993 [2–4], the carbon nanotubes have become an area of intense research activity worldwide. The unique mechanical, optical, and electronic properties and other phenomena exhibited by carbon nanotubes offer many opportunities for their applications [5–9]. SWNTs, in particular, possess a remarkable tensile strength and, depending on their diameter and helicity, can be metallic, semiconducting, or insulating as well as chiral or achiral. The uses of SWNTs and MWNTs for fabrication of reinforced fibers and nanocomposites [10–12], electrochemical devices [9] and field-emission displays [13], nano-size scanning probe tips for atomic force microscopy [14], and their capability of hydrogen storage [15] are being investigated extensively.

Nanotubes tend to self-assemble into bundles in which up to several hundred tubes are held together by van der Waals bonding. For many applications, the separation of individual nanotubes from their bundles is becoming essential. This would improve the dispersion and solubilization of the nanotubes in common organic solvents and/or water, which are needed for their processing and manipulation. To solve this problem, two main approaches based on noncovalent [16–21] and covalent [22, 23] modifications of nanotubes are being pursued. The covalent modifications involve chemical functionalization by the attachment of various functional groups to the ends or sidewalls of the nanotubes through covalent bonds. Besides improving the solubility and processibility, this functionalization also opens an opportunity for altering the structural and electronic properties of the nanotubes and for obtaining new types of nanotube-based materials with useful properties. However, the chemical functionalizations of the nanotube ends bring only a highly localized transformation of the nanotube electronic structure and do not change the bulk properties of these materials. These functionalizations have been most extensively explored through oxidation reactions, which are shown to form shortened nanotubes with carboxylic acid groups at the ends that can be further derivatized [23–26].

By comparison, the side-wall functionalization naturally results in a significant modification of the intrinsic properties of the nanotubes. The challenges faced in these types of chemical modifications are related to the fact that nanotubes are not very reactive due to a much lower curvature of nanotube walls (e.g., in [10,10] SWNTs) than in the fullerenes, which exhibit a rich chemistry [5], and to the necessity of preserving the tubular structure when attaching the functional groups to graphene walls. Therefore, the investigations of a variety of reagents and experimental conditions become important. Besides the technological demands, the research on functionalization chemistry of nanotubes is also fascinating from a fundamental point of view since it can provide an in-depth knowledge of chemical reactivity stemming from the nanoscale size and shape of materials. However, the number of documented results in this new field of chemistry is not yet great, mostly due to a high cost of the nanotubes, which has been limiting the research efforts to only a dozen or so chemical labs and centers. This Section provides a review of these results, which include the

chemical reactions of pristine carbon nanotubes as well as their chemical functionalizations using oxidized or fluorinated nanotubes as precursors for subsequent derivatization.

2. CHEMICAL REACTIONS OF PRISTINE CARBON NANOTUBES

2.1. Oxidation

Oxidation was the first reaction carried out on the carbon nanotubes [27–31]. It was shown that the caps on MWNTs can be opened by oxidation with oxygen, air, or carbon dioxide at temperatures above 700 °C. Carbon nanotubes show fairly high resistance to oxidation in air up to 700 °C, while C_{60} burns in air at a much lower temperature (~500 °C). Oxidation in air or oxygen results in etching away of the tube caps and the thinning of tubes through layer-by-layer peeling of the outer layers, starting from cap regions. Carbon dioxide reacts as a milder oxidizing agent that erodes and strips the cap of the tube, exposing the terminated cylinder layers [27]. Heating MWNTs with an oxide Pb_3O_4 in an inert atmosphere facilitated opening at a lower temperature (~400 °C) [28].

The oxidation by boiling in concentrated HNO_3 or in aqueous solutions of other oxidants, such as $KMnO_4$, OsO_4, RuO_4, and their combinations, leads to an efficient cleavage (up to 91%) of the end-cap regions of carbon nanotubes. The mechanism of cap-opening by these oxidants most probably involves oxidative cleavage of the $C=C$ double bonds and further conversion to vicinal diols followed by oxidative cleavage of diols to form a number of oxygen-containing end-functionalities, such as carboxylic acids, anhydrides, quinones, and esters, and is suggested to be controlled kinetically but not thermodynamically [30].

Treatments of SWNTs by sonication in HNO_3 or H_2SO_4/HNO_3, H_2SO_4/H_2O_2 mixtures [32–34] were found to cut the nanotubes by oxidizing/etching action to lengths ranging from 100 nm to 1 micron and generate carboxyl groups and other oxo-functionalities predominantly on nanotube open ends, according to IR and ^{13}C NMR studies [35, 36]. It was shown that selective oxidation can occur for the thinner SWNTs when burning in oxygen or refluxing in nitric acid [37]. The acid oxidation chemistry has been successfully applied for enrichment of large-diameter nanotubes in the purified SWNT batches, which have been characterized by transmission electron microscopy (TEM) and Raman spectroscopy [38]. The detailed studies have clearly demonstrated that in air the smaller diameter SWNTs are oxidized more rapidly than the larger diameter nanotubes [39, 40]. The increased reactivity of smaller diameter SWNTs was also observed in experiments using room temperature oxidation by ozone [41]. This reaction was localized at the end caps, which have been removed by oxidation thus creating a dangling COOH and other groups, which in their turn could be removed by heating above 350 °C as CO and CO_2, leaving the nanotube sidewalls intact. Heating the acid-oxidized SWNTs to a higher temperature (1000 °C) was shown to produce up to ~5% defective sites both on the nanotube sidewalls and closed end-caps, capable of subsequent oxidation by ozone, which was used as a titration agent for estimation of the surface defect site density [42].

2.2. Fluorination

2.2.1. Preparation of Fluorinated Carbon Nanotubes

The direct fluorination of the SWNTs with elementary fluorine results in sidewall-fluorinated SWNTs (fluoronanotubes). They represent a new family of nanoscale fluorocarbon materials that have been prepared by fluorination of both laser ablation of graphite grown carbon nanotubes (L-SWNTs) [33, 43] and those produced by a high-pressure CO disproportionation process (HiPco-SWNTs) [44, 45] using the technology developed earlier for the fluorination of graphite [46]. Extensive fluorination studies [47–49] were carried out to establish optimal conditions (reaction temperatures, reaction times, addition of HF catalyst) to reach a saturation stoichiometry (nearly C_2F) without destruction of the tube structure. It was also found that the degree of fluorination depends on the residual metal content from catalysts used in the purified SWNTs and the conditions of preparation and treatment of the buckypaper samples (nature of solvent, annealing temperature) prior to fluorination.

The fluorination of L-SWNT buckypaper, pre-baked at 1100 °C in vacuum, was carried out at temperatures ranging from 150 to 600 °C. The IR spectroscopy (KBr pellet method) confirmed the presence of covalently bound fluorine (peaks of the C—F stretches in the 1220–1250 cm^{-1} region) in the samples fluorinated in absence of HF catalyst at temperatures of 250 °C and higher, and not for those fluorinated at 150 °C. The TEM images indicated that the tube structures remained largely intact under treatment at temperatures as high as 325 °C, yielding approximately C_2F product bulk composition according to electron probe microanalysis (EPMA). The SWNTs are essentially all destroyed (i.e., "unzipped") when fluorinated at 400 °C and above to form a fluorographite and some multiwall carbon nanotubelike material. As a result of the sidewall functionalization of the SWNTs by fluorine, the electrical properties of the fluoronanotubes differ dramatically from those of pristine SWNTs. The fluoronanotubes, prepared by fluorination at temperatures of 250 °C and above, are insulators (two-point resistance across the length of buckypaper sample > 20 MΩ), while the pristine nanotubes are good conductors (two-point resistance 10–15 Ω) [48].

With the addition of HF, which is a known catalyst for fluorination of graphite, the saturated C/F ratio (~2) for the L-SWNT tube structure was reached at a lower reaction temperature (250 °C) while maintaining the same reaction time (~5 hrs). The other observed effect of HF addition was a noticeable upshift of the C—F stretching frequency in the attenuated total reflectance (ATR) FTIR spectra of fluoronanotubes (Fig. 1A), which indicated the formation of more covalent and therefore stronger C—F bonds. The same upshifting effect and a higher relative intensity of the C—F band in the IR spectra were also seen when raising the fluorination temperature (Fig. 1B). These phenomena are in agreement with those observed earlier in fluorinated graphite [46].

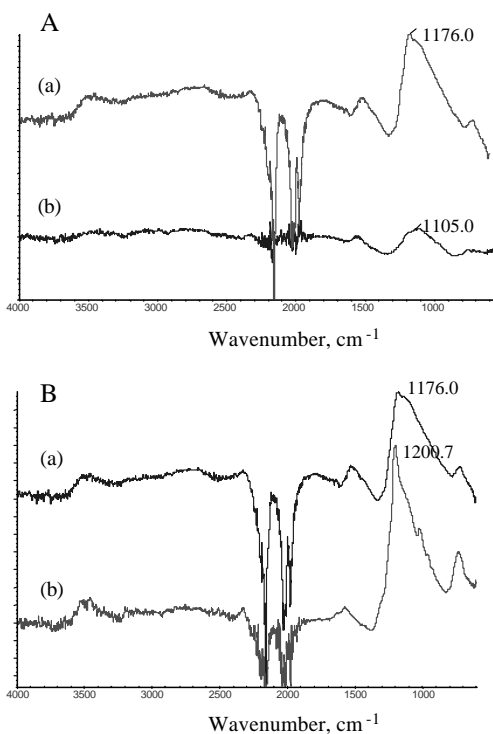
The HiPco-SWNTs have a smaller average diameters (~1 nm for the [8,8] nanotubes) than L-SWNTs (~1.4 nm, corresponding to the [10,10] tubes) and, therefore, due to


Figure 1. ATR-FTIR spectra of L-SWNTs: (A) Fluorinated at 200 °C with HF addition (a), and without HF addition (b); (B) Fluorinated at 200 °C (a), and at 250 °C (b). Negative absorptions at 2000 and 2200 cm^{-1} are due to the diamond crystal of the ATR accessory.

a higher curvature are more reactive. This is particularly indicated by the observation that under the same fluorination conditions more fluorine can be attached onto the sidewalls of HiPco-SWNTs [49]. For instance, in the presence of HF, the near C_2F composition for the tubular structure of the HiPco-SWNTs has been produced at a fluorination temperature as low as 150 °C, while under the same conditions the L-SWNTs yielded fluoronanotubes with a significantly lower fluorine content (C/F ratio higher than 3).

Strong dependence of the fluorination on nanotube diameter was also observed for pyrolytically grown tubes with large diameters, ranging from 10 to over 100 nm [50]. After fluorination with the F_2:HF gaseous mixtures for 19 h at 500 °C, these nanotubes revealed the presence of the C—F bonds in the electron energy loss spectra (EELS) only for tubes with diameters larger than 20 nm, which suggested that thin tubes are not or are minimally fluorinated (if fluorination occurred at all under conditions studied). Elemental mapping studies indicated that F is uniformly distributed within the nanotubes with diameters greater than 20 nm of approximately $C_{12}F$ stoichiometry. EELS calculations using density functional theory confirmed the existence of ionic and covalent bonding of fluorine to carbon in these fluoronanotubes [50].

Multiwall carbon nanotubes, prepared by a template carbonization method and having open ends, reacted with elemental fluorine already at 50 °C and were shown to add more fluorine with increased reaction temperature [51]. When using a gaseous mixture of F_2, HF, and IF_5, the flu-

orination proceeded even at room temperature yielding the fluoronanotubes with $CF_{0.4}$ composition. The C—F bonds in these fluoronanotubes were suggested to possess a semiionic character, as indicated by a peak location of the C—F stretch at 1100 cm^{-1} in the FTIR spectra [52]. The fluorination of arc-discharge produced MWNTs has also been achieved at room temperature by using elemental fluorine on MWNT samples pretreated with a vapor over liquid Br_2 for 24 h and then with a vapor over a solution of BrF_3 in Br_2 for 7 days. This reaction resulted in fluoronanotubes with $C_1F_{0.3}Br_{0.02}$ composition, in which the presence of covalent C—F bonds has been concluded on the basis of X-ray diffraction (XRD), FTIR, and X-ray photoelectron spectroscopy (XPS) characterization data [53].

2.2.2. Solvation Properties of Fluoronanotubes

The fluoronanotubes prepared from SWNTs form metastable solutions in DMF, THF, and alcohols after sonication. They do not dissolve in perfluorinated solvents, water, diethylamine, or acetic acid. The solvation of individual ("unroped") fluoronanotubes was verified by dispersing them on a mica substrate and examining with atomic force microscopy (AFM) [54]. The solutions in alcohols were stable for a few days to over a week. Among the series of alcohols studied, 2-propanol and 2-butanol were found to be the best solvents. Such solvation has been explained by hydrogen bonding between the hydroxyl hydrogen in alcohol and the nanotube-bound fluorine: R—O—H$\cdots$F—(C_nF). This bonding is likely facilitated by an increased ionic nature of the C—F bond in fluoronanotubes in contrast with alkyl fluorides, in which, according to recent studies, the fluorine is suggested to be a poor hydrogen bond acceptor [55]. The XPS analysis of fluorinated SWNTs supports the concept of a more ionic fluorine bonded in fluoronanotubes by revealing an F 1s peak at a binding energy of 687 eV, located at a much lower binding energy than the F 1s peak in poly(tetrafluoroethylene) (691.5 eV).

2.2.3. Structure of Fluoronanotubes

Insights into the possible fluoronanotube structures have been provided by molecular modeling calculations and scanning tunneling microscopy (STM) imaging [56]. Based on the experimentally established C_2F stoichiometry at which fluorinated tubes can still maintain their tubular structure, two isomeric structures, resulting from fluorine addition to either (1,2) or (1,4) positions within a hexagonal ring on the graphene-like side wall of the nanotube, have been proposed (see Fig. 2). Due to the arrangement of the π-bonds, the 1,2-isomer can be conducting through an electron flow along the conjugated bonds parallel to tube axis, whereas the 1,4-isomer with its isolated double bonds will yield insulating fluoronanotubes. From the molecular mechanics (MM+) [49] and semi-empirical (AM1 and CNDO) [56] calculations, it was found that the 1,4-isomer is more stable, although the energy difference between the two isomers is quite small (only 1 kcal/mol per F atom). Higher level calculations on fluorinated armchair (10,10) SWNTs of C_2F stoichiometry using density functional theory (PBE/3 and LSDA/3-21G)
Figure 2. Proposed fluorine addition patterns on the fluoronanotubes: (a) 1,2-addition, (b) 1,4-addition.

and periodic boundary conditions revealed that, on the contrary, the 1,2-isomer is more stable than the 1,4-isomer; however, the total energy difference is again fairly small (about 4 kcal/mol per C_2F unit) [57]. Given such a small difference in the energies of these two isomers, calculated at various levels of theory, and the absence of separation procedures developed so far, it is reasonable to assume that they both coexist in the fluoronanotube material.

STM imaging (Fig. 3a) indicated that the fluorinated regions typically form bands around the circumference of the tube. This may imply that the addition of fluorine to the side wall of the pristine SWNT should occur more favorably around the circumference of the tube. Nevertheless, the AM calculations point out that the addition along the axis of the tube for the 1,2-isomer is about 30 kcal/mol more exothermic than circumferential 1,2-addition, while in the case of the 1,4-isomer the addition around the circumference of the tube is approximately 10 kcal/mol more energetically favorable than propagation along the tube axis [49, 56]. Based on that, the origination of the abrupt band boundaries, observed in the STM images of fluoronanotubes (even those having the saturated C_2F stoichiometry), could be explained by a circumferential addition mechanism proceeding via initiation of the 1,4-isomer at multiple sites along the tube and propagating on alternate pairs of rows (Fig. 3b). However, since the calculated energy difference between the 1,2- and 1,4-isomers is small, the possibility of having both types of fluorine addition occur simultaneously during the fluorination process and form discrete isomeric domains on the nanotube (Fig. 3c) also can be expected. Various defects in the sidewall graphene structure might also play an important role in either initiating or terminating such domains.

2.3. Hydrogenation

The preparation of hydrogenated carbon nanotubes (H-NTs) has been attempted by using the Birch reduction method [58, 59], which was applied previously for the hydrogenation of fullerenes [60]. The reaction of raw SWNTs produced by electric arc discharge with lithium in liquid ammonia did not yield the desirable H-NTs. When the unpurified L-SWNTs were reacted with lithium in ethylenediamine, the final product obtained was showing not only an added hydrogen (2.71%) but also a nitrogen (8.32%) by elemental analysis, meaning incorporation of some nitrogen into the samples. Although their Raman and IR spectra were consistent with the small structural changes in the SWNTs, implying chemical modification, no solid evidence for covalent attachment of hydrogen to the SWNT sidewalls
Figure 3. STM image of an individual fluoronanotube. Note gaps in fluorine decorations of the sidewall (a). Modeling of observed gap formation in STM images: (a) multiple fluorination initiation sites, (b) mixture of both 1,2- and 1,4-additions.

and not to the amorphous carbon present on the walls could be obtained [58].

Use of purified carbon nanotubes and a modified Birch reduction method, utilizing Li and methanol in liquid ammonia, has proven to be more successful in preparation of H-NTs [59]. Two types of nanotubes, L-SWNTs and MWNTs, have been hydrogenated to approximately $C_{11}H$ composition, determined from the yield of hydrogen evolved at elevated temperatures in the course of thermogravimetry-mass spectrometry (TG-MS) studies. Thus obtained H-NTs are thermally stable up to 400 °C. Above this temperature the evolution of hydrogen and a small amount of methane takes place, peaking at 500 °C, which provides firm evidence for covalent C—H bonds present in these hydrogenated samples. Based on these experimental data, it has been suggested that the C—H bonds in H-NTs are weaker than those in aliphatic and aromatic hydrocarbons, but can be compared with the thermal stability of C—H bonds in hydroaromatic compounds. This is supported by the density functional theory (DFT) calculations data, which show that the C—H bonding energy in SWNTs hydrogenated to their maximum capacity for hydrogen storage exceeding 14 wt. % is substantially lower than in methane [61].

2.4. Addition of Carbenes, Nitrenes, and Radicals

Dichlorocarbene was the first electrophilic carbene that was added to carbon nanotube double bonds in a similar reaction known for fullerenes [62]. The dichlorocarbene was generated either from chloroform by reaction with sodium hydroxide in the presence of phase transfer catalyst (PTC) [58] or from phenyl(bromodichloromethyl)mercury by thermal decomposition [23]. The analyses of the addition products to the purified SWNTs by FTIR spectroscopy showed

the C—Cl stretching modes at 798 cm^{-1}, while energy dispersive X-ray (EDX) spectroscopy revealed the presence of only about 2 at. % Cl, thus indicating a fairly low degree of fuctionalization [23]. See Scheme 1.

Scheme 1.

The addition of a nucleophilic carbene, generated by deprotonation of the dipyridyl imidazolium cation, to the SWNTs has recently been reported [63]. The carbene adduct is soluble in DMSO, which permitted ^{1}H NMR analysis. However, it is thermally labile, as it loses the attached carbene as well as its dimer at 50 °C, as detected by mass spectrometry, and shows in the UV-Vis-NIR absorption spectra only slight changes with respect to pristine SWNTs. Therefore, at most these data point at a very modest functionalization achieved in this reaction (Scheme 2). The functionalizations of SWNTs also reported [63] by addition of nitrenes, generated by thermolysis of alkylazidoformates (Scheme 3), and by perfluorooctyl radical, produced photochemically from perfluorooctyl iodide, seem to be similarly questionable until a convincing evidence for covalent sidewall attachment of nitrenes and radicals is obtained from the TG-MS, Raman, and electron microscopy studies.

Scheme 2.

R = tert-Butyl or Ethyl
Scheme 3.

The addition reactions of several aryl radicals generated by electrochemical reduction of aryldiazonium salts [64, 65] or thermally from *in-situ* prepared diazonium compounds [66] to the HiPco-SWNTs have led to a more successful functionalization (Scheme 4). This was evidenced by a complete loss of band structure in the absorption spectra and changes in the Raman spectra showing a significant increase in the relative intensity of the disorder mode at about 1290 cm^{-1} due to the sp^3 carbons. The degree of functionalization by a number of substituted aryl diazonium salts has been estimated as 1 in 40 to 1 in 20 nanotube sidewall

carbons based on thermogravimetric and EDX elemental analyses [64, 66].
R = tert-Butyl, halogen, COOH, NO$_2$, COOH, CO$_2$CH$_3$ as well as

or -OCH$_2$CH$_2$OCH$_2$CH$_2$OCH$_2$CH$_2$OCH$_3$
Scheme 4.

The idea of using the carbon nanotubes as a free radical "sponge" originates from the well-known ability of their fullerene relatives to add a variety of free radicals [5, 67]. In the recent studies [68, 69], HiPco-SWNTs have been reacted with a series of organic peroxides, such as lauroyl, benzoyl, *t*-butyl, and hydrogen peroxides, which are commonly used as radical precursors in polymerization processes, in attempts to functionalize the nanotube sidewalls. In case of acyl peroxides, such as lauroyl and benzoyl peroxide, their thermal decomposition in the presence of SWNTs, both in solution by refluxing at 80–100 °C or in solid state by heating at 200 °C, resulted in undecyl and phenyl radical adducts to the sidewalls, respectively (Scheme 5), while other peroxides yielded mostly oxygen-containing products. Covalent functionalization of SWNTs by this fairly simple approach using the low-cost commercially available peroxides has been established by absorption UV-Vis-NIR and FTIR spectra, and Raman spectroscopy, and also TG-MS and TG-FTIR analyses indicating that approximately 1 in 20 sidewall carbons carries an attached group [69].

R = C$_{11}$H$_{23}$ or C$_6$H$_5$
Scheme 5.

2.5. Cycloaddition

Covalent modification of carbon nanotubes by 1,3-dipolar cycloaddition of azomethine ylides, *in-situ* generated by condensation of an *N*-substituted α-amino acid and an aldehyde, has been performed by Georgakilas et al. [70] utilizing a reaction widely used in functionalization chemistry of fullerene C$_{60}$ [71]. The nanotubes were suspended in DMF

together with aldehyde and aminoacid, and heated at 130 °C for 5 days (Scheme 6).

R₁ = -CH₂(CH₂)₆CH₃, -CH₂CH₂OCH₂CH₂OCH₂CH₂OCH₃

R₂ = H, ⟨phenyl⟩-OCH₃, ⟨pyrene⟩
Scheme 6.

This method was reported to be successful in functionalization of both as-produced and purified SWNTs and also of MWNTs, yielding nanotube derivatives very soluble in polar solvents, such as $CHCl_3$, CH_2Cl_2, acetone, alcohols, and water. For instance, solubility of some SWNT derivatives in $CHCl_3$ was claimed to be as high as 50 mg/ml, and no precipitation from solution was observed after two weeks. The main argument supporting the functionalization of SWNTs was based on NIR spectra, showing the loss of van Hove singularities due to altered electronic structure normally observed for sidewall derivatized nanotubes [22, 49].

2.6. Electrophilic Addition

The first electrophilic addition to carbon nanotubes has been reported by Tagmatarchis et al. [72]. This reaction utilized a commercially available HiPco-SWNTs (95 wt. % purity) for derivatization through electrophilic addition of $CHCl_3$ in the presence of $AlCl_3$ as a strong Lewis acid. The SWNTs were activated by solid state mechanical grinding with $AlCl_3$ and then refluxed in dry $CHCl_3$ for 48 h to produce a yellow colored intermediate adduct with the suggested -$CHCl_2$ and -Cl groups attached to the SWNT sidewalls (Scheme 7).
Scheme 7.

Due to its labile nature, this material could not be isolated and characterized. Nevertheless, the isolable derivative was obtained after hydrolysis of this intermediate in a one-pot procedure with alkaline methanol to substitute the reactive Cl atoms with OH groups, which have been detected by FTIR spectroscopy using DRIFT accessory. Treatment of this derivative with propionyl chloride gave ester-functionalized SWNTs, showing characteristic bands of C=O, C—O, and CH stretches in IR spectrum and having a solubility in chloroform or acetone improved enough to allow characterization by ^1H NMR spectroscopy.

3. CHEMICAL MODIFICATIONS OF OXIDIZED CARBON NANOTUBES

As discussed in Section 2.1., the oxidation of carbon nanotubes results predominantly in open-ended tubes terminated with carboxylic acid groups (-COOH). The reactivity of these groups has been utilized in further chemical modifications of nanotubes. The first derivatization of the open ends of the shortened SWNTs was done by Liu et al. [32] by converting the carboxylic groups to the corresponding acid chloride using $SOCl_2$. Subsequent treatment of the obtained SWNT-COCl with NH_2—$(CH_2)_{11}$—SH yielded an amide linkage of the nanotube end to the alkanethiol. The formation of a free thiol moiety has been verified by tethering the end of the nanotube to 10 nm diameter colloidal gold particles and imaging by AFM. These thiol derivatized SWNTs have been assembled on gold substrates in orientation normal to the surface, providing an ordered array of SWNTs useful for various applications, for example, in field emission devices [73].

Chen et al. [23] and Hamon et al. [24] used a similar acyl chloride modification chemistry for producing the soluble nanotubes by attaching a long-chain octadecylamine $CH_3(CH_2)_{17}$-NH_2 and 4-dodecyl-aniline 4-$CH_3(CH_2)_{13}C_6H_4NH_2$ to the open ends of the SWNTs via formation of the amide functionality. Both SWNT derivatives have shown similar solubility in chloroform, dichloromethane, aromatic solvents (benzene, toluene, chlorobenzene, 1,2-dichlorobenzene), and CS_2. The solubilities in 1,2-dichlorobenzene and CS_2, in particular, were found to be above 1 mg/ml. The IR spectra indicated that the amide derivatization took place, while the presence of long aliphatic chains at the ends of SWNTs was suggested based on solution ^1H NMR spectra. In contrast to the sidewall functionalized SWNTs, no significant alteration of the band electronic structure as compared to pristine SWNTs has been observed in Raman and UV-Vis-NIR spectra of the end-derivatized nanotubes. The direct acid-base reaction of the oxidized nanotubes, SWNT-COOH, with octadecyl amine resulted in noncovalently bonded zwitterionic product {SWNT-COO⁻, ⁺$NH_3(CH_2)_{17}CH_3$}, soluble in THF and CH_2Cl_2 [24, 35]. The improved solubility of the amide end-functionalized SWNTs allowed their high purification by using gel-permeation chromatography [74].

The application of nanotubes, functionalized through modification of carboxyl groups by reactions with benzylamine or ethylenediamine, as nanosized probe tips in atomic force microscopy has been demonstrated by Wong et al. [14, 75]. End-to-end and end-to-side intermolecular nanotube junctions have been formed by reacting an open-end and sidewall acid chloride derivatized SWNTs with aliphatic diamine, NH_2—$(CH_2)_3NH(CH_2)_3NH(CH_2)_{23}$—$NH_2$, which served as a molecular linker [76]. These chemically created interconnections of nanotubes were imaged by AFM. The observed in Raman spectra (623.8 nm) downward shift (to 1578 cm⁻¹) of the tangential mode peak of the modified nanotubes versus that in pristine SWNTs (1583 cm⁻¹) can be explained by the NH_2-terminal group of the sidewall functionality providing electron donation to the carbon π^* bond.

Basiuk et al. [77] have studied a chemical derivatization of the nanotube tips using a direct reaction of simple

aliphatic amines with oxidized SWNTs, which were treated by amine vapors under reduced pressure and temperatures of 160–170 °C. The amines studied included nonylamine, dipentylamine, ethylenediamine, and propylenediamine. It was concluded that the terminal amide functionalities formed on the SWNT tips can not be detected in the IR spectra because their concentrations are too low relative to the whole mass of the nanotube. Therefore, all IR bands observed for amine-treated samples in this and previous studies should be assigned only to corresponding amine molecules physisorbed on SWNT walls. Variable temperature pyrolysis-mass spectrometry (VTP-MS) analysis of the amine-treated samples heated above 200 °C indicated cleavage of alkenes, such as nonene and pentene, in case of nonylamine and dipentylamine-treated samples, respectively. These results were explained by thermal decomposition of the alkylamide groups on the SWNT tips (Scheme 8). DFT calculation data suggest that the direct formation of amides on armchair SWNTs should be more energetically favorable than in case of zigzag ends, although the activation energies are almost equal. This theoretical prediction could promote experimental studies aimed at selective end-functionalization, solubilization, and sorting of different types of SWNTs.

SWNT-C(=O)NH-(CH$_2$)$_8$-CH$_3$ $\xrightarrow{\text{pyrolysis}}$ SWNT-C(=O)NH$_2$ + CH$_2$=CH-(CH$_2$)$_6$-CH$_3$

Scheme 8.

A series of soluble end-functionalized SWNTs and MWNTs has been prepared by Riggs et al. [25], Sun et al. [26], Czerw et al. [78], and Fu et al. [79] using amidation and esterification reactions of oxidized nanotubes. After conversion of their carboxylic acid groups into acyl chlorides, they were reacted with copolymers such as poly(propionylethylenimine-co-ethylenimine) and poly(vinyl acetate-co-vinyl alcohol) at 165 °C for 20 min [25, 78]. The resulting polymer-bound nanotubes are soluble both in organic solvents and water, forming highly colored solutions that show strong luminescence [25]. In a similar procedure, the lipophilic and hydrophilic dendron species terminated with long alkyl chains, and oligomeric poly(ethylene glycol) moieties have been attached to SWNTs and MWNTs [26, 79]. The lipophilic dendron-functionalized nanotubes are soluble in hydrocarbons and weakly polar organic solvents, while the nanotubes with attached poly(ethylene glycol) moieties dissolve in organic solvents and water. It was also shown that these nanotubes can be chemically defunctionalized under base and acid-catalyzed ester hydrolysis conditions, providing evidence for presence of ester linkages in the functionalized nanotubes [79].

4. REACTIONS OF FLUORONANOTUBES

4.1. Pyrolysis for Nanotube Cutting

Examination of the products of thermal decomposition of C$_2$F fluoronanotubes *in vacuo* at temperatures of up to 800 °C by VTP-MS revealed the following species: CF$_3^+$

(m/z = 69), C$_3$F$_5^+$ (m/z = 131), C$_3$F$_7^+$ (m/z = 169), and C$_4$F$_7^+$ (m/z = 181) [48]. These data indicate that the pyrolysis of fluoronanotubes is dominated by formation of volatile carbon-fluorine-containing molecules and not just the loss of elementary fluorine. Along with the observation of the extended dark bands in the STM images of the partially fluorinated SWNTs C$_n$F (n > 2) due to bare nanotube side walls, these results have led to the idea of using fluorination followed by pyrolysis as chemical "scissors" for cutting the nanotubes. Recently, Gu et al. [80, 81] have demonstrated a process that involves the fluorination of catalyst-free purified HiPco-SWNTs to a stoichiometry of C$_5$F followed by pyrolysis at temperatures up to 1000 °C in an argon atmosphere that results in cutting the nanotubes at the fluorinated sites to short lengths (20–200 nm). When the pyrolysis process was monitored *in-situ* with TGA-FTIR, the fluorine was shown to be driven from the fluoronanotube structure as CF$_4$ and COF$_2$ (due to oxygen covalently attached to the SWNT side-wall during the first steps of the purification procedure [82]). The cut SWNTs were characterized by Raman spectra, TGA data, and AFM images. The latter show their drastically shortened lengths in comparison with the pristine SWNTs. Studies of the cut SWNTs are now in progress for potential applications including chemically assisted assembly, gas adsorbants, drug delivery vehicles, and polymer composite reinforcements.

4.2. Chemical Derivatization of Fluoronanotubes

Recent DFT calculations of the electronic densities of states have shown that the Fermi energy of the fluoronanotubes is considerably shifted towards lower values compared to the pristine SWNTs. The conduction bands are energetically lowered as well [57]. This implies that the fluoronanotubes are better electron acceptors than the bare carbon nanotubes, and therefore they should more eagerly interact with strong nucleophilic reagents as well as undergo reduction to bare SWNTs by alkali metals. These chemical reactions are also facilitated by the fact that the C—F bonds in fluoronanotubes as in fluorinated fullerenes are weakened relative to the C—F bonds in alkyl fluorides owing to an eclipsing strain effect [83, 84], and thus fluorine could be more easily displaced. The unique electronic structure and improved solubility of fluoronanotubes and the weaker C—F bond have opened new opportunities for chemical syntheses of a wide variety of sidewall functionalized nanotubes with interesting properties using fluoronanotubes as precursors.

4.2.1. Reactions with Organolithium Reagents

Strong nucleophiles, such as alkyl lithium reagents, can be used to attach alkyl groups to the sidewalls of the nanotubes [49, 85]. The reactions have been carried out by adding the RLi (R = methyl, *n*-butyl, *t*-butyl, *n*-hexyl, phenyl) reagent to the fluoronanotubes, dispersed in THF, ether, or hexane, at −40 °C followed by sonication for 10 min and stirring at room temperature overnight under argon. After completion of the workup procedure [49], the final products were dried

in a vacuum oven and then characterized by ATR-FTIR, UV-Vis-NIR, TGA, and TGA-FTIR techniques.

The alkylated SWNTs have shown in the ATR-FTIR spectra the typical alkyl groups C—H stretching and deformation absorptions in the 2850–2970 cm^{-1} and 1000–1470 cm^{-1} regions, respectively, as well as a peak at about 1580 cm^{-1} due to an activated C=C stretching mode of the nanotubes (Fig. 4). The observed absence of the van Hove electronic transition features in the UV-Vis-NIR spectra supports the occurrence of sidewall functionalization, which dramatically alters the electronic structure of alkylated nanotubes with respect to the pristine SWNTs. As a result, these alkylated SWNTs are soluble in common organic solvents such as THF and chloroform.

Based on the weight loss at 200–450 °C during the TGA runs, the nanotube carbon-to-alkyl ratios were calculated for methyl, *n*-butyl, and *n*-hexyl SWNTs, which indicate that alkylation of the fluorinated HiPco-SWNTs results in a higher degree of functionalization in comparison with the L-SWNTs, in line with the expected enhanced reactivity due to the increased tube curvature. The obtained STM images of the sidewall butylated SWNTs show that for these derivatives the typical fluoronanotubes' banded morphology is no longer visible. Instead, relatively large (∼10 Å) bright spots due to sidewall attached butyl groups with an average spacing of 50 Å are apparent while scanning along the nanotube [56].

The TGA-FTIR analysis has shown on the derivative plots a single maximum for the methylated and two maxima for the *n*-butylated and *n*-hexylated SWNTs, respectively. These maxima were synchronized by the same peaks on the chemigrams of the C—H stretching region in the FTIR spectra of volatile products, demonstrating the presence of corresponding alkyl groups in the nanotubes and also a likely two-step mechanism of the removal of the alkyl groups other than methyl. The VTP-MS studies of the methylated SWNTs have shown that under vacuum conditions the evolution of methyl groups (m/z = 15) is maximized at a temperature of
about 490 °C, which is far too high to be due to physisorbed species [48]. The alkylation of the SWNTs was found to be reversible, since after heating of these materials in Ar at 500 °C, a complete recovery of the pristine nanotubes has occurred.

Due to the steric effect, *t*-butyl lithium did not react effectively, resulting in a low alkylation and a predominant defluorination of the fluoronanotubes to yield a product showing the van Hove transition bands in the UV-Vis-NIR spectra. Steric effects can also account for more extensive alkylation observed in cases when less sterically demanding alkyl lithium reagents, such as methyl lithium, were used. These results are consistent with a multistep process that is initiated by a one-electron transfer to the fluoronanotube from the alkyl lithium reagent. Elimination of fluoride from the resulting radical-anion would lead to a radical site on the SWNT. Recombination of the alkyl radical with this radical site will result in the covalent attachment to the sidewall. This step is likely sterically controlled, suggesting that, due to crowding of the attaching groups, not every fluorine can be replaced by a new functionality, such as an alkyl group.

4.2.2. Reactions with Grignard Reagents

The sidewall alkylation of fluoronanotubes by the Grignard reagents (alkyl magnesium bromide) in THF has also been carried out [86]. These reactions were done simply by bath sonication of the fluoronanotube paper in excess Grignard reagent in THF for several hours. The solubility of the hexylated SWNTs prepared in a such way in chloroform was up to ∼0.6 g/L, as compared to maximum concentration of 0.1 g/L of pristine nanotubes to form stable suspensions in DMF. By heating in air to 250 °C the pristine SWNTs were recovered from the hexylated derivative for which the attachment of a hexyl group to about 1 in every 10 sidewall carbon atoms has been calculated based on the weight loss monitored by TGA. The analyses of AFM images before and after air oxidation show that the recovered individual tubes are thinner by 2–5 Å after burning off the hexyl groups from side walls. The AFM data also indicate that unlike the partially fluorinated SWNTs, this procedure does not shorten the nanotubes. After removal of the hexyl groups, the two-point electrical resistance measurements across the bucky paper have shown a drop from 372.5 kΩ to 144.6 Ω, a value typical of pristine nanotube papers.

Longer alkyl chain substituents have been attached to the sidewalls of the SWNTs by first generating the Grignard reagents *in-situ*, and then adding the fluronanotubes [87]. Thus, the *n*-decylated SWNTs were prepared by reacting 1-bromodecane with magnesium in ether and than quenching the decyl magnesium bromide with the fluoronanotube suspension in dry ether with stirring for 72 hours. The reaction with the di-Grignard reagent, prepared in a similar way from 1,10-dibromodecane, also resulted in sidewall functionalization and also in cross-linked nanotubes through alkane chains. The TGA and TGA-FTIR data indicate loss of attached alkyl groups at temperatures of 320–370 °C leading to a recovery of pristine SWNTs features in the Raman and UV-Vis-NIR spectra.

Figure 4. ATR-FTIR spectra of alkylated SWNTs: (a) [CH$_3$]$_x$-SWNTs, (b) [CH$_3$CH$_2$CH$_2$CH$_2$]$_x$-SWNTs, (c) [CH$_3$CH$_2$CH$_2$CH$_2$CH$_2$CH$_2$]$_x$-SWNTs.

4.2.3. Reactions with Alkoxides

The solubility of fluoronanotubes in alcohols prompted their functionalization reactions with alkoxides. For instance, sonication of the fluoronanotubes ($\sim C_2F$) in methanol solution of sodium methoxide for 2 hrs resulted in the formation of methoxylated tubes with the stoichiometry of $C_{4.4}F(OCH_3)_{0.25}$ suggested from electron probe microanalysis (EPMA). Thermal degradation studies by VTP-MS show that under vacuum conditions this product loses significant quantities of methoxy groups ($m/z = 31$) at temperatures of 650–700 °C, indicating that these groups were originally strongly bonded to the nanotube. Based on these data and on elevated oxygen content from the EPMA, the conclusion was made that the methoxy groups are bonded to the nanotube sidewalls [48, 54]. Recently, the functionalizations of the fluorinated SWNTs by methoxy, ethoxy, and *iso*-propoxy groups were also done by sonication in lithium hydroxide solutions in methanol, ethanol, and *iso*-propanol, respectively [88].

4.2.4. Reactions with Hydrazine and Diamines

The SWNTs, once fluorinated, can be efficiently defluorinated with anhydrous hydrazine via the following reaction: $C_nF + 1/4N_2H_4 \rightarrow C_n + HF + 1/4N_2$, done by stirring at room temperature either in neat hydrazine for 1 hr or after addition of hydrazine to solutions of fluoronanotubes. The EPMA analysis of the solid precipitate yielded a very low fluorine content and no nitrogen, confirming that only defluorination and not the functionalization of the SWNTs by amino moiety has occurred [47, 48, 54]. Such an outcome of this highly exothermic reaction can be explained by the opportunity to produce (in addition to HF) the highly thermodynamically stable N_2 molecules. This defluorination process by hydrazine provides a useful tool for chemical modification of the side walls of the SWNTs, which can be applied for removal of residual fluorine from alkylated fluoronanotubes or for controlled partial defluorination of fluoronanotubes to produce SWNTs with various fluorine contents and, presumably, different properties.

Unlike the defluorinating action of hydrazine, the terminal diamines, $H_2N(CH_2)_nNH_2$ ($n = 2, 3, 4, 6$), can be used to functionalize the SWNTs by creating a direct C—N bonding attachments to the sidewalls. These reactions (Scheme 9) were performed by refluxing the fluoronanotubes in the corresponding diamine for 3 hrs in the presence of a catalytic amounts of pyridine [89, 90].

$$-[\,F\,]_x + H_2N(CH_2)_nNH_2 \xrightarrow[-HF]{\substack{Py \\ 70-170\ ^\circ C}} -[\,NH(CH_2)_nNH_2\,]_y$$

$$n = 2\text{–}6$$
$$x > y$$
Scheme 9.

The elemental analysis of the washed and dried black precipitates by the EDX yielded a nitrogen content within 11–16 at. %, and only a very low fluorine content (1–2 at. %), suggesting its efficient displacement by the *N*-alkylamine functionalities. The TGA-FTIR and VTP-MS

studies have provided strong evidence for covalent functionalization by the diamines, showing a major loss of the corresponding attached groups at $\sim$350–400 °C, which were detected, for example, in mass spectra by peak at $m/z = 59$ ($HNCH_2CH_2NH_2$) in case of ethylendiamino-SWNTs, and by peak at $m/z = 73$ ($HNCH_2CH_2CH_2NH_2$) in the case of propylendiamino-SWNTs. The TEM images of *N*-alkylaminated samples have revealed in addition to the individual sidewall functionalized SWNTs (Fig. 5a) also a number of the nanotubes cross-linked by the diamino chains, which are more abundant in the case of the larger chain derivatives, hexamethylendiamino-SWNTs (Fig. 5b). It is interesting that all *N*-alkylamine functionalized samples have been tested positively by the Kaiser testing procedure for the free NH_2 groups. Their availability makes these nanotubes soluble in dilute acids and water and allows them to react, for example, with the adipyl chloride to form new "nylon tube" materials, as well as to covalently bind to
Figure 5. TEM images of aminoalkyl functionalized SWNTs: (a) ethylendiamino-SWNTs, (b) hexamethylendiamino-SWNTs.

polymer matrixes in nanocomposites or to attach the DNA base to the SWNTs.

4.2.5. Reactions with Peroxides

The fluorinated HiPco-SWNTs have been reacted with lauroyl and benzoyl peroxides under the same conditions as pristine nanotubes (see Section 2.4) in order to compare the reactivity of their corresponding polyaromatic and conjugated polyene π-systems toward radical addition [68, 69]. Both reactions resulted in successful attachment of undecyl and phenyl radicals to the sidewalls of fluoronanotubes along with the substantial removal of fluorine. The addition of undecyl radicals, $C_{11}H_{23}$, generated from lauroyl peroxide, was apparently proceeding more readily in case of fluoronanotubes than pristine SWNTs, as indicated by a much lower reaction time (3 hrs vs. 5 days) required for observation of prominent C—H stretch peaks in the ATR-FTIR spectra of undecylated fluoronanotubes (Fig. 6a). The covalent attachement of long-chain groups to the sidewalls in these derivatized nanotubes was imaged by the TEM (Fig. 6b) and confirmed by the TGA-FTIR and VTP-MS data, indicating the major loss of undecyl radicals and their dimer at temperature of about 350–400 °C (peaks in MS at $m/z = 155$ and 310, respectively).
Figure 6. Characterization of undecyl radical ($C_{11}H_{23}$)-derivatized fluoronanotubes: (a) ATR-FTIR spectrum, (b) TEM image.

4.2.6. Solid State Inorganic Reactions

Studies of the solid state reactions of fluoronanotubes with the series of binary compounds of VA, VIA, and VIIA group elements were prompted by the initial observation of significant reduction of the intensity of the C—F stretch peak in the FTIR spectra of fluorinated SWNTs pressed into KBr pellets as compared to the ATR-FTIR spectra of neat samples [49]. When heating a mixture of fluoronanotubes, C_2F, with KBr at ~120 °C, the evolution of reddish gas was observed, and defluorinated SWNTs and KF were formed according to a reduction-oxidation reaction: $(C_2F)_n + nKBr \rightarrow 2C_n + n/2Br_2 + KF$, as established by the FTIR, Raman, and powder XRD analyses. The other halides, such as KI, LiI, LiBr, and LiCl, have undergone similar transformations, while NaCl and ZnI_2 produced minor changes of the fluoronanotubes [91]. For comparison, fluorinated C_{60} also reacts as an oxidant losing fluorine substantially when heated with KBr, while the fluorographite fluorine remains attached to graphite carbons under the same experimental conditions due to the much stronger C—F bonds [92]. Among the metal compounds of VA and VIA group elements studied, the sulfide anion in lithium sulfide has been easily oxidized to elemental sulfur by the fluoronanotubes already at room temperature, while in the case of zinc sulfide, prolonged heating (24 hrs) at 100 °C was required. The oxides, Li_2O, FeO, PbO, and MnO, did not react even at 200 °C, while lithium peroxide reacted at room temperature to form LiF, O_2, and defluorinated SWNTs. The fluorination of aluminium phosphide by fluoronanotubes to form aluminium trifluoride also took place at room temperature, while the redox reaction with lithium nitride, Li_3N, yielding LiF and N_2, proceeded at 200 °C. It should be noted that when the latter reaction was conducted in a diglyme solution at a lower temperature, no N_2 evolution was observed due to the apparent formation of a SWNT-$(NLi_2)_x$ intermediate, which after subsequent quenching with alkyl chlorides (RCl, R = H, n-butyl, benzyl) yielded sidewall amino- and alkylamino functionalized nanotubes [93] (Scheme 10).
Scheme 10.

In summary, the efficiency of solid state redox reactions of the fluoronanotubes studied are most likely influenced by a combination of two factors: (i) the electronegativity of VA, VIA, and VIIA group elements and (ii) the thermodynamic stability of metal fluoride products to be formed. This explains the mild conditions required for these reactions to proceed in case of lithium halides and a sulfide, and aluminium phosphide, containing the less electronegative elements and producing the very stable fluoride salts, AlF_3 and LiF.

In recent work [94], the fluoronanotubes, C_2F, were also used as cathodes in a lithium electrochemical cell, for which the discharging performance via a solid state redox reaction $C_2F + Li \rightarrow C_2 + LiF$ has been studied. This cell was

found to produce a higher cell potential than that of a commercially used fluorographite CF_x cell; however, it lasted a shorter time, consistent with the lower fluorine content and weaker C—F bonds in the fluoronanotubes.

5. SUMMARY

This review shows that although studies of the chemistry of carbon nanotubes have been in progress only for a few years, they already have led to the development of useful synthetic tools for chemical modification of single- and multi-wall carbon nanotubes. The chemical methods developed include oxidation; hydrogenation, fluorination; and addition of free radicals, carbenes, nitrenes, and 1,3-dipolar intermediates to pristine nanotubes. The oxidized nanotubes as well as fluoronanotubes are becoming in turn widely used as precursors for subsequent derivatizations, thus serving as chemical synthons for new nanoscale materials. The nanotube derivatives covalently functionalized at the open ends or at the sidewalls show improved solubility and processibility in common solvents, and electrical, optical, and spectroscopic properties different from pristine nanotubes. The "chemical scissor" method for chemical cutting of the single-wall carbon nanotubes 20–200 nanometer lengths, utilizing partial fluorination and pyrolysis of SWNTs, will open additional opportunities for the functionalization chemistry and studies of the length related properties of the cut nanotubes. As a result, various applications of chemically modified carbon nanotubes, e.g., in nanocomposites, nano-electronic devices, nanoengineered drug delivery systems, nanolubricants, etc., are expected to emerge from the continuing chemical research in the interdisciplinary field of nanotechnology.

GLOSSARY

Fluoronanotube Fluorinated nanotube. A macromolecule consisting of single-walled tubule surrounded by fluorine atoms chemically bonded to carbon atoms of the sidewall.

Functionalization A modification of the structure of material by attachment of the chemical functional groups bringing new physicochemical properties.

HiPco-SWNT A single-walled carbon nanotube produced by disproportionation reaction of carbon monooxide under high-pressure.

L-SWNT A single-walled carbon nanotube prepared by a process that utilizes laser vaporization of graphite.

Multiwalled nanotube (MWNT) A macromolecule made of concentric graphitic layers surrounding the central tubule.

Single-walled nanotube (SWNT) A macromolecule consisting of a single graphitic cylinder capped with fullerenelike halfsphere.

Chiral Macrocycles

Suk Joong Lee, Wenbin Lin

University of North Carolina, Chapel Hill, North Carolina, USA

CONTENTS

1. INTRODUCTION

A contemporary topic of modern chemistry is concerned with expanding its ability to mimic forms and functions of Mother Nature [1, 2]. Synthetic chemists have strived to accomplish this via spontaneous self-assembly of well-defined, complex supramolecular assemblies from constituent subunits in solution [3]. Since the discovery of crown ethers in 1967 [4], numerous studies have been carried out on cyclic and cage compounds, and as a result, many interesting synthetic receptors are now available and have found important practical applications. Examples of practically useful macrocycles include naturally occurring antibiotic nonactin (**1**) which has been used as the receptor in commercial ion sensitive electrodes for NH_4^+ and a chiral crown ether (**2**) which has been used in commercial high performance liquid chromatography columns for the separation of α-amino acids (Scheme 1) [5]. In addition to their important practical applications, rational design of such nanoscopic supramolecular assemblies represents an important bottom-up approach toward the burgeoning field of nanoscience and nanotechnology [6].

Typically low-yielding synthesis of macrocycles and cages have, however, impeded many more potentially practical applications. In order to avoid the formation of undesired linear oligomers, macrocycles and cages are normally synthesized under high-dilution conditions. Such synthetic conditions require the use of enormous amounts of solvents and present a major burden to the environments and are thus not suitable for their large-scale syntheses. Whereas macrocyclization under the aforementioned kinetic controls is a challenging process, macrocycles can sometimes be obtained in high yields under thermodynamic conditions.

Excellent examples of high yield formation of macrocycles under thermodynamic conditions are provided by phenol-formaldehyde or resorcinol-aldehyde cyclic oligomers (calixarenes) that are formed under equilibrium conditions. Facile synthesis of calixarenes suggests that thermodynamic control should be a good strategy for macrocycle (or cage) synthesis [7].

The concept of thermodynamic control has recently been applied to noncovalent syntheses. Spontaneous generation of well-defined supramolecular architectures has been achieved under thermodynamic conditions via self-assembly driven by noncovalent bonds such as hydrophobic interactions, $\pi-\pi$ interactions, hydrogen bonding, and metal–ligand ligation [8, 9]. In particular, metal–ligand coordination bonding has been extensively used to construct such supramolecular structures as helices, rods, macrocycles, and cages [7]. These structures are spontaneously generated by simply mixing component ligands and metals in solution. Among defined structures, macrocycles and cages are particularly interesting because of their potential application as synthetic receptors. Several excellent reviews have appeared on the topic of coordination-driven self-assembly of metallosupramolecular systems over the past few years [10]. In this chapter, we will focus on recent developments in rational design of discrete chiral macrocycles, with a particular emphasis on chiral metal-containing self-assembled macrocyclic structures. Potential applications of these interesting chiral supramolecular systems will also be presented.

1.1. Rational Design of Macrocycles

A major advance in the design of macrocyclic structures lies in the ability to predict the structures of resulting supramolecular assemblies based on the information contained in their molecular building blocks. Well-defined supramolecular architectures can be rationally assembled via recognition-driven spontaneous assembly of presynthesized subunits. Such a "coden" approach is extremely important for the synthesis of macrocyclic species based on stronger interactions such as covalent and coordination bonds [11]. Unlike supramolecular structures found in Mother Nature which are built from relatively weak hydrogen bonds and van der Waals interactions, macrocycles and cages built from

(1) Nonactin   **(2) Chiral crown ether**

Scheme 1.

Figure 1. Schematic depiction of routes for the self-assembly of cyclic structures. Reprinted with permission from [6], S. Leininger et al., *Chem. Rev.* 100, 853 (2000). © 2000, American Chemical Society.
stronger covalent or coordination bonds do not necessarily exhibit appreciable kinetics for reversible annealing of defects during the self-assembly processes. Therefore, properly designed building subunits with appropriate shapes and functionalities are needed for the assembly of discrete supramolecular assemblies.

Such a "coden"-based approach has been elaborated by Fujita and Ogura [12] and systematized by Stang et al. for the synthesis of metallomacrocycles and metallocages [13, 14]. By using rigid, highly directional multibranched ligands as donor units and unsaturated transition metal moieties with fixed bond angles as the acceptor units, well-defined metallocycles can be readily assembled via metal–ligand coordination [6]. Both angular and linear building subunits are needed for the construction of cyclic structures. While angular subunits contain two reactive sites that are oriented at an angle between 0° and 180° [13], linear subunits possess two reactive sites which are opposite to each other (i.e., ~180°). The combination of these building subunits will lead to a metallosupramolecular system whose structure depends solely on the symmetry and the number of binding sites within each subunit. For example, the assembly of a planar triangle requires the combination of three linear building subunits blocks and three 60° angular ones. A molecular square can be assembled in several different ways, including a combination of four linear and four 90° angular building units and a combination of two different 90° angular subunits. Combining five linear subunits with five angular ones that possess a 108° angle between their binding sites will generate a molecular pentagon as illustrated in Figure 1 [6, 13, 14]. These principles assume total conformational ridigity of subunits, but some distortion of the binding angle can occur. Metallocycles of different shapes from those predicted by these simple geometrical relationships can sometimes result from the combination of building subunits.

1.2. Thermodynamic Factors in the Self-Assembly of Metallocycles

As mentioned earlier, the requirements for thermodynamic self-assembly of a metallocycle are that (i) coordination bonds must form between the donor and acceptor elements involved, (ii) the bonds must be kinetically labile to allow self-correction, and (iii) the desired assembly must be thermodynamically favorable over competing species [8].

Thermodynamic factors in the self-assembly of macrocyclic compounds have been widely examined [15, 16]. It is well established that cyclic structures are preferred over linear ones for enthalpic reasons, while small cycles are favored over large cycles (at low concentrations) for entropic reasons. The enthalpic preference arises from the fact that an increased number of bonds per subunit is possible in a cyclic arrangement relative to a linear one. For example, a square consisting of two angular units and two linear units contains four coordinate bonds, that is, one bond per building block (Fig. 2a). Its equivalent acyclic coordination oligomer is coordinatively unsaturated in one end and therefore contains only three bonds, that is, 0.75 bonds per building block (Fig. 2b).

Acyclic oligomers can polymerize to increase the number of bonds formed. However, the donor and acceptor sites at each end of the polymer will always remain uncoordinated. Thus, the ideal scenario of one bond per building block cannot be achieved unless cyclization occurs. If cyclization is unfavorable, it is likely that the oligomers will polymerize until higher oligomers precipitate as kinetic products.

The entropic preference referred to is a result of Le Chatelier's law, which states that a perturbation to a dynamic equilibrium results in a readjustment of the equilibrium to minimize its effect. Thus, dilution of a solution containing an equilibrium mixture of cyclic oligomers results in a shift of the equilibrium to increase the total number of species present. At low concentrations smaller cycles are consequently favored, with the reverse being the case
Figure 2. Different number of bonds in cyclic and acyclic structures.

at high concentrations. As most self-assembly reactions are performed in dilute solution, the smallest possible cycles are usually favored. In metallocycles, the enthalpic driving forces invariably dominate the entropic ones because of the large enthalpy of coordination bond formation.

2. ORGANIC MACROCYCLES

Molecular recognition is key to many biochemical processes such as antibody–antigen interactions, biocatalytic reactions, and signal transcriptions [17]. The use of single enantiomeric forms of amino acids and sugars in biological systems is largely responsible for these remarkable biochemical processes that make life possible. Synthetic chemists have devoted significant effort to the design and synthesis of chiral macrocycles for the stereoselective recognition of chiral substrates.

Cram and co-workers have carried out pioneering studies of enantiomeric recognition of organic ammonium salts by solvent extraction techniques [18–20], transport of amides through liquid membranes [21], and partial resolution of amino acids on silica gel or polystyrene that are grafted with chiral host materials [22]. Lehn and Sirlin have found that reactivity of the thiolyzation reaction of certain *p*-nitrophenyl esters increased drastically after the addition of chiral host molecules [23]. Many other chiral macrocycles have been designed and used as synthetic receptors for enantioselective recognition over the past few years. Exciting recent developments in nanoscopic cyclopeptides [24–27] and circular oligonucleotides [28, 29] will not be discussed here.

Zhao and Hua [17] reported *α*-amino acid derived chiral macrocycles for enantioselective recognition of D- and L-amino acid methyl ester hydrochloride. These chiral macrocycles were prepared by the acylation cyclization of 2,6-pyridinedicarbonyl dichloride and chiral diamine dihydrobromide intermediates which were obtained from condensation of chiral amino acids and 2,6-bis(hydroxymethyl)pyridine, in highly diluted solution at room temperature. When L-alanine and L-valine derived diamine intermediates were used as the chiral building blocks, both [1 + 1] and [2 + 2] cyclization products **1a–e** were obtained. In contrast, only [1 + 1] cyclization product was obtained when the L-proline derived diamine intermediate was used (Fig. 3). These chiral macrocycles exhibited interesting chiral recognition for the enantiomers of D- and L-amino acid methyl ester hydrochlorides, which have been characterized by fluorescence spectroscopy.

In a recent publication, Kohler and co-workers [30] reported a series of chiral macrocycles, **2a–b**, which consist of two angular chiral building units and two linear building units (Fig. 4). These novel semirigid, chiral cycles were synthesized by condensation of two rigid oligoarylene rods and two chiral spiroindane clips. With electronically interacting arylene chromophores and internal helicity resulting from chiral spiroindane clips, these macrocycles act as chiral dopants of polymeric nematic liquid crystals.

Helically arranged, electronically interacting chromophores are keys to the design of novel chiroptical materials, particularly light-emitting materials that provide intrinsically circularly polarized light. Chiral ensembles of electronically interacting chromophores in such materials will give rise to
Figure 3. Chiral macrocycles for amino acid recognition. Reprinted with permission from [17], H. Zhao and W. Hua, *J. Org. Chem.* 65, 2933 (2000). © 2000, American Chemical Society.

the chiroptical effects which can be interpreted on the basis of the so-called exciton coupling model [31]. Such chiral interactions in a polymeric material can be experimentally studied on model dimers composed of two chromophores that are fixed at a chiral core unit [32], for example, a chiral 3,4-diaminodecaline core. However, this type of chiral model compound has a comparably high degree of remaining conformational freedom and thus does not adequately represent the chiroptical effects in a rigid, chiral conjugated polymer. The cyclic structure of **2a–b** with two rigid chromophores that are fixed by two chiral clips on both ends provides a better model for chiroptical effects in a rigid, chiral conjugated polymer.
Figure 4. Chiral macrocycles containing two arylene chromophores. Reprinted with permission from [30], B. Kohler et al., *Chem. Eur. J.* 7, 3000 (2001). © 2001, Wiley–VCH.

Organic macrocyclic molecules with rings larger than 20 atoms are far less abundant than their smaller ring counterparts [33, 34]. An interesting class of organic macrocycles, polyazamacrocycles, are typically synthesized either by Schiff base condensation between aliphatic diamines and aromatic dialdehydes or by cyclic amide formation between aliphatic diamines and dicarboxylic acids dichlorides under high-dilution conditions [35–38]. These condensation techniques only allow the synthesis of small- to medium-sized rings. An alternative cation templating method is needed to form larger size rings in which multiple components are preorganized by the cation templates. For example, π-conjugated and partially reduced macrocyclic Schiff bases have been obtained by efficient proton-templated $[2+2]$ cyclocondensation of 2,6-diformyl-4-R_1-phenol ($R_1 =$ Me, t-Bu) and 1,2-diamino-4,5-R_2-benzene ($R_2 =$ H, Me) [39].

Larger macrocycles can be obtained in high yields if the intermediates adopt a restricted conformation which favors the cyclization of large rings. The synthesis of hexamethylenetetramine from ammonia and formaldehyde provides an excellent example of an efficient assembly of a multicyclic compound. This reaction is believed to proceed through a diimine intermediate and is directed by the ability of the chair-like 6-membered rings to form an adamantine-like structure [40]. Preferential formation of a 12-membered heterocycle over the open-chain oligomers has also been achieved by taking advantage of conformational effect of the bulky N-tosyl substituents in the diamine component [41]. Recently, Gawroński et al. [42] demonstrated conformationally driven $[3+3]$ cyclocondensations to give chiral macrocyclic triangular structures using $(1R, 2R)$-1,2-diaminocyclohexane as a chiral building unit (Fig. 5). Since this building unit contains a rigid structure and equatorial amino substituents, it would facilitate ring formation in the reaction with planar molecules. The two C–N bonds in angular units are projected at a 60° angle from the center of the cyclohexane ring and provide rigid and equatorial ditopic reaction sites, and hence macrocycle formation is anticipated to proceed through a $[3+3]$ diamine–dialdehyde addition when 180° linear or planar ditopic building units are encountered, with molecules 60° angular unit placed at each vertex of a regular triangle in the final product (Fig. 5).
Remarkably, chiral macrocycles **3a–b** were indeed synthesized in very high yields (ca. 90%) even in high concentrations (ca. 0.4 M). **3a** and **3b** possess D_3 and C_3 point group symmetry, respectively, and they can be readily reduced by $NaBH_4$ to give chiral macrocycles **3c** and **3d**.

The major advantage of the introduction of a cage moiety into the chiral macrocylic system is the generation of rigidity into the macrocycles which influences their overall conformational mobility [43]. Moreover, since the cage moiety can perform as a lipophilic component, the solubility of cage-containing crown ethers in nonpolar solvents can be improved compared to that of the non-cage-containing crown ethers. One of these examples has been demonstrated by Marchand and co-workers [43]. They reported the synthesis of a series of chiral cage-annulated crown ethers for the host–guest interaction study. These novel chiral macrocycles were synthesized by incorporating either an optically active monosccharide derivative or a tartaric acid derivative into each cage-annulated crown ether to generate the chirality via a NaH promoted reaction in dried THF (Fig. 6).

An et al. [44] demonstrated very interesting enantiopure double-helical alkynyl cyclophanes **12** of both enantiopure forms (Fig. 7). As is shown in the crystal structure, the cyclophane backbone is twisted, resulting in the double-helical motif. The alkynyl groups are slightly bent from linearity. Interestingly, the dihedral angles of the two binaphthyl groups are significantly different by about 10 degrees (68° and 78°, respectively). Since the inside hydrogen atoms of the phenylene rings are located very close to each other, the ring strain generates unsymmetrical locations of the binaphthyl ends in the solid state. However, ^{1}H nuclear magnetic resonance (NMR) indicates no unsymmetrical patterns due to the strained structure as observed in solid state. This reflects the rapid fluctuation of the cyclophane framework in solution.

Anderson and co-workers [45] demonstrated a very interesting carbohydrate recognition with 1,1′-binaphthyl based chiral cyclic receptors (Fig. 8). These chiral macrocylic receptors were derived from the 3,3′-diethynyl-1,1′-binaphthyl-2,2′-diol spacer using an oxidative Glaser–Hay coupling reaction. Since this series of chiral macrocycles contains 6, 8, and 10 OH groups that converge upon a central cavity, these receptors generate enough space

for the guest molecules and hydrogen bonding sites for carbohydrates recognition. Specially, ^{1}H NMR titration studies with **14b** and 1-*O*-octyl pyranosides (**15a–c**) in dry CDCl₃, in which the change in chemical shift of the receptor OH protons was monitored as a function of the concentration of guest, showed the formation of stable 1:1 complexes with the association constants K_a of 90 (when the guest was **15b**), 195 (when the guest was **15a**), and 370 L mol⁻¹ (when the guest was **15c**) at 300 K. Interestingly, this type of recognition was not observed when the spacer only was used as a receptor. Therefore, more than one of the three binaphthyl spacers' OH groups in the macrocyclic cavity is required at the recognition event with the pyranosides.

Moreover, the incorporation of phosphodiester groups into 1,1′-binaphthyl-derived cyclophane receptors provides a better driving force for the complexation processes
between anionic phosphodiester groups and the hydroxyl groups of pyranisides in the presence of a protic co-solvent which competes for the hydrogen bonding sites [46]. Similarly, complexation of disaccharides **17a–c** was studied by ^{1}H NMR titration at 300 K in CD₃CN/CD₃OD (88:12 *v/v*) (Fig. 9). Compound **16** exhibited a high binding affinity ($K_a \approx 10^4$ dm³ mol⁻¹, $-\Delta G^0 \approx 5.5$ kcal mol⁻¹) for all three disaccharides **17a–c**. While no selectivity among these substrates was observed, the selectivity over monosaccharides was very high. Interestingly, no evidence of the complexation was observed upon the addition of more than 2 equiv. of receptor to a 0.25 mmol dm⁻³ solution of glucoside **17d**; however, 60–80% saturation binding was observed with disaccharides **17a–c** under this condition. Apparently, the cavity size of the receptor is responsible for this high selectivity.

Lin et al. have successfully demonstrated chiral discrimination of α-hydroxycarboxylic acids via luminescence with binaphthyl-containing chiral macrocycles [47]. The fluorescence technique for enantioselective recognition is one of the most successful techniques because it provides a real-time method for the determination. Since successfully designed sensors have a tendency to screen or enhance the intensity of fluorescence, enantioselective recognition of chiral molecule is possible. The chiral bisbinaphthyl macrocycles (−)-**21** are synthesized by condensation of (*S*)-**18** with (*R*, *R*)-**19** followed by reduction of the macrocyclic salen **20** (Fig. 10). When α-hydroxycarboxylic acid coordinates to chiral macrocycle (−)-**21** through multiple hydrogen bonding, protonation of nitrogen atoms inhibits the photoinduced electron transfer (PIET) of the lone pair electrons of nitrogen atoms [48–50]. Specially, when the solution of (−)-**21** in benzene containing 2% of DME is treated with (*S*)-mandelic acid, the fluorescence intensity of (−)-**21** increases dramatically. However, fluorescence quenching is observed when the (−)-**21** solution is treated with (**R**)-mandelic acid (Fig. 11). The lone pair electrons of macrocycles is not available for the PIET process when the host and the guest molecules form a very strong bond. Therefore, the stronger bond formation between (−)-**21** and (*S*)-mandelic acid provides unusual florescence intensity for enantioselective recognition.

Botta and co-workers have reported a chiral resorcin[4]arene **22$_L$** cavity for enantioselective recognition under solvent-free condition [51]. Since the solvent plays an important role in host/guest complexation in solution and complicates the understanding of the implicit principles, the enantioselective recognition study in the gas phase is often considered. In this work, a synthetic macrocycle, resorcin[4]arene **22$_L$**, with a cavity-shaped very flexible architecture, is considered as an artificial enzyme. The chirality of this macrocycle comes from four axial pendants containing the chiral L-valine group (Fig. 12). The inherent enantioselectivity of the **22$_L$** host is checked by generating proton-bonded complexes with representative amino acids in the gas phase and by monitoring the exchange rate of amino acids with (S)-(+)- and (R)-(−)-2-butylamine. In case of alanine as an amino acid, the exchange rate constants happen to be $k_D = 7.7$ and $k_L = 5.0$ for D-ala and L-ala, respectively, with (R)-(−)-2-butylamine. When (S)-(+)-2-butylamine is used, the exchange rate constants are $k_D = 7.1$ and $k_L = 5.9$ for D-ala and L-ala, respectively. Therefore, these results represent that the chiral resorcin[4]arene is a very promising system for chiral discrimination studies in the gas phase.

3. CHIRAL MACROCYCLES CONTAINING METALS

Compared to covalently bonded organic counterparts, metal-organic supramolecules can be assembled with much ease and higher efficiency. Coordination-driven self-assembly of metallosupramolecular systems can be readily achieved by mixing appropriately designed multitopic ligands and metal ions with suitable binding geometries. Among many metal-organic supramolecular systems, the construction of molecular squares based on metallocorners with ∼90° angles and linear bridging ligands has proven to be the most reliable strategy, as exemplified by successful design of numerous molecular squares based on the *cis*-[M(phosphine)$_2$]$^{2+}$ corners (M = Pd or Pt) by Leininger et al. [6], the *cis*-[M(en)]$^{2+}$ corners (M = Pd and Pt; en is ethylenediamine) by Fujita [7], the *fac*-(CO)$_3$ReX corners (X = halide) by Hupp et al. [52, 53], and the M$_2$(carboxylate)$_2$ corners by Cotton et al. [54]. Some of these metallosupramolecular assemblies have shown promise for applications in host–guest recognition [55–57], inclusion [58, 59], catalysis [60, 61], and fluorescence sensing [62]. Over the past decade, there has been tremendous progress in the catalytic asymmetric synthesis of chiral compounds, both enzymatically and chemically. Rational design of chiral metallosupramolecular systems can thus lead to new enzyme-like chiral pockets and functionalities which may find important applications in chiral sensing and asymmetric catalysis. The progress toward these goals made over the past few years will be surveyed.

Three different approaches have thus far been utilized to construct chiral metallocycles: (1) introduction of metallocorners that are coordinated to chiral capping groups, (2) use of metal-based chirality owing to specific coordination arrangements, and (3) introduction of chiral bridging ligands. Among these, the third approach requires the most synthetic manipulations but also offers the versatility of fine-tuning the chiral pockets or functionalities for potential applications.

Oenyuk et al. [63] demonstrated the first strategy by using optically active metal complexes [M(*R*-BINAP)(OTf)$_2$]

[M = Pd or Pt, BINAP = 2,2′-bis(diphenylphosphino)-1,1′-binaphthalene] as a chiral building block for the formation of chiral molecular squares. When combined with bis(4-(4′-pyridyl)phenyl)iodonium triflate, heteronuclear optically active cyclic species **19a** and **19b** were obtained (Fig. 13). Since the analogous cycles with two triethylphosphines in place of each *R*-BINAP are achiral [6], molecular squares **24a** and **24b** are chiral due only to the chiral transition-metal auxiliary (BINAP) in the assembly. It is also interesting to note that the coordinated pyridine moieties exhibit restricted rotation around the metal–pyridyl linkage; the hydrogen atoms on the pyridine rings become diastereotopic. Both **24a** and **24b** possess D_2 symmetry, with one C_2 axis passing through the center of the binaphthyl rings and the other C_2 axis passing through the two iodine atoms.

Chiral tetranuclear molecular squares were readily synthesized when [M(*R*-BINAP)(OTf)$_2$] was treated with C_{2h}-symmetrical diaza ligands 2,6-diazaanthracene (DAA) in acetone. Only a single diastereomer was obtained as evidenced by a single signal in the ^{31}P NMR spectrum. In contrast, when 2,6-diazaanthracene-9,10-dione was used in place of DAA (Fig. 14), the reaction mixture consisted of a dominant diastereomer of **25a** and **25b** in a d.e. of 81% and minor amounts of other diastereomers. These chiral molecular squares have also been characterized by electrospray mass spectrometry (MS).

Fan et al. [64] have also synthesized a family of interesting chiral molecular squares containing porphyrins by using *trans*-DPyDPP, 5,15-di(4′-pyridyl)porphyrin, **26**, as the linear modules, and *R*(+)-, *S*(−)-BINAP-Pd(II) as the angular units (Fig. 15). The rotation of the metal–pyridyl bonds in **27a–b** is restricted at room temperature but becomes unrestricted at elevated temperatures. The chirality of the metallocorners thus promotes the formation of enantiomeric macrocycles with a puckered geometry. As expected, the porphyrin chromophores in the enantiopure metallocycles **27a** and **27b** show strong circular dichroism around 420 nm. Cooperative coupling of four excitons in **27a** and **27b** leads to Davydov splitting with a very high amplitude.

Coordination chemists have taken advantage of the intrinsic chirality of transition metal complexes with certain geometries for the construction of chiral supramolecular assemblies since Werner's time [65]. Recent work has shown that nonlinear optically active coordination networks can be crystal engineered using such an approach [66]. Zhang and co-workers [67] have investigated the assembly of chiral molecular squares using octahedral metal ions

such as Co(II) and Mn(II). Unlike the square-planar Pt(II) or Pd(II) complexes, octahedral Co(II) or Mn(II) complexes with two chelating ligands are inherently chiral, and no chiral auxiliary ligands are required for the construction of chiral molecular squares. When the D_{2d} symmetric bridging ligand, tetraacetylethylene dianion (tae), was coordinated to octahedral Co(II) metallocorners that are capped with two chelating di-2-pyridylamine (dpa) ligands, the D_{2d} symmetry is reduced to pure rotational symmetries, and chiral molecular squares were obtained. Chiral molecular square Co$_4$(tae)$_4$(dpa)$_4$, **28**, was obtained in 15% yield and characterized by single crystal X-ray crystallography (Fig. 16). Each edge of the square (i.e., each pair of Co$_2$)

Figure 16. Structure of $Co_4^{II}(tae)_4(dpa)_4$. Reprinted with permission from [67], Y. Zhang et al., *J. Am. Chem. Soc.* 120, 9398 (1998). © 1998, American Chemical Society.

has a helical structure similar to that observed in $[Co_2(tae)\text{-}(dpa)_4][(O_2CCH_3)_2(H_2O)_2]$. The overall structure of **28** can therefore be described as a cyclic helicate (Fig. 16). Compound **28** is a rare example of structurally characterized molecular squares with a chiral structure in the solid state. The synthesis of **28** demonstrates that ligands with a ~90° twist between the binding sites can facilitate the formation of chiral molecular squares when octahedral metal ions are employed. The tae ligands in **28** also facilitate the ferromagnetic exchange between the Co(II) centers on the corners, and compound **28** is a weak ferromagnet.

The propeller-like arrangements of three chelating ligands around octahedral metal centers are also inherently chiral and have been used to introduce chirality to supramolecular assemblies at both local and global structural levels [68]. Ali and MacDonnell [69] demonstrated the use of intrinsic chirality at the kinetically inert octahedral metal center as a tool to direct the formation of molecular hexagons with diameters of 5.5 nm. The opposite absolute stereochemistry of the six vertex synthons $[(bpy)Ru(tpphz)_2]^{2+}$, **30a**, or $[(bpy)Os(tpphz)_2]^{2+}$, **30b** (Fig. 17), directs the formation of the ring structure and permits topospecific placement of different metals at unique symmetry sites within the ring. Three mixed-metal self-assembled systems were described, each containing six kinetically inert transition metal complexes (**29a** or **29b**) joined by six labile Pd(II) ions. The Ru_6Pd_6, **30a**, Os_6Pd_6, **30b**, and $Ru_3Os_3Pd_6$, **30c**, structures (Fig. 17) form due to the torsional restraints imposed by the stereochemistry of **29a** or **29b** along with the entropic factors which favor rings systems over polymeric structures. As seen in Figure 17, the metals alternate in a Ru–Pd, Os–Pd, and Ru–Pd–Os–Pd fashion for **30a**, **30b**, and **30c**, respectively. Compounds **30a** and **30b** are achiral due to the presence of both enantiomers of Ru(II) or Os(II) corner units, while compound **30c** is pseudo-*meso* due to the opposite handedness of the Ru(II) and Os(II) corners units. The formation of these mixed metal ring structures has been difficult to verify, due to the inability to obtain a satisfactory mass spectrum.

The preparation of chiral macrocyclic molecules typically requires the use of enantiopure building units or auxiliary ligands. The syntheses of macrocycles using racemic starting materials tend to result in complex diastereomeric

mixtures. Schafer and Tilley [70] have recently demonstrated efficient and high-yield diastereoselective synthetic routes to multigram quantities of BINOL containing macrocycles using zirconocene coupling procedures [71]. Dimeric macrocycle **32** was prepared from the known diyne **31** [72] as shown in Figure 18, using Negishi-type zirconocene coupling conditions [73]. Cyclodimerization of racemic compound **31** could lead to three stereoisomers of macrocycle **32**; however, only one pair of homochiral enantiomers (i.e., *SS* and *RR*) was obtained in this reaction. Enantiopure macrocycles were prepared from (*R*)-**31** and showed the same NMR spectra as the macrocycles obtained from racemic **31** and thus supported the assignment of racemic nature of dimeric macrocycle **32**. Such a diastereoselectivity was confirmed by single crystal X-ray crystallography. Macrocycle **32** has D_2 molecular symmetry and crystallizes as a racemic mixture of homochiral macrocycles. The naphthyl planes of each BINOL unit possess a large dihedral angle (~110°).

Racemic dyines **34** containing the enforced smaller dihedral angle by methylene bridges were also subjected to zirconocene coupling conditions to generate a larger macrocyclic structure, **35**, via zirconocene-mediated cyclotrimerization. The diastereoselective synthesis of homochiral macrocycles is once again achieved, and the product contained only a pair of homochiral enantiomers (i.e., *SSS* and *RRR*) (Fig. 19). In the solid state, the macrocycle adopts a highly folded geometry with pseudo C_2 molecular symmetry (Fig. 19).

Kim and co-workers [74] have demonstrated the formation of an achiral macrocycle from racemic ligands using a ligand self-discrimination strategy in which one enantiopure ligand specifically senses its enantiomer to generate an achiral complex (Fig. 20). This 1,1′-binaphthol-containing ligand **38** was prepared by ester condensation of 1,1′-binaphthol and acid chloride of isonicotinic acid. Interestingly, ¹H NMR titration studies of ᵣₐᶜL with (dppp)Pd(OTf)₂ **37a** in acetone-*d*₆ show a highly symmetric single set of signals at a 2:2 metal:ligand ratio, while ¹H NMR titrations of ˢL with (dppp)Pd(OTf)₂ **37a** show a complicated set of signals. These results imply that ˢL prefers to generate an achiral, heterodimeric complex exclusively with its enantiomer, rather than a homochiral complex.

Habereder et al. [75] reported unusual diastereoselective triangular cyclization from mesomeric starting materials.

The heterocyclic bridging ligand is the dianion of 3-hydroxy-2-methyl-4(1H)-pyridone which is synthesized from 3-hydroxy-2-methyl-4-pyrone (maltol). When this ligand was treated with (Cp*)Ir(III) **40a** or (η⁶-cymene)Ru(II) **40b** in the presence of one equivalent of base, its mesomeric was formed (Fig. 21). The proton bound at the nitrogen atom becomes very acidic and the chlorine ligand is expected to be labile, thus providing the driving force for a base-induced cyclization (Fig. 21). Although the symmetry of supramolecule assembled from metal–ligand interaction depends on the geometry of the ligand and the metal, these complexes possess pseudo-octahedral geometry. Moreover, the bridging ligand acts as an *O,O′*-chelate and simultaneously coordinates through the nitrogen atom in position 4 to another metal atom and sits almost perpendicular to the cyclic plane. Interestingly, these macrocycles can regenerate their monomeric starting complexes by adding three equivalents of HCl. Therefore, this system demonstrates that macrocyclization can be induced and reversed by addition of appropriate amounts of base or acid, respectively (Fig. 22).

Although many chiral metallocycles have been constructed using all three approaches outlined earlier, none of them exhibit functionalities that are exploitable for enantioselective processes. Lee and Lin have recently demonstrated high-yield synthesis of chiral macrocycles based on *fac*-Re(CO)₃Cl corners with 90° angles and chiral linear bridging ligands via self-assembly (Fig. 23) [76]. The chiral ligands **42a–d** were synthesized in seven steps from BINOL with relatively high overall yield. BINOL was chosen as the backbone for the atropisomeric bridging ligands because it is well established that BINOL and derivatives provide outstanding asymmetric differentiation

Figure 21. Mesomeric forms of starting materials and base-indused formation of chiral cycles. Reprinted with permission from [75], T. Habereder et al., *Angew. Chem., Int. Ed. Engl.* 38, 3225 (1999). © 1999, Wiley–VCH.
Figure 22. The assembly–disassembly process by addition of acid or base. Reprinted with permission from [75], T. Habereder et al., *Angew. Chem., Int. Ed. Engl.* 38, 3225 (1999). © 1999, Wiley–VCH.

properties and stable chiral configuration. Chiral macrocycle **43d** shows interesting enantioselective luminescence sensing behavior in THF. The fluorescence signal of enantiopure **43d** at 412 nm is efficiently quenched by both enantiomers of 2-amino-1-propanol, but at significantly different rates. For (*R*)-**43d**, the Stern–Völmer quenching constant K_{sv} is 7.35 M^{-1} in the presence of (*S*)-2-amino-1-propanol and 6.02 M^{-1} in the presence of (*R*)-2-amino-1-propanol. (*R*)-**43d** has an enantioselectivity factor $k_{sv}(R\text{-}S)/k_{sv}(R\text{-}R)$ of 1.22 for fluorescence quenching in favor of (*S*)-2-amino-1-propanol. The opposite trend in enantioselectivity was observed for the quenching of (*S*)-**43d** by 2-amino-1-propanol, which lends further support to a chirality-based luminescence-quenching selectivity between chiral metallocycle **43d** and 2-amino-1-propanol. It is interesting to note that no enantioselectivity was observed for the fluorescence quenching of **43d** by 1-amino-2-propanol, which supports the involvement of amino groups in the formation of a ground-state hydrogen-bonded complex and an excited-state proton-transfer complex. The greater distance of the amino group from the chiral center in 1-amino-2-propanol is responsible for its lack of fluorescence-quenching enantioselectivity. Control experiments show that fluorescence quenching of atropisomeric ligand **42d** by 2-amino-1-propanol does not exhibit enantioselectivity and thus demonstrates the importance of the supramolecular nature of the enantioselective process of **43d**. See Figure 24.

In order to design chiral macrocycles exhibiting favorable solubility in nonpolar solvents which are required for

Figure 24. Energy-minimized structure of **43d**.

many asymmetric catalytic reactions, Lee et al. have taken advantage robust Pt–alkynyl linkages to construct a family of chiral molecular triangles [77]. Treatment of ligands **44a–c** with equal molar equivalents of *cis*-PtCl$_2$(PEt$_3$)$_2$ in the presence of CuI catalyst at room temperature generates chiral cycles **45a–c** in modest yields. Chiral cycle **45d** was obtained quantitatively by treating **45c** with TBAF in THF (Fig. 25). Compounds **45a–d** were characterized by ^{1}H, ^{13}C{^{1}H}, and ^{31}P{^{1}H} NMR spectroscopy, mass spectrometry, elemental analysis, and infrared (IR), ultraviolet-visible (UV-vis), and circular dichroism (CD) spectroscopies. In particular, CD spectra of **45a–d** exhibit an intense band at ∼202 nm, in addition to three lower energy bands corresponding to naphthyl $\pi \rightarrow \pi^*$ transitions and two acetylenic $\pi \rightarrow \pi^*$ transitions (Fig. 26). The new CD band at ∼202 nm can be assigned to the transitions associated with *cis*-Pt(PEt$_3$)$_2$ moieties. This result suggests that triethylphosphines on the Pt centers adopt a propeller-type arrangement (relative to the naphthyl groups), apparently steered by chiral binaphthyl moieties. Cycles **45a–d** exhibit enhanced lower energy CD signals over the free ligands **44a–d**, consistent with the presence of multiple ligands in each metallocycle. See Figure 27.

Chiral molecular triangle **45d** contains dihydroxy functionalities and was used for highly enantioselective catalytic

diethylzinc additions to aromatic aldehydes [Eq. (1)]. With Ti(IV) complexes of **45d** as the catalyst, chiral secondary alcohols were obtained in greater than 95% yield and 89–92% e.e. for a wide range of aromatic aldehydes with varying steric demands and electronic properties (Table 1). In comparison, when free ligand **44d** was used instead of **45d**, a lower e.e. (80%) was obtained for the addition of diethylzinc to 1-naphthaldehyde. The broad substrate scope for catalytic diethylzinc additions using **45d** and Ti(O^{i}Pr)$_4$ suggests that there is significant flexibility in the dihydroxy groups to accommodate aldehydes of various sizes.

$$(1)$$
In contrast to previously discussed chiral triangles, chiral dinuclear metallacyclophanes [*cis*-(PEt$_3$)$_2$Pt(**46**)]$_2$, **47a–c**, were obtained when enantiomerically pure atropisomeric bis(acetylenes) **46a–c** were treated with one equiv. of *cis*-Pt(PEt$_3$)$_2$Cl$_2$ in the presence of catalytic amounts of CuCl in diethylamine at room temperature [78]. Compounds **47a–c** were characterized by ^{1}H, ^{13}C{^{1}H}, and ^{31}P{^{1}H} NMR spectroscopy, HR-MS, elemental analysis, and IR, UV-Vis, and CD spectroscopies.

A single-crystal X-ray diffraction study on compound **47c** unambiguously demonstrated the formation of a chiral metallacyclophane. Compound **47c** crystallizes in chiral

Table 1. Diethylzinc additions to aldehydes catalyzed by Ti(IV) complexes of **40d**.

Entry	Aldehyde	Temp.	Conversion	e.e. (%)
1		RT	>95%	91
2		RT	>95%	91
		0 °C	>95%	92
3		RT	>95%	90
4		RT	>95%	91
5		RT	>95%	89
6		RT	>95%	90

monoclinic space group $P2_1$. Two *cis*-Pt(PEt$_3$)$_2$ units are linked by two enantiopure **46c** ligands to form a cyclic dinuclear structure (Fig. 28). Both Pt centers adopt slightly distorted square planar geometry with the *cis* angles around the Pt1 center ranging from 82.4(2) to 101.3(1)° and the *cis* angles around the Pt2 center ranging from 84.3(2) to 100.3(1)°. The rigid metallacyclophane structure of **47c** is characterized by very small dihedral angles between the naphthyl rings within each **47c** ligand (62.18 and 3.45°). See Figure 29.

As shown in Table 2, the Ti(IV) complexes of **47c** are excellent catalysts for the additions of diethylzinc to 1-naphthaldehyde with 94% e.e. and >95% conversion at 0 °C. The enantioselectivity has, however, dropped significantly when other smaller aromatic aldehydes were used as the substrates. This result differs from the performance of **45d** which has a very broad substrate scope. Such a difference is believed to be a direct consequence of the much more rigid structure of **47c**; the dihedral angles of naphthyl rings in the Ti(IV) catalyst cannot vary to accommodate aldehydes of various sizes to give high enantioselectivity. The chiral dihydroxy groups in **47c** thus differ from those of BINOL and may prove useful for mechanistic work due to their rigid structure.

Aldehyde	Temp.	Time (h)	Conversion	e.e. (%)
	RT	16	>95%	77
	0 °C	16	>95%	84
	RT	16	>95%	91
	0 °C	16	>95%	94
	RT	16	>95%	75
	0 °C	16	>95%	78
	RT	16	>95%	77
	0 °C	40	∼40%	78
	RT	16	>95%	76
	0 °C	40	∼80%	77
	RT	16	>95%	75
	0 °C	16	>95%	78

4. CONCLUDING REMARKS

The examples illustrated in this chapter give testimony to our ability, through chemical manipulation, to create large chiral macrocycles that can potentially serve as mimics of natural enzyme systems. With properly designed building units, chiral macrocycles can be readily synthesized. In particular, through a judicious combination of multitopic bridging ligands and unsaturated metal centers, chiral metallocycles can be constructed with unprecedented predictability and ease. It is also possible to maintain the structural features of the chiral macrocycles and yet fine-tune their properties via a systematic modification of their constituent building units.

Recent work has clearly illustrated supramolecular functions of chiral metallocycles which are reminiscent of biological macromolecular systems. Future work will be directed toward the design and exploitation of such supramolecular functions in the areas of molecular recognition, host–guest interaction, chiral recognition, and catalysis. It can be expected that such research efforts will lead to new materials with desirable tunable properties and ultimately to the demonstration of nanoscale devices and molecular machinery [79, 80].

GLOSSARY

Asymmetric catalysis A catalytic reaction in which one enantiomer is produced in excess of the other.

Chiral A chiral object is not superimposible on its mirror image.

Enantiomer Two stereoisomers that are not superimposable images of each other.

Enantiomeric excess (ee) Percentage by which one enantiomer is in excess over the other in a mixture of two.

Macrocycle A cyclic (macro)molecule that has no end groups.

Metallocycle A macrocycle that contains metal centers in the cycle.

Self-assembly The spontaneous formation of molecules into covalently bonded, well-defined, stable structures.

Supramolecular chemistry The chemistry of the intermolecular bond, concerning the structure and functions of the entities formed by the association of two or more chemical species.
