Université de Bretagne Occidentale, Brest, France

CONTENTS

1. INTRODUCTION

The science of manipulating matter on the nanometer scale has provided scientists and engineers at the forefront of this research with a remarkable diverse set of tools for probing the behavior of nanophases. One of the strengths of this sector is the concomitance of the scientific interests in the universities with the economic interests of the markets for new nanotechnologies. In that respect, the electromagnetic characterization of dry granular materials can be considered a major part of the emerging field of advanced materials relevant to the fields of electronics, photonics, or information technology. Powder metallurgy in particular offers opportunities for engineering and ultimately trying to control novel features, functions, and properties of granular materials on different scales by using appropriate procedures, with promising commercial applications. Over the past decade or so, a substantial amount of research and development across the scientific community has been conducted in the areas of nanotechnology for materials and device structures whose characteristic feature sizes are at or near the nanometer scale and significant fundamental advances have been made; see, for example, [1–12] and references therein. In addition, the increasing demand for new materials that satisfy multiple roles, for example, electrical and mechanical functions, has provided the impetus for an important new area of research of nanomaterials science. An elaborate overview of the most recent advances and emerging new aspects of nanoscience and nanotechnology has been given by Nalwa et al. [13]. The potentially profound implications both for transport properties and optics are only beginning to be explored. Interest in nanophases has expanded as investigators have recognized that many of the properties of finely divided matter strongly depend on the interfacial properties of the constituents by virtue of the high fraction of the overall material that is in the vicinity of an interface as well as of the confinement of electrons, excitons, and photons in small volumes. This allows the exploration of a vast range of experimental regimens, from noninteracting to strongly correlated. Their highly specific surface area combined with their smallness led to the observation of many unique behaviors, such as superparamagnetism in Fe clusters embedded in a nonmagnetic medium [14]. Observe that usual microwave materials, such as the ferrites, are often heavy, and may not have very desirable mechanical properties. In contrast, micro- and nanostructured composite materials can be designed with considerable magnetic activity and can be made extremely light. One of the interesting and important issues in predicting and understanding nanostructures and their functional behaviors is whether the properties of matter evolve gradually from bulk, as system size is reduced, and what determines this evolutionary behavior. Because electronic properties of interfaces affect the carrier mobility and scattering in a material, plasmon excitations at planar interfaces and at nanoparticle interfaces have also been studied [15–17]. Recently, it has been argued that the electronic band structure of nanocrystals can be different from the band structure of the bulk semiconductor, that is, the opening of the semiconductor band gap due to electron confinement [2, 13]. From the technological point of view, the observation of giant magnetoresistance [18, 19] or large coercivities [20, 21] in various nanophase materials has attracted much attention. Despite a number of notable contributions, theory has often been outpaced by these rapid experimental advances. From an applications standpoint, powder metallurgy is a particularly attractive technique for preparation of nanophase materials in that it offers a rapid, cost-effective, and controllable route to yield materials with specific properties. To improve performance and reliability of powder metallurgy, experimenters have

developed a range of techniques for performing characterization of properties of nanophases such as structural, dielectric, magnetic, and/or coupling between of these properties. The practical importance and industrial interest in these materials demand optimization of several types of properties in these materials. These properties include polarization, magnetization, and stability of the materials to mechanical, electrical, and magnetic fields applied during processing and operation. One of the fundamental goals of this field should be the understanding of the relationships of these properties on the composition, particle size and boundaries variations, defect structure, and separation of the residual pores, but in most cases they are not well understood.

1.1. Powder Metallurgy Composites and Magnetic Properties

Although extensive literature exists on the properties of nanophase materials, only a limited number of systematic studies have been reported on the electromagnetic and magnetic properties of granular systems. It is useful to succinctly summarize existing studies. Shaikh and co-workers [22] were among the first to report on the dielectric properties of ultrafine grained $BaTiO_3$: the permittivity was observed to increase with decreasing grain size, reaching a peak value at 1 μm and decreasing subsequently with any further decrease of the grain size. Panina and co-workers [23] found that the effective permeability of composite materials containing micrometer-sized, Fe particles tends to zero near the percolation threshold. Newnham and Trolier-McKinstry [24] examined ferroelectric nanocomposites consisting of particles in the nanometer scale dispersed in a matrix to get higher frequencies as well as other advantages such as miniaturization. Also noteworthy is the observation of Xiao and Chien [25] that the coercivity changes in a dramatic variation in granular Fe/silica mixtures, which was interpreted by invoking percolation effects. In recent years a number of studies [7, 19, 26–30] have focused on the behavior of fine magnetic particles in a nonmagnetic metallic matrix. Until now, the vast majority of these publications suggest that the magnetic state of the particles is influenced by the effect of the surface whose contribution becomes predominant. On another front, questions concerning the coercivity and reversal magnetization in nanophases have also come to the fore. Particles of ferromagnetic metals with dimension typically below 100 nm are too small to show well-developed domain structures [31] because the exchange correlation length is much greater than the particle size. For ultrafine magnetically ordered particles, there exists a critical size below which the grains can acquire only single magnetic domains even in zero applied magnetic field. The critical size of a single domain particle can be evaluated $D^* \cong \frac{36}{2\pi}(AK_1)^{1/2}M_S^{-2}$, where A is the exchange constant and K_J is the magnetocrystalline anisotropy constant. For Fe, Ni, and Co, D^* is on the order of a few tens of nanometers, depending on the shape of the particle. As areal recording density in magnetic storage devices approaches a few 10^2 Gbits/in^2, the medium should possess magnetically isolated fine grains (less than 10 nm in gram size) exhibiting a narrow-size distribution. The areal density remains limited by the random size of the grains that may couple to form larger magnetic switching units. Moreover, there is a fair amount of experimental evidence that shows an enhanced coercivity for nanoparticles [32]. In the sintering process, compaction occurs due to the enhanced diffusion between neighboring particles. The advantage of the hot isostatic pressing process is that the porosity of the final product is negligible, and therefore the basic properties of the product are better. The technique of mechanical alloying typically involves the high-energy ball milling of elemental powder mixtures. During the milling process, large powder particles may undergo plastic deformation and/or fragmentation, and small powder particles may coalesce by cold welding. The repeated fragmentation and coalescence of powder particles causes the intimate mixing of particles on the nanoscale. Meanwhile, the exchange coupling between neighboring magnetic particles can overcome the anisotropy and demagnetizing effect of individual particles [33]. From the theoretical point of view, Stoner and Wohlfarth (SW) were pioneers in studying the hysteretic behavior of a random distribution of noninteracting magnetic particles [34, 35]. This early, insightful, work (in 1948) has pointed toward interesting effects that are specific to single-domain particles, for example, the reduced remanence ratio $\frac{M_r}{M_s}$ is equal to 0.5 for uniaxial particles, and the coercivity is $H_c = 0.48\left(\frac{2K_1}{M_s}\right)$, where K_1 is the magnetocrystalline anisotropy constant. Since its introduction, the SW model was expanded by others [36] for multiaxial cubic or competing types of magnetic anisotropy. However, the SW model is static theory and does not take into account thermal fluctuations in the magnetization process: therefore, its range of validity is restricted to low temperatures or very strong anisotropies [37]. Still in use in the current literature to explore the case of higher temperatures and/or if anisotropies are small is the superparamagnetic Néel–Brown approach eventually modified to include (magnetostatic) dipolar interactions among magnetic nanograins, which provides an important framework for the understanding and interpretation of experimental data [38–40]. Within this framework, magnetization reversal takes place by thermal activation over finite energy barriers, leading to temperature and time dependences of the magnetic behavior. However, it is worth noting that the effect of interparticle interactions cannot be easily included in this model, except as a mean-field approximation. Some authors argued that the enhanced remanence ratio (>0.5) observed experimentally in nanoscale isotropic magnetic materials may be due to the exchange coupling between neighboring nanograins [41, 42]. It should, perhaps, be emphasized in this context that one important, and as yet not completely answered, question concerns the understanding and the control of the dynamic magnetization processes in these granular materials on nanosecond time scales. A general framework for understanding the damping mechanism in nanostructures is proving elusive. Finally, we observe that these basic and applied considerations have stimulated much research concerning the effect of both dipolar and exchange interactions on the magnetic and transport properties of interacting nanoscale particles [27, 29, 35, 43]. However, it is worth noting that some of the results are controversial, and several studies reaching contradictory conclusions exist.

1.2. Electromagnetic Transport in Heterostructures

Theoreticians pointed out that the theoretical framework used in many instances to explain the electromagnetic transport in granular materials is a modelization in terms of a continuum media. As previously observed elsewhere [44], the basic assumption used is that there exist length scales above which fluctuations at the microscopic level may be ignored. In this way, useful predictions of a granular material's bulk properties can be made with no references to its discrete nature. At issue is the manner in which these local fluctuations influence the dynamics of ensemble-averaged quantities such as the effective permittivity ε and the effective permeability μ. A related basic question is to examine the links with coarse-graining models based on the effective medium approximation (EMA). This major simplifying approximation is based on a self-consistent procedure in which a grain of one component is assumed to have a convenient shape and to be embedded in an effective medium whose properties are determined self-consistently. In particular, it is natural to ask if this long-wavelength physics approach is still relevant to describe (and, if so, how) the response of the material at microwave frequencies by the materials parameters ε and μ and what happens in granular media, such as those made up of very fine grains. Particularly related to the current work are earlier model calculations which showed that the macroscopic character of the materials parameters ε and μ of two-phase systems depends sensitively on the microstructural properties such as grain size, particle shape, and grain boundaries type [45]. Early conceptualizations of EMA approaches arc given in [44–47]. Another classic review we found useful for general information is that of Bergman and Stroud [48]. Historically, one fruitful venue for studying the electromagnetic properties of random heterostructures has been the concept of percolation, which may shine light on the importance of the three-dimensional (3D) metal-insulator transition [49]. The fundamental precept of the percolation model is the prediction of a percolation threshold above which particles form a connecting network. Additionally, advances in *ab initio* computational techniques along with constantly growing computational resources now provide opportunities for the development of a much more profound understanding of the bulk magnetic and transport properties of granular magnetic solids [45, 46]. The power of these computational techniques, as a viable alternative to expensive or complicated laboratory experiments, provides theoreticians with a tool for exploring and predicting the electromagnetic properties for nanostructured materials. In the past it has been demonstrated that there are numerous questions or unresolved issues on the effective materials properties of heterostructures. One such issue is the effect of size on the materials parameters ε and μ. There are also interesting microwave μ measurements on submicrometer-size dispersed Co_x, Ni_{1-x} particles, where it was shown that losses are associated with domain structure or surface effects [50]. Additionally, there are few quantitative data on the effect of the distribution of the magnetostatic interaction fields between the particles. There is another good motivation to study this issue.

In recent years, a new race for the understanding of magnetoelectric properties in condensed matter systems was initiated by the recent discovery of new types of unconventional materials, that is, bianisotropic media in which the electric displacement and the magnetic field vectors depend on both the electric field and the magnetic induction vectors [51]. However, the problem remains unsolved due to its intrinsic many-body complexity from intergranular magnetostatic and exchange interactions. The interplay between collective magnetic properties and transport properties in these systems presents a rich phenomenology and offers the prospect of new functionality for specific applications [35, 51]. This chapter is intended to introduce the reader to the field by providing some insights into some of the theoretical and experimental approaches that have been employed thus far to understand the relationships between particle size and the dynamical and hysteretic properties of granular solids consisting of heterogeneous dispersions of magnetic particles with dimensions ranging from nanometers to micrometers in a nonmagnetic host. The intriguing prospective of extending magnetic and electromagnetic studies of heterostructures into the domain of nanophases may be hindered by the collective transport properties of strongly correlated spins systems. Therefore, magnetic and electromagnetic behaviors in nanosystems are challenging in terms of both experimental observation and development of theoretical analyses.

2. NANOGRANULAR METAL OXIDES

To our knowledge, to date few experimental studies have addressed the physical mechanisms involved in the electromagnetic wave transport in nanogranular metal oxides, with only a few systems having received significant attention; see Table 1 for a summary. It should be emphasized parenthetically that the oxidation mechanisms of metal nanoparticles have considerable fundamental and technical importance and have been the focus of many experimental and theoretical studies during the past decade. Due to the high fraction of the overall material in the vicinity of the surface, nanoparticles can be extremely susceptible to oxidation. One way to ensure the chemical stability of nanoparticles is to encapsulate the reactive particles in a protective matrix. In clinical applications, the coating protects the nanoparticles from leaching in an acidic environment. In the current work, we will examine the links between the properties of the individual particles with those of the bulk materials. The study of these materials offered the opportunity to explore the use

Table 1. Composite materials studied.

Composite materials	Ref.
Fe/SiO_2	[42]
Fe/Al_2O_3	[42]
γ-Fe_2O_3/ZnO	[29, 66, this work]
$MgO/Ba_xSr_{1-x}TiO_3$	[99]
$LaAlO^3/Ba_xSr_{1-x}TiO_3$	[100]
$SrTiO^3/Ba_xSr_{1-x}TiO_3$	[101]

Note: In recent years, understanding of the electromagnetic properties of nanogranular metal oxides has advanced steadily. The materials studied along with the corresponding reference are listed in the table.

of powder metallurgy as a route to tunable magnetoelectric materials, with properties tailored to the demands of various applications. In writing this chapter, we have chosen naturally to draw on our expertise, which is electromagnetism of nanostructures. We consider the ZnO–Fe_2O_3 system as a prototype system to illustrate the magnetic and electromagnetic transport properties of particulate composite materials for at least four main reasons. First, these metal oxides are commonly found in technological applications; for example, ZnO is a remarkable II–VI semiconductor with wide applications for various devices such as optical waveguides [52], piezoelectric transducers [53], and varistors [54–56], and maghemite (γ-Fe_2O_3) is the most popular general-purpose magnetic tape material [57–59]. Second, characterization of the crystal oxides has been carried out by a variety of experimental techniques. For example, the magnetic behavior of γ-Fe_2O_3 has been studied extensively: it is a ferrimagnetic spinel with a bulk saturation magnetization of $390 \, kA \, m^{-1}$ [60–62]. Much work has been devoted to the magnetic properties of γ-Fe_2O_3 nanoparticles; for example, Dai et al. [62] found that the long-range magnetostatic interactions between surfactant coated γ-Fe_2O_3 nanoparticles and the blocking temperature (below which the moments are blocked) can be increased by decreasing the average interparticle distance through an increase of the applied pressure on the bulk samples. γ-Fe_2O_3 is of particular interest because of its applications in devices such as magnetic recording media. γ-Fe_2O_3 is a metastable phase at ambiant conditions and tends to transform to a stable-phase, antiferromagnetic hematite (γ-Fe_2O_3), when heated up to 400 °C. Ferrimagnetic oxides of iron combine the properties of a magnetic material with that of an insulator. Commercially available pure ZnO and γ-Fe_2O_3, powders were used as basic components of the composite materials and had different origins. Third, the low cost and ease of fabrication of these materials make study of the electromagnetic and magnetic properties of their small clusters, where the size and composition can be varied, extremely interesting. Fourth, nanostructures of these materials exhibit materials properties that can differ strongly from those of the bulk phases [62–66]. We are convinced that the comprehension of complex problems posed by nanogranular metal oxides has the potential to produce a substantial advance in electromagnetism and magnetism of condensed matter nanophases

and nanostructures and will eventually shed light into other unsolved problems.

Because there is no review that covers electromagnetism of nanophases, our emphasis has been on producing a self-contained account of the basic physical pictures, while referring the reader to the original literature for details. Computerized literature searches citing "electromagnetism of nanogranular metal oxides" as key words find very few articles. As a result, it is impossible to give a comprehensive review of the electromagnetic properties of many of these materials. We shall therefore limit ourselves to discussing an overview of some of the electromagnetic and magnetic properties of heterostructures composed of metal oxide nanoparticulate powders, Samples consist of grains of the magnetic phase (γ-Fe_2O_3) homogeneously dispersed in a nonmagnetic insulating background (ZnO). In this review the starting powders had different origins. The micro oxide powders were purchased from Aldrich Chemical Co. and marked as $\geq 99\%$ pure, whereas the nano oxide powders were supplied from Nanophase Technologies Corp. (Burr Ridge, II). The manufacturer's specifications are listed in Table 2. Control over the average particle size and shape was achieved by transmission electron microscopy (TEM). Epoxy resin (Scotchcast 265) purchased from 3M and was used as binder phase. Composite materials for this investigation were prepared by a four-step procedure. (1) The appropriate amounts of metal oxide powders were first preheated at 200 °C for dehydratation, and then, after cooling to room temperature, the powders were subsequently mixed with acetone and a certain amount of epoxy resin in a bath sonicator for 1 h; the mixture was then cast into a culture dish and the acetone was allowed to evaporate slowly at room temperature. (2) The mold was filled by the resulting mixturer. (3) The powder was compacted to a specified size and shape. (4) The dense powder compact was ejected from the mold. Room temperature-pressed ZnO/Fe_2O_3 compacts were made under a pressure of $10^7 \, N \, m^{-2}$ for 2 min. As a result of this procedure, test samples with a toroidal shape of 7 mm outside diameter were used for electromagnetic spectroscopy experiments. In the following we refer to the samples containing micrometer-sized particles and those containing nanometer-sized particles as M-type and N-type samples, respectively. We studied three sets of samples that nominally had volume fractions of 0.10, 0.15, and 0.25 of

Table 2. Selected physical properties of the powders investigated in this study.

Powder	ZnO	ZnO	γ-Fe_2O_3	γ-Fe_2O_3
Average particle size[a, b]	1 μm	49 nm	5 μm	23 nm
Powder color	White	White	Purple	Brown
Specific surface area BET (m^2 g^{-1})		22		51

epoxy. The fractional volume of voids (porosity) is deduced knowing the volume fractions of ZnO, Fe_2O_3, and epoxy and was controlled by density measurements. Throughout the text, f denotes the volume fraction of Fe_2O_3 and ϕ indicates the volume fraction of the epoxy resin.

3. PHYSICAL PROPERTIES

In this chapter we focus on the present understanding of what we think are the most remarkable electromagnetic properties of nanogranular metal oxides, observed by state of the art experiments and interpreted with modem theories. We have organized the discussion into three main modules: (1) zero-field (ZF) permittivity and permeability of a set of mixtures having different compositions and grain sizes (see Appendix A for the measurement details), (2) gyromagnetic resonance, and (3) magnetic hysteresis loop data for these samples. We end the chapter with some concluding remarks and a brief look at some open questions that remain in the electromagnetic properties of particulate nanophases.

TEM bright field using a JEOL microscope at an accelerating voltage of 100 kV was used to reveal the grain size and shape of the as-received ZnO and Fe_2O_3 particles. The particles in solution were brought onto holey carbon films suspended over copper grids for TEM observations. From TEM micrographs of the powders, we have observed that the individual ZnO particle is elongated with an average aspect ratio of about 3:1 whereas γ-Fe_2O_3 particles are nearly spherically shaped. To obtain information on the morphology of the mixtures, scanning electron microscopy (SEM) data were collected using JEOL 6400 scanning electron microscopy operating at an accelerating voltage of 25 kV and magnification of 60,000. Samples were mounted on an aluminium stub using an adhesive carbon tab and were gold-coated. A representative SEM image of a cross-sectional view of a composite sample is displayed in Figure 1. A visual examination of Figure 1 reveals a finely dispersed structure and a large void distribution. The identification of the crystalline phases was carried out by powder X-ray diffraction (XRD) with Cu K$_\alpha$, radiation. ZnO crystallizes in the hexagonal wurtzite structure whereas the crystal structure of Fe_2O_3 is maghemite

Figure 1. SEM micrographs of fracture cross-section view of a composite sample ($f = 0.53$ and $\phi = 0.25$) showing the distribution of particle sizes. The black bar in the lower right corner is 500 nm.

(cubic spinel). The average grain sizes were obtained in the XRD analysis from the line broadening of the diffraction peak and by using the Scherrer formula and are consistent with the estimates obtained from TEM.

3.1. Dielectric Properties

Representative frequency dependence curves of the real and imaginary parts of the relative effective permittivity ε for N and M composite. samples ($f = 0.53$ and $\phi = 0.25$) are plotted in Figure 2a and b. Upon inspection of these figures we observe that ε' is a slowly decreasing function for N samples and constant for M samples in the range of frequencies explored. The larger conductivity for N composite samples, shown in Figure 2b, can probably be attributed to the increase of the density of interfaces as surface-to-volume ratio increases in magnetic nanostructures. Figure 2c and d show the corresponding plots for the real and imaginary parts of the relative permeability μ. From Figure 2c and d, one can see the differences between the permeability of M samples and that of N samples. Perhaps the most intriguing fact is that whatever the volume fraction of Fe_2O_3 investigated (from 0 to 58 vol%), M samples do not show absorbing properties in the microwave range. To gain a better understanding of how the composition affects the permittivity and permeability, a set of experiments was conducted in which the volume fraction of Fe_2O_3 is varied, as illustrated in Figure 3a and d. It is noticeable that the data in Figure 3a and b, corresponding to M and N samples at $F = \frac{\omega}{2\pi} = 1$ GHz, are almost coincident. Another important observation is that there is no evidence for a percolation threshold over the whole volume fraction of Fe_2O_3 range investigated. Figure 3c and d indicate that the $\mu'(f)$ and $\mu''(f)$ curves show substantial changes from M and N samples; for example, μ' is enhanced by a factor of 3 and μ'' is enhanced by a factor of 20 for $f \approx 0.5$

The experimental plots of $\varepsilon'(f)$ and $\varepsilon''(f)$ were compared with the results of simple calculations in Figure 3a and b using the Bruggeman symmetric medium equation; that is, $\sum_i f_i((\varepsilon - \varepsilon_i)/(2\varepsilon + \varepsilon_i)) = 0$, where f_i and ε_i denote the volume fraction and permittivity of the constituent i ($i = Fe_2O_3$, ZnO, epoxy resin or air). See Appendix B for details. The inputs Bruggeman's equation were obtained from our measurements and the literature [66–70]. The permittivities predicted by this model are inconsistent with experiment in magnitude and in composition trend.

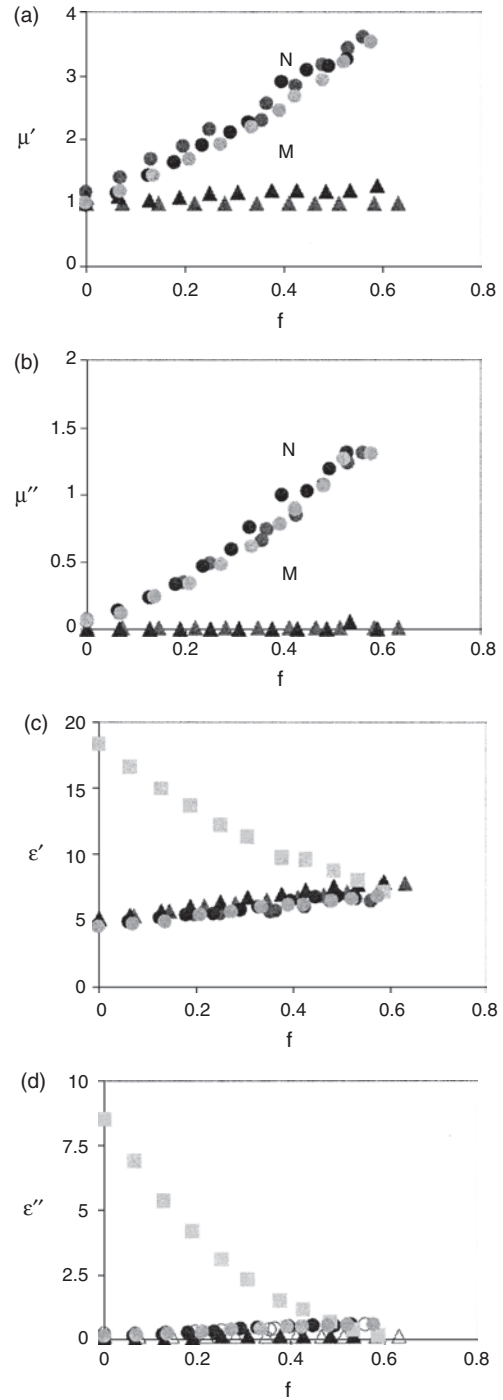
We believe that the discrepancies originate from two assumptions. First, the theory of Bruggeman assumes that the electric dipole–dipole interactions between the inclusions is taken into account in an average way. Unlike the dilute limit case, for which dipolar interactions provide a good description of the electrostatic interactions between the inclusions provided that the composite has the assumed geometry (in which a material of one type is embedded in an identifiable host material), such an approach fails to account for high concentrations of inclusions. Moreover, it does not depend explicitly on the size of the grains. This is because only the dipole term, which is proportional to grain volume, is retained in the series expansion of the amplitude of the magnetic field scattered by a single grain. Thus, only volume fractions appear in this approach. A second source of this
Figure 2. The frequency dependence of the relative permittivity ε and the relative permeability μ for micrometer-sized (M, red curve) and nanometer-sized (N, thick red curve) ZnO/Fe$_2$O$_3$ composite samples and a given value of the volume fraction of Fe$_2$O$_3$, $f = 0.53$. Room temperature. $\phi = 0.25$ (a) Real part ε', (b) imaginary part ε'', (c) real part μ', and (d) imaginary part μ''.


Figure 3. Variation of the relative permittivity as a function of the volume fraction Fe$_2$O$_3$, for M-type (triangles) and N-type (circles) ZnO/Fe$_2$O$_3$ composite samples at a given value of frequency, $F = 1$ GHz. Room temperature. Squares in (a) and (b) indicate the values of ε' and ε'' calculated using the mean-field Bruggeman model and taking as inputs $\varepsilon_{ZnO}(1\ GHz) = 38.2 - j0.3$, $\varepsilon_{Fe_2O_3}$ (1 GHz) $= 14.2 - j0.3$, ε_{cpoxy} (1 GHz) $= 5 - j0.01$, and ε_{air} (1 GHz) $= 1 - j0$. Observe that the caluculated values take into account the porosity of the samples. Red symbols correspond to $\phi = 0.25$, green symbols correspond to $\phi = 0.15$, and light blue symbols correspond to $\phi = 0.10$. (a) real part ε' of the relative permittivity, (b) imaginary part ε'' of the relative permittivity, (c) real part μ' of the relative permeability, and (d) imaginary part μ'' of the relative permeability.

discrepancy is that the parameters for the material are not uniform, but rather they are influenced by the presence of defects such as impurities and grain boundaries. It is usually argued that EMA approaches have the disadvantages typical of all mean-field theories because they Ignore the fluctuations in the system. It assumes that the local electric field is the same in the volume occupied by each constituent in the heterostructure. The microscopic local fields near the interfaces may differ considerably from those in the bulk regions because of the existence of the scattering fields from boundaries [71]. We call attention to the fact that the standard effective (continuous) medium approximations underlying the present calculations were done under the simplifying assumption of spherical particles, even if there is a significant departure from perfect sphericity for the ZnO particles. However, the use of depolarizing factors to account for shape anisotropy of the ZnO particles still leads to a significant deviation between the mean-field theory and experiment.

Observe also that no conduction (percolation) threshold is evidenced, indicating a disconnected Fe_2O_3 particles network. In these powder compact composites, the presence of insulating grains and of the amorphous epoxy resin increases the conduction barrier height and therefore is expected to decrease the overall conductivity of the samples. However, even if the volume fraction of Fe_2O_3—and hence the intergrain spacing—and grain size were independently adjustable, we have not yet studied the local charge transport mechanisms. A difficulty is that transport through such systems often involves processes that are strongly influenced by local fluctuations, including variations in morphology and particle sizes.

3.2. Gyromagnetic Resonance

An interesting observation can be made in the results of Figure 3. In addition, a 3D rendering of the $\mu'(f, F)$ and $\mu''(f, F)$ surfaces over the f–F plane is exhibited in Figure 4a and b. It is apparent from Figure 4c that the resonance frequency F_0 is slightly increased the percentage of Fe_2O_3 is increased. One can see from Figure 4d that the resonance width at half-height ΔF decreases significantly as the percentage of Fe_2O_3 is increased. For completeness, we also show the three sets of data corresponding to $f = 25$ vol% for ε', ε'', μ', and μ'' in Figure 5a through d, where the epoxy concentration is increased from $\phi = 10$ vol% to $\phi = 15$ and 25 vol%. Careful inspection of the μ'' curves with different epoxy volume fractions reveals a fine structure of the broad resonance line. This effect is most pronounced for the curve corresponding to $\phi = 25$ vol% in Figure 5d.

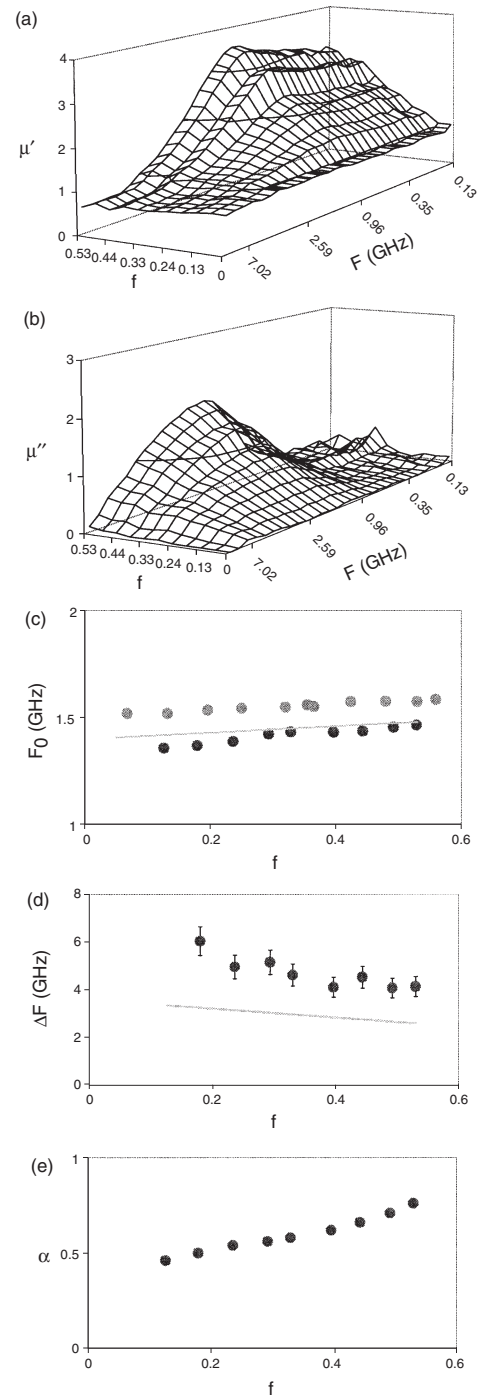
We now turn our attention to a phenomenological analysis of the gyromagnetic resonance observed in N-type samples. To go further one must fit the gyromagnetic resonance to an appropriate functional form for the dynamics of magnetization. We now give technical information about the calculations and analyze the results in detail. The dynamics of an individual magnetic moment can be described by a magnetization vector $\vec{M}$. In theoretical aspect, the response of this magnetization vector to the effective field is commonly described by the Landau–Lifshitz–Gilbert (LLG) equation of motion, which has the


Figure 4. (a) Real part μ' of the permeability on a (f, F) surface. $f = 0.53$ and $\phi = 0.25$. (b) Same as in Figure 4a for the imaginary part μ''. $f = 0.53$ and $\phi = 0.25$. (c) The resonance frequency F_0 as a function of the volume fraction of Fe_2O_3. The blue line shows the calculated values using our modeling approach (see text). Red symbols correspond to $\phi = 0.25$ and green symbols correspond to $\phi = 0.15$. (d) The resonance width ΔF as a function of the volume fraction of Fe_2O_3. The blue line shows the calculated values using our modeling approach (see text). Same notation for the symbols as in Figure 4c. (e) The damping constant α, obtained from the fit of the gyromagnetic resonance, as a function of the volume fraction of Fe_2O_3.
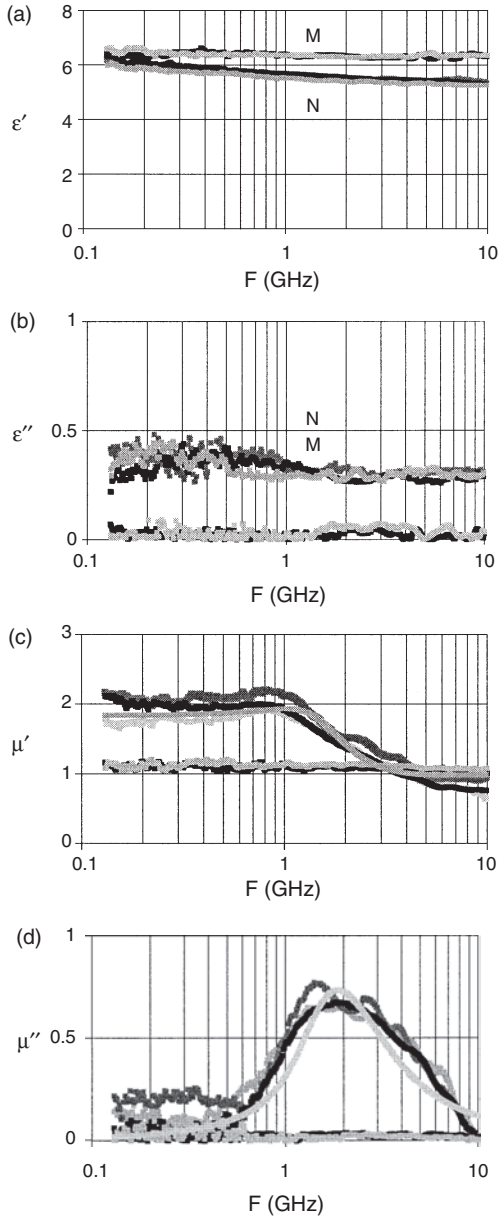

Figure 5. The frequency dependence of the relative permittivity ε and the relative permeability μ for micrometer-sized (N) ZnO/Fe$_2$O$_3$ composite samples for different volume fractions of epoxy and a given value of the volume fraction of Fe$_2$O$_3$, $f = 0.25$. Room temperature. The different colors are: (red, $\phi = 0.25$), (green, $\phi = 0.15$) and (dark blue, $\phi = 0.10$) for N-type samples, and (black, $\phi = 0.25$) and (orange, $\phi = 0.15$) for M-type samples. The light blue curves in (c) and (d) are fits of μ' and μ'' data by the Landau–Lifshitz–Gilbert equation (see text) using one free parameter: $\alpha = 0.5$. The magnetic dilution was described using the Bruggeman equation (see text). (a) Real part ε', (b) imaginary part ε'', (c) real part μ', and (d) imaginary part μ''.

form $\frac{\partial \vec{M}}{\partial t} = -\gamma \vec{M} \times \vec{H}_{\text{eff}} + \frac{\alpha}{M_s} \vec{M} \times \frac{\partial \vec{M}}{\partial t}$. The first term of the right-hand side of this equation accounts for the gyromagnetic precession of the magnetization $\vec{M}$. The second term arises from viscous damping and was introduced phenomenologically just from simple geometric considerations. At high damping, the magnetization rotates more or less directly toward the direction of the field as the second term

is dominant. The term γ is the gyromagnetic ratio of the free electron spin ($\gamma = 0.0176$ Oe^{-1} ns^{-1}), and α is the Gilbert dimensionless damping constant [72, 73]. The effective field term H_{eff} follows from the variation of the magnetic Gibbs free enthalpy G with respect to the magnetization (i.e., $\vec{H}_{\text{eff}} = \frac{-\partial G}{\partial \vec{M}}$) and includes the external applied field H_0, the exchange field, the magnetocrystalline field, and the demagnetizing field. Our approach can be quantified in the following manner. Because all of our experiments were conducted at wavelengths much larger than the characteristic internal lengths, that is, interparticle spacing and particle size, and because the Fe$_2$O$_3$ particles are polycrystalline with no preferred orientation in the samples giving all possible angular variations with respect to the magnetization, it is convenient to use the Bruggeman symmetric equation (i.e., $\sum_i f_i((\mu - \mu_i)/(2\mu + \mu_i)) = 0$, where μ_i represents the permeability of the ith component with volume fraction f_i), for it can explicitly provide the composition dependence of the bulk effective permeability. As before, the summation has four terms corresponding, respectively, to γ-Fe$_2$O$_3$ ($\mu_1 = \mu_1' - j\mu_1''$), ZnO ($\mu_2 = 1 - j0$), epoxy resin ($\mu_3 = 1 - j0$), and porosity ($\mu_4 = 1 - j0$). The other ingredient of the model was to describe the dynamics of magnetization by the phenomenological LLG equation. Following Suhl [72], are can easily show that

$$\mu_1' = 1 + \frac{\omega_0 \omega_M (\omega_0^2 - \omega^2) + \omega_0 \omega_M \omega^2 \alpha}{[\omega_0^2 - \omega^2(1 + \alpha^2)]^2 + 4\omega_0^2 \omega^2 \alpha^2}$$

and

$$\mu_1'' = \frac{\omega_0 \omega_M [\omega_0^2 + \omega^2(1 + \alpha^2)]}{[\omega_0^2 - \omega^2(1 + \alpha^2)]^2 + 4\omega_0^2 \omega^2 \alpha^2}$$

where ω_0 and ω_M are respectively, the gyromagnetic angular frequency given by γH_0 and the saturation magnetization frequency given by γM_s. The procedure described above was applied to fit the shape of the resonance line with only one adjustable parameter α. The result is given in Figure 5c and d. A reasonable agreement between theory and experiment is observed, considering the simplicity of the model; that is, the calculated $\mu'(F)$ and $\mu''(F)$ spectra are nicely reproduced but show some deviations that cannot be removed by tuning α. We found the following value for α: 0.50. Our appraisal of the literature indicates that the room temperature values of α, obtained from ferromagnetic resonance (FMR) linewidths, of about 0.33–0.45 were found for nanocomposites of iron particles dispersed in a ZnO matrix [29]. It must, however, be emphasized that smaller values of α have been reported for pure polycrystalline Fe films [74], but as explained by the authors of [74], the actual linewidths observed by FMR are somewhat larger than those attributable only to intrinsic damping. While our modeling of the gyromagnetic resonance line seems reasonable, it apparently is not the whole story. A remaining and crucial question comes from the origin of the large value of the Gilbert dimensionless damping constant α. It should be remembered that an enhanced Gilbert damping constant was found in ultrathin iron films [75] although this provides a different configuration of surface interface regions because the surface area is parallel to the sample's magnetization (assuming that the magnetization is held in the plane of

the film). Lack of microscopic theories is one reason for the remaining fundamental questions and debate concerning the interpretation of a large value of α. We tend to be cautious about the actual prediction of the damping constant as discussed here because this value may be exaggerated. Knowledge of the damping constant in nanophases is minimal because it is difficult to probe it directly. Two (possibly interrelated) aspects are important here: the origin of the damping mechanism and its intensity. In any event, it would appear that, even if the notion of exchange interaction beyond nearest neighboring grains notably affecting the high-frequency spin dynamics seems reasonable, the details have not been completely disentangled. One has no rigorous calculation of the characteristic length scale on which this process ought to proceed. It is desirable to develop an analysis based on micromagnetics calculations to check the result displayed in Figure 5.

As can be shown in Figure 4c, this model reproduces satisfactorily the experimentally observed slight increase of the resonance mode F_0 as the volume fraction of Fe_2O_3 is increased within experimental uncertainty. We also note from this picture that the results obtained for the two lowest concentrations of epoxy are close to each other. It is also instructive to examine the relative importance of the resonance width at half-height ΔF shown in Figure 4d as a function of composition. The decrease of ΔF with increasing f that we obtained by the above model is also shown in Figure 4d for reference. The amount of decrease is lower than the experimental results, but is consistent with the same trend. The variations $F_0(f)$ and $\Delta F(f)$ are inconsistent with the results of previous measurements on the microwave behavior of soft ferrites for which a broadening of the resonance band was evidenced [76]. We are led to believe that the enhanced value of the resonance model F_0 we observe is due, at least partly, to the polydispersity of the nanoparticles. It is immediately apparent from Figure 4e that the damping constant, obtained from those simulations, has the interesting feature that the composition dependence of α follows an increase from 0.46 for $f = 15$ vol% to 0.73 for $f = 53$ vol%.

It is intriguing to contrast the above results for nanometric composites with experimental results for micrometric composites using a similar sample configuration. The absence of gyromagnetic resonance for M-type samples in the frequency range explored seems puzzling. We have examined the possibility that this effect could be instrumental or due to the sample preparation. This has been shown not to be the case because the results were reproducible when both the preparation procedure and the epoxy content varied. At least three factors may contribute to the differing behaviors between M and N samples that are displayed in Figure 3c and d: reduced exchange coupling between the grains, porosity, and a possible effect of the binder. In the isotropic nanocrystalline mixtures of ZnO and Fe_2O_3, exchange interactions override the anisotropy of the individual grains, and we expect that particles with this small size will avoid large demagnetizing fields. One possible explanation for the absence of resonance in M samples is that the nonmagnetic phases separating adjacent grains induce a screening effect for the electromagnetic field.

A closer look at the gyromagnetic resonance and its shape dependence, at constant volume fraction of Fe_2O_3,

on the binder concentration is shown in Figure 5d. As the epoxy concentration increases, the tendency to form multiresonances becomes apparent. Actually, several ideas have been discussed in the literature relating the multiresonance observed with submicrometer-sized particles. For example, Toneguzzo et al. [77] have established that the $\mu''(F)$ spectrum of Co_xNi_{1-x} and $Fe_z[Co_xNi_{1-x}]_{1-z}$ particles systems with a mean diameter lower than 400 nm presents several resonance bands in the 0.1–18 GHz range. For this reason, the authors of [77] argued that the nonuniform resonance modes resulting from the exchange energy contribution to the magnetization precession and the particle size distribution may be possible mechanisms responsible for this multiresonant behavior in these materials. Key to these arguments is the idea that surface anisotropy is expected to play a dominant role for describing the magnetization mechanisms in nanophases. The reader may find also enlightening the article by Toneguzzo et al. [77], in which this issue is discussed.

3.3. Magnetization and Hysteretic Properties

After an investigation of the permeability has been conducted, we now turn to the magnetization data of M and N samples. The magnetization was studied as a function of particle size, composition, and epoxy content. Magnetic hysteresis measurements in magnetic field perpendicular ($H_\perp$), and parallel ($H_\parallel$) to the torus axis were performed at room temperature using vibrating sample mangetometry (VSM). No distinction was made between M–$H_\parallel$ and M–$H_\perp$, loops. Thus, we note that the shapes of these loops are isotropic in field direction. In what follows, consider only M–H loops, where H is defined as the magnetic field parallel to the torus axis. Figure 6 shows a representative example of such M–H loops, after normalizing them to saturation, for both M and N samples corresponding to a Fe_2O_3 volume fraction $f = 0.53$ and an epoxy concentration $\phi = 0.25$. From the inset of Figure 6 showing the full hysteresis loop, we observe that the magnetization saturates at a large magnetic field ($H_s > 10$ kOe) whereas the coercivity is relatively small ($H_c < 200$ Oe). The set of hysteresis curves reveals that the saturation magnetization M_s (normalized to the amount of Fe_2O_3) and the coercive field H_c do not vary substantially, within the limits of the experimental errors, when the volume fraction of Fe_2O_3 is varied in the samples at a specified particle size, as illustrated in Figure 7a through c, respectively, while the hysteresis loop squareness, that is, the remanence magnetization M_r normalized to M_s, decreases by increasing the volume fraction of $Fe2O_3$, as shown in Figure 7b. In Figure 7a through c, we also collect the values for H_c, $\frac{M_r}{M_s}$, and M_s for the three concentrations of epoxy resin investigated. Finally, over the whole volume fraction range of Fe_2O_3 investigated, it is noteworthy that the saturation magnetization of N samples is much lower (by an order of magnitude) than the saturation magnetization of M samples, whereas the opposite is true for the coercivity, that is, H_c (N samples) $\approx 2H_c$ (M samples) and the squareness $\frac{M_r}{M_s}$.

As a final point, we would like to comment on the room temperature magnetization measurements $M(H)$. There are a number of features worthy of discussion in these plots. All the loops show a smooth demagnetization curve and a
Figure 6. The magnetic hysteresis loops has a function of the applied magnetic field for N-type (red line) and M-type (green line) $ZnOFe_2O_3$ composite samples. $f = 0.53$ and $\phi = 0.25$. Room temperature. For the sake of comparison, the magnetization is normalized to the full saturation value. (a) Minor hysteresis loop and (b) major hysteresis loops.

Figure 7. Dependence of the reduced remanence ratio M_r/M_s of M-type (triangles) and N-type (circles) ZnO/Fe_2O_3 composite samples as a function of the volume fraction of Fe_2O_3 for two different volume fractions of the epoxy resin $\phi = 0.10$ (blue), $\phi = 0.15$ (green), and $\phi = 0.25$ (red). Room temperature. (b) Same as in Figure 7a for the coercivity. (c) Same as in Figure 7a for the saturation magnetization M_s normalized to the mass content of Fe_2O_3.

moderate saturation magnetization ($\cong 50$ em μg^{-1} for N-type samples), suggesting a very fine and uniform particle size in the samples. The hysteretic behavior shows that the saturation magnetization (resp. coercivity) takes higher (resp. lower) values for larger particles. This observation is consistent with recent reports by several groups [42, 78, 79], in which the authors reported similar particle size variations of coercivity and remanence for different types of magnetic fine particles in the size range of a few to a few tens of nanometers. For instance, Chen et al. [42] have shown that the coercivity curves of Fe/SiO_2 and Fe/Al_2O_3 granular films show a maximum at particle diameter $d \cong 20$ nm and then the coercivity decreases according to $1/d$, independently of the matrix material. The results of the above-mentioned studies and other reports [65, 80, 81] suggest that surface anisotropy and spin disorder at the particle surface play a dominant role in the magnetization mechanisms in such fine particle systems. Over the years several models have been proposed to explain this size dependence. Chen et al. [42]

provided remarkable new insight into this issue by the following argument. Consider an assembly of spherical, random, noninteracting single-domain particles with uniaxial surface anisotropy constant K_s and diameter d. The magnetization reversal of fine particles should overcome an energy barrier whose height is assumed to be independent on sample volume and depends only on surface area. This barrier may be overcome by thermal agitation. After some calculations, these authors concluded that the coercivity describing the physics of the 3D random uniaxial assembly can be written as

$$H_c = \frac{5.76\,K_s}{M_s d}\left[1 - \left(\frac{25\,kT}{K_s \pi d^2}\right)^{1.155}\right]$$

where T is the temperature. Applying Chen et al.'s calculations to our N-type samples, we found that $K_s = 0.48$ erg cm^{-2}. This is similar to the values of 0.4 erg cm^{-2}

for ultrafine particle systems of α-Fe found in [42]. On general grounds, it is natural to expect that the lower values of H_c corresponding to the M-type samples may come from the multidomain structure and the bulk anisotropy of the particles. Very recently, Verdes et al. [43] suggested a model that turned out to be successful for explaining the experimental findings for the magnetic and transport properties of Co nanoparticles with uniaxial anisotropy. The physics behind the model discussed by Verdes et al. considers a system of single-domain particles coupled via magnetostatic and short-range exchange interactions. It is found that the magnetic properties are strongly dependent on the ratio $\beta = \frac{KV}{kT}$, with K being the anisotropy constant and V being the mean particle volume. For small β the interactions lead to an increase in H_c with packing density. For large β the anisotropy and magnetostatic interaction fields are comparable and the competition between these effects leads to a decrease in the coercivity H_c as the packing density is increased. Unfortunately, the results are numerical, making it difficult to use them quantitatively for a general case.

The saturation magnetization changes only slightly with f. We observed also that the coercivity exhibits a monotonic behavior insensitive to the concentration of nonmagnetic particles. A similar observation is made for the remanence ratio except for the lower values of f investigated ($f < 0.1$). Moreover, the samples have very low remanence ratio compared with the value predicted by the SW model under the assumption of uniaxial anisotropy in the reversal process; that is, $\frac{M_r}{M_s} < 0.5$. It is widely believed that the remanence ratio sheds light on the interaction between particles [82]. Although it has long been recognized that the hysteretic behavior of these multiphase heterostructures depends not only on the intrinsic properties and the grain size distribution of the different phases but also on the exchange and magnetostatic interphase coupling [83, 84], the lack of methods to accurately compute or measure the relative strength of these interactions has limited the understanding of the magnetic properties of nanophases.

The lack of a significant Fe_2O_3 volume fraction dependence of M_s, H_c, and $\frac{M_r}{M_s}$ requires additional attention. One would expect that the coercivity of samples will increase with their concentration of nonmagnetic particles because the variation of the demagnetizing field around the nonmagnetic particles, especially for large particles, causes a domain wall energy increase during the magnetization. Within the SW model, only coherent rotation of the magnetic moments can cause the magnetization and demagnetization processes in single-domain particles. However, many experimental studies revealed that the SW theory does not explain magnetic properties of fine particle systems even when the particles can be considered as single-domain regions [25, 42]. It is by now well established that the magnetization reversal in an assembly of small-sized particles with high magnetocrystalline anisotropy is controlled by nucleation of reversed domain walls at the particle surface where the anisotropy is lower than the interior of the particle due to the presence of surface defects or large localized demagnetization factors [41, 85]. The nucleation field is much higher for nanometer-sized particles because each grain has a small surface area and thus less surface defects. To close this section, we also note that in the composite materials considered here, the

Fe_2O_3 particles are strongly bonded to the insulating background and may be subjected to very large stresses. Consequently, the magnetic phase–nonmagnetic phase interfaces may dominate the behavior of the coercivity as the packing is varied.

APPENDIX A: MICROWAVE MEASUREMENTS OF ε AND μ

For the purposes of this review it is not necessary to go into the details of the various ingenious schemes that have been developed over the last decades for investigations of the permittivity and permeability of materials. We will concentrate our discussion on measuring ε and μ having special relevance to isotropic materials in the microwave region of the electromagnetic spectrum. Research into the characterization of the permittivity and permeability tensors in dielectric and magnetic heterostructures having anisotropy is still very new and is in its developing stage [96]. Different experimental techniques and geometries measure different components of these tensors; for these topics, the reader is referred, for example, to [47].

The ZF effective complex permittivity $\varepsilon = \varepsilon' - j\varepsilon''$ and permeability $\mu = \mu' - j\mu''$ of the composite samples were measured using the transmission/reflection method based on the Nicolson and Ross and Weir [97] and Baker-Jarvis et al. [98] algorithms for the broadband characterization of isotropic solid materials. This experimental technique is based on the measurement of the scattering parameters (S parameters) of a toroidal sample of the test material that has been machined so that the geometrical dimensions fit well with those of the coaxial line used (to avoid the presence of air gaps between the sample and the line walls). The geometries of the cell and the material to be tested are illustrated in Figure 8a and b. The method enables us to calculate simultaneously ε and μ of the material from the measurement of the transmission S_{21} and reflexion S_{11} parameters (i.e., Fig. 8c) of a coaxial line that contains it. The electromagnetic analysis of the propagation line permits us to write

$$S_{21} = \frac{(1 - \Gamma^2)T^2}{1 - \Gamma^2 T^2} \tag{A1}$$

$$S_{11} = \frac{(1 - T^2)\Gamma^2}{1 - \Gamma^2 T^2} \tag{A2}$$

From Eqs. (A1) and (A2), one gets ε and μ [97]:

$$\mu = \mu' - j\mu'' = \left(\frac{1 + \Gamma}{1 - \Gamma}\right)\frac{j\ln(T)}{2\pi d}\frac{c}{F} \tag{A3}$$

$$\varepsilon = \varepsilon' - j\varepsilon'' = \frac{\left(\frac{j\ln(T)}{2\pi d}\frac{c}{F}\right)^2}{\mu} \tag{A4}$$

where c denotes the velocity of the wave in free space, d is the thickness of the material sample (Fig. 8c), and F is the frequency of the wave, respectively.

In this coaxial line measurement the fundamental transverse electromagnetic mode is the only mode that

propagates in the coaxial line. An error analysis indicates modest uncertainties in ε' ($<5\%$), ε'' ($<1\%$), μ' ($<3\%$), and μ''($<1\%$) for the data. A Hewlett Packard HP 8510B network analyzer setup is used to measure the S parameters of the cell containing the material under test over a wide range of frequencies (10 MHz–20 GHz) with SOLT calibration. Typical dimensions of the sample are inner diameter $=$ 3.04 mm, outer diameter $=$ 7 mm, and thickness $=$ 2–4 mm. All experiments were carried out at room temperature. In addition we have used VSM to measure the hysteresis loops at room temperature. In this arrangement, the sample could be oriented either parallel or perpendicular to the direction of the applied horizontal magnetic field.

APPENDIX B: BRUGGEMAN EFFECTIVE MEDIUM APPROXIMATION (EMA) THEORY

Several basic assumptions underlying the Bruggeman symmetric effective-medium theory deserve note. They are the following. (1) The applicability of this approach rests firmly on the quasistatic assumption, that is, when the typical size of inclusions (or inclusions clusters), a, is small compared with the wavelength of the electromagnetic wave probing the system. This puts an upper limit on angular frequency $\omega \ll \frac{c}{a}(\varepsilon\mu)^{-1/2}$, where c is the vacuum light velocity, ε is the effective relative permittivity, and μ is the effective relative permeability ($\mu = 1$). Within this assumption, the system can be described by an average (effective) permittivity. The no-scattering condition leads to absorption losses only. (2) The inclusions do not interact with one another. (3) The various inclusions of any single homogeneous material constituent are assumed to be embedded in an effective medium and are statistically equivalent; in particular, they exhibit the same form. (4) The constituents are distributed randomly without interstices. (5) The rationale behind this self-consistent (mean-field) approach lies in the notion that the volume average polarization in the composite material is equal to zero. It is important to recall that while this dipolar approximation is adequate to describe the dielectric properties for sufficiently low volume fraction of the inclusions, it must ultimately fail for predicting the dielectric behavior at high concentrations where quadrupoles and higher-order interactions are required, that is, near the percolation threshold. This point has been debated in the literature without, until recently, satisfactory resolution. The difficulty is addressed by the so-called generalized effective medium theory, first developed by McLachlan, that combines elements of the percolation theory with the conventional Bruggeman effective medium theory [44].

Although limited to a dipolar description, the popularity of the Bruggeman theory among the researchers is obviously due to one great virtue—its simplicity. Moreover, its prediction offers a means to get parameters with clear physical meaning, which could be related to direct experimental observations. In the most commonly used form, the Bruggeman effective medium theory for spherical inclusions (of permittivity ε_1) embedded in a host matrix (of permittivity ε_2 and treated as a continuum medium enveloping the inclusions) leads to the self-consistency condition

$$f\frac{\varepsilon - \varepsilon_1}{2\varepsilon + \varepsilon_1} + (1 - f)\frac{\varepsilon - \varepsilon_2}{2\varepsilon + \varepsilon_2} = 0 \qquad (B1)$$

where f is the volume fraction of the more conducting constituent. It should be noticed that the Bruggeman formula is still valid if the properties of the constituent materials have complex values; that is, $\varepsilon = \varepsilon' - j\varepsilon''$, where j is the imaginary unit, thus enabling a prediction of complex valued properties of filled polymers. Although the definition, in a two-component system of what is the filler and what is the matrix can be confusing when in the case of certain composites the volume fraction occupied by the filler is higher than that of the matrix, the Bruggeman model assumes no explicit choice of the host material [Eq. (B1) is symmetrical with respect to the constituents]. The procedure amounts to finding the roots of a second-order polynomial and the physical root of Eq. (B1) is determined from requirements of positivity of ε' and ε''. Although this approach was originally designed for a two-component system, it can be straightforwardly extended to mixtures of any number of components

[46]. The concentration at which the system undergoes an insulator–conductor transition is designated as f_c. In the dilute limit (low concentration of the particles and $f < f_c$), one has $\varepsilon = \varepsilon_2(1 + 3f)$. This model can be useful within its range of validity. However, a basic difficulty arises in using it to describe real composite materials. The derivation of Eq. (B1) assumes that each inclusion is surrounded by a mixture of the two constituents that have the effective value for the medium. This is not the case for percolating systems in which the inclusions come in contact with each other. Thus, in practice, the range of validity is limited to $f < f_c$ and often does not encompass the actual experimental conditions. The Bruggeman symmetric medium equation is particularly appropriate for composites and polycrystals in which the grains of the various components are randomly and symmetrically distributed, so that none of the components is identifiable as a host in which the others are preferentially embedded.

4. CONCLUSIONS

This work has yielded stable and reproductible data on the composition, size, and frequency dependences of the complex permittivity and permeability of nanometer- and micrometer-sized Fe_2O_3 particles dispersed in a nonmagnetic metal oxide matrix. We described a number of previously unreported features for magnetic nanophases. We conclude two things based on the discussion and experimental evidence above. The first is that manipulations of the composition in metal oxide composite materials and the grain size can be good approximations of reduced dimensionality systems and offer a means of precisely tailoring the electromagnetic properties of these materials. The second feature of our results is that there are correlations in these multiphase nano- and microstructured systems that go far beyond a standard coarse graining description of the dielectric response, that is, the Bruggeman theory, which makes no reference to the arrangement and the size of the constituents [46, 86]. Some possible reasons for this discrepancy have been discussed above. For example, we expect that clustering effects, surface defects, size, shape, and separation of the residual pores and the fact that ZnO and Fe_2O_3 are wholly surrounded by an epoxy layer are key points to describe the polarization mechanisms. It would be interesting to test whether the combination of fractal boundaries with spheres arranged in a simple cubic array, such as that proposed in [68], is an efficient model to describe this mesostructure under confinement. On the other hand, the complex effective permeability of these particulate dispersions can be rationalized in terms of the general framework of mean-field theory, that is, the Bruggeman theory, coupled to the LLG equation describing the dynamic behavior of the magnetization. It is also important to realize that treating the effective magnetic permeability by a mean-field approach is not inconsistent with the result mentioned above for the effective permittivity. This state of affairs can be understood if we view the polarization and magnetization mechanisms in these materials as decoupled. There are several mechanisms for the damping term, which is responsible of the losses in the material [87]. What is of paramount

physical relevance in ascertaining a realistic damping mechanism is the magnitude of the Gilbert constant α. In this regard, the comparison of the value of α deduced from the tit of the gyromagnetic resonance with that obtained from the FMR linewidth will be important. It is fair to say that the shape of the gyromagnetic curve in Figure 5 reflects, in part, the uncontrolled polydispersity of the nanophases. It should perhaps be emphasized once again that this information is necessary if we aim to understand the basic physics behind the magnetic properties of these materials [88]. In addition, the experimental behavior observed does not follow the general trend that had been predicted from the SW model for magnetization reversal. After several years of intense theoretical studies, it is clear that we do not have the proper skills and tools to deal with the collective transport properties of strongly correlated spin systems whose internal interactions modify the influence of external applied fields. Missing from this work is any information regarding the scale of fluctuations of the local fields experienced by the moments. For this, it is necessary to go beyond the mean-field formalism considered here, which neglects composition fluctuations. As mentioned in the Introduction, these difficulties have led numerous groups to study computational methods that address fundamental issues in nanomagnetism.

There are several directions that we could see taking our work in the future. In light of our earlier discussion concerning the likely significance of the multiresonance structure observed at high epoxy concentrations, it appears extremely interesting to further investigate composites with even smaller particles with controlled size. The biggest bottleneck for the preparation of well-defined systems is the homogeneous dispersion process of the particles. Obtaining samples with well-separated particles is far from trivial and becomes more difficult the higher the packing density. Meanwhile, the puzzling feature of the absence of gyromagnetic resonance for M-type samples has not been satisfactorily explained, and this a question to be pursued in future studies. To tackle this problem experimentally it would clearly be of general interest to investigate whether the behavior observed here persists for another choice of the dielectric matrix and the magnetic component. In future work, we plan also to give a detailed discussion of the study of the magnetic properties, for example, exchange coupling between the grains, using ^{57}Fe Mössbauer spectrometry elsewhere. We should note that this work has also highlighted the fact that refined first-principles (and realistic) micromagnetics simulations combined with experimental measurements are needed to understand the magnetic behavior of nanophases. It is an area of much current interest; for example, see [89]. Computational results can contribute to the acceptance or rejection of mean-field based theories and can also indicate directions, in which new approaches should be developed. Furthermore, we would like to point out that this work highlights the importance (and complexity) of particle characteristics (particle size and shape) in comparison of bulk (effective) electromagnetic properties. To understand the significance of these results in the study of wave transport in nanocomposites, it will be interesting in the future to see more and more experiments realized with increasingly smaller particles. The exploitation of interfacial properties,

especially at the nanometer length scale will be central to developments of nano-technical devices of the future, for example, for applications in high-density magnetic storage [90]. The resolution of these issues will be a target of future investigation.

It is a conspicuous implication of the present experiments that manipulation of the composition, the preparation procedure, and the grain sizes offered a means to "tailor," to a particular need, the electromagnetic properties of a (isotropic) distribution of fine magnetic particles embedded in a nonmagnetic matrix, where complementary parameters, such as permittivity and permeability, are interestingly combined. For example, very small coercivity, high remanence, high permeability, low dielectric, and low magnetic loss soft magnetic material having a square hysteresis loop is required for microwave operation. Other requirements for a nearly ideal material eventually include fine grain, defect-free, and dense [91]. Materials that simultaneously exhibit a large permittivity and a large permeability with corresponding low losses are of significant technological interest as components of magnetoelectric sensors and actuators [24, 92, 93]. Observe that the utility foreseen for magnetoelectric materials rests on the possibility of tailoring their electric and magnetic properties on the same footing. Another related question is how all of this can be related to investigations of the electromagnetic properties of materials with simultaneously negative permittivity and permeability or left-handed materials (LHMs). In 1968 the Russian physicist Victor Veselago [94] theoretically investigated the electromagnetic consequences of a LHM and predicted that such a medium would have dramatically different propagation characteristics stemming from the sign change of the group velocity, including reversal of the Doppler shift and Cherenkov radiation, anomalous refraction, and even reversal of radiation pressure to radiation tension. However, at that time, these effects could not be experimentally verified since, as Veselago pointed out, materials with negative permeability were not available. Recently, a number of authors have made progress in preparing artificial LHMs, for example, arrays of conducting nonmagnetic split ring resonators or metallic magnetic granular composites [95]. Nanostrctured LHMs can potentially be applied to alternative technologies to be used in displays and devices such as antenna radoms, band-pass filters, microwave couplers, and high-resolution optical lithography in the semiconductor industry.

GLOSSARY

Effective medium approximation (EMA)   The basic idea is to describe the system by a simple average permittivity or (permeability) and is based on a self-consistent procedure in which a grain of one of the constituents is assumed to have a convenient shape (usually taken as spherical or ellipsoidal) and to be embedded in an effective medium (homogeneous) whose properties are determined self-consistently. This requires that the wavelength of the electromagnetic radiation probing the system has to be larger than a typical scale of length that characterizes the inhomogeneities in the material medium.

Gyromagnetic resonance   This is the spin of the electron that is the main cause of magnetization. In ferromagnetic materials, there exists a predominance of either left- or right-handed spins. Moreover, there is a restraining force that tends to keep electrons near each other spinning in the same direction. Ferromagnetic materials, also called cooperative materials, can retain their magnetic properties. This is due to the restraining force. Normally, in an unmagnetized state, the electron spins are randomly oriented so that the net sum of all the Bohr magnetons is zero. When a magnetic field is applied, the material changes to the magnetized state, where all the tiny magnets line up and add together. In an experiment the sample is subjected to a microwave field of fixed frequency and to an applied static field, the magnitude of which is varied. At each field value, the reflected or absorbed power from the sample is measured. These may yield one or more minima and maxima, respectively, corresponding to resonance modes of the ensemble. The field at which this gyromagnetic resonance occurs, the so-called resonance field, depends on several magnetic parameters.

Hysteresis   This represents the history dependence of physical systems. When a ferromagnetic material is magnetized in one direction, it will not relax back to zero magnetization when the imposed magnetizing field is removed. It must be driven back to zero by a field in the opposite direction. If an alternating magnetic field is applied to the material, its magnetization will trace out a loop called a hysteresis loop. The lack of retraceability of the magnetization curve is the property called hysteresis, and it is related to the existence of magnetic domains in the material. Once the magnetic domains are reoriented, it takes some energy to turn them back again. This property of ferromagnetic materials is useful as a magnetic "memory."

Magnetoelectric materials   These hybrid nanostructures form a fascinating melting pot for studying the interplay between dielectric and magnetic properties. In fact, the addition of the spin degree of freedom to conventional electronics know-how is paving the way to the appealing field dubbed "spintronics." This emerging area includes the active control of carrier spin dynamics and transport in electronics materials, with the final goal of nanolithic integration of the nanoscale with larger structures.

Particulate composite materials   In the most general sense, a particulate composite material can be defined as the combination of many materials (or the same material in different states) present as separated components (particles) with different geometric and physical properties and mixed together to form structures that may improve a specific property.

Electron Beam Writing in Nanoparticle Films

Y. Chen, R. E. Palmer

The University of Birmingham, Birmingham, United Kingdom

CONTENTS

1. INTRODUCTION

In recent years, significant progress has been made in creating a variety of functional, nanometer-scale architectures, such as molecular-scale wires and switches [1–4], molecular-scale transistors based on nanotubes [5], and semiconductor nanowires [6]. Even logic circuits, constructed from individual carbon nanotube molecules [7] and semiconductor nanowires [8], have been reported, presenting dramatic advances toward the realization of nanoelectronics and especially nanocomputers.

The main challenge to the advance of molecular-scale electronics from the single-device level to the circuit level lies in the assembling together of the component devices, each of which must be addressable. Fabrication techniques coping with the size region from the nanometer to the micrometer are essential to assemble the nanocomponents and link them to the macroscopic world. Here, we introduce one of these techniques, namely, electron beam (e-beam) writing in passivated nanoparticle films.

This chapter is divided into five sections. Passivated nanoparticles, the building materials for the films modified by the direct e-beam writing process, are surveyed in Section 2. Section 3 gives a review of the effect of electron irradiation of self-assembled monolayers and films of nanoparticles,

which provides the background to the e-beam writing process. The direct e-beam writing technique is demonstrated in Section 4, which provides details of the basic experimental process and its quantitative assessment and also discusses the underlying mechanism. Section 5 gives some examples of the application of this technique to create structures of technological interest, aiming to give the reader a flavor of potential applications. Finally, the future development of the technique is discussed in Section 6.

2. PASSIVATED NANOPARTICLES

Passivated nanoparticles are nanometer sized colloidal particles chemically terminated by organic monolayers, typically alkanethiol molecules. They can be produced from many materials and show a diversity of functional behavior beyond that of the corresponding bulk materials, with many of their electronic [9], optical [10, 11], and catalytic [12–14] properties originating from their quantum-scale dimensions. The organic layer, typically bound to the nanoparticle core by a metal–sulphur (thiolate) bond, prevents the particles from aggregating together, in solution or on a surface, which is more likely to occur in the case of bare particles (clusters), so that they retain their unique, size-dependent functionality.

2.1. Self-Assembly of Passivated Nanoparticles

Passivated metal (e.g., gold) nanoclusters can be used as "building blocks" to form ordered monolayers and thin films. The diameter of these nanoparticles (1–10 m) makes them ideal for constructing nanoscale architectures and devices. X-ray diffraction of the superlattice formed by a three-dimensional assembly of passivated gold nanocrystals shows a sequence of intense, sharp Bragg peaks in the small angle region, in addition to the peaks arising from the planes of Au atoms within individual nanocrystal cores.

The low angle peaks arise from the ordered layers of nanocrystals stacked to form a giant three-dimensional superlattice [15]. The macroscopic properties of the nanoparticle superlattice are determined by both the properties of each individual particle and the coupling/interaction between the nanocrystals (via the ligands). Thus the organic ligands serve not only as a protective layer for the particles, preventing direct contact between the cores, but also regulate interparticle bonding. For example, the tuneable interparticle spacing, derived by changing the length of the molecular chain, allows control over structural, optical, and transport properties [16].

Since a variety of organic molecules can be employed to passivate the nanoparticle cores, it is possible to choose ligands with a range of functionalities, allowing attachment to particular substrates or molecules. For example, one can envisage the selective attachment of individual nanoparticles to selected substrate regions, as part of the fabrication of a nanodevice. The electronic properties of single nanoparticles are already the subject of active research [17, 18], which exploits the size-dependent properties of nanoparticles to fabricate individual single-electron devices [19, 20] and similar structures [21, 22].

2.2. Patterning the Nanoparticle Assembly

In order to manufacture nanostructures or, ultimately, devices using nanoparticles, one needs to be able to assemble these "artificial atoms" from solution onto technically interesting substrates and possibly also to process these assemblies further to create robust structures with practical functions. Exciting advances toward the self-assembly of nanoparticles into ordered structures on various substrates have been reported in recent years [23]. As an example, linear structures of width ~1–50 nm are of technological importance for potential applications and also hold great fundamental interest for quantum confinement behavior. A number of such "wires," based on gold and silver nanoparticles, have been prepared by various methods. The spontaneous alignment of silver nanoparticles to form wires several micrometers long and 20–300 nm wide was observed by Chung and co-workers at the water/air interface [24]. Simon and co-workers reported the spontaneous formation of a wire consisting of a single line of clusters [25]. A metal particle chain, which formed a bridge between a pair of nanoelectrodes, was created by Burghard and co-workers by self-assembly under directional flow conditions [26]. Another approach to the fabrication of nanowires is self-assembly of nanoparticles along linear templates. One example, reported by Hutchinson and colleagues, is the self-assembly of gold nanowires from ligand stabilized gold nanoparticles drop cast onto a corrugated amorphous carbon thin film with topographical features of nanometer dimensions, followed by heat treatment [27]. The continuous wire segments resulting from the sintering of the nanoparticles were typically 3 to 5 nm wide and up to 100 nm long. Another example of the use of linear templates was reported by Fullam and co-workers, who decorated bundles of single-walled carbon nanotubes with gold particles and obtained continuous, polycrystalline gold nanowires after sintering the

particles under heat treatment [28]. Passivated gold nanoparticles have also been deposited from solution onto silicon dioxide surfaces prepatterned by photolithography and preferential cluster accumulation is observed along the edges of the resist structure after a lift-off of the photoresist [29]. A guided flow along the boundary between a resist and a silicon surface can extend for over 600 μm across the surface, producing cluster chains as narrow as ~120 nm [30].

Recently, nanoparticles of CdTe were found to spontaneously reorganize into crystalline nanowires upon removal of the protective shell of organic ligands. The stabilizer was removed by precipitating the CdTe colloids by methanol addition and redissolving in pure water. Then the obtained dispersion was allowed to age in darkness at room temperature for several days. Nanowires were formed during this period through pearl-necklace aggregates. It is believed that the strong dipole–dipole interaction is the driving force of nanoparticle self-organization. The produced nanowires have high aspect ratio (100–500) and their diameters were determined by the diameter of the nanoparticles [31].

Patterning of nanoparticle assembly can also be achieved by modifying surfaces with electrons or photons in a way such that the exposed area is functionalized with molecules to which the nanoparticles bind selectively [32–34]. For example, focused e-beam writing to a self-assembled monolayer incorporation of an aromatic nitro derivative allows the unreactive nitro functionality to be converted to a nucleophilic amino group which could subsequently react with simple carboxylic acids in solution to form amide bonds. Nanoparticles with designed ligands can thus be selectively assembled to an e-beam modified area.

2.3. Electron Transport in Nanoparticle Film

The conductivity of nanoparticle assemblies is important for both fundamental reasons and technical applications and has been the subject of several studies in recent years. It is found that the resistance of a nanoparticle network depends on factors such as the particle size and particle separation, as well as the number of particle layers (in a thin film). Gold nanoparticle networks connected by alkanedithiol linkers demonstrated nonmetallic conductivity behavior when the temperature was varied, probably involving activated electron hopping from particle to particle [35]. Significantly different surface resistances were measured for multilayers of gold nanoparticles separated by alkanedithiol molecules of various chain lengths [36]. It has also been reported that colloidal gold multilayers undergo a metal–insulator transition at a critical particle density [37, 38]. Films of nanoparticles (diameter 11 nm) with density up to 25×10^{11} cm^{-2} were found to be insulating, with a resistance in excess of 10^7 Ω, but an increase in the number of gold particle layers resulted in an enormous decrease in the resistance. When the particle density was doubled (50×10^{11} cm^{-2}), the resistance was below 100 Ω, a change of five orders of magnitude. Reversible metal–insulator transitions in ordered silver nanoparticle monolayers have been observed when the Langmuir–Blodgett (LB) films are compressed and decompressed [39]. As the interparticle separation is reduced, the mechanism of charge transport changes from hopping to

tunnelling and then to metallic transport, resulting in significant conductivity changes. In contrast to the many studies of nanoparticle films, relatively little has been reported in the area of electron transport by linear nanoparticle structures.

3. ELECTRON BEAM EFFECTS ON SELF-ASSEMBLED MONOLAYERS AND NANOPARTICLE FILMS

3.1. Electron Beam Irradiation of Self-Assembled Monolayers

Self-assembled monolayers (SAMs) are close-packed arrays of chainlike molecules which are chemically bound to a planar substrate via their head groups. SAMs are formed from the same kinds of molecules (e.g., alkanethiols) used to terminate nanoparticles. Thus the response of SAMs to electron irradiation provides clues as to the response of nanoparticle films to the same type of irradiation. SAMs also provide structurally and chemically well-defined organic substrates, relevant to biological interfaces and membranes, corrosion protection, electrochemistry, and molecular devices [40, 41]. The formation of well-defined organic surface phases by the immersion of a clean gold substrate in a dilute solution of a long-chain dialkyldisulfide was first reported in 1983 [42]. A typical example of a self-assembled monolayer is the thiol/Au system (see [43, 44] and references therein), where S–Au bonding leads to the formation of a gold thiolate. A $(\sqrt{3} \times \sqrt{3})R30°$ overlayer structure results, with domains hundreds of square nanometers in size. It is found that the chains are fully extended and tilted with respect to the surface normal by around 30°.

The response of SAMs to ion, X-ray, and electron beam irradiation is a substantial issue for scientific and technological applications. Many experimental techniques applied to characterize SAMs involve the exposure of the sample to such irradiation. On the other hand, modification of SAMs by irradiation can be used to pattern the self-assembly monolayers and thus represents a novel method of lithography. Moreover, the initial pattern generated in a SAM (e.g., by electron beam writing) can be transferred into the underlying substrate (e.g., by chemical etching or ion beam milling) [45].

An understanding of the nature of the beam damage in SAMs, especially the changes of the physical and chemical properties of the organic films in the exposed region, is important for the optimization of the lithography process and also for the selection of appropriate molecules. So far, investigations into the modification of alkanethiol SAMs by X-ray and electron exposure have explored the chemical and structural changes within the monolayers [46–52], the relation between packing density and the extent of irradiation-induced damages [53], changes in tribological properties due to cross-linking driven by electron irradiation [54], and the effect of irradiation by secondary electrons originating from the substrate [55]. Dehydrogenation of alkanethiol/Au/mica films has been reported, principally via dissociative electron attachment [56]. A well-resolved maximum in the probabilities for C–H bond cleavage was observed at ∼10 eV in these experiments. Electron irradiation also causes a whole

series of other effects: cleavage of C–C bonds resulting in the partial desorption of fragments, a reduction in the film thickness, the appearance of C–C/C=C cross-links, the loss of conformational and orientational order within the alkanethiolate films, the breaking of Au–S bonds, the formation of disulphide bonds, and incorporation of sulfur into an alkyl matrix [57–59].

3.2. Low Energy Electron Impact on Films of Passivated Nanoparticles

In contrast to the wealth of knowledge on SAMs of alkanethiol molecules on planar metal surfaces, the nature of the adsorption of organic ligands on metal clusters is a relatively unexplored field [60, 61]. Moreover, the specific characteristics of the clusters, such as the shape, electronic structure, and surface reactivity derived from their limited size, may introduce new aspects to the interaction of the ligands with low energy electrons. The effect of electron impact on the organic shells of passivated metal nanoclusters is thus not only of relevance to practical e-beam writing but is also of fundamental scientific interest.

Chen et al. have investigated films of gold particles, passivated with alkanethiol (octanethiol, $C_8H_{17}S$) ligands and deposited from a toluene solution onto the graphite surface, using high resolution electron energy loss spectroscopy (HREELS) [62]. A typical HREELS spectrum from this film (Fig. 1) shows vibrational modes of the CH_x groups of the ligands, together with their overtones. Impact energy dependent HREELS measurements reveal an enhancement in the intensity of these vibrational modes at an energy of around 10 eV, as displayed in Figure 2, indicating the formation of a negative ion resonance state resulting from low energy electron attachment [63]. Olsen and Rowntree [56], who investigated the electron-induced dehydrogenation of alkanethiols on planar Au films, found C–H dissociation probabilities with a well-resolved maximum at 10 eV, which is close to the resonance value observed in the HREELS study of the nanoparticle film. The width of the resonance, about 7 eV, is significantly greater than found in SAM (4 eV). One possible explanation is that the resonance lifetime is reduced in the passivated cluster film (e.g., by the opening of new decay channels for the transient negative ion). In the film of passivated Au clusters, one can envisage interactions between the ligands of adjacent clusters [61, 64], for example, by interdigitation, which might lead to broadening of the resonance.

Low energy electron impact on gold nanoparticles passivated with dialkyl sulphide molecules ($H_{21}C_{10}SC_{10}H_{21}$) has also been investigated [65]. Dialkyl sulphide is an interesting passivating agent because the Au–S bond is weaker (60 kJ mol^{-1}) than in the alkanethiol case (126 kJ mol^{-1}) [66], which might result in a higher probability for Au–S bond cleavage during electron beam exposure [67, 68].

A typical HREELS spectrum obtained from a film of dialkyl sulphide passivated gold nanoparticles on graphite is shown in Figure 3a. Energy loss peaks observed in the 700–3000 cm^{-1} region are related to CH_x and C–C vibrational modes of the organic ligands (see [65] and references therein). The Au–S stretching mode at 230 cm^{-1} is also clearly visible in this case [69]. After prolonged exposure
Figure 1. HREELS spectrum from a film of gold nanoparticles passivated with alkanethiol ($C_8H_{17}S$) ligands deposited on the graphite surface.

Figure 2. Incident energy dependence of the intensities of the CH stretch (v_a) vibrational mode and first overtone (upper panel) and of two overtones of the CH_2/CH_3 vibrational modes around 1400 cm^{-1} (v_b) (lower panel) obtained from HREELS spectra taken in the specular scattering geometry from a film of passivated gold nanoparticles on graphite.

of the film to electron beam irradiation at 50 eV, with a dosage of approximately 360 $\mu C\,cm^{-2}$, significant changes were found in the HREEL spectra (Fig. 3b). The Au–S stretch mode disappears and a new feature at 460 cm^{-1} appears, indicating the cleavage of the Au–S bond and, possibly, the formation of sulphoxide. Thus the HREELS measurements provide evidence of direct Au–S bond cleavage upon low energy electron irradiation, possibly related to the relatively weak Au–S bond in the dialkyl sulphide–gold system.

The picture emerging of the interaction between low energy electrons and passivated nanoparticle films resulting in cleavage of the C–H, C–C, and Au–S bonds is thus rather similar to the picture of electron beam–SAM interaction.

3.3. High Energy Electron Irradiation on Nanoparticles

The morphology changes in a nanoparticle film as a result of high energy electron beam irradiation can be imaged directly with a transmission electron microscope (TEM). Figure 4 was obtained after alkanethiol passivated gold nanoparticles, deposited onto an SiO_2 substrate, were exposed to a focused electron beam (200 kV, 36 nA), giving an approximate dose (assuming a probe of 10 nm) of 55 $nC\,nm^2$. Figure 4 shows
TEM images taken before and after electron beam irradiation; only the gold cores of the nanoparticles are visible in the TEM (not the ligands). The coalescence (sintering) of local clusters within the exposed area is clearly illustrated in the TEM images. High resolution TEM imaging also show that grain boundary diffusion occurs during sintering [70].

4. DIRECT ELECTRON BEAM WRITING IN NANOPARTICLE FILMS

4.1. Electron Beam Lithography

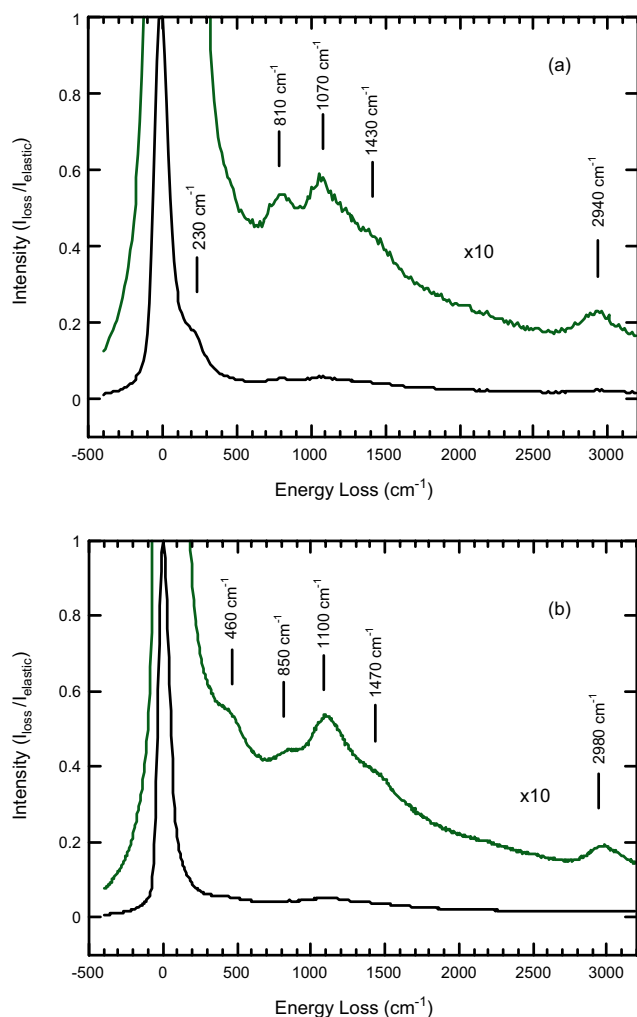
Electron beam lithography utilizes the fact that certain chemicals (e-beam resist) change their properties after electron irradiation and creates extremely fine patterns by scanning a highly focused energetic electron beam across a surface covered with resist and thus deposits energy in the desired area. The electron beam can be generated by either thermionic sources or field emission sources and is focused on the substrate by a multilens system to a spot size on the order of nanometers. In order to expose arbitrarily shaped patterns, the electron beam is vector scanned


Figure 3. (a) Typical HREELS spectrum from a film of dialkyl sulphide ($H_{21}C_{10}SC_{10}H_{21}$) passivated gold nanoclusters on graphite. Incident electron energy 4.5 eV; incident angle 60°; specular scattering geometry. (b) HREELS spectrum taken after the film was exposed to a low energy electron dose of approximately 90 μC at 50 eV. Scattering conditions as for (a).

under computer control by electrostatic deflectors. A commercial e-beam lithography system can maintain a focus e-beam in a diameter of 8 nm or less throughout a typical 100 μm × 100 μm writing field with beam currents in the

Figure 4. TEM images taken before and after the sample was exposed to a focused electron beam (200 kV, 36 nA) for 2 min (an approximate dose of 55 nC nm^2, assuming a probe diameter of 10 nm).

10 pA range at an acceleration voltage of 50 kV [71]. In addition to sophisticated and expensive commercial electron beam lithography systems, standard scanning electron microscopes or scanning transmission electron microscopes (STEM) may be used for pattern exposure. In this case, the SEM or STEM is interfaced with a pattern generation system, which controls the deflection system in the microscopes during the exposure.

Depending on the chemical structure of the resist, the electron either intersects the polymer chains (positive tone) or cross-links the small chain (negative tone), thus changing the solubility in organic developer compared to the unexposed area. For a positive tone resist the exposed material is removed, whereas for a negative tone resist only the exposed material remains after development. PMMA (polymethylmethacrylate) is a most commonly used positive tone high resolution e-beam resist for a typical exposure dose of several hundred μC cm^{-2} at 50 keV [72].

Figure 5 schematically shows the basic steps for the fabrication of a patterned material structure on a substrate using electron beam writing with a positive tone resist and lift-off process. The e-beam resist is first spin coated onto a substrate and then the e-beam writing process doses electrons to selective areas. The following development step removes the materials in the exposed area. Then a thin layer of materials (metal or insulator) is evaporated on the sample. Finally in a lift-off process, the unexposed resist together with its (metal or insulator) coating is removed with a suitable solvent. Only the materials in the area where they are directly deposited on the substrate surface remain.

The e-beam lithography technique is capable of high resolution pattern generation, flexible to create an almost infinite number of patterns, but slow in comparison to optical lithography. It is currently used in making masks for photolithography, advanced prototyping device fabrication, and research on novel physics phenomena at very small dimensions.

4.2. Direct Electron Beam Writing in Passivated Nanoparticles

Section 3 shows that the organic ligands, which prevent the aggregation of the metal cores when passivated nanoparticles are deposited on a surface, can be removed by

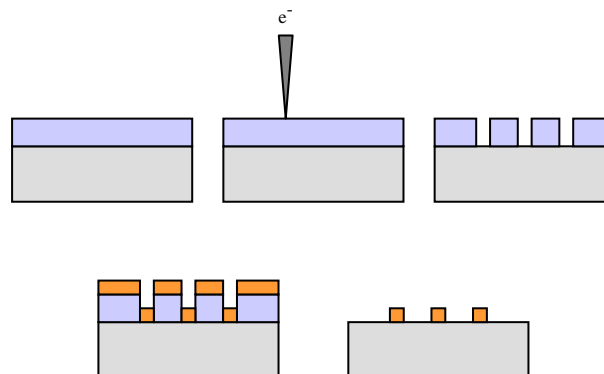

Figure 5. Basic steps for the fabrication of patterned materials on a substrate using e-beam lithography with positive tone e-beam resist.

electron beam irradiation. A metal-based nanostructure can thus be obtained, provided aggregation of the metal cluster cores takes place. Previous work on electron beam writing in films of passivated metal nanoparticles has demonstrated the creation of nanoscale architectures of different conductivity. Forty kV electron beam writing in multilayers of passivated gold clusters was employed to fabricate structures that demonstrated room temperature Coulomb blockade conduction characteristics [73–75]. The carbon residuals arising from the exposed ligands are exploited to create a series of tunnelling gaps between metal islands in 100 nm wide structures. Structures with genuinely metallic conductivity have also been observed after an additional annealing stage [76–78]. In this case, passivated Pd clusters were used to fabricate 70 nm structures with a STEM operated at 100 kV.

In general terms, the technique of direct electron beam writing in nanoparticles is a three-step process consisting of coating, writing, and rinsing, as schematically shown in Figure 6. First of all, a substrate is coated with nanoparticles, which can be achieved by spin coating, the Langmuir–Blodgett technique, liquid drop deposition, or simply dipping a substrate into a solution of nanoparticles [23, 79–87]. Then the nanoparticle film is patterned though direct electron beam writing, such that decomposition of the ligands of the nanoparticles takes place in the exposed area and may result in sintering to continuous structures. Following the patterning, a rinsing process is employed to remove unexposed nanoparticles by dissolution in a suitable solvent.

Thus direct e-beam writing is a relatively simple process for production of metal nanostructures compared with the more conventional e-beam lithography and lift-off process, which usually employs five steps as shown in Figure 5, namely, resist coating, e-beam exposure, resist development, metal deposition, and lift-off. Note that the development of the resist after exposure may result in some loss of resolution [88, 89]. Moreover, since the ultimate resolution possible in electron beam writing is limited by the molecular size of resist, a further attraction of passivated nanoparticles is the selectable size of the particles, which can be chosen to be as small as 2–3 nm in diameter.

The use of organometallic compounds for direct write e-beam production of metal-based structures is well established. As long ago as 1986, the formation of metal lines of 250 nm width was demonstrated by e-beam lithography in gold mercaptides [90]. The major difficulty with using conventional organometallic molecules as precursors is the carbon contamination, which results from the relatively low metal content [e.g., Au:C ratio of 1:7 in Me2-Au (tfa), $(CH_3)_2$–Au–$(C_5H_4F_3O_2)$] [91]. The level of carbon impurity affects the conductivity of the structures and may thus determine the effectiveness of this technique for electronic device
fabrication. Passivated nanoparticles provide a greater metal loading than typical organometallics, (Au:C ratio of 1:1 for a 4 nm Au core capped with decanethiol molecules). Therefore e-beam writing in nanoparticle films may allow fabrication of nanowires with superior conductivity [92].

Figure 7 gives a typical example of the result of e-beam writing in thin films of passivated gold nanoparticles [93]; in this case the gold cores were 4–4.5 nm in diameter and surrounded by hexadecanethiol ($C_{16}H_{33}S$) ligands. They were deposited from solution in octane onto clean Si and a thermally grown SiO_2 film (thickness 65 nm). Thin films of monolayer coverage ($\sim$6 nm thick), calibrated by ellipsometry measurements, were exposed to an electron beam at 6 keV in an ISI DS-130 field emission scanning electron microscope equipped with an electron beam lithography system (Raith Elphy Quantum). The unexposed nanoparticles were removed by rinsing in octane. Figure 7 shows an atomic force microscopy (AFM) image (contact mode) of lines fabricated by e-beam writing with different doses on a thermally grown SiO_2 film (thickness 65 nm) on a Si wafer. It was found that the linewidth increases as the dose increases. The average linewidth of the upper most line, corresponding to the lowest e-beam dose (11.7 mC cm^{-2}), is only 26 nm [93]. This resolution lies well below the smallest feature sizes (currently) employed in integrated circuit, $\sim$100 nm.

Direct e-beam writing of nanoparticles on Si_3N_4 has been carried out by Lin et al. [94]. It was reported that the electron beam exposure strips the passivating molecules (dodecanethiol) from the gold cores, enabling the cores to stick to the underlying substrate. A subsequent washing step removes unexposed nanoparticles, leaving behind the desired pattern.

Recently, Werts et al. reported nanometer scale patterning of Langmuir–Blodgett films of gold nanoparticles by electron beam lithography [95]. Nanowires of sub-50 nm wide with thickness controlled at the single particle level are created with e-beam doses in the mC cm^2 region. It was

Figure 6. Schematic showing the three steps involved in the direct electron beam writing process: (a) coating, (b) writing, and (c) rinsing.

shown that the patterns are formed by radiation-induced cross-linking of the alkyl chains. Interestingly, these wires can be "etched" away by prolonged exposure to a solution of capping agent, which is probably due to a replacement of cross-linked ligand shell by "fresh" passivating agents and therefore making the particles soluble again.

4.3. Quantitative Evaluation of Direct E-Beam Writing in Passivated Nanoparticles

The primary goals of e-beam lithography are high resolution and high speed, the latter requiring high resist sensitivity. In the direct electron beam writing technique described in the preceding section, the layer of passivated gold nanoparticles can be viewed as a negative tone e-beam resist. To investigate the sensitivity of nanoparticles as a resist, it is necessary to evaluate the e-beam writing process quantitatively.

The lines fabricated by e-beam writing can be characterized quantitatively using AFM. Indeed, the AFM image of Figure 7, showing lines of 1 μm long and 200 nm apart, was obtained as part of this procedure. The height of the lines varies little as a function of dose, always lying in the range of $\sim$8–12 nm. This confirms the nominal thickness of the nanoparticle layer as 1 ($-$2) monolayers. The average linewidth of the four lines, measured by AFM, ranges from 26 to 92 nm.

For a monolayer resist, standard measures of the resist sensitivity, based on the depth of resist exposed as a function of dose, are not applicable. Thus the linewidth as a function of dose was defined as a practical, quantitative measure of the sensitivity of the cluster film resist, resulting in dose curves of the kind shown in Figure 8. In fact, this plot is effectively a measurement of the degradation of the resolution with increasing dose, so that the finest resolution is obtained just after the onset of lithography, as labelled in Figure 8. If the sensitivity of the nanoparticle film resist is

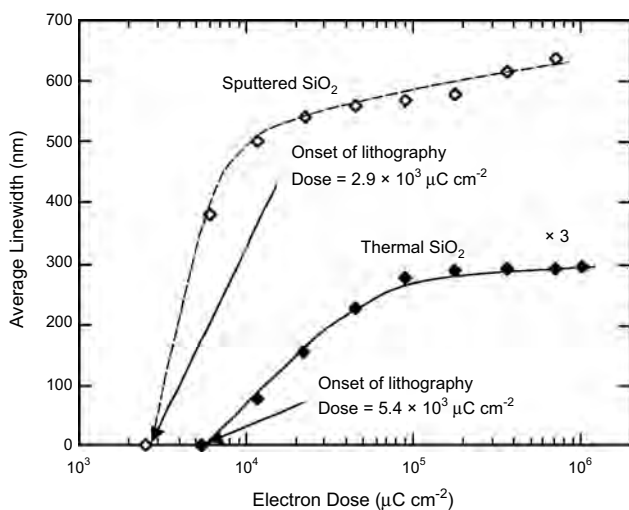

Figure 8. Response curve for passivated gold nanoparticle films ($\sim$6 nm) on thermal and sputtered SiO$_2$. Shown is the width of the lines produced by direct e-beam writing at 6 kV as a function of electron dose. The threshold doses obtained from the curves are marked (see text).

described by the threshold dose for production of exposed lines, then a sensitivity for the film on thermal SiO$_2$ of $5.4 \times 10^3 \mu$C cm^{-2} can be quoted. It is observed from Figure 8 that the feature size (linewidth) increases with dose and after that the rate of increase slows down considerably after a linewidth of $\sim$100 nm is reached.

Bedson's result (i.e., $5.4 \times 10^3 \mu$C cm^{-2}) on thermally grown SiO$_2$ on Si wafer is comparable to those recently published by other groups. Werts et al. reported $1 \times 10^3 \mu$C cm^{-2} for a film of AuC$_{12}$ particles on SiO$_2$ coated Si wafer [95] and Lin et al. found $7.7 \times 10^3 \mu$C cm^{-2} for gold nanoparticles on Si$_3$N$_4$ substrate [94]. As will be discussed in the following section, the threshold dose and the rate of growth of the linewidth with dose rely not only on the nature of the nanoparticle film but also the substrate, since secondary electrons from the substrate play an important role in the electron exposure.

In comparison to the sensitivity of a well established e-beam resist such as PMMA (quoted as $0.13 \times 10^3 \mu$C cm^{-2}) [96], the nanoparticle film is about 40 times less sensitive. However, the sensitivity is comparable to that of other high resolution negative tone e-beam resists, for example, calixarene MC6AOAC ($7 \times 10^3 \mu$C cm^{-2}) [97], C$_{60}$ ($10^4 \mu$C cm^{-2}) [98], and hexapentyloxytriphenylene ($2.5 \times 10^3 \mu$C cm^{-2}) [99].

One minor advantage arising from the modest sensitivity of the nanoparticle film is that SEM imaging for a short time period does not expose the film. Therefore, it is possible to locate a selected area on the specimen with the help of SEM imaging and align the writing field properly to this area before e-beam exposure.

4.4. Mechanism of Electron Beam Writing in Passivated Nanoparticles

When the incident electrons impinge on the nanoparticle film, they experience many small angle scattering events (forward scattering) and propagate through the cluster film into the substrate. Here the electrons occasionally undergo large angle scattering events and may thus return to the cluster film (possibly at some distance from the incident beam), causing additional resist exposure. The electron backscattering probability depends on the substrate material; low atomic number materials give less backscattering. Like the primary electrons, the backscattered electrons can also generate secondary electrons, with energies less than 50 eV. The cross-section for bond breaking is generally large for these low energy electrons.

In the case of a thin cluster film, these effects mean that the nature of the substrate plays an important role in the e-beam writing process, whereas the nature of the cluster film itself regulates the exposure of a thick film.

Figure 8 also illustrates results from a study intended to shed light on the mechanism of direct e-beam writing in passivated nanoparticle films. Passivated Au nanoparticles were deposited from solution onto a variety of substrates, namely, highly oriented pyrolitic graphite, silicon (with the native oxide layer intact), thermally grown silicon dioxide, and sputtered silicon dioxide. Thin films of monolayer coverage (i.e., thickness $\sim$6 nm) were calibrated by ellipsometry measurements. Thicker films of multilayer coverage

(thickness ∼135 nm) were also prepared as a reference. A response curve describing the exposure of monolayer films of passivated gold nanoparticles on sputtered and thermally grown SiO_2 is shown in Figure 8, which plots the width of the exposed lines as a function of electron beam dose. The threshold for electron beam writing obtained in the case of sputtered SiO_2 is 2900 $\mu C\,cm^{-2}$. This is about half the value obtained with thermally grown SiO_2, 5400 $\mu C\,cm^{-2}$. In addition, it is evident from Figure 8 that the linewidth increases at a much faster rate above the onset of lithography in the case of the sputtered SiO_2. Moreover, saturation of the linewidth on sputtered SiO_2 starts at ∼500 nm compared with ∼100 nm in the case of thermal SiO_2. However, complete saturation was not observed in either case even at the highest doses used (28.5 $C\,cm^{-2}$), which is possibly due to the ability of the weakly bound nanoclusters to diffuse across the surface to the region where the line is being fabricated and thus provide a continuous supply of material for further growth of the structure.

The quantitative difference between the response curves for passivated nanoparticles on the two different (sputtered and thermally grown) SiO_2 substrates demonstrates that the substrate plays a key role in the mechanism of exposure of thin nanoparticle films. This is consistent with the generation of backscattering and secondary electrons in the vicinity of the initially irradiated region. Indeed, nanowires were first found to be formed in the layer of nanoparticles directly on the substrate. AFM imaging of nanowires created on a three layer thick AuC_6 LB film reveals that the height of the nanowire increased with exposure in the case of underexposure and structures of monolayer or multilayer thickness were observed [95].

Monte Carlo simulations of the scattering process confirm this prehension. Figure 9 shows results for (a) thin and (b) thick nanoparticle film on a thermal SiO_2 surface. The thin cluster film (∼6 nm) increases the total scattering width of the primary electron beam—defined as the distance between the outermost emerging electrons—when compared with the thick nanoparticle film (∼135 nm).

The predominant role of substrate electron scattering in the exposure of thin passivated nanoparticle films is confirmed by the experimental results for graphite and silicon (with native oxide) substrates. In neither case was it possible to write lines in monolayer cluster films [100]. This is consistent with the much reduced secondary electron coefficients, δ, for these materials (1 for graphite and 1.1 for silicon) compared with SiO_2 (where δ lies between 2.1 and 4) [100]. It is likely that low energy secondary electrons, generated both by the primary beam and the backscattering electrons, are the electrons which actually expose the passivated clusters, via dissociation or removal of the ligands.

5. APPLICATIONS

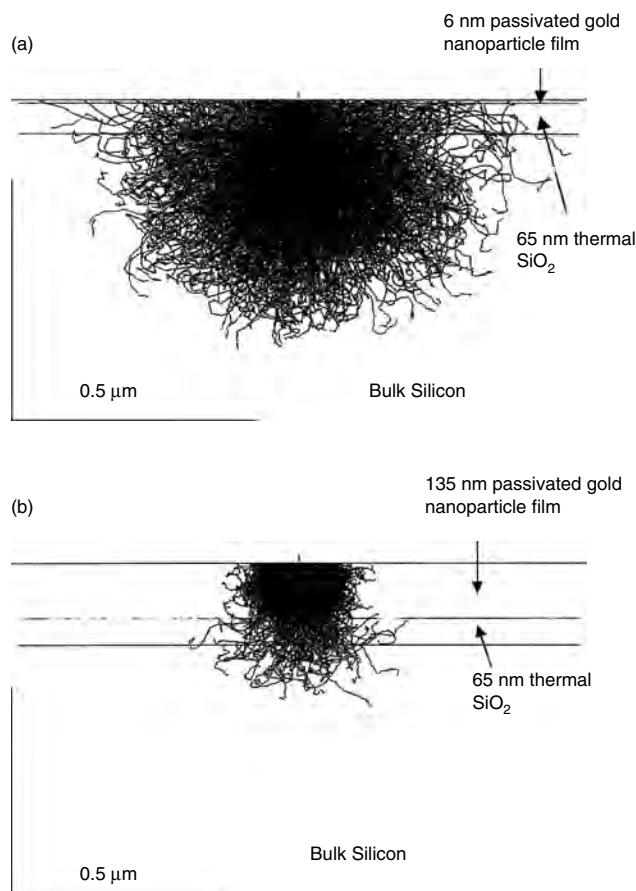
Direct e-beam writing in passivated nanoparticle films, like conventional e-beam lithography, is capable of creating various types of nanoscale architectures. As an example, we shall consider the fabrication of linear structures with potential applications as nanoscale electrodes and connections.


Figure 9. Monte Carlo simulations of a 6 keV electron beam scattering through (a) thin (∼6 nm) and (b) thick (∼135 nm) films of passivated gold nanoclusters on a thermal SiO_2 layer (65 nm thick) on bulk silicon. One thousand trajectories are shown in each case.

5.1. Fabrication of Nanowires

Figure 10 illustrates the fabrication of individual wires obtained via direct electron beam writing in thin films of alkanethiol passivated Au nanoparticles on a Si substrate with a thermally grown SiO_2 layer. The line is 20 μm long but only 40–50 nm wide and written with a 7 keV electron beam. The pattern shown in Figure 10 above the line is an alignment mark. Success in obtaining long lines lies mainly in the quality of the nanoparticle film; large voids in the film result in a discontinuous line.

One potential application of such wires is to make electrical contacts to nanometer-scale objects (e.g., nanoparticles). The creation of a gap structure provides a template for the incorporation of the molecule or nanoparticles whose transport properties are to be explored. In recent years, a number of techniques have been developed to fabricate small gaps between two electrodes, including shadow deposition [101], electrochemical deposition [102], electromigration [103], scanning probe lithography [104], and controlled e-beam lithography [105]. Direct e-beam writing can also create such gaps, as Figure 11 illustrates. A clear gap of 20 nm is visible. It is expected that the gap can be further narrowed via proximate effect correction.

Figure 10. SEM image of a line 20 μm long and 40–50 nm wide, produced by direct electron beam writing in a film of passivated gold nanoparticles on a thermal SiO_2 substrate (7 keV, electron dose, 50×10^3 μC cm^{-2}). An alignment mark is shown above the wire.
5.2. Nanowires on Patterned Surfaces

The realization of a true nanoscale device involves the connection of a nanometer-scale component to the microscopic (and thence macroscopic) world. It is necessary to combine both microfabrication and nanofabrication techniques. The direct e-beam writing technique is compatible with conventional lithography as illustrated in Figure 12. Micrometer scale gold patterns were prepared via photolithography and ion beam milling on an SiO_2/Si substrate. After coating of this sample with alkanethiol passivated gold nanoparticles, direct e-beam writing was applied, as illustrated in Figure 12a, to create a long wire running across four gold microelectrodes with 5 μm gaps. The whole length of
Figure 11. SEM image of a wire produced by direct electron beam writing in a film of passivated gold nanoparticles on a thermal SiO_2 substrate. The wire contains a narrow gap (generated without proximity effect correction) to create a pair of electrodes.
Figure 12. SEM images of nanowires fabricated on patterned substrates. (a) A long (40 μm) wire running across four Au electrodes with 5 μm gaps fabricated on SiO_2/Si substrate via photolithography and ion beam milling. The average width of the wire is ~70 nm; (b) perpendicular nanowires connecting two pairs of Au electrodes.

the wire is 40 μm with an average width of about 70 nm. Another example, Figure 12b, is a cross formed by two nanowires bridging two pairs of electrodes.

5.3. Conductivity Evaluation of Nanowires

One critical issue regarding the application of the nanowire as electrodes or electrical connection is the conductivity of the wires themselves. Figure 13 demonstrates that "wires" produced by e-beam writing in nanoparticle film are indeed
Figure 13. Linear I–V characteristic obtained from a nanowire fabricated via direct electron beam writing in a film of alkanethiol passivated gold nanoparticles on a thermal SiO_2/Si substrate.

metallic. A wire of dimension of 60 nm was produced between patterned Au/Cr electrodes. A linear *I–V* characteristic is observed, with a resistivity of 40 $\mu\Omega$ cm^{-1} (and scope for optimization in future). This compares with a value of 2.44 $\mu\Omega$ cm^{-1} for bulk Au [106]. The increase in resistance compared with bulk most likely originates from impurities due to fragmentation of the passivating ligands.

6. CONCLUSIONS

Direct electron beam writing in films of passivated nanoparticles is a new technique with clear potential for the creation of metallic wires and contacts of 10–100 nm in size. Future improvements include the use of nanoparticles with specially designed organic ligands. Employing shorter chain ligands would enhance the metal loading in the initial nanoparticle film, while molecules other than alkane thiols (e.g., dialkyl sulphides with a weaker S–Au bond) may lead to ligand removed at low electron beam dose. Again, the choice of ligand molecules, which produce "volatile" fragments under electron irradiation, may reduce the impurity level in the resulting wires and hence increase their conductivity. E-beam writing in the presence of oxygen or hydrogen gas may have a similar effect.

While we have so far considered the fabrication of linear structures (i.e., nanowires), the advanced capabilities of a modern e-beam writer also suggest much more complex patterns from production of arrays of nanosize dots right up to the creation or repair of integrated circuits. Further research into the interaction of electrons with nanoparticles is essential to understand and thus optimize the fabrication processes. This should involve detailed structural and compositional analysis. For example, *in-situ* high resolution TEM images of the direct e-beam writing process would give insights into the formation and growth of the nanowires as a function of the electron dose. By combining this structural information with the compositional analysis and electrical measurements, it may be possible to improve both the sensitivity and the resolution of the technique as well as to optimize the conductivity of the resulting nanometer-scale metallic structures for advanced applications.

GLOSSARY

Atomic force microscope (AFM) A microscope that produces an image by scanning a tip attached to the end of a cantilever across the sample surface while monitoring the change in cantilever deflection due to the tip-surface interaction with a split photodiode detector.

High-resolution electron energy loss spectroscopy (HREELS) A sample surface is irradiated with a monoenergetic and well-collimated electron beam and a spectrum obtained as a function of energy and momentum transfer by energy analysis of the backscattered electrons.

Highly oriented pyrolitic graphite (HOPG) A special type of graphite with highly oriented monocrystal grains prepared by pyrolysis of organic compounds.

Langmuir–Blodgett (LB) film A mechanically assembled array of amphiphilic molecules on a water surface often transferred to a solid support once the molecules are compressed into a desired phase. An LB film can consist of single or many layers.

Polymethyl methacrylate (PMMA) A polymer that changes its properties under irradiation by electron, UV photons or X-rays and can be used as a resist, providing high contrast, high resolution lithography.

Scanning electron microscope (SEM) A microscope that produces an image by scanning an electron beam across the surface of a specimen and collecting the backscattered or secondary electrons. Examination of microstructural features with a resolution below 10 nm is possible.

Scanning tunnelling microscope (STM) A microscope that produces an image by scanning a sharp tip across a conducting sample surface and (usually) recording the tip-surface distance required to keep tunnelling current constant.

Self-assembled monolayers (SAM) An ordered and highly oriented single layer of molecules spontaneously assembled on a solid surface, as governed by the molecule-surface and intermolecular interactions.

Transmission electron microscope (TEM) A microscope that produces an image by using electron beams that transmitted (passed through) a thin specimen and provides internal structural information of the specimen at high magnification.

Electron Dynamics in Metallic Nanoparticles

M. Aeschlimann

University of Kaiserslautern, Kaiserslautern, Germany

CONTENTS

1. INTRODUCTION

The excitation and relaxation of electrons in metallic nanoparticles play a key role in a number of important physical phemomena, including linear and nonlinear optical effects. The main motivation for the interest in these systems is related to the possibility of tailoring, to a considerable extent, their electrodynamical behavior on the basis of size and shape. Furthermore, by studying the temporal evolution of collective electronic excitations (e.g., after a laser excitation), on the time scale from a few femtoseconds to several picoseconds, one can improve the knowledge about basic properties of the light–matter interaction in metallic nanoparticles.

A typical signature of the optical response of metallic nanoparticles is given by the presence of a local plasmon resonance (Mie-plasmon; see Section 2.1) [1–4]. While the positions of the resonances of Mie-plasmon excitation as a function of particle size, shape, and dielectric properties are well understood (as an overview, see [1]), the ultrafast dynamics of these collective electronic excitations have remained a highly interesting topic to be revealed in much greater detail. An essential issue is how rapidly the collective excitation lose their phase coherence. Further, one would like to investigate the mechanisms responsible for dephasing. After these dephasing processes, typical internal and external thermalization processes set in to distribute the energy of the excited quasiparticles (single excited *hot* electron) into the electron gas and nanoparticle lattice, and finally to the nanoparticle–substrate complex.

With the advance of ultrashort pulsed laser systems, a transient (nonthermal) electron distribution can now be created and probed. Compared to the time scale of these laser pulses, the long-lasting nonequilibrium situation offers the unique possibility of analyzing the interactions (energy exchange) between the different subsystems (electron gas, phonon system, substrate/matrix complex).

In this chapter, the different mechanisms, which can lead to phase destruction as well as energy dissipation of the collective electron motion, are revealed, and pioneering experiments in this new field are reviewed. All different energy dissipation steps after an ultrashort laser pulse are described in a sequential approach. However, one should keep in mind that this is a straightforward view. All processes start at once, but they are finalized on different time scales, that is, electron gas energy losses occur before the electron gas is fully thermalized. It is just the time scale of the different energy exchange mechanisms which differs over several magnitudes (from 10 fs to 120 ps) that allows, with some exception, this simplified treatment.

It is also important to mention that all considerations discussed in this chapter are relevant for metallic nanoparticles larger than 10 Å. The metal is still considered as a three-dimensional system. When the size becomes smaller than 10 Å, the discrete nature of the electronic states (quantum effects) shows up [5–9]. Above that size, the width of the discrete levels becomes comparable to or larger than the separation between them. That is, the conduction band is quasicontinuous, and the behavior of the nanoparticles tends to approach that of the bulk metal, presenting, however, some significant differences concerning the electrodynamic properties.

2. ADSORPTION OF LIGHT IN METALLIC NANOPARTICLES

2.1. General Considerations

The optical properties of nanostructured systems have been extensively investigated in order to reveal their fundamental processes and to examine possible technological applications

[1, 2]. Concerning the interaction of visible light with metals, the conduction electrons are of central importance. As a useful approximation, all electrons can be described collectively as a plasma with density N_e [10]. A collective excitation of the dense electron gas in a metal is called a *plasmon*. In the most general case, the term *plasmon* describes a longitudinal collective oscillation of the electron plasma relative to the crystal lattice [11]. This excitation consists of a coherent motion of a high number of electrons in contrast to those excitations in which the external perturbation acts on a single electron. In general, one has to distinguish among bulk, surface, and particle (Mie) plasmons.

The *bulk plasmon* denotes a collective excitation of the electron gas in the bulk of the metal, which propagates as a longitudinal charge density fluctuation at a resonance frequency [12]:

$$\omega_{Pl} = \sqrt{\frac{N_e \cdot e^2}{\varepsilon_0 m}} \qquad (1)$$

The quanta of these bulk plasmons possess an energy $\hbar\omega_{Pl}$ which is, for most metals, on the order of 10–15 eV. Excitation of bulk plasmons with light is not possible due to the longitudinal nature of bulk plasmons.

At *surfaces*, the mobility of the electrons in a plane parallel to the surface is high (quasifree electrons), whereas perpendicular to the surface, the mobility is limited due to the border of the metal. This results in a reduced energy of the collective mode ω_{SP} regarding the bulk value ω_{Pl} [1, 13]:

$$\omega_{SP} = \frac{\omega_{Pl}}{\sqrt{2}} \qquad (2)$$

Because the phase velocity of surface plasmons is slower than that of a photon with the same energy, direct coupling of freely propagating light to an excitation of surface plasmons is forbidden in a smooth metal film. However, the coupling is possible by means of two well-known methods [1, 14, 15]: (1) the grating coupling method invokes modification of the surface with a lattice structure which adds additional reciprocal lattice vectors to the initial wavevector of the light, and (2) the attenuated total reflection method exploits the total internal reflection inside a prism which is attached to the metal film. Surface plasmons have been extensively studied with different optical methods, mainly because of their extremely high sensitivity to interface structures and adsorbates [1, 16].

In *metal nanoparticles* with sizes smaller than the wavelength of light as well as the optical penetration depth, all atoms in the particle can be collectively excited. Hence, collective electronic oscillations, the so-called Mie-plasmons, can be excited by light, and are therefore detectable as a pronounced optical resonance in the visible or UV parts of the spectrum [1, 17, 18]. The resonance frequency of the oscillation is determined by the dielectric properties of the metal and the surrounding medium, and by the particle size and shape. The collective oscillation can be interpreted as a displacement of the center of mass of all electrons in the particle against the positively charged background of the atomic cores [19]. There is no propagation of a (longitudinal) charge density fluctuation; hence, a plasmon in a metallic nanoparticle has to be distinguished from a propagating surface plasmon, not often done in the literature. This collective charge oscillation causes a large resonant enhancement f of the local field inside and near the particle [20]. This resonance dominates the linear and nonlinear response of the materials. The particle-size dependence and host-matrix dependence of the absorption spectrum have been discussed in many systems with Mie scattering theory [21]. In general, these studies took into account two contributions to the dielectric function $\varepsilon(\omega)$: a Drude term $\varepsilon_{\text{intra}}(\omega)$ originating from free electrons, and an interband term $\varepsilon_{\text{inter}}(\omega)$ reflecting the band-to-band transitions [22].

Considerable interest has been focused on silver nanoparticles as they exhibit a particularly strong size-dependent optical resonance in the visible spectral range (1.8–3 eV), that is, at energies below the interband transition threshold ($\sim$4 eV). Consequently, the absorption cross section in the visible region is dominated by the Drude term [23]. The contribution due to interband transitions is negligible. Quite the contrary, investigation on isolated copper and gold nanoparticles allows us to study the influence due to the strong overlap between the Mie-plasmon resonance ($\sim$2.3 eV) and the interband ($d \rightarrow sp$) transition at $\sim$2.4 eV. Hence, both the intraband and interband optical processes are involved in the material response to a light excitation.

2.2. Plasmon Decay Time

The most important factor for the coherent interaction of light with nanoparticles is the dephasing time

$$T_2 = 2\hbar/\Gamma_{\text{hom}} \qquad (3)$$

where Γ_{hom} is the homogeneous line width of the plasmon resonance. This dephasing time T_2 corresponds to the time scale on which the decay of the coherent electron plasma oscillation (and hence the local-field enhancement) takes place, for example, the time scale on which the electron oscillation preserves the memory of the optical phase of the excitation pulse. This dephasing time is essential because, for example, the enhancement factor f of the electric field near the particle surface due to the collective excitation is expected to be proportional to T_2 [2, 24]. Note that many authors use the expression plasmon lifetime $\tau_{sp} = \hbar/\Gamma_{\text{hom}}$. According to Eq. (3), the plasmon lifetime τ_{sp} is related to the dephasing time T_2 by $2\tau_{sp} = T_2$.

In recent years, several line width measurements and time-resolved second- and third-harmonic generation autocorrelation measurements (for the technique, see, e.g., [25–28]) on metallic nanoparticles have been published, reporting a dephasing time of the Mie-plasmon excitation on the order of 4–20 fs. All experimental studies have been performed in the low-excitation regime, where the energy optically transferred to the system is too small to strongly perturb the nanoparticle [29]. In the following, different experimental techniques will be discussed which allow us to determine the dephasing time T_2. The different mechanisms, which can lead to this phase destruction of the collective electron motion, are discussed in the next section.

First experimental knowledge of the line width of metallic nanoparticles in a two-dimensional arrangement was gained

for thermally evaporated ultrathin films, which show a broad distribution in particle size and shape [2]. By this randomness, a strong inhomogeneous broadening of the absorption band results which is much broader than the resonance of a single individual particle. This inhomogeneous broadening is caused by variations in the size, shape, surface structure, and environment of the individual particles within the cluster ensemble. Since the magnitude of the inhomogeneous broadening is not known quantitatively, the homogeneous width Γ_{hom} and, hence, the dephasing time T_2 cannot be extracted [28]. The absorption spectra only provide a lower limit of T_2.

Craighead and Niklasson reported the first extinction spectra of a lithographically produced regular two-dimensional array of identical metal nanoparticles [30]. In contrast to thermally evaporated ultrathin films, by nanofabrication, the size and shape of particles can be designed and the distribution width of these parameters can be extremely narrowed.

The potential of nanodesigned optical films in order to study plasmon decay dynamics has also been nicely demonstrated by Gotschy et al. They deposited nearly identical, parallel-oriented silver particles on a transparent ITO substrate by use of electron-beam lithography [31]. Figure 1 shows SEM pictures of two-dimensional arrays of elliptic-shaped, nearly identical, parallel-oriented silver particles. As the particle size and interparticle distances can be varied independently, this method allows us to tailor the optical properties of single particles. In addition, elliptic-shaped metal nanoparticles show two different plasmon resonances which lie at different wavelengths for light polarized parallel to the short and long axes (see, e.g., Fig. 6). From the experimentally obtained line widths, Gotschy et al. expected a plasmon decay time of a few femtoseconds.

Another way to overcome the problem of inhomogeneous broadening due to variations in the size and shape is the spectroscopy of a single particle. Using SNOM spectroscopy, Klar et al. measured the homogeneous line shape of the plasmon resonance in single gold nanoparticles [24]. The

measured line width varies around a value of 160 meV, which corresponds to a plasmon dephasing time T_2 of 8 fs. Besides the single-mode resonances, they also observed more complex line shapes caused by electromagnetic coupling between close-lying particles.

Träger and co-workers applied an interesting novel technique where the size and shape selectivity of the clusters was obtained by optical hole burning after deposition [32, 33]. They used this technique to extract dephasing times of silver nanoparticles with radii smaller than 10 nm, dimensions which are not accessible by lithographic techniques.

Spectral hole burning is a well-known technique in atomic, molecular, and solid-state physics. The achievement of the authors was to adopt the method for the specific needs in order to investigate T_2 in metallic nanoparticles. The idea of the method is as follows. First, nanoparticles with a broad size distribution are prepared on a transparent substrate. After measuring their optical absorption spectrum, the nanoparticles are irradiated with nanosecond laser pulses, the photon energy being located within the inhomogeneously broadened absorption profile. The fluence of the light is chosen such that the temperature increase of the particles induced by rapid conversion of the absorbed energy into heat is sufficiently high to stimulate evaporation of atoms. As a result, the distribution changes, and a hole is permanently burned into the absorption profile. Finally, the optical spectrum is measured a second time, and subtracted from the spectrum of the particles as grown to determine the width of the hole, that is, Γ_{hom}. From the experimental results and a theoretical model of hole burning, the line width of 260 meV corresponding to a decay time of 4.8 fs was extracted for silver nanoparticles with a radius of 7.5 nm. This T_2 value is at least a factor of 2 smaller than one would expect from the bulk dielectric function of silver. The authors concluded that additional damping mechanisms, in particular surface scattering, come into play in this size regime.

A further way to obtain accurate decay time constants is by means of time- instead of frequency-resolved measurements. In principle, all femtosecond real-time measurements use a two-pulse (pump–probe) technique: the first laser pulse drives the systems, and the second, suitably delayed, probes the actual state. Lamprecht et al. fabricated noncentrosymmetric particles in order to study the decay time of particle plasmons by means of a real-time second-order nonlinear optical (SHG) autocorrelation experiment [34]. SHG can be considered as an optimal noninvasive probe of plasmon dynamics, but a shape without centrosymmetry is an essential condition for high SHG efficiency. Figure 2 shows an interferometric autocorrelation measurement (thin line) for gold nanoparticles. Also shown is the autocorrelation function of the laser pulse (bold line) measured with a nonlinear crystal (BBO). For gold, the experiment revealed a dephasing time T_2 of 12 fs. In the case of silver, the experimentally obtained values T_2 vary between 14 and 20 fs.

Using the same time-resolved SHG technique, Rubahn and co-workers studied the plasmon lifetime of Na nanoparticles with mean radii of $5 < r_0 < 55$ nm [35]. They found a pronounced maximum in T_2 of 20 fs ($\tau_{sp} = 10$ fs) for nanoparticles of an average radius of 22 nm, with lifetimes

decreasing both for smaller and for larger particle radii (see Fig. 3).

The major drawback of the real-time SHG method, the restriction to noncentrosymmetric particle shapes, can be eliminated by using third-harmonic generation (THG). Lamprecht et al. used this technique to study the decay of resonant and slightly off-resonant driven plasmons in gold nanoparticles [36]. By comparing the measured third-order interferometric autocorrelation function of the plasmon field with a simulation based on a simple harmonic oscillator model, they obtained the same dephasing time T_2 of 12 fs in both (resonant and off-resonant) cases. For off-resonant excitation, the results show that the phase difference between the driving laser field and the driven plasmon oscillation is no longer constant at $\pi/2$ as in the resonant case, but varies with time (beating, see Fig. 4).

2.3. Mechanisms for Damping

While the dephasing time T_2 of metallic particles as a function of particle size, shape, and dielectric properties is well investigated, the physical mechanism responsible for dephasing has remained a highly interesting and debated topic. Knowledge of the dephasing mechanisms is essential for basic science and for a large variety of applications. Depending on the size, size distribution, shape, dielectric constant of the surrounding medium, and so on, the potential mechanisms are as follows. First, the plasmon can dephase by internal decay, for example, a decay of the fixed phase correlation between the individual electronic excitations of the whole oscillator ensemble, described by the *pure dephasing time* T_2^*. A typical mechanism is the decay of the collective mode due to inhomogeneous phase velocities caused by the spread of the excitation energy or the local inhomogeneity of the nanoparticles. Second, the plasmon can also decay due to a transfer of energy into quasiparticles (electron–hole pairs, i.e., due to surface scattering, phonon scattering, or e–e scattering) or reemission of photons (radiation damping and luminescence [37–40]), described by T_1. The total dephasing of the plasmon is given by

$$\frac{1}{T_2} = \frac{1}{2T_1} + \frac{1}{T_2^*} \qquad (4)$$

In general, it is predicted that, for sizes below about 10 nm, surface scattering is quite essential [1, 32]. For larger particles, however, radiation damping becomes more pronounced. According to Liebsch and co-workers [23], the overall broadening $\Gamma(\omega)$ due to Drude damping γ and radiation losses is given by the function

$$\Gamma(\omega) = \gamma + \omega B(\omega)/A_i \tag{5}$$

The term $B(\omega)$ characterizes radiation damping, and is given by

$$B(\omega) = \frac{4\pi^2 V}{3 \lambda^3} \tag{6}$$

where λ is the wavelength of the laser pulse and V is the volume of an isolated metallic particle. A_i represents the depolarization factors. For an ideal spheroid, the A_i satisfies the same rule $A_1 + A_2 + A_3 = 1$; in the case of a sphere, $A_i = 1/3$. The Drude damping γ includes all microscopic damping processes due to photons, phonons, impurities, surface scattering, and electron–electron interactions. Compared with Drude damping, the radiation damping is explicitly frequency dependent. In particular, this implies that the damping near the maximum of the plasmon resonance is not representative of the damping far from resonance. Below the resonance, radiation damping is weaker than at resonance, while above the resonance, it becomes rapidly stronger (see Fig. 5).

This theoretical prediction has been experimentally verified by Scharte et al. [23]. They used elliptically shaped metal nanoparticles with semiaxes of 40 nm × 80 nm and a height of 45 nm. Elliptic-shaped metal nanoparticles show two different plasmon resonances which lie at different wavelengths for light polarized parallel to the short (b) and long (a) axes, respectively (see Fig. 6). Tuning the laser wavelength to one of these two resonances allows us to distinguish between resonance excitation and off-resonance

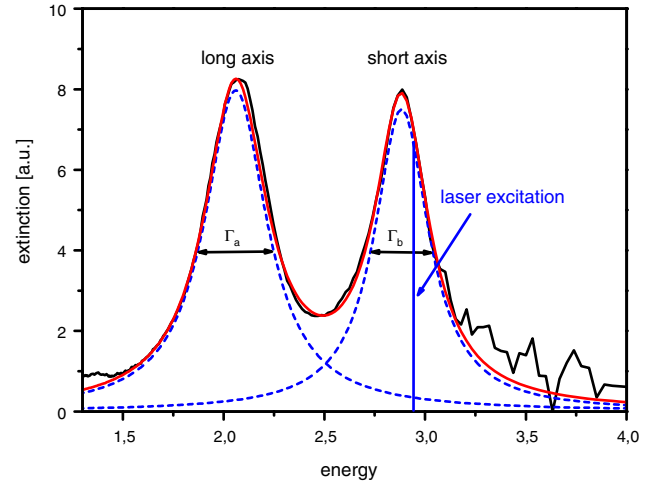

Figure 6. Measured extinction spectrum of the nanoparticle array (solid black line). The low- and high-frequency peaks correspond to the Mie plasmon, excited along the long and short axes of the elliptical Ag particles, respectively. Reprinted with permission from [23], M. Scharte et al., *Appl. Phys. B* 73, 305 (2001). © 2001, Springer-Verlag.

excitation by simply changing the polarization of the laser pulse. In both cases, the excitation is the result of an intraband process since the excitation energies of the Mie plasmons in those silver nanoparticles lie below the interband transition threshold (~4 eV). Consequently, the absorption cross section in the visible region is dominated by Drude damping. The contribution due to interband transitions is negligible.

Liebsch's theory predicts that collective plasma oscillations within the nanoparticles are subject to the same microscopic Drude damping processes due to phonons, impurities, and electron–electron interactions as off-resonance excitations [23]. None of these inelastic scattering mechanisms is reduced or absent if the electrons oscillate near the resonance excitation. The plasma mode signifies a larger amplitude of oscillation, but not the presence or absence of a particular microscopic scattering mechanism.

However, as pointed out above, radiation damping is strongly laser wavelength dependent [see Eq. (5)], which leads to a different damping along the axes of the ellipsoid, as shown in Figure 5. Hence, at first sight, it is surprising that two different resonances in the extinction spectrum at $\omega_a = 2.1$ eV and $\omega_b = 2.95$ eV exhibit about the same FWHM, that is, about the same Γ (see also Fig. 6). However, as evident from Eq. (5), the radiation damping scales inversely with the depolarization factor A_i, that is, the damping is also determined by these coefficients. Thus, for the low (high)-frequency Mie plasmon, both $\omega B(\omega)$ and A are small (or large), so that $\Gamma_a(\omega) \approx \Gamma_b(\omega)$.

An interesting question arises concerning the lifetime of the plasma oscillation in the nanoparticle near resonance and off resonance. The experimental method used to investigate the dynamical parameters T_1 and T_2 of optically excited electrons in a metal is the time-resolved two-photon photoemission (TR-2PPE). This method is known to be a highly accurate method to determine the dynamics of hot electrons in unoccupied and occupied states. The pump–probe technique enables a direct measurement of the dynamical

Figure 5. Plasmon broadening $\Gamma_l(\omega)$ as a function of frequency. Solid curve: damping of high-frequency mode $\Gamma_b(\omega)$ ($\omega_b = 2.9$ eV, short axis); dashed curve: damping of low-frequency mode $\Gamma_a(\omega)$ ($\omega_a = 2.1$ eV, long axis); dot–dashed curve: Drude damping γ derived from bulk optical data. properties in the time domain with a resolution in the range of few femtoseconds [41–43]. The principle is schematically shown in Figure 7. A pump pulse excites electrons out of the valence band into usually unoccupied states (on or off a plasmon resonance) with energies between the Fermi and vacuum level. A second probe pulse subsequently photoemits the excited electrons. The photoemission yield depends on the transient population of these intermediate states as a function of the temporal delay of the probe pulse with respect to the pump pulse. The measured pump–probe signal contains information on the energy relaxation time T_1 of the population in the intermediate state, as well as its dephasing time T_2.

In Figure 8, the FWHM derived from the autocorrelation 2PPE traces is plotted as a function of the state of polarization relative to the short axis (b). For comparison, the behavior of polycrystalline tantalum is also shown. The FWHM for tantalum is not affected by rotating the polarization angle of the incoming light. Therefore, any effect caused by an increase of the dispersion due to rotation of the half-wave plate can be excluded. For the elliptical Ag nanoparticles, however, a rotation of 90° reduces the FWHM from almost 75 fs in the b direction (short-axis mode, resonant plasmon excitation) to 69 fs in the a direction (long-axis mode, off-resonant plasmon excitation). Further rotation of the polarization to the short axis b restores the long lifetime of the plasmon excitation. One should be aware that these FWHM values still include the autocorrelation of the laser pulse width. The autocorrelation traces of tantalum were measured at an intermediate state energy $E - E_F = 2.8$ eV. In this energy range, the lifetime of excited electrons in a transition metal is on the order of 1 fs, and hence, the traces obtained for tantalum represent the pure laser autocorrelation curve. Any increase in the FWHM in the autocorrelation measurement for Ag nanoparticles compared to the Ta values must be caused by a lifetime effect of the optically excited electron system.

According to Eq. (5), the different damping rates obtained under on- and off-resonance conditions can be explained by different magnitudes of radiation damping along the short and long axis of the elliptical particles, as shown in Figure 5. The increase in the FWHM of the TR-2PPE autocorrelation curve in Figure 8 is about a factor of 2

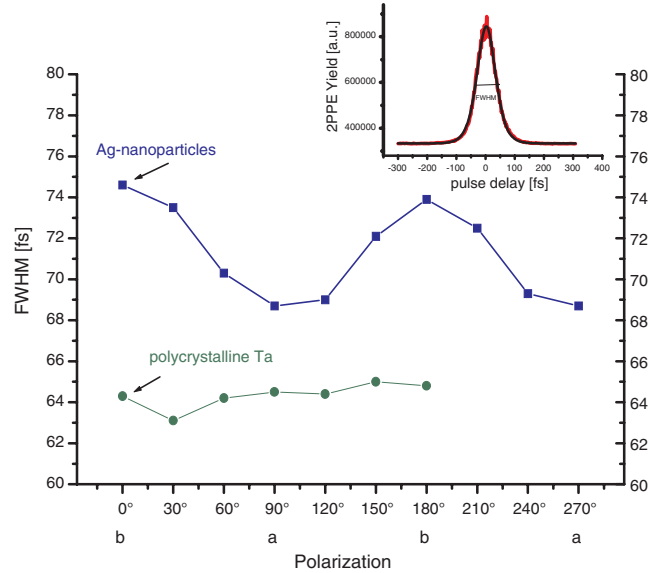

Figure 8. Nanoparticles show a variation of the FWHM of the autocorrelation over rotating states of polarization, while tantalum shows no effect. In the inset, a typical autocorrelation measurement can be seen from which the data points have been derived. Reprinted with permission from [23], M. Scharte et al., *Appl. Phys. B* 73, 305 (2001). © 2001, Springer-Verlag.

smaller for the long-axis mode as compared to the short-axis mode, taking into account that the FWHM of the Ta measurements represents the FWHM of the laser autocorrelation curve. This trend agrees well with the theoretical calculation, as shown in Figure 5. For a light polarization along the short b axis, we would expect to observe a damping given approximately by $\Gamma_b = \Gamma_b(\omega_b)$. If we now rotate the polarization direction toward the long a axis without changing the laser frequency, we excite the high-frequency tail of the ω_a plasma mode (see Fig. 5), and expect to find the damping $\Gamma_a = (\omega_b)$, which is about twice as large as Γ_b.

It might be tempting to conclude from the FWHM results of Figure 8 that on-resonance collective excitations in general have a longer lifetime than excitations far from resonance. This is not correct, however, since the exact opposite should be obtained if we perform the analogous experiment near the frequency ω_a a of the long-axis mode: for a polarization along the a axis, we observe this mode on resonance with a damping given by $\Gamma_a = \Gamma_a(\omega_a)$. If we rotate the polarization toward the short b axis, while keeping the laser frequency fixed at ω_a, we should observe a strong decrease in damping since excitations of the nanoparticle along the short axis are less subject to radiation losses. Thus, in this alternative configuration, the collective mode ω_a detected on resonance has a shorter lifetime than the excitations in the low-frequency tail of the ω_b mode. To test this theoretical prediction, it would be desirable to repeat the two-photon photoemission measurement with about 2.1 eV pump laser frequency.

On the basis of the above theoretical analysis, we can give the following tentative interpretation of the observed two-photon photoemission spectra: the initial pump pulse excites an electron from an occupied state 1 to an intermediate

Figure 7. Principal mechanism of the time-resolved two-photon photoemission (TR-2PPE).

state 2. The effective field governing this excitation consists of a superposition of an external field and an induced field generated by the dynamical response of the electrons of the Ag particle. Accordingly, the amplitude of this excitation process is greatly enhanced if the laser frequency coincides with the Mie resonance. Because of the strong intrinsic broadening of the Mie plasmon, the induced contribution to the effective electromagnetic field exciting state 1 is coherent over rather short times on the order of 0.6–6 fs, corresponding to $\Gamma \approx 0.1$–1.0 eV (see Fig. 5). Since the energy of the intermediate state is about 2 eV above the Fermi energy, the excited electrons scatter quasielastically via phonons and impurities and inelastically via electron–electron processes, giving a typical overall lifetime of about 6–10 fs, corresponding to an imaginary part of the Ag quasiparticle self-energy of about 0.06–0.1 eV [42]. The probe beam excites the electron from the intermediate state to the final state 3 above the vacuum level such that it can be detected as an emitted electron. The probability of the second excitation process is also greatly enhanced if the probe laser is in resonance with the Mie plasma frequency. The probe pulse is subject to the same frequency-dependent damping mechanisms as the pump pulse. The measurements discussed in the present work suggest that time-resolved two-photon photoemission is sensitive not only to the decay of the intermediate electronic state, but also to the intrinsic damping of the field enhancement causing the single-electron transitions.

Similar time-resolved 2PPE experiments have been performed by Lehmann and co-workers [44–46]. They investigated the nonlinear response due to surface plasmons in silver nanoparticles on graphite. The results provide direct evidence for multiplasmon excitation and allow identification of two of their decay channels, namely, decay into one or several single-particle excitations. In another work, they reported similar studies on Au nanoparticles on graphite, although the resonance was much less pronounced compared to Ag nanoparticles [47]. The resonance of the nanoparticles (2.1 eV) was detected by the peak in the yield in the high-energy tail of the photoemission spectrum, and was compared with the resonant excitation seen in EELS (2.5 eV). The rather complicated shape of the photoemission spectra is explained by multiphoton-assisted thermionic emission from the nanoparticles and resonant emission via the image-potential state on graphite.

3. DISSIPATION OF ENERGY

3.1. Internal Thermalization

As pointed out above, Drude and radiation damping are the dominant mechanisms for the decay of the collective excitation in a metallic nanoparticle with sizes >10 nm. In the case of Drude damping, the energy is primarily transferred into one or several quasiparticle pairs (electron–hole pairs). The next step of the energy relaxation corresponds to an *internal* thermalization of the electron gas. The excited electronic states tend to a Fermi–Dirac distribution with a well-defined temperature which depends on the laser pulse intensity. It has to be noted, however, that the expression "thermalization time" has never been deeply discussed so far, for example, the question of what fraction of electrons

have to lie within the Fermi distribution until the electron gas can be called thermalized.

The electron–electron scattering is the most efficient process to redistribute the energy to thermalize the electron gas. Quasielastic electron–phonon and electron–surface scattering do not play a dominant role in the dissipation of the excess energy of laser excited hot electrons; hence, no strong size effect in the thermalization process is expected. Also, surface-plasmon-assisted resonant scattering of d holes into the conduction band as described by Bigot and co-workers is only relevant for sizes <10 nm [48].

Fann and co-workers have shown, in a time-resolved photoemission experiment performed in Au films, that the temporal scale of this thermalization process is a few hundreds of femtoseconds [49, 50]. No comparable direct measurement of the thermalization time has been reported so far for metallic nanoparticles. However, there are few indirect indications for a transient nonthermal component of the electron gas. Bigot et al. studied the nonthermal component in Ag nanoparticles (size 6.5 nm) embedded in a transparent matrix, using the pump–probe femtosecond spectroscopy [51]. Figure 9 shows the differential transmission $\Delta T/T(t)$ excited with pulses of 30 fs duration at 800 nm, far from the plasmon resonance. The maximum of the signal is reached after a delay of ≈ 200 fs with respect to the laser pulse autocorrelation. This delay is a measure for the evolution from a nonthermal to a thermal Fermi–Dirac distribution, and is just slightly longer than the corresponding dynamics in silver film (delay ≈ 120 fs) as measured by del Fatti et al. [52]. This indicates that the thermalization process due to electron–electron scattering is not much slower in metallic nanoparticles compared to a metal film, in agreement with time-resolved two-photon photoionization measurements on free noble metal nanoparticles by Fierz et al. [53].

Similar electron dynamic studies in gold nanoparticles (size 22 nm) have been completed by Link et al. [54]. Taking into account that they used longer laser pulses (100 fs), the delay rise of the signal is in good agreement with the results of Bigot et al. The authors modeled their results (decay of

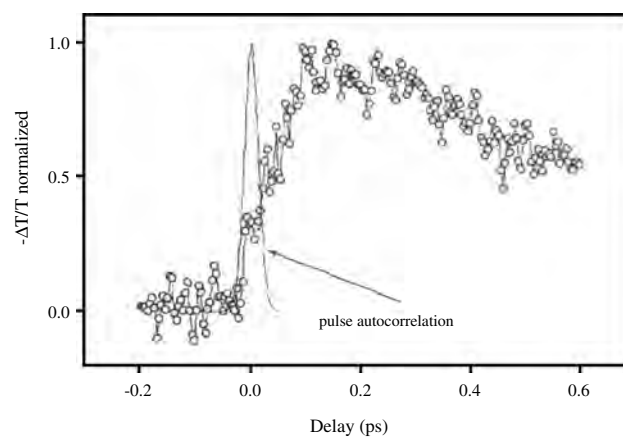

Figure 9. Differential transmission $\Delta T/T(t)$ of 6.5 nm Ag nanoparticles excited with pulses of 30 fs duration at 800 nm. The normalized pulse autocorrelation is shown as a reference. Reprinted with permission from [51], J.-Y. Bigot et al., *Chem. Phys.* 251, 181 (2000). © 2000, Elsevier.

the bleach data) by a rate equation derived by Sun et al. [55]. The model consists of a modification of the two-temperature model (see below), including a nonthermal electron distribution part. From the obtained fitting parameter, a thermalization time between 400 and 500 fs was obtained, in very good agreement with the values obtained by Sun et al. for 20 nm thin gold films.

Stella and co-workers also found a rise time in the transient reflectivity change on the order of 100 fs for tin nanoparticles embedded in an Al_2O_3 matrix [56]. They found that the build up of the hot Fermi distribution was constant in the size range from 2 to 6 nm. It is expected that transition metals have a shorter thermalization time compared to noble metals, caused by the increased phase space for electron–electron scattering due to the unfilled d band [42].

3.2. External Thermalization

Let us now discuss the energy transfer from the hot-electron system to the still cold lattice of the nanoparticles, often called external thermalization. In general, it takes about a few picoseconds until a quasiequilibrium state is formed between the electron system and the phonon system. This heat-exchange process is usually described by the electron–phonon coupling model developed for thin metallic films [57–59]. The electron system is characterized by an electron temperature Θ_e, and the phonon system is characterized by a lattice temperature Θ_l, where each subsystem is assumed to be in local equilibrium. The time evolution of the temperatures is obtained with the heat equations [60, 61]

$$C_e(\Theta_e)\frac{\partial \Theta_e}{\partial t} = -G(\Theta_e - \Theta_l) + p(t) \qquad (7)$$

$$C_l\frac{\partial \Theta_l}{\partial t} = G(\Theta_e - \Theta_l) \qquad (8)$$

where G reflects the e–p coupling constant, $C_e(\Theta_e)$ and C_l are electronic and lattice heat capacities, and $p(t)$ is the absorbed laser power density. The heat capacity of the electron gas is about two orders of magnitude smaller than the heat capacity of the lattice [11]. Therefore, a high maximum electron gas temperature of several thousand kelvins can be reached, although the rise of the equilibrium temperature is only a few hundred kelvins [62].

In Eqs. (7) and (8), the electron energy losses are supposed to be proportional to the difference between the electron and lattice temperatures; the e–p coupling constant G governs the thermal equilibrium process. Due to the reduced dimensionality of the nanoparticles, however, the surface modes of the metallic particles will influence the energy transfer between the electrons and the lattice. Hence, a major goal in many studies has been to determine how the e–p coupling constant G changes as the particle size changes.

Most of the published results are obtained by means either of transient transmission and reflectivity measurements or transient absorption spectra as a function of the temporal delay between the pump and the probe beam. The increase in the electronic temperature induced by the pump laser changes the real and imaginary part of the complex dielectric function $\varepsilon(\omega, t)$ of the particles, which causes

transient changes in the spectrum (decrease in intensity, broadening and shift of the plasmon absorption band). The subsequent electron cooling via phonon emission results in a characteristic decay time τ of the modification of the optical constants [63]. It has to be noted that the electronic heat capacity $C_e(\Theta_e)$ depends on the electron temperature Θ_e. Hence, the effective rate constant $\tau^{-1} = G/C_e$ for the decay of the electronic temperature decreases as the initial electronic temperature increases, that is, longer decay times are obtained for higher pump laser powers [64].

The response of the transient absorption spectra with respect to a nonthermal and thermal electron distribution at higher temperature can be modeled by combining the Mie equation with a theory developed by Rosei et al. [65, 66].

Faulhaber et al. [67] measured the energy relaxation of gold particles (size 12–18 nm) by means of femtosecond absorption spectra, and obtained a decay of about 7 ps, much larger than the decay on thin ($d <$ optical penetration depth) gold films ($\tau < 2$ ps [57]). The authors explained that the slower decay observed in nanoparticles is because there is less nonequilibrium electron transport due to the spatial size confinement of the electrons in three dimensions.

In a gold nanoparticle system, Inouye and co-workers made white-light pump–probe experiments in the picosecond region too [68]. They discussed the origin of the change in the transient differential absorption spectra for various delay times by decomposing the temporal behavior into two decay components: a fast component (<3 ps), and a slow decay component (>100 ps). They suggested that the fast decay reflects the thermal equilibrium process between the electron system and the lattice system within the nanoparticles, and the slow decay comes from the heat transfer between the nanoparticles and the host matrix, as will be discussed below. Quite contrary to the work of Faulhaber et al., Inouye and co-workers reported an e–p coupling constant G which was about two times larger than the result of a gold film [49, 57], indicating a faster decay in the particles.

The electron–phonon coupling time constant has also been investigated by Rubahn and co-workers for Na nanoparticles [35]. They measured the relative change in the reflected second-harmonic generation (SHG) signal of a pump–probe setup. They obtained a decay of 1.1 ps, which is comparable to the values for thin metal films [57], opposite to the observation for gold nanoparticles by Inouye et al. [68] and Faulhaber et al. [67].

Also, Hodak et al. found, for Au (11 nm) and Ag (10 nm, 50 nm) nanoparticles, similar relaxation times to those of bulk metals, which implies that there are no size-dependent effects in the heat exchange between the electron and phonon system [69]. A similar result was obtained by del Fatti et al. on Ag nanoparticles for the size range 3 nm $\leq$ $R \leq 13$ nm [70]. Hence, one can assume that, after a few tens of femtoseconds, the electrons have no memory of the way (intraband, interband, on or off Mie resonance) they have been excited. Furthermore, Hodak et al. reported relaxation times which are strongly dependent on the pump laser power. This means that it is not possible to fit high-power (pump laser pulse) data using the simple two-temperature model calculations using a constant electronic heat capacity C_e in order to obtain G. They performed a series of measurements at successively lower pump laser powers, and

extrapolated the measured time constants τ to zero power. From the obtained data, the authors drew the conclusion that surface interaction has a remarkably small effect on the electron–phonon coupling constant G for noble metal particles with diameters greater than 10 nm.

Nisoli et al. investigated the thermalization dynamics in gallium nanoparticles of different sizes in the solid and liquid phase [71]. They found clear size-dependent characteristic time constants ($\tau \sim 0.6$–1.6 ps by increasing the size), but a quite similar temporal behavior of the electron energy relaxation in both phases (solid and liquid). In bulk, the electron energy loss mechanisms are quite different in the two phases. These results shed some light on the role of the energy exchange with surface phonons in small metallic structures.

On the basis of all published results, one can summarize that the thermal equilibrium process between an electron system and a lattice system within the nanoparticles is larger than the internal thermalization time to a Fermi distribution, but still of the same magnitude [64]. Hence, for a deeper theoretical treatment, both processes have to be simultaneously included in the calculation. At present, the reason for the rather different results for the electron–phonon coupling constant versus size is not clear. One possibility for these discrepancies has been addressed by Bigot and co-workers [51, 72]. They investigated the dynamics of Cu and Ag films in order to compare their behavior with the corresponding Cu and Ag nanoparticles, using the same experimental apparatus. The simultaneous measurement of the differential transmission and reflection as a function of the pump–probe delay allows retrieval of the time-dependent complex dielectric function $\varepsilon(t)$ of the metal. Figure 10 shows the normalized $\Delta\varepsilon_2$ and $-\Delta\varepsilon_1$ for the Cu film investigated for two probe wavelengths probed near and far from the interband optical transition. The curves show quite different relaxation times; in particular, the relaxation of the real part is much faster off resonance (0.4 ps) compared to on resonance (1.3 ps). The authors explained the differences due to the nonthermal character of the electron distribution after the pump laser pulse. This nonthermal population can persist for a long time near the Fermi level, and has a strong effect on $-\Delta\varepsilon_1$. A similar effect was reported on Cu nanoparticles by the same authors. In Figure 11, the time dependence of $\Delta T/T$ decays with a longer relaxation time when the laser energy is at the plasmon resonance. One should keep in mind that, in the pump–probe experiment, the collective character of the electrons excited by the pump is lost within a few tens of femtoseconds. Therefore, it is the plasmon that is created by the *probe*, which is sensitive to this mechanism. Hence, these effects have to be taken into account by comparing results of different groups obtained on the same metallic nanoparticles, but at different wavelengths. This counts, in particular, for Cu and Au, for which the $d \rightarrow sp$ interband transition occurs at approximately the same frequency as the plasmon resonance. The situation is somehow simpler when the dynamics is studied far from the interband transition, for example, for Ag, where the interband transition is displaced to the plasmon resonance by >0.7 eV.

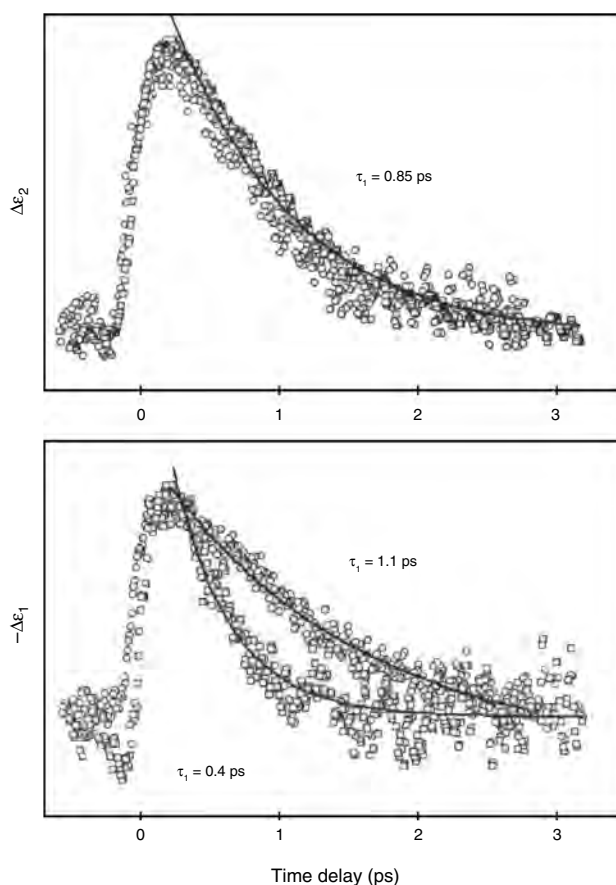
Feldmann and co-workers investigated the vibrational dynamics of ellipsoidal silver nanoparticles after


Figure 10. Dynamics of the normalized $\Delta\varepsilon_2$ and $-\Delta\varepsilon_1$ for the Cu film for two probe wavelengths near (circles: $\lambda = 570$ nm, 2.175 eV) and far (squares: $\lambda = 611$ nm, 2.03 eV) from the interband optical transition. Figure 11. Time dependence of $\Delta T/T$ in Cu nanoparticles of 10 nm diameter in the vicinity of the surface plasmon resonance. The dotted line is the cross correlation between the 60 fs pump and 10 fs probe pulses. Reprinted with permission from [51], J.-Y. Bigot et al., *Chem. Phys.* 251, 181 (2000). © 2000, Elsevier.

femtosecond laser pulse excitation [73]. They measured the differential transmission $\Delta T/T$ induced by a 150 fs laser pump pulse at $h\nu = 3.1$ eV, and found the typical two-step decay (fast and slow decay) as discussed by Hodak et al. In addition, the signals exhibit periodic modulations during the second decay step. The modulation periods are in the range of 20–50 ps, and are found to be independent of pump intensity, but show a strong dependence on the particle axis probed. They explained their results in the following way. The heating by the pump pulse results in a thermal expansion of the particle. The electron pressure to this expansion is extremely large due to the high temperature of the electron gas. During this expansion, the inertia of the ions will make them overshoot their new (high-temperature) equilibrium positions. This overshoot will be followed by a reversal of the expansion, due to the elasticity of the metal, resulting in an oscillating behavior of the particle length. These particle-length oscillations are expected to induce a plasmon shift, which can even quantitatively explain the observed modulation in the differential transmission change $\Delta T/T$.

3.3. Heat Transfer to the Support

The last step in the energy relaxation is the heat transfer between the nanoparticles and the support (host matrix, substrate). A single electronic cluster–substrate interaction process happens in the femtosecond time scale, as reported by Reihl and co-workers [74]. Photoemission spectra of silver particles on a graphite surface reveal distinct deviations in the Fermi-level onset from the step-like shape typical for metals. These deviation could be explained by using a simple model that takes into account the finite lifetime of the photohole remaining on the metal cluster during the photoemission process and the cluster–substrate.

The time to establish a thermal equilibrium between the cluster and substrate takes much longer; in general, it happens in a time scale above 100 ps. This process is sensitive to the thermal conductivity of the surrounding medium. In this time region, we can consider that the lattice temperature of the nanoparticles is the same as the electron temperature.

First, we consider the thermal diffusion from the metallic nanoparticle to the substrate by a simple diffusion equation:

$$\frac{\partial \Theta_{subst}}{\partial t} = D_{subst} \nabla^2 \Theta_{subst} \tag{9}$$

where D_{subst} is the diffusivity of the heat in the substrate. From Eq. (9), we obtain the thermal distribution function outside the metal nanoparticle as a function of the distance r and time t. In the case of a dielectric substrate, thermal diffusion inside the nanoparticle can be neglected because, in general, the diffusivity of metal D_m is 10^3 time larger than D_{diel}.

As already mentioned above, Inouye and co-workers found, in a gold nanoparticle, a slow decay component ($\sim$120 ps), and elucidated it as the heat transfer between the nanoparticles and the host matrix [68]. Also, Hodak and co-workers found a slow component on a $\sim$100 ps time scale in their transient bleach data recorded with a high-power (>1 mJ/cm^2) pump laser for Au particles (10 nm) in a solvent [69]. For sufficiently high pump power, the heat

deposited into the lattice by the electrons causes the particles to expand. This shifts the plasmon band to the red, leading to a long-lived transient absorption and bleach signals on the red and blue sides of the plasmon band, respectively. For gold particles with a mean diameter of 30 nm in a sol–gel matrix, Perner et al. found a slow decay constant of 200 ps [75].

4. CONCLUSION

The impact of ultrafast excitation and relaxation of the conduction band electrons of metallic nanoparticles has been reviewed. The attention is confined to metallic nanoparticles with sizes larger than 100 Å, for example, the metal is still considered as a three-dimensional system. Quantum size effects due to the discrete nature of the electronic states [6] do not show up, and do not play a role in the energy dissipation processes. However, the size of the nanoparticles is smaller than the wavelength of light, as well as the optical penetration depth. Hence, all atoms in the particle can be collectively excited. This in turn influences the excitation (optical properties) and relaxation (electrodynamic properties) process.

Summarizing the general trend, only the interaction of light with the nanoparticles shows a strong size dependency, especially the damping (dephasing time), and hence, the resonant enhancement f of the local field depends critically on the size of the particles. But as soon as the energy is stored in the electron system (e.g., in electron–hole pairs), the following thermalization processes (electron cooling dynamics) show—if at all—only a slight size dependence. In addition, independent of whether the light is absorbed due to plasmon absorption or interband transition, no difference is observed in the femtosecond electron dynamics, as clearly shown by Link et al. [54].

So far, most of the published work has been performed on noble metal nanoparticles; only a few results were reported on transition metal particles [56, 71]. The detailed study of the electron dynamics in transition metal nanoparticles would help us understand the influence of the more localized d band to the energy dissipation dynamics. Also, from the point of catalytic reaction, the move to the more reactive transition metals would be desirable [76].

Furthermore, spin- and time-resolved measurements open the possibility to study the spin-dependent electron dynamics in magnetic nanoparticles, a new research field which has just emerged in the last years [77, 78].

GLOSSARY

Drude damping Includes all microscopic damping processes of excited electrons due to photons, phonons, impurities, surface scattering, and electron-electron interactions.

External thermalization Cooling of the optically excited electron gas via phonon emission. This heat-exchange process is usually described by an electron-phonon coupling model.

Inelastic decay time T$_1$ Decay of the plasmon population via transformation into photons (radiation damping) and via decay into electron-hole excitations.

Interface damping   Contribution to the plasmon decay due to electron scattering off the particle surface and interaction with adsorbates.

Interferometric autocorrelation   Autocorrelation of two laser pulses performed with interferometric accuracy. If the pulses are sent through an optically nonlinear material, higher order interferometric autocorrelation function can be obtained.

Internal thermalization   Thermalization of optically excited electronic states towards a Fermi-Dirac distribution with a well defined temperature. Electron-electron scattering is the most efficient process to redistribute the energy to thermalize the electron gas.

ITO substrate   Indium tin oxide, an often used transparent and electrically conducting substrate to investigate deposited metallic nanoparticles.

Local field enhancement   The electromagnetic field in the particle near field is enhanced due to the resonantly driven charges in the nanoparticles. Resonant and nonresonant excitation result in different amounts of field enhancement.

Particle (Mie) plasmon   A collective excitation of the electron plasma in a nanoparticle gives rise to polarization charges at the particle surface which act as a restoring force like an oscillator system. On the contrary to the bulk and the surface plasmon, the particle plasmon can be directly excited by freely propagating light waves.

Plasmon dephasing time T_2   Corresponds to the time scale on which the decay of the coherent electron plasma oscillation (and hence the local-field enhancement) takes place, e.g. the time scale on which the electron oscillation preserves the memory of the optical phase of the excitation pulse. T_2 is inverse proportional to the homogeneous linewidth Γ in the spectral domain and is related to the inelastic decay time T_1 and the pure dephasing time T_2^*.

Plasmon resonance   A collective excitation of a dense electron gas. This excitation consists of a coherent motion of a high number of electrons in contrast to those excitations in which the external perturbation acts on a single electron. The effective field governing this excitation consists of a superposition of external field and induced field generated by the dynamical response of the electrons system. In general, one has to distinguish between bulk, surface, and particle (Mie) plasmons.

Pump-probe technique   A stroboscopic method, a first laser pulse drives the systems and a second, suitable delayed, probes the actual state. This technique enables a direct measurement of the dynamical properties in the time domain.

Pure dephasing time T_2^*   Elastic phase-loss process, e.g. a decay of the fixed phase correlation between the individual electronic excitations of the whole oscillator ensemble.

Radiation damping   Coherent reemission of photons from the oscillating electron plasma. It is the origin of the reflected beam.

CONTENTS

1. INTRODUCTION

The transmission electron microscope (TEM) is a powerful and widely used tool for characterizing the microstructure and chemistry of materials. There are many different TEM imaging modes, but most suffer from the major drawback that the final recorded image is a spatial distribution of intensity. All information about the phase shift of the high-energy electron wave that has passed through the sample is lost. The technique of electron holography, which was originally described by Denis Gabor [1, 2] and is based on the formation of an interference pattern or "hologram," overcomes this limitation by allowing the phase shift of the electron wave to be recovered. As the phase shift is sensitive to both the in-plane component of the magnetic induction and the electrostatic potential in the sample, an electron hologram can provide quantitative information about magnetic and electric fields in materials to a spatial resolution that can approach the nanometer scale. The earliest attempts at electron holography were restricted by the limited brightness of the tungsten hairpin filaments used as electron sources [3], but the development of the high-brightness field-emission electron gun (FEG) for the TEM [4] now allows the practical implementation of electron holography in commercial instruments. Since the first of these instruments (the 200 kV Hitachi HF-2000 FEG-TEM) became available in 1990, FEG-TEMs have been sold widely, and electron holography has been applied to a wide variety of materials such as quantum well structures, magnetoresistive films, nanowires, and semiconductor devices.

In this chapter, the application of electron holography to the characterization of magnetic and electrostatic fields in nanostructured materials is reviewed. The properties of such materials differ significantly from those observed in larger structures. For example, magnetic interactions between closely spaced, deep-submicrometer magnetic elements depend sensitively on their size, shape, composition, and spacing. The characterization of such interactions is of great importance if these materials are to be used in future magnetic recording and sensing applications. Such applications may require specific values of the coercive fields and remanent magnetizations of individual magnetic nanostructures, as well as stable and reproducible magnetic domain states. Most of the experimental results that are presented in this chapter were obtained using the off-axis, or "sideband," mode of electron holography in the TEM, which is ideally suited to the characterization of nanostructured materials for reasons that will be discussed. As a result, this mode will be described in detail, while other modes will only be mentioned briefly or in passing.

A particular advantage of electron holography for the analysis of magnetic or electric fields in nanostructured materials is that unwanted contributions to the contrast from local variations in composition and sample thickness can be removed from a holographic phase image more easily than from images recorded using alternative phase contrast techniques such as Lorentz microscopy. As the dimensions of magnetic storage and electronic devices continue to shrink, electron holography provides an increasingly unique approach for solving industrial problems, as well as providing advances to fundamental scientific knowledge.

This chapter begins with an outline of the experimental and theoretical procedures that are used to obtain amplitude and phase information from electron holograms, as well as some of the limitations and pitfalls that may be encountered when using the technique. Applications of electron holography to the characterization of nanostructured materials are then reviewed, in three distinct sections. First, the use of measurements of mean inner potential and sample thickness to characterize the morphologies of fine particles and steps on the surfaces of materials is described. The influence of dynamical diffraction and chemical bonding on such measurements is discussed.

Second, the characterization of magnetic domain structures in a wide variety of nanostructured materials using electron holography is reviewed. Examples of "optical" holographic reconstruction of magnetic fields in nanostructures that are larger than a few hundred nanometers in size include the characterization of bubble memories, ferromagnetic wires that are wide enough to contain domain walls, fine particles, recorded magnetic tapes, and the experimental confirmation of the Aharonov–Bohm effect. In smaller magnetic structures, particularly those below 100 nm in size, the measured holographic signal is dominated by unwanted contributions to the measured phase shift from local variations in sample thickness and composition. Digital acquisition and analysis of electron holograms are then essential in order to recover the weak magnetic signal of primary interest. The procedures that can be used to characterize deep-submicrometer magnetic nanostructures are illustrated for hard magnets, magnetic nanowires, lithographically patterned elements, chains of strongly interacting single-domain nanocrystals, magnetic tunnel junctions examined in cross-section, magnetic force microscopy tips, and fluxons in superconductors. Both the need to perform micromagnetic simulations to understand the observed magnetic microstructure and the quantitative nature of the results that can be obtained using electron holography are emphasized.

Third, the application of electron holography to the characterization of electrostatic fields in nanostructured materials is reviewed. Experiments that are described include the measurement of electrostatic fringing fields around charged latex particles and field-emitting carbon nanotubes, electrostatic potentials associated with depletion regions in doped semiconductor devices, and space charge layers at interfaces in ceramics. Special attention is given to factors that currently limit the accuracy of results obtained from doped semiconductors, in particular the effect of different TEM sample preparation techniques on the contrast recorded from such samples. Recent results from the application of electron holography to working semiconductor devices, which are examined *in-situ* with a current flowing through them, are reported. Finally, several alternative modes of electron holography are described, and their respective advantages for different experiments are discussed.

The reader is referred to several books (e.g., [5–7]), review papers (e.g., [8–13]), and special journal issues (e.g., [14]) on the subject of electron holography, which offer comprehensive descriptions of other aspects of the technique that cannot be covered adequately here.

1.1. Basis of Off-Axis Electron Holography

The electron microscope geometry required for the TEM mode of off-axis electron holography is shown schematically in Figure 1a. The sample is examined using defocused, highly coherent illumination, which is usually provided by a FEG electron source. In reality, the source is never perfectly coherent, either spatially or temporally, but the degree of coherence must be such that an interference fringe pattern of sufficient quality can be recorded within a reasonable acquisition time, during which specimen and/or beam drift must be negligible. Cold FEGs have high temporal coherence ($\Delta E \sim 0.3$ eV) and high spatial coherence, but they require an ultrahigh vacuum environment for reliable operation. In addition, the beam current usually falls during operation as a result of gas molecules adhering to the tip. Schottky FEGs, which are used in JEOL and FEI FEG-TEMs, do not require such stringent vacuum conditions, and they provide a beam with a higher total current that is also more stable over time. Although electron holograms have historically been recorded on photographic film, digital acquisition using charge coupled device (CCD) cameras is now commonly used.

In order to acquire an off-axis electron hologram, the region of interest on the sample is positioned so that it covers approximately half the field of view. A positive voltage (or a negative voltage depending on the electron-optical configuration [15]) of typically between 50 and 200 V is then applied to an electrostatic biprism wire [16, 17], which is located close to a conjugate image plane in the electron microscope (most often in place of one of the conventional selected-area apertures). The biprism is usually a fine (<1 μm diameter) wire made from either Pt- or Au-coated quartz, and it may be rotatable. The optimal position for the biprism has been calculated by Lichte [18]. The voltage applied to the biprism acts to tilt the reference wave that has passed only through vacuum (or alternatively through a thin region of amorphous support film) relative to the wave that has passed through the sample, so that the two waves overlap and interfere to form a hologram in a slightly defocused image plane of the object.

The application of a voltage to the biprism results in an electron-optical configuration that is equivalent to the use of two electron sources S_1 and S_2, as shown in Figure 1a. The width of the interference region, W, is increased by applying a larger voltage to the wire, which in turn moves the two virtual sources further apart. This places a greater constraint on the spatial coherence of the source required to maintain
Figure 1. (a) Schematic illustration of the setup used for generating off-axis electron holograms. The sample occupies approximately half the field of view. Essential components are the field-emission electron gun electron source, which provides coherent illumination, and the positively charged electrostatic biprism, which causes overlap of the object and (vacuum) reference waves. The Lorentz lens allows imaging of magnetic materials in close-to-field-free conditions. The symbols are defined in the text. (Taken from Dunin-Borkowski, unpublished work.) (b) Off-axis electron hologram of a chain of magnetite (Fe_3O_4) crystals from a bacterial cell, recorded at 200 kV using a Philips CM200 FEG-TEM. The crystals are supported on a holey carbon film. Holographic phase changes can be seen most clearly, in the form of bending of the holographic interference fringes as they pass through the crystals, by looking along the fringes at a shallow angle to the plane of the paper. Coarsely spaced Fresnel fringes from the edges of the biprism wire are visible within the overlap region in addition to the holographic fringes. A hole in the support film is visible at the top left corner of the image. (Taken from McCartney, unpublished work.)

sufficient fringe contrast. The interference width is given by the expression

$$W = 2\left(\frac{d_1 + d_2}{d_1}\right)\left(\alpha \frac{d_1 d_2}{d_1 + d_2} - R\right) \qquad (1)$$

where R is the radius of the biprism. α, the deflection angle introduced by the biprism, is directly proportional to the voltage applied to the wire [19, 20]. Equation (1) highlights the importance of making the biprism wire as narrow as possible. The voltage that must be applied to the wire to achieve overlap between the two parts of the electron wave on either side of it is directly proportional to the wire diameter. The interference fringe spacing in the overlap region, s, is inversely proportional to the biprism voltage and is given by the expression

$$s = \lambda\left(\frac{d_1 + d_2}{2\alpha d_1}\right) \qquad (2)$$

where λ is the wavelength of the incident illumination. The total number of fringes in the overlap region is approximately proportional to the square of the applied biprism voltage.

A representative off-axis electron hologram from a chain of ~100 nm magnetite crystals is shown in Figure 1b. In this image, the biprism has deliberately been rotated to achieve overlap between the crystals and a hole in the carbon support film (top left). Although the hologram is superficially similar to a bright-field image, the field of view is also covered by two distinct sets of interference fringes. The coarser (and lower contrast) fringes are Fresnel fringes from the edges of the biprism wire, while the finer fringes are the holographic interference fringes. The amplitude and phase shift of the electron wave that leave the sample are recorded in the intensity and position of the holographic interference fringes, respectively. Hence, the hologram contains information about the complete wavefunction transmitted by the specimen.

When examining magnetic materials in the electron microscope, holograms are usually acquired with the conventional microscope objective lens turned off, as its strong magnetic field would saturate the sample magnetization along the electron beam direction. A high-strength minilens located below the sample may then be used to provide high magnification with the sample in a field-free environment, as well as to provide a large overlap width of 1–2 μm with a small interference fringe spacing of 1–5 nm.

1.2. Imaging Theory

For most cases of electron microscope imaging, the imaging process may be assumed, as a first approximation, to be coherent. Imaging is described in terms of the modification of the electron wavefunction by the object and the imaging objective lens. The intensity of an image is then found from the modulus squared of the corresponding wavefunction [21]. The Abbe description of the imaging process is valid for electron microscopy, and a small-angle approximation can be made since typical scattering angles rarely exceed 10^{-1} radians. For coherent imaging in the TEM, the electron wavefunction at the exit surface of the sample can be written in the form

$$\psi_s(\mathbf{r}) = A_s(\mathbf{r})\exp[i\phi_s(\mathbf{r})] \qquad (3)$$

where $\mathbf{r}$ is a two-dimensional vector in the plane of the sample with components x, y. The corresponding wavefunction in the image plane can be written as

$$\psi_i(\mathbf{r}) = A_i(\mathbf{r}) \exp[i\phi_i(\mathbf{r})] \qquad (4)$$

In Eqs. (3) and (4), A and ϕ refer to amplitude and phase, and the subscripts s and i refer to the sample and image planes, respectively. In a standard bright-field TEM image, the recorded intensity distribution is given by the expression

$$I(\mathbf{r}) = |A_i(\mathbf{r})|^2 \qquad (5)$$

The back focal plane of the electron microscope objective lens contains the Fraunhofer diffraction pattern (i.e., the Fourier transform) of the object wave $\psi_s(\mathbf{r})$, denoted $\psi(\mathbf{q}) = \text{FT}[\psi_s(\mathbf{r})]$, where $\mathbf{q}$ is a two-dimensional vector in reciprocal space. Subsequent transfer from the back focal plane to the image plane is expressed as an inverse Fourier transform, denoted $\text{FT}^{-1}[\ ]$.

For a perfect thin lens, neglecting any magnification and rotation of the image, the complex image wave would be exactly equivalent to the object wave $\psi_s(\mathbf{r})$. In practice, severe and unavoidable objective lens aberrations result in modifications to the amplitude and phase of the electron wave. These modifications are usually represented by a multiplication of the electron wavefunction in the back focal plane by a transfer function of the form

$$T(\mathbf{q}) = B(\mathbf{q}) \exp[i\chi(\mathbf{q})] \qquad (6)$$

In Eq. (6), $B(\mathbf{q})$ is an aperture function that has a value of unity for values of q less than the objective aperture size and zero beyond the edge of the aperture. The effects of defocus and spherical aberration of the objective lens are included in the phase factor

$$\chi(\mathbf{q}) = \pi \Delta z \lambda q^2 + \frac{\pi}{2} C_S \lambda^3 q^4 \qquad (7)$$

where Δz is the defocus of the lens and C_S is its spherical aberration coefficient. (A more complete form of contrast transfer theory for electron holography that takes partial coherence into account has also been derived [22].) The complex wave in the image plane can then be written in the form

$$\psi_i(\mathbf{r}) = \text{FT}^{-1}[\text{FT}[\psi_s(\mathbf{r})] \times T(\mathbf{q})] \qquad (8)$$
$$= \psi_s(\mathbf{r}) \otimes t(\mathbf{r}) \qquad (9)$$

where $t(\mathbf{r})$ is the inverse Fourier transform of $T(\mathbf{q})$, and the convolution $\otimes$ of the object wave $\psi_s(\mathbf{r})$ with $t(\mathbf{r})$ describes the loss of resolution that results from lens imperfections. Since both $\psi_s(\mathbf{r})$ and $t(\mathbf{r})$ are in general complex, the intensity in the image plane, which can be expressed in the form

$$I(\mathbf{r}) = A_i^2 = |\psi_s(\mathbf{r}) \otimes t(\mathbf{r})|^2 \qquad (10)$$

is not normally related simply to the object structure.

The intensity in an off-axis electron hologram can be obtained from the previous expressions by adding a plane reference wave with a tilt corresponding to $\mathbf{q} = \mathbf{q}_c$ to the complex object wave in the image plane, to give

$$I_{\text{hol}}(\mathbf{r}) = \left|\psi_s(\mathbf{r}) \otimes t(\mathbf{r}) + \exp[2\pi i \mathbf{q_c} \cdot \mathbf{r}]\right|^2 \qquad (11)$$
$$= 1 + A_i^2(\mathbf{r}) + 2A_i(\mathbf{r}) \cos[2\pi \mathbf{q_c} \cdot \mathbf{r} + \phi_i(\mathbf{r})] \quad (12)$$

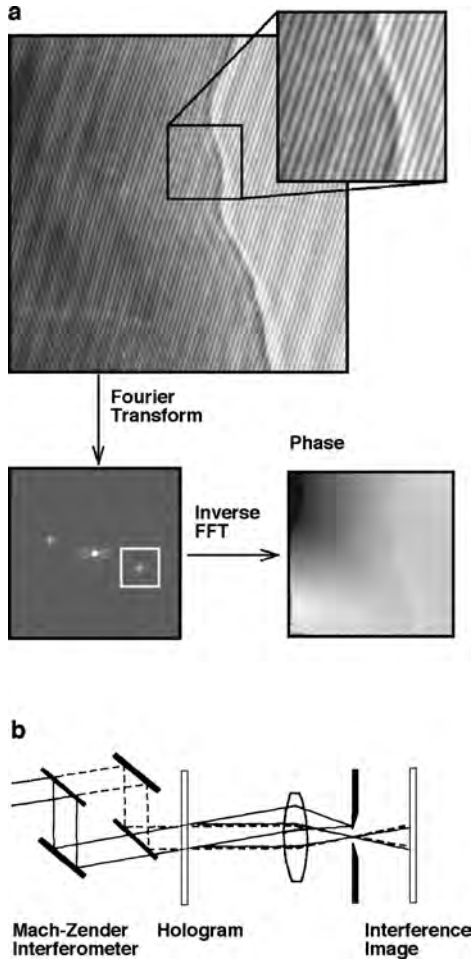
Equation (12) can be interpreted as follows. The intensity in the hologram is the sum of three terms: the intensities of the reference and image waves, and an additional set of cosinusoidal fringes with local phase shifts ϕ_i and amplitudes A_i that are equivalent to the corresponding phases and amplitudes of the image wave, respectively. These are the fine fringes visible in Figure 1b.

1.3. Reconstruction of Electron Holograms

The procedure typically used to "reconstruct" an electron hologram (i.e., to obtain amplitude and phase information about the image wave) is summarized in Figure 2a. The hologram is first Fourier transformed. The complex Fourier transform of the hologram can be expressed in the form

$$\begin{aligned}
\text{FT}[I_{\text{hol}}(\mathbf{r})] = {} &\delta(\mathbf{q}) + FT[A_i^2(\mathbf{r})] \\
&+ \delta(\mathbf{q} + \mathbf{q_c}) \otimes [A_i(\mathbf{r}) \exp[i\phi_i(\mathbf{r})]] \\
&+ \delta(\mathbf{q} - \mathbf{q_c}) \otimes [A_i(\mathbf{r}) \exp[-i\phi_i(\mathbf{r})]] \quad (13)
\end{aligned}$$

Equation (13) contains four terms: a peak at the origin ($\mathbf{q} = 0$) corresponding to the Fourier transform of the uniform intensity of the reference image, a second peak centered on the origin ($\mathbf{q} = 0$) comprising the Fourier transform of the intensity distribution of the normal TEM image, a peak centered on $\mathbf{q} = -\mathbf{q_c}$ comprising the Fourier transform of the desired image wavefunction, and a peak centered on $\mathbf{q} = +\mathbf{q_c}$ comprising the Fourier transform of the complex conjugate of the image wavefunction. In the Fourier transform of the hologram visible at the bottom left of Figure 2a, these contributions are visible as a central "autocorrelation" peak and two "sidebands." The two sidebands contain identical information apart from a change in the sign of the phase; experimentally, neither choosing the other sideband nor moving the biprism to the other side of the region of interest provides any additional information.

The reconstruction procedure involves using an "aperture" to select a single sideband from the Fourier transform. The chosen sideband is then inverse Fourier transformed, as shown in the lower half of Figure 2a. Complete separation of the sideband region from the central peak of the Fourier transform can only be achieved if a large enough value of $\mathbf{q_c}$ (i.e., a small enough fringe spacing) is chosen, while the optimal aperture size depends on the object being studied [23]. The aperture used to select the sideband is normally circular, and it can be given diffuse edges during processing to minimize effects due to the abrupt loss of information at the mask edge. The larger the radius of the aperture, the higher the spatial frequencies that are retained and thus the higher the spatial resolution, but paradoxically the higher the noise, in the reconstructed image. It is often the case that the highest spatial frequencies are not required, and a reduction in mask radius may remove high frequency


noise from the reconstructed amplitude and phase. This procedure is particularly applicable to electromagnetic fields, since the phase shift may vary slowly across the image and only the lowest frequencies are required to portray the field accurately. However, care is required since the use of a small aperture can lead to extremely serious artifacts (e.g., [24]).

The reconstruction of electron holograms can be carried out either digitally with a computer [25, 26] or "optically" on a light bench. In common with many experimental techniques in the physical sciences, electron holography benefits greatly from the use of quantitative recording. Indeed, CCD cameras are now becoming the most widely used medium for recording holograms. They have a linear response over many orders of magnitude, they have a high detection quantum efficiency, and the recorded information is immediately

accessible for digital processing. Moreover, fast and inexpensive computers and sophisticated image processing software (e.g., [27]) are now readily available. The convenient combination of digital recording with computer processing also facilitates novel applications of electron holography, some of which are described below. In particular, computational approaches make it straightforward to isolate the desired magnetic contribution to the holographic phase from other sources. Although many CCD cameras are still only 1024×1024 pixels in size, which limits the number of holographic fringes that can be sampled, 2048 and 4096 pixel cameras are now also available to relieve this limitation. As with any recording medium, the CCD camera has a point spread function that describes how much intensity has spread from one pixel to its neighbor, as well as a detection quantum efficiency, which is a measure of the electron dose required to separate an image detail from noise [28–31]. Although the accurate measurement of fringe contrast requires deconvolution of the point spread function from a hologram, this procedure can increase noise substantially. As a result, deconvolution approaches are rarely applied to medium resolution electron holograms.

When a hologram is reconstructed digitally, it is usually multiplied by a two-dimensional apodization function such as a Hanning window before its Fourier transform is calculated. This procedure eliminates streaks in the Fourier transform associated with the mismatch in intensity between opposite edges of the hologram. For an image of size N pixels on each side, a Hanning window of order τ is defined [32] by the expression

$$H^\tau(m, n) = H_x^\tau(m) H_y^\tau(n) \tag{14}$$

where

$$H_x^\tau(m) = \left(\frac{N}{2\pi}\right) \sum_{j=1}^{\tau} \frac{(-1)^j}{j} \sin\left[\pi j\left(\frac{N-1}{N}\right)\right] \cos\left[\left(\frac{2\pi jm}{N}\right) - 1\right] \tag{15}$$

and

$$H_y^\tau(n) = \left(\frac{N}{2\pi}\right) \sum_{j=1}^{\tau} \frac{(-1)^j}{j} \sin\left[\pi j\left(\frac{N-1}{N}\right)\right] \cos\left[\left(\frac{2\pi jn}{N}\right) - 1\right] \tag{16}$$

The Hanning window, which primarily affects the reconstructed amplitude image, can be removed from the complex image wave after a sideband has been selected and inverse Fourier transformed.

Although it is rarely used, it should be mentioned that a *real-space* digital reconstruction approach for electron holography has also been proposed [33]. A neural network approach has also been applied to this problem [34].

Optical reconstruction involves the use of a laser bench that has been configured as a Mach–Zender interferometer to illuminate a hologram that has been recorded photographically (Fig. 2b). The approach involves splitting a plane parallel light wave from a collimated laser into two separate beams, which, by proper adjustment of optical mirrors, pass through the hologram at slightly different angles and are then recombined using a lens. Similar to Figure 2a,

the fringe modulation of the hologram acts as a diffraction grating and produces three primary beams in the back focal plane of the lens: the central beam and two diffracted beams, with a separation that is inversely proportional to the holographic fringe spacing. One of the diffraction maxima contains amplitude and phase information about the object, while the other contains the complex conjugate. When the region around one of the diffraction spots is selected physically using the aperture, the amplitude and phase of the resulting optical image are the same as those of the original electron image (i.e., the electron wavefronts are reproduced as optical wavefronts).

Whereas electron holograms that have been recorded digitally can be used to provide either raw phase images that have 2π phase jumps remaining or "unwrapped" phase images, optical reconstruction typically provides either "interferograms" (formed by adding a phase ramp to the image) or "interference images" (contour maps), which are equivalent to displaying the cosine of the measured phase. Two times phase amplification can be achieved optically by interfering the first order (+) spot produced by one laser beam (the reconstructed wavefront) with the first order (−) spot from the other beam (the conjugate wavefront) instead of with a plane wave. Greater phase amplification may be achieved by using nonlinear photographic reproduction of the hologram to produce a series of several diffraction orders on each side of the central spot in the back focal plane, instead of just one order on each side as given by the cosinusoidal fringes. The higher-order reflections are correspondingly more sensitive to phase changes and may be chosen to give contours at phase intervals as small as ($\pi/100$). Alternatively, the phase amplification factor can be increased by forming a new hologram that has twice the phase sensitivity of the original. After processing, the original hologram may be replaced in the laser bench by the newly formed hologram and the procedure repeated to obtain greater phase amplification [35]. An alternative phase amplification scheme that is based on the difference between the phases of two holograms obtained using different biprism voltages has also been proposed [36].

1.4. Experimental Considerations

1.4.1. Microscope Alignment

The basic requirement for high electron beam coherence would imply demagnification of the electron source as far as practicable within the constraint of the available current density per unit solid angle imposed by the finite brightness of the source. Consideration of the imaging geometry shows, however, that the use of rotationally symmetric illumination is not required. A significant improvement in the coherence available with a given electron source and condenser lens system can be achieved by employing highly elliptical illumination. The condenser lens stigmators and focus settings are deliberately misaligned to produce illumination that is very wide in the direction perpendicular to the biprism wire when the condenser lens is overfocused but relatively narrow in the parallel direction. For example, in a typical medium resolution electron hologram obtained with the image located below the biprism, the minor axis of the ellipse may be

adjusted to be 2–5 times greater than the overlap width, while the major axis may be 50–100 times greater again. The typical experimental illumination condition for acquiring an off-axis electron hologram is shown in Figure 3a [37].
Figure 3. (a) Highly elliptical illumination formed by deliberately misadjusting the condenser stigmators, showing the typical condition used for recording electron holograms. The major and minor axis dimensions are 9.5 and 0.1 μm, respectively. Holographic interference fringes are formed within the central bright band (indicating the position and direction of the biprism wire) visible within the ellipse. The major axis of the illumination is aligned accurately perpendicular to the direction of the biprism wire. Images (b) and (c) show the effect of changes in the biprism voltage on hologram formation, recorded at 200 kV using a Philips CM200 FEG-TEM, for biprism voltages of 0 and 80 V, respectively. Fresnel fringes at the edges of the wire are visible outside the shadow of the wire in (b) and inside the overlap region in (c). Reprinted with permission from [37], D. J. Smith and M. R. McCartney, in "Introduction to Electron Holography" (E. Völkl, L. F. Allard, and D. C. Joy, Eds.), pp. 91–92. Kluwer Academic/Plenum, New York, 1998. © 1998, Kluwer Academic/Plenum.

Accurate alignment of the condenser stigmators can be achieved when the illumination is underfocused so that the major axis of the ellipse is parallel to the biprism wire direction. It is convenient to perform this adjustment with a relatively low biprism voltage, since the holographic fringes then have higher contrast and larger spacing. Even when using a FEG electron source, a small spot size, small condenser aperture size, and low gun extraction voltage are required to maximize coherence. As a result of the inevitable trade-off between intensity and coherence, the loss of signal must be balanced with a loss in coherence to achieve a reasonable hologram acquisition time [38].

Figure 3b illustrates the fact that when the biprism wire is initially inserted into the field of view, it creates a black shadow that has Fresnel fringes on either side. As the voltage is applied to the wire, the black shadow becomes progressively narrower until overlap is achieved. As the overlap region continues to expand with increasing biprism voltage, it appears bright and contains increasingly finer holographic interference fringes that run parallel to the length of the wire (in addition to the Fresnel fringes that remain from the edges of the biprism). This condition is shown in Figure 3c.

1.4.2. Vacuum Reference Wave

The requirement for a (vacuum) reference wave that can be overlapped onto the region of interest by the application of a voltage to the biprism wire usually implies that a hologram can only be recorded from near a specimen edge. The region of interest and the reference wave must be within a few μm of each other in order to achieve sufficient fringe contrast in the overlap region, and the orientation of the biprism wire may need to be optimized to satisfy this criterion. The latter restriction can be relaxed if a thin and clean region of electron-transparent support film, rather than vacuum, can be overlapped onto the region of interest. An alternative proposal involves acquiring holograms of the same area of the sample using two different biprism voltages [39].

Great care should always be taken to assess the effect on the reference wave of long-range electromagnetic fields that may extend outside the sample [40–42]. Both the object wave and the reference wave may then be affected by the field from the sample. The observed phase image may be altered from one that would be recorded using a perfect reference wave, as illustrated in Figure 4 for simulations of a small magnetic bar. Figure 4a shows the phase image that would be recorded using a perfect reference wave, while Figure 4b shows the effect of using a reference wave that is modulated by the long-range magnetic field from the object [43]. Although a possible numerical method for correcting experimental phase images for this effect has been suggested [44], care should in general be taken both to avoid using a perturbed reference wave in the first place and to recognize its presence if it cannot be avoided.

1.4.3. Reference Hologram

In most standard microscope applications, image distortions are small enough to be ignored. Off-axis electron holography, however, stores information in the lateral displacement of interference fringes, and distortions can cause similar

Figure 4. Simulations of phase lines around a small magnetic bar, calculated (a) assuming a perfect reference wave and (b) using a reference wave that has been perturbed by the long-range magnetic field extending into vacuum around the object. Reprinted with permission from [43], B. G. Frost and G. Matteucci, in "Introduction to Electron Holography" (E. Völkl, L. F. Allard, and D. C. Joy, Eds.), p. 193. Kluwer Academic/Plenum, New York, 1998. © 1998, Kluwer Academic/Plenum.

displacements. The reconstructed phase image may therefore carry long-range phase modulations that stem from a number of factors, including inhomogeneities in the charge and the thickness of the biprism wire, distortions caused by the projector lenses and the recording system, and charging effects in the path of the electrons (e.g., at fixed apertures). In some cases, these distortions can be distinguished from true phase information if the phase information is bandwidth-limited to higher spatial frequencies. As distortions characteristically show up in the lower frequency range, a simple background filtering may be sufficient to remove their contribution. In general, however, since these distortions are geometrical in nature and invariant in time, it is a simple matter to remove them. A reference hologram is obtained by carefully removing the sample from the field of view without changing any of the optical parameters of the microscope. Correction is then possible by a complex division of the reconstructed (sample and reference) image waves in real space, to reveal the distortion-free phase of the image wave [45–47]. This procedure is illustrated dramatically in Figure 5 for a wedge-shaped crystal of InP. Figure 5a shows a reconstructed phase image obtained before distortion correction, with the vacuum region outside the edge of the sample on the left side of the image [48]. Figure 5b shows the corresponding vacuum reference phase image, which has been acquired with the sample removed from the field of view but with all other imaging parameters unchanged. The equiphase contour lines now delineate only the distortions that must be removed from the phase image of the sample. Figure 5c shows the distortion-corrected phase image of the sample, obtained by subtracting Figure 5b from Figure 5a. This subtraction is in practice carried out by dividing the complex image wave. The vacuum region in Figure 5c is flattened substantially by
Figure 5. Illustration of distortion correction procedure for phase images acquired at 100 kV using a Philips 400ST FEG-TEM equipped with a Gatan 679 slow-scan CCD camera. (a) Initial (six-times-amplified) phase image of a wedge-shaped InP crystal. (b) Phase image obtained from vacuum, with the sample removed from the field of view, showing distortions due to the microscope imaging system. (c) Distortion-corrected phase image, obtained by subtracting phase image (b) from phase image (a). This procedure is best carried out by dividing the complex image waves obtained by inverse Fourier transforming the sideband obtained from each hologram, and by calculating the phase of the resulting wavefunction. Reprinted with permission from [48], D. J. Smith et al., in "Introduction to Electron Holography" (E. Völkl, L. F. Allard, and D. C. Joy, Eds.), p. 116. Kluwer Academic/Plenum, New York, 1998. © 1998, Kluwer Academic/Plenum.

this procedure, which allows relative phase changes within the sample to be interpreted faithfully.

The acquisition of a reference hologram has the additional advantage that it allows the true center of the sideband in Fourier space to be determined more accurately.

Although the interference fringes in a hologram usually form the strongest contribution to a single spatial frequency in Fourier space, the true center of the sideband may not be the pixel that has the highest amplitude. This is a problem for automated reconstruction procedures, particularly for strong electric and magnetic fields as these can have a significant influence on the reference wave. Using a reference hologram, however, allows the position of the sideband to be determined to within ±1 pixel accuracy by selecting the pixel with the highest amplitude from the sideband of the reference hologram. The use of the same location for the sideband in the Fourier transforms of both the sample and reference waves removes any tilt of the recorded wave introduced by the inability to locate the exact (subpixel) position of the sideband frequency in Fourier space.

1.4.4. Phase Unwrapping

When a phase image is calculated digitally it is usually evaluated modulo 2π, which means that 2π phase discontinuities that are unrelated to specimen features will appear at positions where the phase shift exceeds this amount. The phase image must therefore be "unwrapped" carefully using suitable algorithms before reliable interpretation of image features becomes possible. Although several phase unwrapping algorithms exist to locate and unwrap such discontinuities, none appears to solve all of the problems. The most straightforward approach involves searching the image by row or column for adjacent pixels with phase differences that are more than a prespecified threshold value, and then adding or subtracting 2π to the subsequent pixels [49]. This method may be unsuitable when noise is significant (e.g., for a thick sample or when the fringe contrast is poor), when the phase gradient exceeds 2π over three pixels, or when the interference field is smaller than the image. In an alternative approach [50], a second phase image may be calculated after multiplying the complex image wave by $\exp[i\alpha]$ to move the phase jumps to different positions in the image. In this manner, areas of the first phase image that were difficult to unwrap may be replaced by identical areas of the second phase image where there are no wraps. This method is more applicable for noisy images, although in practice a combination of the two approaches is often best. Advanced phase unwrapping techniques (e.g., [51]), many of which have been developed in fields outside electron microscopy, are now being introduced into the software that is used to process and analyze electron holograms.

1.4.5. Aberration Correction

If required, the aberrations of the objective lens can be removed by multiplying the complex image wave by a suitable phase plate corresponding to $T^*(\mathbf{q})$ to provide the amplitude and the phase of the *object* wave $\psi_s(\mathbf{r})$ rather than the *image* wave $\psi_i(\mathbf{r})$, and hence to improve the interpretable resolution of the image beyond the point resolution of the electron microscope. This procedure is usually only applied to high-resolution electron holograms, for which an optimal defocus can be defined in order to maximize the resolution of the reconstructed object wave after correction of aberrations [52–62]. The value of the optimal focus for

recording a high-resolution electron hologram is given by the expression

$$\Delta z_{opt} = -\frac{3}{4}C_S(\lambda q_{max})^2 \qquad (17)$$

where q_{max} is the maximum desired spatial frequency. The spatial frequency of the holographic fringes should be at least $3q_{max}$ for strong objects and $2q_{max}$ for weak objects [63]. At this defocus, the minimum number of fringes required in the hologram is given by the expression

$$N_{fringes} \geq 6C_S\lambda^3 q_{max}^4 \qquad (18)$$

although a prefactor of 4 rather than 6 in this equation has been quoted also [64].

Figure 6 illustrates the application of aberration correction to an electron hologram of crystalline Si imaged at the ⟨110⟩ zone axis, at which characteristic "dumbbell" contrast, of spacing 0.136 nm, is expected [65]. The original hologram was acquired using an interference fringe spacing of 0.05 nm on a CM30 FEG-TEM, which has a point resolution of 0.198 nm and an information limit of 0.1 nm at 300 kV. Figure 6a and b shows, respectively, the reconstructed amplitude and phase of the hologram after aberration correction using a phase plate. The phase image reveals the expected white "dumbell" contrast, at a spatial resolution that is considerably better than the point resolution of the microscope, after the lens aberrations, which include the residual astigmatism and off-axis coma, have been measured and removed.

In contrast to high-resolution electron holography, the final focus is not so critical when characterizing electromagnetic fields at moderate resolution. In such experiments, the complex image wave can be manipulated in different ways by applying an aperture or phase plate to the sideband to reproduce images of the same sample that would normally be obtained using different techniques such as the Fresnel, Foucault, coherent Foucault, or differential phase contrast imaging modes of electron microscopy.

Figure 6. High-resolution (a) amplitude and (b) phase images of the aberration-corrected object wave reconstructed from an electron hologram of [110] Si, obtained at 300 kV on a CM30 FEG-TEM. The spacing of the original hologram fringes was 0.05 nm. The sideband contained {111}, {220}, {113}, and {004} reflections, corresponding to lateral information of 0.136 nm. The characteristic Si-dumbbell structure is visible only after aberration correction. Reprinted with permission from [65], A. Orchowski et al., *Phys. Rev. Lett.* 74, 399 (1995). © 1995, American Physical Society.

1.5. Magnetic and Mean Inner Potential Contributions to the Phase

The phase shift of an electron wave that has passed through a TEM sample is sensitive both to the electrostatic potential and to the in-plane component of the magnetic induction in the sample integrated in the incident beam direction. The phase changes are given by integrating along the electron paths, although it should be noted that electric and magnetic fields may extend into the surrounding vacuum and may be of considerable extent, as shown in Figure 4. For the magnetic case, the beam is deflected perpendicular to both the incident electron beam direction and the magnetic field direction.

Neglecting dynamical diffraction effects (i.e., assuming that the sample is thin and weakly diffracting), the measured phase shift can be expressed in the form

$$\phi(x) = C_E \int V(x,z)\,dz - \left(\frac{e}{\hbar}\right) \int A_z(x,z)\,dz \qquad (19)$$

$$= C_E \int V(x,z)\,dz - \left(\frac{e}{\hbar}\right) \iint B_\perp(x,z)\,dx\,dz \qquad (20)$$

where

$$C_E = \left(\frac{2\pi}{\lambda}\right)\left(\frac{E+E_0}{E(E+2E_0)}\right) \qquad (21)$$

z is the incident electron beam direction, x is a direction in the plane of the sample, A_z is the component of the magnetic vector potential **A** in the beam direction, $B_\perp$ is the component of the magnetic induction in the sample perpendicular to both x and z, V is the electrostatic potential, λ is the (relativistic) electron wavelength, and E and E_0 are, respectively, the kinetic and rest mass energies of the incident electron [66]. The energy-dependent constant C_E has the value 7.29×10^6, 6.53×10^6, and 5.39×10^6 rad V^{-1} m^{-1} at microscope accelerating voltages of 200 kV, 300 kV, and 1 MV, respectively. (The refractive index of a TEM sample for high-energy electrons is only slightly larger than unity; the phase shift is appreciable because of the small wavelength of the electron.)

In addition to electrostatic fields associated with the long-range redistribution of charge (e.g., at depletion layers in semiconductors [67]), the dominant contribution to the electrostatic potential is from the mean inner potential, which depends on the local composition and density in the sample, as will be discussed.

If neither V nor $B_\perp$ varies in the incident beam direction, then Eq. (20) can be simplified to

$$\phi(x) = C_E V(x)t(x) - \left(\frac{e}{\hbar}\right) \int B_\perp(x)t(x)\,dx \qquad (22)$$

where t is the sample thickness. Differentiation with respect to x then leads to

$$\frac{d\phi(x)}{dx} = C_E \frac{d}{dx}\{V(x)t(x)\} - \left(\frac{e}{\hbar}\right)B_\perp(x)t(x) \qquad (23)$$

In a sample of uniform thickness and composition, the first term in Eq. (23) disappears and the phase gradient is

directly proportional to the in-plane component of the magnetic induction

$$\frac{d\phi(x)}{dx} = \left(\frac{et}{\hbar}\right)B_{\perp}(x) \tag{24}$$

A direct representation of the magnetic induction in the sample is then readily obtained by adding contours to the phase image, as shown in Figure 4. These contours correspond to magnetic line of force, along which $\int \mathbf{B} \cdot d\mathbf{S} = 0$. The fact that phase differences of 2π between adjacent contours correspond to $\int \mathbf{B} \cdot d\mathbf{S} = (h/e) = 4 \times 10^{-15}$ Wb provides the basis for the measurement of magnetic fields on an absolute basis. Subject to the limitations of signal-to-noise, smaller phase differences can be measured by decreasing the spacing of the contours obtained from the phase image.

An experimental phase image does not need to be unwrapped in order to evaluate its first differential for use in Eq. (24). In fact, the phase differential can be calculated directly from the reconstructed image wave (the inverse Fourier transform of the sideband selected from the Fourier transform of the hologram) without any introduction of artificial phase "wraps". If the real and imaginary parts of the reconstructed image wave are designated $\text{Re}(\psi)$ and $\text{Im}(\psi)$, then two of the possible ways of calculating the phase differential in the x-direction directly from the image wave are given by the expressions

$$\frac{d\phi}{dx}\left(\frac{\text{Re}(\psi)\frac{d}{dx}\text{Im}(\psi) - \text{Im}(\psi)\frac{d}{dx}\text{Re}(\psi)}{\text{Re}(\psi)^2 + \text{Im}(\psi)^2}\right) \tag{25}$$

and, more simply,

$$\frac{d\phi}{dx} = \text{Im}\left(\frac{\frac{d}{dx}\psi}{\psi}\right) \tag{26}$$

1.6. Limitations

A major restriction of electron holography is that holograms are usually processed off-line so that dynamic events cannot be followed in real time [68–70]. Moreover, the field of view is typically limited to about 5 μm (unless a wide field, low magnification mode with the objective lens weakly excited is used [71]), either by the dimensions of the recording medium (e.g., the finite size of the CCD array) and the sampling of the holographic fringes or by the width of the fringe overlap region if the electron-optical magnification and the biprism voltage are reduced.

1.6.1. Contrast and Noise

Loss of interference fringe contrast occurs because of finite source size, beam energy spread, stray magnetic fields, the mechanical stability of the biprism wire, and the point spread function of the recording medium. The contrast of holographic interference fringes is determined largely by the lateral coherence of the electron wave at the specimen level. As a result, the contrast decreases when the voltage on the biprism wire is increased, and as the interference fringe spacing decreases. Experimentally, the biprism voltage is increased, first, to achieve a large field of view, second, to minimize the influence of the Fresnel fringes from

the edges of the wire (which are independent of biprism voltage), and third, to minimize the fringe spacing to obtain the best spatial resolution in the reconstructed phase image. The decrease in fringe contrast is usually incorporated into Eq. (12) in the form

$$I_{\text{hol}}(\mathbf{r}) = 1 + A_i^2(\mathbf{r}) + 2\mu A_i(\mathbf{r})\cos[2\pi\mathbf{q_c} \cdot \mathbf{r} + \phi_i(\mathbf{r}) + \theta] \tag{27}$$

where μ is referred to as the fringe contrast or visibility and θ represents an arbitrary phase offset that is independent of position.

The standard experimental method of determining fringe visibility involves taking a line trace across a holographic interference fringe pattern that has been recorded in the absence of a sample. μ is then defined according to the relation

$$\mu = \left(\frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}\right) \tag{28}$$

where $I_{\max}$ and $I_{\min}$ are the maximum and minimum intensities of the interference fringes, respectively, in a part of the hologram where the Fresnel fringes from the biprism can be neglected [72]. An alternative method of determining μ involves applying a Hanning window to the hologram, taking its Fourier transform, and then measuring the heights of the central peak and the two sidebands. The fringe visibility is then defined as twice the amplitude of the sidebands divided by the amplitude of the central peak [32, 73]. Although the fringe visibility should be as close to its theoretical maximum value of unity as possible, some decrease in μ is inevitable. Should it decrease too much, no reconstruction of the image wavefunction will be possible.

The spatial resolution of a phase image is determined primarily by the choice of magnification and the biprism voltage used. The interference fringe spacing varies inversely with biprism voltage and depends on the accelerating voltage, the focal length of the objective lens, and the distance between the back focal plane of the objective lens and the biprism wire [74, 75]. The phase detection limit [76] for electron holography is often determined by the signal-to-noise ratio of the recorded phase image, which may be low because of the weak intensity of the signal being measured. Off-axis electron holograms are typically recorded at electron doses of 100–500 electrons per pixel, so the recording process is dominated by Poisson-distributed shot noise [48, 77]. The recorded hologram is also affected by the detection quantum efficiency of the CCD camera (the spatial-frequency-dependent ratio of the squared signal-to-noise ratios at the output and the input of the camera, where the squared signal-to-noise ratio at the input is equal to the number of electrons incident on the pixel [28]) and the fringe visibility, which is in turn affected by parameters such as the illumination diameter, exposure time, and biprism voltage. The recording medium may have a detrimental effect on the recording process; film has a nonlinear response and a finite grain size, whereas digital recording involves a finite pixel size and strong attenuation of higher spatial frequencies due to the point spread function of the detector [78].

The minimum phase difference between two pixels that can be detected is given by the expression

$$\Delta\phi_{\min} = \frac{\text{SNR}}{\mu}\sqrt{\frac{2}{N_{\text{el}}}} \tag{29}$$

where SNR is the signal-to-noise ratio, μ is defined in Eq. (28), and N_{el} is the number of electrons collected per pixel [79]. In practice, some averaging of the measured phase image is often implemented, particularly if the features of interest vary slowly across the image or only vary in one direction (e.g., in a layered cross-sectional sample).

1.6.2. Artifacts

The effects of Fresnel diffraction at the biprism wire can cause phase and amplitude modulations of both the image and the reference wave [80]. These disturbances can be removed to some extent by using a reference hologram, although the positions of the Fresnel fringes in the sample and reference holograms are not always identical. They can also be minimized by using the undistorted part of a broader hologram for recording and reconstruction. Residual effects can be removed by Fourier filtering the sideband before reconstructing the image wave or, alternatively, by making use of criteria such as the fact that a recorded magnetic signal must satisfy the Laplace equation [81].

A further geometrical effect known as vignetting results from the fact that a thin strip of the hologram close to the shadow of the biprism wire contains only single-sideband information about certain spatial frequencies because of screening by the biprism. The object wave in this region cannot be determined uniquely, and the reconstructed wave should be interpreted with care. The width of the hologram that is free from vignetting is

$$W_{\text{free}} = W\left(1 - \frac{q_{\max}}{q_c}\right) - 2R\frac{f}{d_1}\left(\frac{q_{\max}}{q_c}\right) \tag{30}$$

where W is the full width of the hologram [82]. In this expression, $q_{\max}$ is the maximum spatial frequency to be recorded, q_c is the carrier fringe frequency, R is the biprism radius, f is the objective lens focal length, and d_1 is defined in Figure 1a. The second term is usually much smaller than the first, and so for $q_c = 3q_{\max}$ only 2/3 of the hologram is free from vignetting. However, if the maximum frequency of interest is oversampled, as is usually the case for medium resolution electron holography of electric and magnetic fields, then this problem is easily minimized. The use of a window of finite size to select the sideband may also lead to artifacts around the outer edges of the reconstructed phase image. Analysis indicates that about three-quarters of the field of view should be reconstructed correctly [82].

2. MEASUREMENT OF MEAN INNER POTENTIAL AND SAMPLE THICKNESS

Electron holography has been widely used to obtain medium-resolution information about sample morphology and composition. In this section, we consider phase changes that are associated solely with local variations in mean inner potential and sample thickness. The characterization of magnetic and electrostatic fields is considered in the following Sections 3 and 4.

The mean inner potential, V_0, is defined as the volume average, or the zero-order Fourier coefficient, of the electrostatic potential in a material [83]. It can be written in the form

$$V_0 = \left(\frac{1}{\Omega}\right)\int_{\Omega} V(x, y, z)\, dx\, dy\, dz \tag{31}$$

where Ω is the volume of the region over which the integral is evaluated. V_0 is proportional to the second moment of the atomic charge density and can be calculated from its mean square radius [84, 85]. Exchange and correlation contributions to the potential are negligible for high-energy electrons [86], and the measured mean inner potential can be regarded as a basic property of the material and not of the electrons that are used to probe it. For low-energy electrons, exchange and correlation effects cannot be neglected, and the mean inner potential varies with the energy of the incident electrons [87–89].

In the absence of magnetic and long-range electric fields (such as those occurring at depletion regions in semiconductors), and assuming that dynamical diffraction effects can be neglected, Eq. (19) can be rewritten as

$$\phi(x) = C_E \int V_0(x, z)\, dz \tag{32}$$

where x is in the plane of the sample, z is the incident electron beam direction, and C_E is defined in Eq. (21). If the sample has uniform structure and composition in the electron beam direction, then Eq. (32) reduces further to

$$\phi(x) = C_E V_0(x) t(x) \tag{33}$$

where t is the sample thickness. Equations (32) and (33) are kinematical expressions because they ignore multiple scattering in the sample and are therefore only applicable to crystalline samples when they are tilted to a weakly diffracting orientation.

Electron holography provides the most accurate technique currently available for measuring the mean inner potential of a sample through the use of Eq. (33), but an independent measure of the sample thickness is required. The most straightforward sample that can be used is either a cleaved wedge or a spherical particle of known size and geometry, in which the thickness changes in a well-defined manner as a function of distance from the edge of the sample. This behavior is shown in Figure 7a for a line phase profile obtained from a 90° crystal wedge of GaAs that has been tilted to a weakly diffracting orientation. The procedure that is used to determine V_0 from such a profile is described in Section 2.2.

2.1. Calculation of Mean Inner Potential

The simplest approach that can be used to calculate V_0 is to treat the sample as though it contains an array of neutral, free atoms. In this "nonbinding" approximation, Eq. (31)
Figure 7. (a) Phase profile plotted as a function of distance into the sample, obtained from a 90° GaAs cleaved wedge tilted away from zone axes and systematic row orientations. The phase change increases approximately linearly with sample thickness, as predicted kinematically. (b) Equivalent phase profile obtained from a GaAs wedge tilted close to a [100] zone axis. Strong dynamical effects make the phase change nonlinear. Reprinted with permission from [90], M. Gajdardziska-Josifovska and A. Carim, in "Introduction to Electron Holography" (E. Völkl, L. F. Allard, and D. C. Joy, Eds.), p. 270. Kluwer Academic/ Plenum, New York, 1998. © 1998, Kluwer Academic/Plenum.

can be rewritten in the form

$$V_0 = \left(\frac{h^2}{2\pi me\Omega}\right)\sum_{\Omega} f_{el}(0) \tag{34}$$

where $f_{el}(0)$ is the electron scattering factor at zero scattering angle for each atom in volume Ω [$f_{el}(0)$ is approximately proportional to atomic number Z] and Ω is the summation volume (typically a single unit cell for a crystalline material) [90, 91, 101]. Values of $f_{el}(0)$ for neutral atoms to be included in Eq. (34) have been calculated from relativistic atomic wavefunctions, most recently by Doyle and Turner [92] and Rez et al. [93], in both tabulated and parameterized forms. Earlier calculations (e.g., [94, 95]) are occasionally also referred to. The electron scattering factors of Rez et al. [93], which were converted from X-ray scattering factors calculated using the multiconfiguration Dirac–Fock code of Grant et al. [96] and the Mott formula, are within 0.1% of the values calculated by Doyle and Turner [92].

2.1.1. Ionicity and Bonding

A limitation of the "nonbinding" approximation (i.e., the use of neutral atom scattering factors) is that calculated values of V_0 are overestimated because the redistribution of valence electrons due to bonding (which typically results in a contraction of the average electron density around each atom) is neglected. Radi [97] considered this nonbinding approximation as an upper limit to the true value of the mean inner potential. A lower limit for V_0 can be calculated by assuming that the crystal contains ions at the lattice

points, with the remaining valence electrons distributed uniformly. The contribution of p free electrons to V_0 is given by the expression

$$V_0 = \left(\frac{3}{10}\right)\left(\frac{ep}{4\pi\varepsilon_0 r_0}\right) \tag{35}$$

where r_0 is chosen so that a sphere of radius r_0 has the same volume as the atom within the crystal [98]. A lower limit for V_0 is then provided by the sum of V_0 calculated for a p-times-ionized free atom (with the p outermost electrons of the neutral atom missing) and V_0 calculated for p free electrons using Eq. (35). Lower bound values calculated using this approach have been compiled by Gajdardziska-Josifovska and Carim [90] for both elemental and compound crystals and are reproduced in Tables 1 and 2, respectively. Table 1 also provides nonbinding values of V_0 calculated using the scattering factors of both Radi [93] and Doyle and Turner [92]. Differences between the two sets of values presumably arise because they are calculated using different scattering factors. The upper and lower limits for V_0 are plotted for a wide range of elements in their solid state in Figure 8a. The graph is plotted as a function of mean atomic number per unit volume because, according to Eq. (34), V_0 is expected to be approximately proportional to this parameter.

An empirical rule for evaluating the influence of bonding on V_0 has been proposed by Ross and Stobbs [91]. By analyzing the ratio between values of V_0 calculated using the scattering factors of Doyle and Turner [92] and Radi [93] (the average of the upper and lower limits given in Table 1), which is plotted as a function of mean atomic number per unit volume in Figure 8b, the following phenomenological dependence was found,

$$\frac{V_0(\text{Radi})}{V_0(\text{Doyle–Turner})} \approx 0.0325\frac{Z}{\Omega} + 0.6775 \tag{36}$$

where Z is atomic number and Z/Ω is given in units of 10^3 nm^3. Equation (36) provides a procedure for calculating an approximate value of V_0 that includes the effects of bonding by starting from Eq. (35), and subsequently using Eq. (36) to include the effects of charge redistribution. Figure 8b shows that the effect of bonding on V_0 decreases with increasing atomic number density.

2.2. Measurement of Mean Inner Potential

Experimental measurements of V_0 reported in the literature are sparse in number, and the scatter in the quoted values is wide. Values obtained using both refraction and phase-shifting techniques have been compiled by Gajdardziska-Josifovska and Carim [90] and are reproduced in Table 3. A similar table has been published by Spence [83]. Electron holography permits much greater accuracy to be obtained.

One approach to measure V_0 has used electron holograms of 20–40 nm diameter Si nanospheres coated in layers of amorphous SiO_2 [99]. The contribution to the phase images from the uniform SiO_2 overlayer can be separated from the contribution of the Si core if the particle is assumed to be exactly spherical, yielding measurements of the mean inner potential for both the surface layer and the core. Using

Note the difference between the nonbinding values for V_0 resulting from the use of different neutral atom scattering factors.

this approach, the mean inner potential of crystalline Si was found to be 12.1 ± 1.3 V, that of amorphous Si 11.9 ± 0.9 V, and that of amorphous SiO_2 10.1 ± 0.6 V. Similar measurements obtained from spherical latex particles embedded in vitrified ice have provided values of V_0 of 8.5 ± 0.7 and 3.5 ± 1.2 V for the two materials, respectively [100].

In principle, V_0 can be determined from phase profiles such as that shown in Figure 7a by measuring the gradient

[a] Radi [97] gives a nonbinding value of 16.23 V only for MgO.

of the phase $d\phi/dx$ and then making use of the relation

$$V_0 = \left(\frac{1}{C_E}\right)\left(\frac{d\phi/dx}{dt/dx}\right) \tag{37}$$

This approach, which is independent of any contributions to the phase shift from amorphous overlayers on the sample surfaces (for which $dt/dx = 0$ if these layers are of uniform thickness), has been used successfully to measured the mean inner potentials of cleaved wedges and cubes of Si, MgO, GaAs, PbS [101, 102], and Ge [103]. The values of V_0 determined for MgO, GaAs, PbS, and Ge using this approach are 13.0 ± 0.1, 14.5 ± 0.2, 17.2 ± 0.1, and 14.3 ± 0.2 V, respectively [101, 103]. In these studies, the value of an independent measure of sample thickness using a technique such as weak-beam dark-field imaging cannot be overemphasized. This need arises because semiconductor materials such as Si or Ge that appear to have cleaved on ⟨110⟩ planes may have different thickness profiles at their very edges [103]. Such variations in wedge angle most likely account for the anomalous value of the mean inner potential of Si reported in the literature [101].

In a similar study, wedge-shaped Si samples with stacked Si oxide layers on their surfaces have been used to measure the mean inner potentials of the oxide layers [104]. Values of 10.51 ± 0.35, 10.65 ± 0.32, 11.19 ± 0.38, and 10.58 ± 0.69 V were measured for undensified thermal oxide, densified thermal oxide, undensified deposited oxide, and densified deposited oxide, respectively. Chemical etch rate differences between the oxide layers were also used to provide thickness differences between different oxide layers, which could be recorded using electron holography. The widths of silicon oxide–nitride–oxide layers have also been measured using electron holography [105].

2.2.1. Dynamical Effects

In practice, dynamical contributions to the phase should be evaluated and taken into account when determining V_0 from a crystalline sample such as a cleaved semiconductor wedge, even when the phase profile is as linear as that shown in Figure 7a [106]. These corrections can be calculated using either multislice or Bloch wave algorithms and are still required even when an electron hologram has been acquired at a supposedly weakly diffracting orientation for greatest

a

b

Figure 8. The effect of bonding on calculated values of mean inner potential V_0. (a) V_0 plotted as a function of mean atomic number per unit volume. All elements from $Z = 3$ to 90 are shown in their solid state. The small filled circles are "free-atom" values calculated using the scattering factors of Doyle and Turner [92], while the squares are values calculated according to Radi [97] using an approximation for bonding in which n electrons per atom (see key) are assumed to be free. Each square is joined by a line to the value calculated by Radi [97] assuming free-atom wavefunctions, which should be comparable to the Doyle and Turner [92] values. Experimentally measured values of V_0 for Si, Al, Ge, Cu, Au, and W are also shown. (b) Ratio of the values of V_0 calculated according to Radi [97] [the average of the two values given in (a)] to those calculated according to Doyle and Turner [92]. There is a trend for this ratio to increase with atomic number density. The structure of each crystal is given by the following symbols. Filled circle: face-centered cubic (fcc); open square: hexagonal close-packed (hcp); plus sign: body-centered cubic; and open circle: diamond structure. Reprinted with permission from [91], F. M. Ross and W. M. Stobbs, *Philos. Mag. A* 63, 37 (1991). © 1991, Taylor and Francis Ltd.

possible accuracy. It is essential to record the precise orientation of a crystalline sample when the hologram is acquired, using a technique such as convergent beam electron diffraction [101, 103]. For measurements obtained from crystalline Ge at several weakly diffracting orientations, dynamical corrections to V_0 were found to be typically between 0.1 and 0.2 V [103].

The fact that Eq. (34) is no longer valid when the sample is tilted to a strongly diffracting orientation is shown in Figure 7b for a GaAs 90° cleaved wedge sample tilted to a $\langle 110 \rangle$ zone axis. The measured phase shift now varies nonlinearly with sample thickness and is extremely sensitive to small changes in sample tilt from the exact zone axis

Values in brackets were obtained using other techniques, predominantly based on measurements of refraction effects in electron diffraction patterns.

orientation. If a strong two-beam condition is set up, then it is possible to measure both V_0 and V_g using electron holography [38].

Additional experimental factors that may affect measurements of V_0 include the presence of electrical dipoles at sample surfaces, which are sensitive to the chemical and physical state of the surface and its crystallographic orientation [107, 108] and unwanted charging of the sample surface, which has been observed directly using electron holography

for a wide range of materials that include semiconductors and sapphire [109].

2.3. Measurement of Sample Thickness and Morphology

If the mean inner potential of a sample is constant, and if dynamical contributions to the contrast are small, then Eq. (33) indicates that a phase image can be used to provide a map of the projected thickness of the sample. Electron holography can be used to study surface topography and the shapes of nanoparticles.

The local sample thickness $t(x)$ can be inferred from a holographic amplitude image in units of λ_{in}, the mean free path for inelastic scattering, using the equation

$$\frac{t(x)}{\lambda_{in}} = -2\ln\left(\frac{A_i(x)}{A_r(x)}\right) \qquad (38)$$

where $A_i(x)$ and $A_r(x)$ are the measured amplitudes of the sample and reference holograms, respectively [110]. (Although the information in the sideband of an electron hologram is, in principle, perfectly energy filtered, the degree to which inelastically scattered electrons interfere with each other and with a vacuum reference wave has recently been debated [111–114].) One disadvantage of using Eq. (38) to measure the sample thickness is that the recorded amplitude image is always more noisy than the corresponding phase image. In addition, the value of λ_{in} may be unknown, and this parameter is different for each material in the sample and depends on the objective aperture size used. Values of λ_{in} can, on occasion, be measured from samples of known geometry. For example silicon and polystyrene nanospheres were analyzed to give values of λ_{in} for Si of 88.6 ± 6.9 and 53.8 ± 5.5 nm at 200 and 120 kV, respectively, and corresponding values for polystyrene of 113.0 ± 5.9 and 78.1 ± 3.4 nm [115].

Whether the sample thickness profile is measured from a phase image or an amplitude image, interpretation may be complicated if the sample has nonuniform composition. Most TEM sample preparation methods yield nonuniform sample thickness profiles. For example, defects and interfaces between materials often thin at a different rate to the material that surrounds them. If necessary, the thickness dependence of the phase and amplitude images can be removed by combining Eqs. (33) and (38). This approach results in the expression

$$\frac{\phi(x)}{-2C_E\ln\left(\frac{A_i(x)}{A_r(x)}\right)} = V_0(x)\lambda_{in}(x) \qquad (39)$$

Equation (39) can be used to generate an image that has contrast equal to the product of the local values of the mean inner potential and the inelastic mean free path [110]. Both parameters depend only on the local composition of the sample. This approach has been used to interpret images obtained from samples with varying compositions but unknown thickness variations, including multilayers of amorphous Si and polycrystalline Mo [116] and interfaces between amorphous Si and SiN_x [117].

Alternatively, if the composition of a sample is required, an approach based on electron holography and an (002) chemically sensitive reflection in a sphalerite-type material has been proposed [118, 119]. The phase of the (000) beam from the sideband of a high-resolution electron hologram acquired slightly away from a axis orientation, and the amplitude of the chemically sensitive (002) beam, are used together to evaluate both the local composition and the local thickness of the sample.

2.3.1. Fine Particles

The morphology of a wide range of fine particles has been studied by electron holography by making use of Eq. (33). The projected thickness of a polyhedral particle provides information about the locations and sizes of the particle's edges and faces without the need to tilt the sample to multiple zone axes, although complications may arise because of the unknown relative inclinations of the entrance and exit surfaces. A significant advantage of examining small particles (in particular those below 50 nm in diameter) is that dynamical contributions to the phase are more likely to be small. When examining magnetic particles in low-field conditions, the mean inner potential and magnetic contributions to the phase must still be separated.

Figure 9a shows a high-resolution lattice image of a 15 nm cuboctahedral ZrO_2 crystal that has {111} and {001} faces [90, 120]. Schematic diagrams of the expected shape and [110] projection of the crystal are shown in Figure 9b. A reconstructed electron holographic phase image of the particle, and line profiles obtained across different sections of the phase image, are shown in Figure 9c–g and are consistent with the expected geometry. A void within the particle is apparent in one of the profiles (Fig. 9g). Similar surface structures and internal voids have been reported for 5–15 nm Pd particles supported on amorphous silica spheres [121–124].

Electron holography has been applied to the study of cubic single crystals of MgO, which have {100} faces and are produced by burning magnesium wire or ribbon and collecting the resulting smoke (e.g., [120, 125–127]). Further applications of holographic phase imaging have included the formation of 1.3 nm thickness contours on a 200 nm Be particle by making use of 32-times phase amplification [127] and the examination of carbon nanotubes [128, 129], voids in Si [130, 131], SiGe quantum dots [132], the tobacco mosaic virus [133], bacterial flagellae [134], strands of DNA [135], and both organic polymers and mesoporous silica [136].

2.3.2. Surface Steps

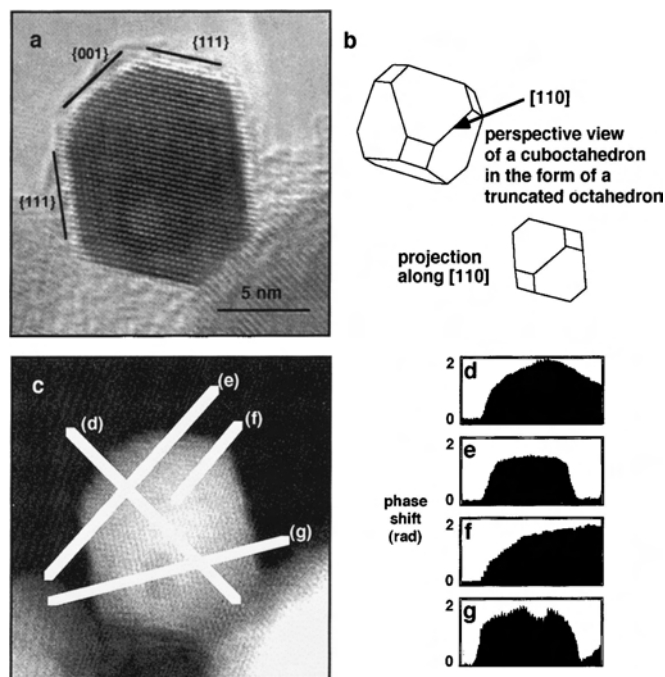
A subtle use of phase imaging with electron holography involves the examination of atomic-height steps on clean surfaces. Figure 10 shows a 24-times phase-amplified interference micrograph of a molybdenite (MoS_2) thin film [137]. In this image, thickness changes due to steps of height five, three, and one atomic layers are observed at positions A, B, and C, respectively. The fringe shift at C corresponds to a thickness change of 0.62 nm, which is the height of a single growth step. Similar observations have been performed by using reflection off-axis electron holography to examine Pt (111) surfaces [138, 139] and strain fields around screw


Figure 9. (a) High-resolution lattice image of an apparently cubocta-hedral ZrO_2 particle. (b) Sketch of the corresponding cuboctahedral shape and its expected [110] projection. (c) Phase image reconstructed from a hologram of the particle shown in (a). Line profiles across different sections of the phase image are shown in (d), (e), (f), and (g). Each profile starts at the label end of the corresponding line in (c). All are consistent with the postulated geometry, with the exception of one area where there is a void in the particle, as seen in (g). Reprinted with permission from [90], M. Gajdardziska-Josifovska and A. Carim, in "Introduction to Electron Holography" (E. Völkl, L. F. Allard, and D. C. Joy, Eds.), p. 292. dislocations on GaAs {110} surfaces [140]. This approach involves formation of the reference wave by the reflection of electrons from an atomically flat part of the surface. The object wave is then formed from parts of the surface that contain the features of interest, an objective aperture is used to select the specularly reflected beam, and a biprism is used to superimpose the reference and object waves. A related experiment has involved the examination of the surface

Lett.* 54, 60 (1985). © 1985, American Physical Society.

potential of MgO in cross-section at atomic resolution using electron holography [141].

2.3.3. Three-Dimensional Information

Electron tomography has been used widely in the biological sciences to recover the three-dimensional structures of bacteria, viruses, and other macromolecules from tilt series of two-dimensional images [142, 143]. The technique is starting to be applied in the physical sciences, primarily using annular dark field imaging [144, 145]. By acquiring successive holograms over a range of tilts, electron tomography can be combined with electron holography to allow sample morphology to be determined directly in three dimensions based on tilt series of phase images. Figure 11a shows an individual electron hologram of three latex particles taken from a tilt series of holograms obtained in 5° steps between ±60°. Two views of the reconstructed three-dimensional shapes of the particles obtained after applying tomographic techniques to the tilt series are shown in Figure 11b and c [146]. Despite the successful demonstration of the combination of electron tomography with electron holography shown in Figure 11, the techniques are still rarely applied together because the acquisition, processing, and alignment of a large number of holograms is necessarily time-consuming. Considerable patience and care are required since maximum sample tilt angles of at least ±60°, small tilt steps (ideally every 2° or less), and accurate alignment of the phase images are all essential to avoid reconstruction artifacts.

3. MAGNETIC FIELDS IN NANOSTRUCTURED MATERIALS

The most successful and productive applications of electron holography have involved the characterization of magnetic fields both within and surrounding materials. This work has followed primarily from the pioneering work carried out in the 1980s by the research group of Tonomura, which has been the subject of several monographs and review articles (e.g., [7, 8, 35, 147–151]). Many alternative techniques exist for the characterization of magnetic microstructure in the electron microscope [152]. These techniques include the Fresnel and Foucault modes of Lorentz microscopy

[153–161], coherent Foucault imaging [162], and differential phase contrast imaging in the scanning transmission electron microscope (STEM) [163–167]. Each of these techniques is best applied to a particular type of magnetic material. More general literature on the subject of electron microscopy of magnetic materials should be consulted for further detailed information (e.g., [168, 169]).

3.1. Results Obtained Using Optical Reconstruction

Results for magnetic materials obtained using optical reconstruction of off-axis electron holograms acquired on photographic film are reviewed in this section. Applications using digital reconstruction are discussed separately below. This distinction between optical and digital reconstruction is made primarily to highlight the different ways in which holograms can be analyzed and interpreted using the two approaches and to emphasize the different types of results obtained.

3.1.1. Fringing Fields in Vacuum

Figure 12 illustrates two examples where electron holography has been used to characterize magnetic fringing fields that extend into vacuum. In such experiments, no

Figure 12. (a) Interference micrograph obtained from a hologram of microscopic horseshoe magnets (chevron patterns) from the propagation circuit of a bubble memory made from permalloy (Ni 80% Fe 20%), supported on a thin C film. The period of the chevron is 8 μm and its thickness is 350 nm. A 20 Oe magnetic field was applied to the sample during hologram acquisition in the direction shown in the figure. Reprinted with permission from [170], T. Matsuda et al., *J. Appl. Phys.* 53, 5444 (1982). © 1982, American Institute of Physics. complications arise from contributions to the measured phase shift from variations in sample composition or thickness. However, care is required when interpreting these types of results because magnetic leakage fields outside TEM samples are three-dimensional. In contrast, electron holography only records a projection in the electron beam direction of the components of the magnetic induction B that lie in the plane of the sample. Thus, comparisons with micromagnetic simulations may be necessary before quantitative statements can be made about the results.

The two-times phase-amplified interference micrograph shown in Figure 12a was obtained from a hologram of a line of microscopic horseshoe magnets, which were part of the propagation circuit of a bubble memory [170]. Each magnet is 350 nm in thickness, made from permalloy ($Ni_{0.8}Fe_{0.2}$), and supported on a thin C film. The period of the chevron pattern is 8 μm. A 20 Oe magnetic field was applied to the sample during hologram acquisition in the direction shown. The contours, which are separated by a constant magnetic flux of $h/2e$, show the magnetic lines of force that leave one end of each magnet, being directed both to its neighbor and to a smaller extent in the opposite direction. The magnetic field strength in the gap between adjacent magnets is estimated from the contours to be in excess of 1000 Oe.

A similar interference micrograph, acquired from a 0.3 μm Fe wire that contains a single domain wall at its center [171], is shown in Figure 12b. A strong magnetic leakage field, which originates at the position of the domain wall, is visible outside the wire. A schematic diagram that illustrates the origin of the flux leakage associated with the domain wall is shown in Figure 12c.

Results equivalent to those shown in Figure 12 have been obtained from single Fe_2O_3 [172] and barium ferrite [173] particles. In the latter case, each particle could only support a single magnetic domain. As a result, the magnetic lines of force were no longer entirely contained within the particles. The leakage field was then clearly identified using electron holography.

3.1.2. Recorded Magnetic Tape

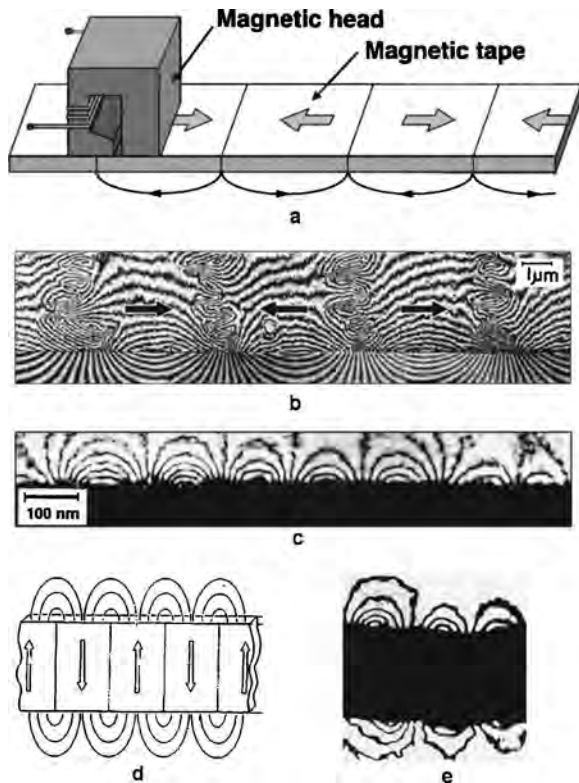
A practical application of electron holography, which required the characterization of magnetic microstructure within the sample as well as the leakage fields outside, involved the examination of magnetic fields in high-density magnetic recording media. Figure 13a shows a schematic diagram of the method used to record bits on a magnetic film. Figure 13b shows results obtained from an in-plane-recorded high-coercivity evaporated Co film that had a thickness of 45 nm, a coercive field of 340 Oe, and a bit length of 5 μm [174]. The sample was prepared by evaporating the Co film obliquely onto a glass substrate that had been coated with photoresist. The Co film was partly oxidized to control its coercive field and remanent magnetization, and the recording was performed using a ring-type magnetic head with a track width of 300 μm and gap lengths of 200 nm and 1 μm. The interference micrograph in Figure 13b shows the projected magnetic lines of force both inside and outside the film. The recorded track runs parallel to the film edge, the film is observed in the upper half of Figure 13b, and the lower half shows empty space. The magnetization


Figure 13. (a) Schematic diagram showing the method used to record bits on a magnetic film. (b) Interference micrograph formed from a holographic phase image of a 45-nm-thick recorded Co film with a bit length of 5 μm. The magnetic stray field in vacuum at the side of the thin film is visible at the bottom of the image. (c) Interference micrograph of a 30-nm-thick recorded Co film with a bit length of 0.15 μm, showing periodic stray fields in vacuum outside the edge of the sample. (d) Schematic diagram and (e) interference micrograph of a perpendicularly recorded 80-nm-thick Co–Cr film with a bit length of 0.25 μm. Reprinted with permission from [176], K. Yoshida et al., *IEEE Trans. Magn.* 23, 2073 (1987). © 1987, IEEE.

directions within the film are indicated by arrows. The maximum packing density for longitudinal recording in such films is limited by the widths of the transition regions between two oppositely magnetized regions. Oppositely magnetized regions in adjacent domains can be seen to collide with each other head-on to produce vortexlike patterns. The magnetic field then meanders to the edge of the film edge and leaks out into the vacuum. (Although stray fields above the film are read by the magnetic head, the contour lines visible at the bottom of Fig. 13b are at the side of the film.)

Figure 13c shows an interference micrograph obtained from an electron hologram of a 30-nm-thick Co film that had been recorded with a bit length of 0.15 μm [174]. Periodic stray fields are again visible in the vacuum outside the sample edge. The narrowest transition region that has been characterized using this approach is 100 nm. Corresponding results have been obtained from recorded CoCr films [175]. Figure 13d and e shows a schematic diagram and an interference micrograph, respectively, of the magnetic field emerging from both the top and the bottom surfaces of a

perpendicularly recorded 80-nm-thick Co–Cr film that has a bit length of 0.25 μm [176].

3.1.3. Fine Particles

Figure 14 shows representative results obtained by applying off-axis electron holography and optical reconstruction to particles of Co and permalloy. The Co fine particles shown in Figure 14a–d were prepared by gas evaporation of Co in an inert gas atmosphere [177]. Figure 14a shows a bright-field image of a 55-nm-thick plate-shaped Co particle, which has {111} surfaces and ⟨110⟩ edges and is uniform in thickness. In this image, only the outline of the particle can be

seen. In contrast, in the holographic interference micrograph that has been phase-amplified two times (Fig. 14b), contour lines are visible running parallel to the three edges of the particle. The outer, more closely spaced contours arise from sample thickness variations and can be used to show that the thickness of the particle increases rapidly at its edge to 55 nm. The inner, more widely spaced contours are magnetic lines of force, which are clearly visible in the region of the particle that is uniform in thickness. A flux of $(h/2e) = 2 \times 10^{-15}$ Wb flows between adjacent contours in Figure 14b. Although the particle consists of three distinct magnetic domains, the magnetic lines of force are almost circular since the particle radius is so small. Stray magnetic fields outside the particle are estimated to be small from the contour map. The widths of the three domain walls in the particle are measured to be 40 nm.

The contours in Figure 14b cannot be used to establish whether the magnetization in the particle rotates clockwise or counterclockwise. Instead, the rotation direction can be determined from an interferogram, which is obtained by tilting the reference beam during optical reconstruction (Fig. 14c). In Figure 14c, the interference fringes are displaced downward at the particle edges and downward further inside the particle. As an electron beam travels faster in the crystal than in vacuum and consequently has a shorter wavelength, the wavefront of the transmitted beam through the particle must be retarded. Depending on whether the magnetization is clockwise or counterclockwise, the beam is either further retarded or advanced. Analysis of Figure 14c shows that the magnetization direction in the particle is counterclockwise. If the particle was inverted inside the electron microscope, then the rotation direction would be reversed and the wavefront would be retarded rather than advanced. This behavior can be observed directly in Figure 14d, which shows an interferogram recorded from a triangular Co particle that has the opposite rotation direction of magnetization to the particle shown in Figure 14a–c [35]. Equivalent results from thinner triangular Co particles of similar size, which show simpler magnetization configurations, have also been obtained [170].

Figure 14e–g shows results obtained by applying optical holographic reconstruction to an array of 2 μm × 2 μm × 40 nm permalloy particles that have been fabricated directly onto an electron-transparent C film using electron beam lithography [178]. The particles are arranged in a square array of side 4 μm and are largely magnetically isolated from each other. A Lorentz micrograph (i.e., a Fresnel defocus image) of two of the particles, which is shown in Figure 14e, reveals the positions of domain walls as bright or dark lines for a four-closure domain and a seven-closure domain. A corresponding interference micrograph is shown in Figure 14f, and a schematic diagram showing the magnetic domain structure is shown in Figure 14g. The spacing of the contours in Figure 14f has been used to confirm that the in-plane magnetization of the particles is consistent with that of bulk permalloy. Similar results have been obtained as the domain structure evolves when a range of both in-plane and out-of-plane external fields is applied to the particles [178].

The interference micrographs presented in Figure 14 from both Co and permalloy particles show strong contrast at the particle edges, where the sample thickness, and therefore the measured phase, changes rapidly. Such compositional contributions to the contrast can be removed to leave just the magnetic signal of primary interest. Some of these approaches, which are straightforward to apply if holograms are recorded and analyzed digitally, are described in section 3.2.

3.1.4. Verification of the Aharonov–Bohm Effect

One of the most elegant scientific contributions of electron holography is the experimental confirmation of the Aharonov–Bohm effect [179]. The Aharonov–Bohm effect states that when an electron wave from a point source passes on either side of an infinitely long solenoid then a relative phase shift should occur between the two parts of the wave. This phase shift should be proportional to the magnetic flux flowing inside the coil and should occur as a direct result of the presence of vector potentials. The significance of the Aharonov–Bohm effect is that it provides the only observable phenomenon that confirms the physical reality of gauge theory. It implies that vector potentials are more fundamental physical quantities in quantum mechanics than electric and magnetic fields, and that electrons can be influenced by electromagnetic fields "without touching them."

A series of increasingly complicated and difficult electron holography experiments was performed in order to confirm the Aharonov–Bohm effect unambiguously. Initial measurements were obtained from iron whiskers [180–183]. Although the measured phase shifts across the whiskers agreed with predictions, the results received a skeptical reception since it was believed that magnetic stray fields around the whiskers, rather than vector potentials, were influencing the electron beam [184]. Subsequent experiments were performed on tiny toroidal permalloy (80% Ni, 20% Fe) magnets of various sizes that exhibited negligible magnetic flux leakage [185, 186]. These magnets were fabricated lithographically by vacuum-evaporation of the permalloy onto glass substrates covered with NaCl. They were then floated off in water onto 10-nm-thick C films. Electron holography observations involved the interference of electrons that passed through toroids of different sizes with electrons that passed outside them. Figure 15a shows an interferogram obtained from an electron hologram of a toroidal magnet prepared from a 40-nm-thick film of permalloy. The arms of the toroid are approximately 640 nm in width. [185]. The phase differences measured from results such as Figure 15a were proportional to toroid width and agreed with predictions. Critics still claimed, however, that the observed phase shifts were not due to the Aharonov–Bohm effect because the electron wave could penetrate the magnetic material and therefore interact with it directly [187].

In response, 20-nm-thick permalloy toroidal magnets were entirely covered with 300-nm-thick layers of superconducting Nb. The Nb was deposited both to prevent electrons from penetrating the magnetic material and to confine the magnetic flux by exploiting the Meissner effect. A scanning electron micrograph of a toroidal permalloy magnet covered with superconducting Nb is shown in Figure 15b, and a

The arms of the toroid are approximately 640 nm in width. Reprinted with permission from [185], A. Tonomura et al., *Phys. Rev. Lett.* 48, 1443 (1982). © 1982, American Physical Society. (b) Scanning electron micrograph of a toroidal permalloy magnet covered with superconducting Nb. (c) Schematic diagram of the structure of the sample. (d)–(g) Interferograms showing the existence of the Aharonov–Bohm effect. (d) and (e) are for a toroid in which the magnetic flux is quantized below T_c in units of $n(h/2e)$, where n is even. For (f) and (g), n is odd. For (d) and (f), $T = 15$ K, whereas for (e) and (g) $T = 5$ K (phase amplification × 1). Reprinted with permission from [188], N. Osakabe et al., *Phys. Rev. A* 34, 815 (1986). © 1986, American Physical Society.

schematic diagram of the structure is shown in Figure 15c. It was estimated that a negligible proportion ($\sim10^{-6}$) of the electron wave should see the magnetic field coherently in such a toroid. Holograms were obtained using a liquid–helium temperature specimen stage [188, 189]. Each toroid was attached to a Nb plate to cool it effectively and covered with a thin layer of Au or Cu to discount the effects of contact potential differences in the sample. The observations, which are summarized in Figure 15d–g, showed that the measured phase difference became quantized to a value of 0 or π when the temperature was reduced below the superconducting critical temperature for Nb (5 K), that is, when a supercurrent was induced to circulate in the magnet. An even number of flux quanta ($h/2e$) trapped in the toroid corresponded to a phase shift of 0 when the Nb was super-

conducting (Fig. 15e), while an odd number corresponded to a phase shift of π (Fig. 15g). Figure 15d and f shows corresponding images obtained at a temperature of 15 K, when the Nb was no longer superconducting and flux quantization no longer occurred. The observed quantization of magnetic flux and the measured phase differences with the magnetic field entirely screened by the superconductor provided final confirmation of the Aharonov–Bohm effect.

3.2. Results Obtained Using Digital Reconstruction

Electron holography studies of magnetic materials that have involved the digital acquisition, reconstruction, and analysis of electron holograms are now presented. Digital approaches are often more suitable for many applications, either because of the small feature size or because the sample exhibits rapid variations in thickness or composition. Digital analysis can be readily used to separate the magnetic and mean inner potential contributions to the measured holographic phase, particularly at the edges of nanostructured elements where rapid changes in sample thickness are likely to dominate the measured phase and phase gradient. Digital analysis also facilitates the construction of line profiles from phase images, which can then provide quantitative information such as the widths of domain walls.

The magnetic contribution to the measured holographic phase shift for a nanostructured material is much smaller than the mean inner potential contribution, as inferred from Eq. (22). Neglecting any return flux associated with magnetic leakage fields, the magnetic contribution to the phase shift is proportional to the width of a small magnetic element, whereas the mean inner potential contribution to the phase shift of an element of the same thickness is independent of its lateral dimensions. For a small magnetic element of width a, the ratio of the magnetic to the mean inner potential contributions to the phase shift is given by the expression

$$\frac{\Delta\phi_{MAG}}{\Delta\phi_{MIP}} = \frac{eB_\perp a}{\hbar C_E V_0} \tag{40}$$

which is directly proportional to the width of the element.

3.2.1. NdFeB Hard Magnets

Hard magnetic materials such as NdFeB alloys have large magnetic remanence and high coercivity, which lead to many practical applications. Figure 16a shows a Lorentz (Fresnel defocus) image of a die-upset $Nd_2Fe_{14}B$ sample that was prepared for electron microscopy by standard dimpling and ion-milling [190–192]. The serpentine and "Y"-shaped domains that extend to the sample edge are similar to those previously observed at grain boundaries in sintered NdFeB [193]. An electron holographic phase image obtained from the same area of the sample is shown in Figure 16b. Figure 16a and b was recorded at room temperature using a Philips CM200 FEG-TEM operated at 200 kV in Lorentz mode, and the electron hologram had an interference fringe spacing of 2.5 nm.

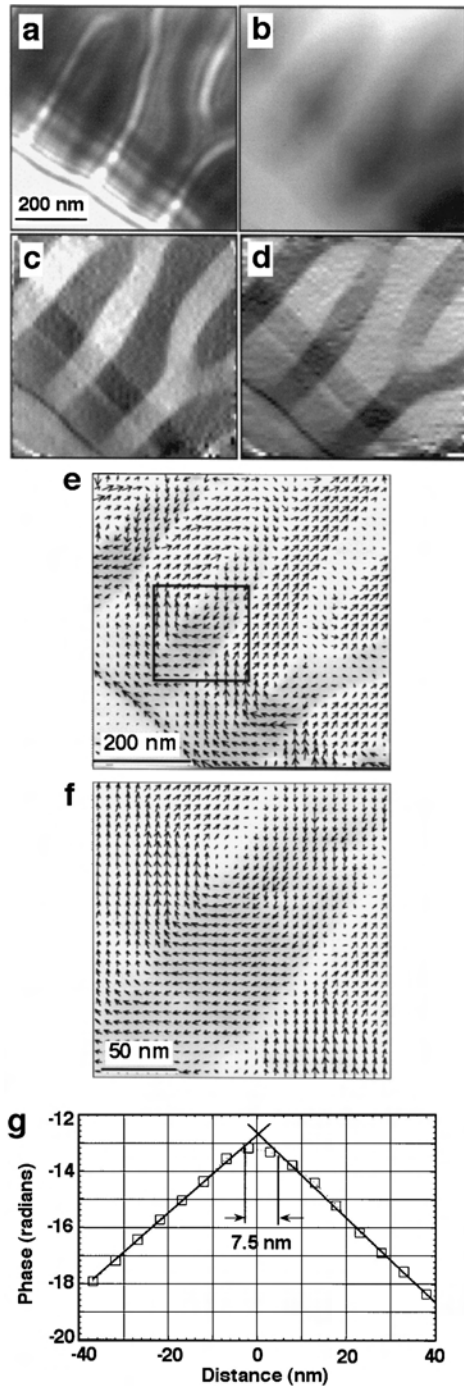
In order to map the magnetic induction in the sample, gradients of the phase image were calculated digitally along the $+x$ and $-y$ directions, as shown in Figure 16c and d,


Figure 16. (a) Room temperature Lorentz (Fresnel underfocus) image of a die-upset $Nd_2Fe_{14}B$ hard magnet, recorded at 200 kV using a Philips CM200 FEG-TEM operated in Lorentz mode. (b) Phase image of the same area of the sample reconstructed from an electron hologram obtained using an interference fringe spacing of 2.5 nm. (c) and (d) Gradients of the phase image shown in (b), calculated along the $+x$ and $-y$ directions, respectively. (e) Induction map derived from the phase gradients shown in (c) and (d). (f) Enlargement of the area indicated in (e), showing singularities and domain wall character. (g) Line scan obtained from the phase image shown in (b) across a 90° domain wall that appears as a bright ridge near the center of (b). The line profile provides an upper limit for the domain wall width of 10 nm. Reprinted with permission from [190], M. R. McCartney and Y. Zhu, *Appl. Phys. Lett.* 72, 1380 (1998). © 1998, American Institute of Physics.

respectively. The two gradient images were combined to form a vector map of the magnetic induction in the domains, which is shown in Figure 16e. The vector map in Figure 16e is divided into 20 nm × 20 nm squares and has a low contrast image of one of the original phase gradient images superimposed onto it for reference purposes. The minimum vector length is zero (which is indicative of out-of-plane induction), while the maximum vector length is consistent with a measured induction $B = 1.0$ T at an estimated sample thickness of 90 nm. The vector map shows that the domains in this region of the sample are oriented at approximately 90° to each other rather than at 180°, as might be expected for a material that has such strong uniaxial anisotropy. Pairs of singularities visible in the image are reminiscent of cross-tie walls that contain periodic arrays of Bloch lines of alternating polarity [194]. A vector map of the area outlined in Figure 16e is shown at higher magnification in Figure 16f. This map is divided into 6.7 nm × 6.7 nm squares. There is an apparent tendency for the induction in the center domain to rotate toward a 180° orientation near the vortices. The vortices show Bloch-like character, with vanishingly small vector length. However, it is emphasized that care is needed when interpreting fine details in such induction maps due to the undetermined effects of the fringing fields immediately above and below the sample surfaces, as well as due to possible contributions to the vector maps from variations in sample thickness rather than from the strength of the local magnetic induction. Finally, a single pixel line scan obtained across a 90° domain wall, which appears as a bright ridge near the central part of Figure 16b, is shown in Figure 16g. This line profile places an upper limit of 10 nm on the domain wall width, which agrees well with theoretical estimates [194]. Similar observations were carried out after heating the sample to 300 °C and then cooling it to room temperature. The well-defined domains disappeared, and reduced phase gradients showed that the remaining structure had a large out-of-plane component. Domain walls were released from the thin edge of the sample, although some remaining domains were found to have interacted with structural features that were identified as planar defects and grain boundaries. Further heating to 400 °C, which is above the Curie temperature of 312 °C [195], resulted in complete disappearance of the domain structure. In a separate study, electron holography was used to examine as-quenched NdFeB permanent magnets, as well as samples that had been annealed at a range of temperatures [196]. Approaches based on noninterferometric phase reconstruction (including the transport of intensity equation) have also been used to study the magnetic microstructure of polycrystalline NdFeB samples [197].

Similar results that show both the magnetic fields within a TEM sample and the fringing fields outside it were obtained by applying digital reconstruction to holograms of continuous thin films of magnetic Fe_xPt_{1-x} [198]. Spontaneous ordering of Fe–Pt can occur during deposition, causing the development of an anisotropic ordered phase with the $L1_0$ crystal structure [199]. The tetragonal c-axis may then be predominantly out-of-plane or in-plane, depending on the substrate used for growth. As a result, thin films of Fe–Pt can have large magnetic moments with either longitudinal (in-plane) or perpendicular (out-of-plane) magnetization.

A reconstructed phase image was used to show the presence of magnetic fringing fields outside an epitaxial $Fe_{0.5}Pt_{0.5}$ ordered alloy that had been deposited using molecular beam epitaxy onto an MgO (110) single-crystal substrate. In this growth direction, the anisotropic $L1_0$ ordered alloy phase had the (001) easy axis parallel to the film. Adjacent domains within the FePt film were shown to have opposite polarity.

Magnetic fringing fields have been characterized outside ball-milled, nanocrystalline iron particles [200] using electron holography. Measurements were made at temperatures of between 300 and 1220 K and were used to provide insight into temperature-induced reversible variations in the exchange correlation length and saturation magnetization of the material. Nanocrystalline FeZrN films with a variety of grain sizes and thicknesses have also been charazterized using electron holography [201], as have CoNiAl shape memory alloys [202]. Most recently, electron holography was used to verify that charge order exists both in regions that have no net magnetization and in ferromagnetic regions in the mixed-valent manganite $La_{0.5}Ca_{0.5}MnO_3$ [203].

3.2.2. Layered Magnetic Nanowires

Low-magnification electron holography in field-free conditions has been used to study the remanent magnetic states of magnetic nanowires, prepared by electrodeposition of Co, Cu, or Ni in the cylindrical pores of polycarbonate track-etched membranes that are between 6 and 10 μm in thickness [204–206]. The composition of the wire may be changed during deposition to form multilayered wires that contain alternating metals. The wires themselves have diameters of between 20 and 150 nm. After dissolution of the track-etched membrane, the wires can be placed on standard C films for electron holography. Figure 17a shows an electron hologram of an electrodeposited, layered Co/ Cu nanowire that has a radius of 40 nm and a length of 5.3 μm. Successive Co and Cu segments in the wire have lengths of 1.2 and 0.3 μm, respectively. The holographic interference fringe spacing in this image is 80 nm. Figure 17b shows a four-times-amplified reconstructed phase image of the same wire, where the arrows indicate the local magnetization direction and the approximate lengths of the Co grains. Figure 17c shows the corresponding best-fitting simulated phase image, also four-times-phase-amplified. Because of the large holographic interference fringe spacing in these experiments, only the magnetic leakage fields outside these wires could be interpreted.

In general, considerable care is required when applying low magnification modes of electron holography to nanostructured materials, since gross artifacts may result if the magnetic fields in the sample are undersampled by the holographic fringes. As a result, more recent experiments on the remanent magnetic states of single crystalline 4-nm-diameter ferromagnetic Co wires have been carried out at high spatial resolution using a microscope equipped with a Lorentz lens [207]. In contrast to earlier holographic experiments on larger diameter magnetic nanowires [208], the magnetic and mean inner potential contributions to the measured phase shift were separated successfully in these experiments.

Figure 17. (a) Electron hologram of an electrodeposited, layered Co/Cu nanowire that has a radius of 40 nm and a length of 5.3 μm, obtained using a Hitachi HF-2000 FEG-TEM. Successive Co and Cu segments have lengths of 1.2 and 0.3 μm, respectively. A fragment of another nanowire is visible near the left end of the layered Co/Cu wire. (b) Four-times-amplified reconstructed phase image. Arrows indicate the local magnetization direction and the approximate lengths of the Co grains. (c) Corresponding simulated phase image, also 4-times-phase-amplified. Reprinted with permission from [204], C. Beeli et al., *Ultramicroscopy* 67, 143 (1997). © 1997, Elsevier Science.

3.2.3. Separation of Magnetic and Mean Inner Potential Contributions to the Phase

The mean inner potential contribution must be removed from the measured phase image in order to interpret the magnetic contribution to the phase shift of a nanostructured magnetic element. This separation of the two contributions to the signal becomes more important for smaller nanostructures. There are several ways to achieve this separation, all of which can be understood with reference to Eqs. (22) and (23). For example, the sample may be inverted to change the sign of the magnetic contribution to the signal and a second hologram recorded. The sum, and the difference, of the two measured phase images can then be used to provide twice the magnetic contribution and twice the mean inner potential contribution to the phase, respectively [209, 210]. An alternative method involves acquiring two holograms from the same area of the sample at two different microscope accelerating voltages. In this case, the magnetic signal is independent of accelerating voltage, and subtraction of the two phase images can be used to provide the mean inner potential contribution.

In many practical situations, it is neither feasible to turn the sample over during an experiment nor convenient to change the microscope accelerating voltage. A simpler method of removing the mean inner potential contribution involves performing a magnetization reversal experiment *in-situ* in the electron microscope and subsequently selecting pairs of holograms that differ only in the (opposite) directions of the magnetization within each element. The magnetic and mean inner potential contributions to the phase

can be calculated by taking half the difference and half the sum of the phases of such pairs of holograms, respectively. The mean inner potential contribution can then be subtracted from all other phase images acquired from the same sample [211].

3.2.4. Lithographically Patterned Magnetic Nanostructures

An understanding of the interactions between magnetic nanostructures is important because of their potential applications as magnetic random access memory cells, which should have a limited number of magnetically accessible states. However, such elements are susceptible to interactions with their neighbors [212–215], particularly as switching in submicrometer cells often involves the propagation of magnetic domains that have larger stray fields than the magnetic vortices that accompany switching in larger cells [216].

For the experiments on lithographically patterned experiments described here, a Lorentz minilens ($C_S = 8$ m and 1.2 nm line resolution at 200 kV), located in the bore of the objective lens pole-piece of a Philips CM200ST FEG-TEM, allowed electron holograms to be obtained at magnifications of up to 70 k× with the main objective lens switched off and the sample located in an almost field-free environment. The objective lens could then be excited slightly and the sample tilted by angles of up to ±30° (Fig. 18a) in order to apply known magnetic fields to the sample, allowing magnetization processes to be followed *in-situ* over entire hysteresis cycles. Phase images that differed only in the opposite directions of the magnetization within the field of view could then be identified in order to subtract the mean inner potential contribution to the measured phase. Figure 18b shows a Hall probe calibration of the vertical magnetic field at the position of the sample in this microscope, plotted as a function of objective lens current. The residual vertical field of ~130 Oe was unaffected by the excitation of the Lorentz lens.

Bright-field images of linear arrays of magnetic elements patterned onto self-supporting electron-transparent membranes using electron beam lithography and lift-off processes are shown in Figure 19. These magnetic elements were patterned from a variety of different magnetic materials and included layered spin-valve structures. Adjacent linear arrays were separated from each other by at least 5 μm. The samples were made by coating 55-nm-thick silicon nitride windows with polymethyl methacrylate (PMMA) and then exposing them to the rastered electron beam of a scanning electron microscope. The exposed parts were removed using a solution of 11:10:1 methyl isobutyl ketone:cellusol:methyl alcohol. An electron-beam evaporator was then used to deposit the magnetic materials at a rate of ~0.05 nm/s. Immersion in acetone was used to remove the unwanted PMMA and overlying material. Electrostatic charging of the membranes during examination in the electron microscope was reduced by depositing a further thin (~1 nm) layer of Al, as well as by using a small objective aperture. Each membrane contained at least 10 different array designs, and each design was repeated for several different exposure times during patterning to ensure that an optimal electron dose

was achieved. The narrowest feature sizes produced were approximately 7 nm in width. The elements included rectangles of varying aspect ratio (Fig. 19a) and diamonds, rectangular bars, and ellipses of varying size (Fig. 19b). At least two adjacent elements could typically be included within the field of view of a single electron hologram.

Figure 20a and b shows the amplitude and unwrapped phase of a hologram of two representative rectangular magnetic elements that were patterned from 30-nm-thick Co [217, 218]. The elements are polycrystalline, with a grain size of below 5 nm, and they form one end of a linear array similar to that shown in Figure 19a. The elements in the array are 275 nm in width, between 220 and 800 nm in length, and are typically separated from their neighbors by gaps of between 170 and 350 nm. The rectangles in Figure 20 are 275×220 and 275×300 nm in size and are separated by 170 nm. The hologram was recorded at 200 kV using a rotatable biprism located in the selected-area aperture plane and a 1024×1024 pixel Gatan 794 multiscan CCD camera. A biprism voltage of 100 V was used, corresponding to an overlap width of about 0.6 μm at the sample level. The hologram was obtained by overlapping a clean region of the silicon nitride support film onto the magnetic elements, since no regions of vacuum were available on this sample. A reference hologram was also acquired from

the adjacent silicon nitride to ensure that artifacts caused by local irregularities of the imaging/recording system were removed. Horizontal line traces that pass through the center of the amplitude and phase image of each element are also shown in Figure 20. When performing magnetization reversal experiments, the in-plane component of the applied magnetic field was always parallel to the line joining the rectangles shown in Figure 20. Figure 20c and d shows the mean inner potential and magnetic contributions to the phase, calculated using the approach described previously, from a pair of phase images similar to that shown in Figure 20b but which showed a reversed direction of the magnetic induction everywhere across the field of view. The bright areas at the edges of the elements in Figure 20c may originate from material left on the elements after the lift-off procedure. The fact that the magnetic signal is much smoother and more slowly varying than the compositional signal is also apparent from the figures.

Before obtaining electron holographic phase images such as that shown in Figure 20b, a preliminary examination of the magnetic domain structures in such elements is always performed. These images are usually obtained using the Fresnel mode of Lorentz microscopy, which relies on highly defocused images to reveal lines of dark and white contrast at domain walls [219]. Although the resolution of the technique is inherently limited, it permits real-time viewing of dynamic processes and it was used to provide an ini-
tial assessment of the micromagnetic structure in the samples. Suitable ranges for the applied magnetic fields can then be selected for more detailed examination by electron holography.

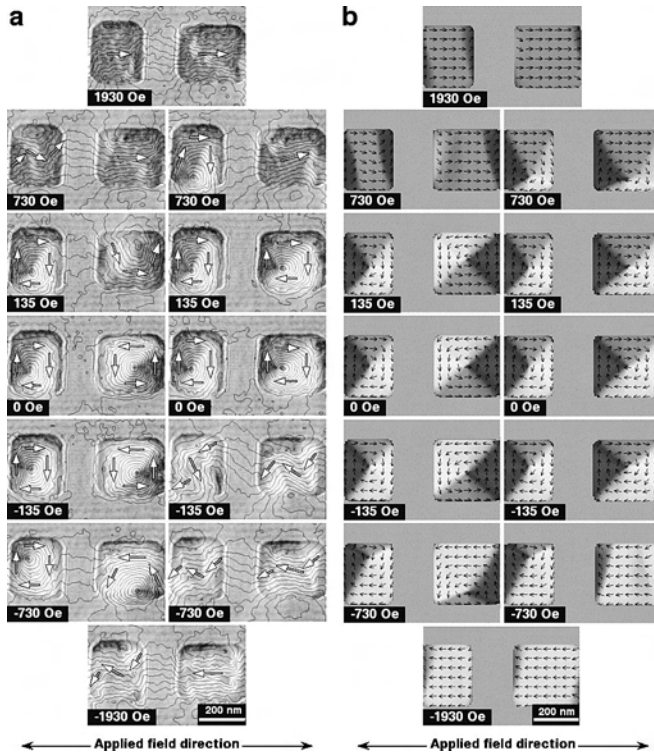
Magnetization Reversal Holograms of the Co elements were recorded over an entire magnetization reversal cycle, and the resulting magnetic contributions to the measured phase are shown in Figure 21a. The in-plane component of the applied field is indicated at the bottom left corner of each image, and the hysteresis cycle should be followed in a counterclockwise sense. The external field points toward the right in the image shown at the top of the cycle and toward the left in the image at the bottom. The images are displayed at a sampling density of ∼6 nm/pixel. In each image in the montage, contours have been generated from the measured magnetic contribution to the phase and superimposed onto the original hologram. The local separation of the phase contours, 0.21π radians, is inversely proportional to the in-plane component of the magnetic induction in the sample integrated in the incident beam direction. Arrows have also been added to show the local direction of the magnetic induction in the sample. The advantage of separating the magnetic and mean inner potential contributions is clear from these figures; contours can easily be followed from within the nanostructures to outside, allowing the magnetic


Figure 21. (a) Magnetic contributions to measured phases of holograms of 30-nm-thick Co rectangular elements for an entire magnetization reversal cycle, for the applied in-plane fields indicated. Phase contours lie parallel to lines of constant magnetic induction integrated in the incident beam direction. The contour spacing is 0.21π radians. The images, which should be followed in a counterclockwise sense, were recorded with an average out-of-plane field of 3600 Oe. Reprinted with permission from [218], R. E. Dunin-Borkowski et al., *J. Appl. Phys.* 84, 374 (1998). © 1998, American Institute of Physics. (b) Best-fitting micromagnetic simulations to hysteresis cycle shown in (a). Initial states in the top image are an S-state for the smaller rectangle and a C-state for the larger rectangle. Reprinted with permission from [224], R. E. Dunin-Borkowski et al., *Appl. Phys. Lett.* 75, 2641 (1999). © 1999, American Institute of Physics.

interactions between adjacent elements to be quantified at all points across each image. In particular, the effects of strong variations in sample thickness that were at the edges of the Co and NiFe particles in Figure 14 are now absent.

The images in Figure 21 show a variety of domain structures that include vortices and both S-shaped and C-shaped configurations. Few contours are visible between the elements when they both exhibit flux closure, whereas the strongest interactions occur when they both have S-shaped domain structures. Although the magnetic flux enclosed by adjacent contours is known, quantitative measurements of the local magnetic field strength both within and between the elements would require accurate models for the magnetic fringing fields around them. The strength of the magnetic fringing field above and below each element can be estimated by comparing the spacings of the contours within the elements between the nonsolenoidal and solenoidal configurations.

The phase contours show that complete saturation of the magnetization is never achieved at the extreme ends of the

cycle, even for large applied fields at which the domain structures are nonsolenoidal and the surrounding fringing fields are strong. The initial almost saturated state transforms to a vortex, which then moves up or down the element before finally switching to an almost saturated state in the opposite direction. The stability of a single vortex appears to influence the field at which an S-shaped domain structure forms irreversibly in each element at large values of the applied in-plane field. The solenoidal domain configurations contrast with the single-domain structures reported previously for 100–300 nm wide Co elements [220].

Differences are observed between the magnetic domain structures seen in successive cycles similar to that shown in Figure 21a [217]. These differences arise in part because the magnetic microstructure is sensitive to the strength of the out-of-plane field used in the experiment, but also from the sensitivity of the domain structure to the starting magnetic state and the statistical nature of the reversal process. This lack of reproducibility is of obvious importance for potential device applications. The extent to which the magnetization is saturated at the end of a hysteresis cycle also has a strong influence on the evolution of the domain structure. For example, if a vortex is still present in the "saturated" state then it will be retained in the second half of the cycle. The persistence of such vortices during switching will produce a variability in the switching field that will seriously diminish the ability of a nanostructured magnetic device to discriminate between states [221].

Results similar to those shown in Figure 21a have been obtained for a variety of remanent magnetic states, with the two Co rectangles only in the residual field of the microscope objective lens after being subjected to a variety of different applied magnetic fields [217, 218]. The remanent states showed domain configurations that were not observed in the hysteresis cycle, including a double-vortex structure in the larger element and a "vertical" S-shape in the smaller element. These observations highlight the importance of recording remanent states, which are particularly significant for device applications in which an element is first magnetized and the external field is then removed with the objective of retaining a nonsolenoidal domain structure.

One of the primary strengths of the digital analysis of electron holograms is that quantitative measurements can be made easily from recorded phase images. For example, Figure 22 shows hysteresis loops for the two Co elements, generated from the phase images in Figure 21a by plotting the fractional magnetization M/M_s (where M_s is the saturation magnetization in the direction of the applied field) for each element. The vertical steps in the loops correspond to the irreversible steps between S-shaped and solenoidal domain structures. The graphs highlight the fact that, as the applied field is reduced, the smaller element forms a vortex before the larger element and then retains it to larger fields before switching to an S-shaped domain structure in the opposite direction.

Similar experiments have also been performed for elements of different thickness, shape, and composition [217]. Domain structures in thinner (10-nm-thick) Co rectangles were found to be much simpler than those observed in Figure 21a, with no distinct vortex states at any stage of the
Figure 22. Best-fitting curves to measured hysteresis loops for the rectangles shown in Figure 21a. The curves were generated by measuring the fraction of each element magnetized in the direction of the applied field and are plotted as a function of the magnitude of the applied field. Reprinted with permission from [218], R. E. Dunin-Borkowski et al., *J. Appl. Phys.* 84, 374 (1998). © 1998, American Institute of Physics.

cycle. For 10-nm-thick Ni elements, it was found that a large component of the magnetization was pulled out of plane by the external field. The Ni elements were also found to oxidize over time, resulting in the presence of a magnetically "dead" layer. The general topic of magnetic domains in elements of different size has been treated comprehensively elsewhere [222].

Need for Micromagnetic Simulations The benefit of comparing electron holographic measurements, such as those shown in Figure 21a, with micromagnetic simulations is illustrated through comparisons of experimental results with solutions to the Landau–Lifshitz–Gilbert (LLG) equations [223]. The room temperature parameters used to simulate the magnetic microstructure of the Co rectangles included the exchange stiffness, $A = 1.55$ μerg/cm, and the saturation magnetization, $M_s = 1414$ emu/cm^3. The magnetocrystalline anisotropy constant, K, in the polycrystalline films was set to zero as the grain size was below 10 nm. Letting $K = 0$ is consistent with the observation that the coercivity in the submicrometer cells (ascribed to shape anisotropy) is much larger than that typical of bulk films of the same thickness, implying that magnetocrystalline anisotropy plays only a minor role in the energetics of switching. The effects of temperature fluctuations were not included. The gyromagnetic frequency, $\gamma = 17.6$ MHz/Oe, and a damping constant, $\alpha = 1$, were used in the LLG equations. Square, in-plane, discrete moments ranged in size between 5.4 and 6.9 nm on a side. Changing the out-of-plane discretization between 7.5 and 30 nm produced identical magnetization distributions; hence, a single layer of moments was used. Magnetization reversal cycles were followed by assigning an initial condition and then integrating the LLG equations in a fixed external field until equilibrium was reached. The exit criteria (equilibrium) corresponded to the largest change in the residual direction cosine of all discretized moments in the grid changing by less than 2 to 5×10^{-5}.

Effect of Initial Magnetic State Figure 21b shows a computed magnetization reversal cycle, where the initial conditions were selected to provide a best fit to the measurements

shown in Figure 21a [224]. In the initial state (at the top of the figure), the smaller cell is oriented in an S-state and the larger cell is in a modified C-state. The 3600 Oe vertical field is oriented into the plane. The larger element exhibits a flowerlike divergence at its right side, coupling the flux back to the smaller bit along both the top and bottom edges of the cell. The simulated vortex helicities match those measured, and almost all of the S-shaped domain structures are reproduced. The main differences between the measurements and the simulations were the inability to match the S-shaped domain structure at one end of the reversal cycle and the fact that vortices formed at higher fields in the simulation. The most important point established from the simulations was the sensitivity of the magnetic domain structure to the detailed magnetic history of each element. Differences in the initial state that were often on a scale too small to be distinguished visually were found to be of paramount importance to the formation of the subsequent domain structure, and in particular to the sense (the handedness) with which the vortex in each element unrolled. In general, these initial states will be determined by the magnetic history of each cell and may differ even though the magnetization may appear to be saturated.

Interactions between Neighboring Elements Simulations similar to those shown in Figure 21b were used to illustrate the way in which the presence of neighboring cells affected the magnetic domain structure in the linear array [224]. In a simulated magnetization reversal cycle of the two adjacent cells, the magnetic microstructure evolved differently as a result of intercell coupling depending on whether the cells were simulated as a pair, or whether they were simulated separately and then displayed as a pair. The energy difference between the simulations of the individual cells and the simulation of the pair was found to be on the order of the thermal energy.

Effect of Out-of-Plane Component of Applied Field The dependence of the domain structure on the out-of-plane component of the applied field, which is often assumed to be unimportant in such experiments, is illustrated in Figure 23. Calculations of hysteresis cycles were performed for identical initial conditions for perpendicular fields (of 3600 Oe) both into (Fig. 23a) and out of (Fig. 23b) the plane. The simulations show that the sense of the perpendicular field affects the domain structure appreciably, with the primary effect being to define the handedness of the vortices that evolve during magnetization reversal [224].

In combination with the results shown in Figures 21 and 23, the sensitivity of the simulated magnetic domain structure to the initial magnetization state, as well as the out-of-plane component of the applied magnetic field and intercell coupling, emphasizes the need to correlate high quality experimental holographic measurements with micromagnetic simulations.

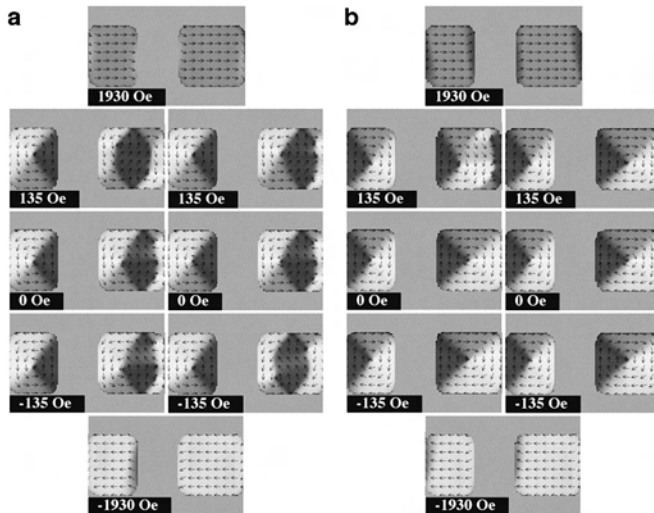
Interlayer Coupling within Individual Elements Electron holography can be used to provide information about magnetic interactions between closely separated, ferromagnetic layers within an individual lithographically defined structure. For example, spin valves and magnetic tunnel junctions [225] consist of two ferromagnetic layers separated by a thin nonmagnetic spacer layer. Changes in either


Figure 23. Micromagnetic simulations of hysteresis cycles for 30-nm-thick rectangular Co elements, for the applied in-plane fields indicated. An S-state was used as the initial state for both elements. A 3600 Oe out-of-plane field was included in the simulations, in a direction (a) into and (b) out of the plane of the page. Figure 24. (a) Off-axis electron hologram of elements with a nominal layer sequence of Co (10 nm)/Au (5 nm)/Ni (10 nm) that have been patterned into ellipses. (b) Corresponding hysteresis cycle, with a contour spacing of 0.064π radians and an average out-of-plane field of 3600 Oe. The external in-plane field is applied vertically (parallel to the major axes of the ellipses). (c) Hysteresis loop deduced from magnetic contributions to the holographic phase shown in (b) for the smaller ellipse. Reprinted with permission from [217], R. E. Dunin-Borkowski et al., *J. Microsc.* 200, 187 (2000). © 2000, Blackwell Science Ltd.

the separation of the ferromagnetic layers or their parallel to antiparallel magnetic alignment can cause substantial changes in electrical resistance when the magnitude and direction of an externally applied magnetic field is varied. This effect is termed giant magnetoresistance [226].

Trilayer Co (10 nm)/Au (5 nm)/Ni (10 nm) spin-valve elements were patterned into ellipses [227]. Figure 24a shows a representative off-axis electron hologram of a pair of elliptical spin-valve elements, for which the corresponding hysteresis cycle is shown in Figure 24b. The direction of the in-plane component of the applied field is now parallel to the long axis of each element (i.e., perpendicular to the line joining the elements). As a result of their narrow width, these elements do not show complicated domain structures. A solenoidal vortex state is occasionally visible during both forward and reverse cycles (at −168 and +336 Oe). In contrast, vortex states are never observed in similar rectangular bars, which have narrower dimensions (width of 70 nm) and a more dominant influence of shape anisotropy on their magnetic response. Significantly, the bars are also too thin and narrow to form end domains, which govern the reversal of larger rectangular elements. Instead, the phase contours curve at their ends by a maximum angle of ~45° just before magnetization reversal [227].

A measured hysteresis loop (Fig. 24c) was obtained from the ellipses by plotting the magnetic contribution to the measured phase difference across the midpoint of each element. The most significant observation from Figure 24b is the presence of two different contour spacings at different applied fields within each element (narrower at higher applied fields and wider close to remanence), and corresponding steps in the hysteresis loop in Figure 24c, in agreement with simulated loops [227]. The magnetization direction of the Ni layer in each element reverses well before the external field is reduced to zero as a result of flux closure associated
with the strong fringing field of the magnetically more massive and closely adjacent Co layer. An antiferromagnetically coupled state is the normal remanent state that would be obtained after saturation of the element followed by removal of the external field. The drop in Figure 24c that occurs before 0 Oe is reached corresponds to reversal of the Ni. In the simulation, the drop occurs later and is more abrupt than observed experimentally [227], perhaps reflecting a variability in the grain size and orientation in the experimental Ni film that facilitates earlier reversal. The simulations confirm that the two different contour spacings arise because of the strength of the coupling between the Co and Ni layers within each element at low values of the in-plane applied field.

Exchange-Biased Elements Exchange-biased elements, consisting of Ti (5 nm)/Pd (15 nm)/$Fe_{54}Mn_{46}$ (10 nm)/ $Co_{84}Fe_{16}$ (2.8 nm)/Al_2O_3 (2 nm)/Pd (7.5 nm), were characterized in a manner analogous that used for the spin valves [228]. In such elements, the magnetization direction of the ferromagnetic CoFe layer is pinned, or "exchange biased," by the adjacent antiferromagnetic FeMn layer [229]. In this sample, the ferromagnetic layer was very thin ($\sim$3 nm) relative to the total element thickness ($\sim$42 nm). As a result, the magnetic signal was very weak, and in addition the fringe contrast was low because of the presence of heavy Pd layers in the structure. Electron holographic phase measurements of two submicrometer-sized patterned elements were obtained over a magnetization reversal cycle. No solenoidal or vortex states formed in either particle, and the measured hysteresis loop was shifted sideways from zero by about 90 Oe due to the influence of the pinning layer. Best-fitting simulations corresponded to an exchange field of 79 Oe.

3.2.5. Chains of Magnetic Nanocrystals

The application of electron holography to closely spaced magnetic nanocrystals, such as those in the hologram shown in Figure 1b, is now described.

Magnetite in Magnetotactic Bacteria Magnetotactic bacteria synthesize intracellular, membrane-bounded ferrimagnetic crystals that are known as magnetosomes. These are composed of magnetite (Fe_3O_4) and/or greigite (Fe_3S_4), and they are usually arranged in one or more linear chains within each cell [230, 231]. The magnetosomes have a narrow size distribution, are specific to each cell type, and usually have their magnetic easy axes aligned (roughly) parallel to the chain axis. The fact that they are typically only 40–200 nm in size suggests that they should each contain a single magnetic domain [232]. The magnetic moment that they impart to the cell results in its alignment and subsequent migration along the Earth's magnetic field lines. This attribute is thought to increase the efficiency with which the cells find their optimal location in a vertical chemical or redox gradient within aquatic environments [233]. The ability to obtain high spatial resolution, quantitative information about the magnetic microstructure of bacterial magnetosomes is likely to be crucial to understanding magnetic-field-sensing mechanisms in a wide range of organisms [234, 235], as well as providing magnetic biomarkers that may be used to establish the occurrence of ancient life [236]. Such measurements may also have implications for understanding the

interaction of external fields with iron biominerals that form in the human brain [237–239].

Magnetic Microstructure Holograms obtained from two chains of magnetite crystals that formed within a single bacterial cell are shown in Figure 25a and b. This bacterial cell is a magnetic coccus, which was collected from Sweet Springs Nature Reserve in Morro Bay, California. The sample was prepared by placing drops of water that had been enriched in bacteria onto a 3-mm-diameter C-coated Ni grid for TEM examination. The two chains of crystals, with morphologies that have been described as "truncated hexahedral prisms" [240, 241], lie on opposite sides of the cell body. The holograms were acquired at 300 kV in a Philips CM300ST FEG-TEM using a biprism voltage of 160 V, an acquisition time for each hologram of 32 s, and a 2048 × 2048 pixel

Figure 25. (a) and (b) Electron holograms of two chains of magnetite crystals from within a single bacterial cell (a coccus) collected by Professor R. B. Frankel at Sweet Springs Nature Reserve, Moro Bay, California. The holograms were acquired in Lorentz mode (in field-free conditions) at 300 kV using a Philips CM300 FEG-TEM equipped with a Gatan Imaging Filter. The crystals are elongated parallel to their $\langle 111 \rangle$ crystallographic axes. (c) and (d) Corresponding magnetic contributions to the electron holographic phase shift, obtained by acquiring holograms after reversing the direction of the magnetization in each chain (see text for details). (e) 0.5 radian contours generated from (c) and (d) and overlaid onto a bright-field image of the cell, showing the direction and the strength of the local magnetic flux both within and around each chain of crystals. (Taken from Dunin-Borkowski, unpublished work.)

CCD camera located at the end of a Gatan Imaging Filter 2000. The long acquisition time was required because the cell has a thickness of 3 μm in the electron beam direction. The biprism is oriented in such a way that the entire length of each chain is contained within a single hologram.

Figure 25c and d shows magnetic contributions to the holographic phase for the two chains. As for the patterned elements described above, the direction of magnetization in each chain was reversed *in-situ* by tilting the sample by $\pm 30°$ and turning on the conventional microscope objective lens to provide a large (>10,000 Oe) component of the applied in-plane field parallel to the chain axis. The objective lens was then turned off and the sample tilted back to 0° for hologram acquisition in field-free conditions. In this way, holograms were recorded with the chain of crystals magnetized in opposite directions. On the assumption that the magnetic field in the chain reversed exactly, the mean inner potential and magnetic contributions to the measured phase were then obtained by taking half the difference and half the sum of the phases of each pair of holograms, respectively. As for Figure 20, the magnetic signals in Figure 25c and d vary across each phase image smoothly, and the positions of the individual crystals are no longer visible. The step in the magnetic contribution to the phase across each chain is approximately 4.5 radians. The height of the corresponding mean inner potential contribution to the phase at the position of each crystal is approximately 9 radians. Contours of spacing 0.5 radians, which have been generated from the magnetic phase images shown in Figure 25c and d, are shown superimposed onto a bright-field image of the entire cell in Figure 25e. The contours provide a semiquantitative map of the strength of the local magnetic field along the chain. As predicted, all of the crystals in the chains are single magnetic domains that are magnetized approximately parallel to the chain axes. The contours are most closely spaced within the crystals, where the field is strongest, and an increase in separation occurs at the ends of the chains where the field becomes weaker. The noise in the contours is most visible where their spacing is large.

The identification of single magnetic domains in bacterial cells such as that shown in Figure 25 is consistent with the qualitative prediction of a single- to multidomain transition when the crystal size is comparable to the domain wall width of ~100 nm in bulk magnetite. The particle size at which this transition occurs, as well as the external factors that may affect it, have been uncertain. Numerical micromagnetic modeling predicts that the transition should occur at a size of ~70 nm for perfect cubes, although this value is predicted to increase with axial ratio [242]. The situation is complicated by the fact that metastable single domains may exist in the multidomain regime, particularly in the presence of interactions between closely spaced particles. Results similar to those shown in Figure 25 have been obtained [243] from chains of smaller magnetite nanocrystals originating from cells of the bacterial marine vibrioid strain MV-1 [244] and the aquatic strain *Magnetospirillum magnetotacticum* MS-1.

Magnetic Moment   Although the contours in Figure 25e provide much useful information, one of the strengths of electron holography is its ability to provide quantitative information about magnetic properties. One of the most straightforward parameters that can be obtained from the magnetic contribution to the phase is the magnetic moment of a nanocrystal or, in this case, a chain of nanocrystals. Two approaches for measuring this parameter are now outlined.

By definition, the magnetic moment of a chain of magnetite crystals (or any other magnetic nanostructure) along the x and y directions is given by the relations

$$m_x = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} B_x(x,y,z)dx\,dy\,dz \qquad (41)$$

and

$$m_y = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} B_y(x,y,z)dx\,dy\,dz \qquad (42)$$

respectively. However, according to Eq. (20) the magnetic contribution to the phase

$$\phi_{\text{mag}}(x,y) = -\left(\frac{e}{\hbar}\right)\int_{z=-\infty}^{z=\pm\infty} \int_{x=\pm\infty}^{x} B_y(x,y,z)dx\,dz \qquad (43)$$

$$\equiv -\left(\frac{e}{\hbar}\right)\int_{z=-\infty}^{z=+\infty} \int_{y=\pm\infty}^{y} B_x(x,y,z)dy\,dz \qquad (44)$$

It follows from Eqs. (43) and (44) that

$$\frac{\partial}{\partial_x}\phi_{\text{mag}}(x,y) = -\left(\frac{e}{\hbar}\right)\int_{z=-\infty}^{z=+\infty} B_y(x,y,z)dz \qquad (45)$$

and

$$\frac{\partial}{\partial_y}\phi_{\text{mag}}(x,y) = +\left(\frac{e}{\hbar}\right)\int_{z=-\infty}^{z=+\infty} B_x(x,y,z)dz \qquad (46)$$

By combining Eqs. (41), (42), (45), and (46), the magnetic moment can be expressed in the form

$$m_x = +\left(\frac{\hbar}{e}\right)\int_{y=-\infty}^{y=+\infty} \int_{x=-\infty}^{x=+\infty} \frac{\partial}{\partial y}\phi_{\text{mag}}(x,y)dx\,dy \qquad (47)$$

and

$$m_y = -\left(\frac{\hbar}{e}\right)\int_{y=-\infty}^{y=+\infty} \int_{x=-\infty}^{x=+\infty} \frac{\partial}{\partial x}\phi_{\text{mag}}(x,y)dx\,dy \qquad (48)$$

The magnetic moment of a chain of crystals in a given direction can thus be obtained by measuring the area under the first differential of the measured magnetic contribution to the phase evaluated in the *perpendicular* direction. The application of Eq. (48) to the MV-1 cell mentioned above [243] gives a magnetic moment (along the average directions of the chain axis) of $(7.5 \pm 0.3) \times 10^{-16}$ A m^2 (7.5×10^{-13} emu).

An alternative, simpler approach for measuring the magnetic moment results from the fact that, to a good approximation, Eq. (48) can be rewritten in the form

$$m_y \approx +\left(\frac{\hbar}{e}\right)\int_{\text{chain}} \Delta\phi_{\text{mag}}(x,y)dl \qquad (49)$$

where $\Delta\phi_{\text{mag}}$ is the local change in the magnetic contribution to the phase across the chain and l is a direction along the chain axis. The moment can therefore be calculated by multiplying the average value of $\Delta\phi_{\text{mag}}$ along the chain by its length and by $(h/2\pi e)$. This approach gives a moment for the MV-1 cell of 7×10^{-16} A m^2 (7×10^{-13} emu), in good agreement with the more accurate approach described previously.

Remanent Magnetization and Coercive Field Measurements of either the magnetic moment of a chain of crystals parallel to its axis or the parameter $\Delta\phi_{mag}$ [defined in relation to Eq. (49) above] can be used to infer the magnetization state of the constituent crystals. (For an isolated crystal, this would require a model for the magnetic fringing field that surrounds it). Electron holographic data obtained from chains of magnetite are consistent with a value for the magnetization of the crystals of 0.60 T (480 emu/cm^3) [245]. To within experimental error, this value is equal to the known magnetization of magnetite. This approach may be used to measure values of magnetization that are still not well known, such as that of greigite (Fe_3S_4) magnetosomes. However, care should be taken when examining crystals with easy axes that are not parallel to the chain axis or when examining chains that do not lie perpendicular to the incident electron beam direction.

The magnetization reversal process in a magnetosome chain may also be followed *in-situ*. For example, electron holograms may be acquired at successive sample tilts with the objective lens excited to provide a known component of the applied field in the plane of the sample. This approach was used to measure the coercive field of an MV-1 cell (the in-plane component of the applied field at which the magnetization direction of the chain reversed) [245]. By monitoring the difference in the measured phase shift across the chain as a function of applied field, the coercive field was measured to be between 300 and 450 Oe. The sensitivity of the coercive field to the size, separation, morphology, and the number of crystals in a chain [246], as well as to magnetocrystalline anisotropy, highlights the importance of studying individual magnetosome chains rather than obtaining statistical measurements from large numbers of bacteria. A comparison of the measured value with a chain-of-spheres calculation for magnetite [247] suggests that magnetization reversal proceeds by a symmetric fanning mechanism rather than by the parallel rotation of the magnetic moments of the crystals.

Morphology The experimental approach used to generate the phase images of the chain of bacterial crystals shown in Figure 25c and d provides both the mean inner potential and the magnetic contributions to the holographic phase shift. Whereas only the magnetic contribution is required to generate the contours shown in Figure 25e, the mean inner potential contribution can be used to provide additional information about the morphology and orientation of the magnetite crystals, particularly if it can be assumed that the external shape of each crystal can be formed only from a combination of {111}, {110}, and {100} faces. Figure 26a and b shows phase contours generated from, respectively, the mean inner potential and magnetic contributions to the phase shift of the end of a chain of magnetite crystals. The crystals are from the "Itaipu 1" and "Itaipu 3" strains of bacteria and were collected from a brackish lagoon at Itaipu in Brazil. In each case, the contours have been overlaid onto the measured mean inner potential contribution to the phase. The contours in Figure 26a are confined primarily to the crystals, while those in Figure 26b extend smoothly from within the crystals to the region surrounding them. Figure 26c shows line profiles that have been measured across the large and small magnetite crystals visible

Figure 26. Phase contours showing (a) the mean inner potential and (b) the magnetic contribution to the reconstructed phase shift of the end of a chain of magnetite crystals from "Itaipu 1" and "Itaipu 3" strains of magnetotactic bacteria collected from a brackish lagoon at Itaipu in Brazil. In each case, the contours have been overlaid onto the measured mean inner potential contribution to the phase. (c) Line profiles obtained from images (a) and (b) across the large and small magnetite crystals close to the center of each image. The experimental data are shown as open circles. The darker solid line shows the best-fitting simulation to the data for the larger crystal, corresponding a distorted hexagonal cross-sectional shape (shown above the figure). The lighter line shows the worse fit provided by assuming a diamond shape in cross-section (also shown above the figure). (Taken from McCartney, unpublished work.)

close to the center of Figure 26a and b. Individual experimental data points are shown as open circles on the line profiles. Corresponding simulations are shown on the same axes. The darker solid line shows the best-fitting simulation

to the data for the larger crystal, which corresponds to a distorted hexagonal shape in cross-section (shown as an inset above the figure). The lighter line shows a worse fit, provided by assuming a diamond shape in cross-section (also shown as an inset above the figure).

Small Crystals and Superparamagnetism The smallest crystals in some of the bacterial magnetite chains examined by holography should be superparamagnetic if they were isolated. At room temperature, this transition would occur when the crystals are below approximately 20 to 35 nm in size. As a result, their magnetization direction should fluctuate rapidly and their measured magnetization should be zero. However, the crystals are still found to be magnetized approximately parallel to the chain axes [245]. The expected thermal fluctuations may be overcome by interactions between the smallest crystals and the field of the larger crystals in the chain, rather than by local magnetostatic interactions between the small crystals themselves.

Modeling the Phase Shift of a Spherical Magnetic Nanocrystal The magnetization and the mean inner potential of a uniformly magnetized, isolated spherical particle [248] can be measured by fitting a line trace obtained across a phase image of the particle to an analytical expression for the expected phase shift, including the effect of magnetic fringing fields [249], which can in turn be derived from an expression for the vector potential of a uniformly magnetized sphere [250]. For a spherical particle of radius a, magnetization $B_\perp$ (along y), and mean inner potential V_0, the resulting expressions for the phase shift across the particle are

$$\phi(x, y)|_{(x^2+y^2)\leq a^2} = 2C_E V_0 \sqrt{a^2 - (x^2 + y^2)}$$
$$+ \left(\frac{e}{\hbar}\right) B_\perp \left(\frac{x}{x^2 + y^2}\right)$$
$$\times \left[1 - \left(1 - \left(\frac{x^2 + y^2}{a^2}\right)\right)^{\frac{3}{2}}\right] \quad (50)$$

$$\phi(x)|_{(x^2+y^2)>a^2} = \left(\frac{e}{\hbar}\right) B_\perp a^3 \left(\frac{x}{x^2 + y^2}\right) \quad (51)$$

For a line profile obtained through the center of the particle in a direction perpendicular to that of $B_\perp$, these expressions reduce to

$$\phi(x)|_{x\leq a} = 2C_E V_0 \sqrt{a^2 - x^2} + \left(\frac{e}{\hbar}\right) B_\perp \left[\frac{a^3 - (a^2 - x^2)^{\frac{3}{2}}}{x}\right] \quad (52)$$

$$\phi(x)|_{x>a} = \left(\frac{e}{\hbar}\right) B_\perp \left(\frac{a^3}{x}\right) \quad (53)$$

Figure 27a and b shows a hologram and a reconstructed phase image for a chain of spherical Co particles [251] that are suspended over a hole in a C support film. Figure 27c and d shows corresponding line traces obtained from the phase image across the centers of two particles. Each line trace is obtained in a direction perpendicular to the chain

Figure 27. (a) Off-axis electron hologram of a chain of Co particles suspended over a hole in a carbon support film, acquired at 200 kV using a Philips CM200 FEG-TEM and a biprism voltage of 90 V. (b) Corresponding unwrapped phase image. (c) and (d) Experimental line profiles formed from lines 1 and 2 in (b), and fitted phase profiles generated for spherical Co nanoparticles. Reprinted with permission from [249], M. de Graef et al., *J. Microsc.* 194, 84 (1999). © 1999, Blackwell Science Ltd.

axis. Care is required when applying Eqs. (52) and (53) to chains of crystals, since these equations are strictly only applicable to isolated particles. Nevertheless, least squares fits of Eqs. (52) and (53), which are also shown in Figure 27c and d, to the data points provide respectable best-fitting values for a, $B_\perp$, and V_0 of 17 nm, 1.7 T, and 26 V, respectively. A decrease in the apparent remanent magnetization of a magnetized sphere with particle size may be attributed to the formation of nonuniform domain structures as the particle size increases [252].

As a point of interest, the height of the step in the magnetic contribution to the phase shift across a uniformly magnetized sphere of radius a can be determined from Eqs. (52) and (53) to be given by the expression

$$\Delta\phi_{\mathrm{MAG}} = \left(\frac{2\sqrt{2}\left(1 - \left(1 - \frac{\sqrt{3}}{2}\right)^{\frac{3}{2}}\right)}{3^{\frac{1}{4}}}\right) \left(\frac{e}{\hbar}\right) B_\perp a^2$$

$$\equiv 2.044 \left(\frac{e}{\hbar}\right) B_\perp a^2 \quad (54)$$

which can be contrasted with the equivalent expression for a uniformly magnetized cylinder of radius a of

$$\Delta\phi_{\text{MAG}} = \pi\left(\frac{e}{\hbar}\right)B_\perp a^2 \tag{55}$$

3.2.6. Nanomagnet Arrays Patterned Using Interferometric Lithography

TEM sample preparation presents a challenge for certain samples that contain nanostructured magnetic materials. An example involves the characterization of nanomagnet arrays that have been fabricated using interferometric lithography [253] directly onto Si substrates rather than onto self-supporting electron-transparent membranes of silicon nitride, alumina, or carbon. Figure 28a shows a scanning electron microscope image of 100-nm-diameter, 20-nm-thick Co dots fabricated on Si in a square array of side 200 nm. The dots were prepared for TEM examination using focused ion beam milling in plan-view geometry, by micromachining a trench from the substrate side of the sample to leave a freestanding 10×12 μm membrane of crystalline Si, which was approximately 100 nm in thickness and contained approximately 3250 Co dots. Figure 28b shows an off-axis electron hologram from part of the electron-transparent membrane containing the dots, prepared using focused ion beam (FIB) milling. The hologram was acquired at 200 kV using a Philips CM200 FEG-TEM, a biprism voltage of 160 V, a holographic interference fringe spacing of 3.05 nm, and an overlap width of 1.04 μm. The holograms were recorded in zero applied field, with the samples tilted slightly away from zone axis orientations of the underlying Si substrate to minimize diffraction contrast. The sample edge is toward the bottom left of the figure. Although great care was taken to minimize damage from sample preparation, it is possible that the elliptical shape of the dots results from damage sustained during FIB milling [254].

Figure 28c and d shows contours that have been added to the (slightly smoothed) magnetic contribution to the holographic phase for two different remanent magnetic states of the Co dots. Subtraction of the mean inner potential contribution to the measured phase before forming the contours was essential for successful characterization of the magnetic microstructure. The contour spacing is $0.033 \approx \pi/94$ radians. In Figure 28c, which was recorded after saturating the dots upward and then removing the external field, the dots are all oriented magnetically in the direction of the applied field. In contrast, in Figure 28d, which was formed by saturating the dots upward, applying a 382 Oe downward field, and then removing the external field, the dots are magnetized in a range of directions. The experiments show that the dots are sometimes magnetized out of the plane (e.g., at the bottom left of Fig. 28d) and also that shape anisotropy does not seem to dominate their behavior. The measured saturation magnetizations are smaller than expected for pure Co, possibly because of oxidation or damage sustained during sample preparation. Similar electrodeposited 57-nm-diameter, 200-nm-high Ni pillars arranged in square arrays of side 100 nm, which were prepared for TEM examination using focused ion beam milling in cross-sectional geometry, have also been examined. Despite their shape, not all of

Figure 28. (a) Scanning electron microscope image of 100-nm-diameter, 20-nm-thick Co dots fabricated on Si in a square array of side 20 nm using interferometric lithography. (b) Off-axis electron hologram of part of an electron-transparent membrane containing the dots, prepared using focused ion beam milling. The hologram was acquired at 200 kV using a Philips CM200 FEG-TEM, a biprism voltage of 160 V, a holographic interference fringe spacing of 3.05 nm, and an overlap width of 1.04 μm. (c) and (d) Magnetic contributions to the measured electron holographic phase for two remanent states. The contour spacing is 0.033 radians. (c) was formed by saturating the dots upwards and then removing the external field. (d) was formed by saturating the dots upward, applying a 382 Oe downward field and then removing the external field. Reprinted with permission from [254], R. E. Dunin-Borkowski et al., *Inst. Phys. Conf. Ser.* 168, 485 (2001). © 2001, Institute of Physics Publishing.

the Ni pillars were magnetized parallel to their long axes. Instead, the pillars interacted with each other strongly, with two, three, or more adjacent pillars frequently combining to form vortices [254].

3.2.7. Magnetic Force Microscopy Tips

Magnetic force microscopy (MFM) offers an inexpensive way of measuring magnetic microstructure by scanning a magnetized tip across the surface of a sample. However, the observed contrast is a complicated function of the magnetic fields emanating from the tip and the sample, both of which may be unknown. Electron holography has been used by several groups, in combination with micromagnetic simulations, to interpret the magnetic fields surrounding MFM tips.

As an example, Figure 29a shows a schematic diagram of the coating procedure applied to a pyramidal thin-film ferromagnetic MFM tip. Figure 29b shows the magnetic leakage field measured using electron holography outside a commercially available silicon nitride tip similar to that shown in Figure 29a, which was mounted on the end of a cantilever, coated on one of its faces with a 100-nm-thick layer of $Co_{80}Ni_{20}$ and subsequently magnetized in a direction parallel to the pyramid axis [255, 256]. In Figure 29b, the magnetic material covers only the left hand side of the tip. Figure 29c shows a best-fitting simulation to the con-
toured phase image shown in Figure 29b. The simulation was obtained by describing the tip using a uniform distribution of magnetic dipoles, which were initially oriented randomly and were then each allowed to rotate freely until a best fit to the experimental data was obtained. In contrast, similar results obtained from a thin Ni wire [40] were modeled more simply by comparing them with the field of a $20\text{-}\mu\text{m}$-long dipole.

Figure 30a shows a reconstructed holographic phase image from a sputter-coated MFM tip obtained using the far-out-of-focus mode of STEM electron holography in a VG HB5 STEM [257]. The nominal radius of the tip is 30 nm, and the spacing between adjacent phase contours is $\pi/2$ radians. Even though the MFM tip magnetic field is three-dimensional, in this case the experimental electron holographic data were interpreted quantitatively on the assumption that the field was cylindrically symmetrical. Figure 30b shows a best-fitting simulation, superimposed onto the part of the experimental phase image close to the tip, which was obtained by fitting a multipole expansion of the magnetic scalar potential to the phase image. The fitting coefficients include monopole, dipole, and quadrupole (tensor) terms, with no assumption made about either their size or their orientation. As in Figure 29, the clear agreement between the experimental data and the simulation is evident, and the strength of the magnetic field along the tip axis can be derived directly from the multipole fit to the data. The

resulting field, shown in Figure 30c, falls from about 2500 Oe near the tip surface to 500 Oe at a distance of 100 nm in front of the tip. The fitted dipole is oriented nearly along the tip (15° off-axis), which is consistent with the fact that the tip was oriented ~12° from the magnetic field direction during the magnetization process.

3.2.8. Cross-Sectional Samples—Removal of Sample Thickness Effects

One of the most challenging problems for electron holography of magnetic materials is the quantitative measurement of the magnetic properties of nm-scale magnetic layers that are examined in cross-section. The primary difficulty is the presence of rapid and unknown variations in both the composition and the thickness of the sample, from which the weak magnetic signal must be separated. In a cross-sectional sample, magnetic contributions to the phase and the phase gradient are then much smaller than the mean inner potential contribution. This point has been illustrated both experimentally and using simulations [211] for an AlO_x tunnel barrier sandwiched between CoPtCr and CoPt ferromagnetic layers. In this work, the similarity noted between the shapes of the magnetization profile and the magnetic contribution to the phase gradient evaluated across the ferromagnetic layers suggested the possibility that differences in the phase gradient between images in which the magnetization has been reversed could provide the basis for more accurate magnetization characterization. In contrast, the magnetic contribution to the phase was observed to change cumulatively across the layers. In such samples, the magnetization profile differs from the magnetic contribution to the phase gradient only because of variations in specimen thickness within the magnetic layers. These contributions due to specimen thickness cannot be eliminated by using the normalized amplitude of the hologram defined in Eq. (38), both because the mean free path λ_{in} in each material in such a cross-sectional sample is unknown and also because the amplitude image is in general noisy and may contain strong contributions from diffraction contrast and Fresnel contrast.

Rearrangement of Eqs. (22) and (23) indicates that sample thickness effects may be removed by plotting the difference in the phase gradient between images in which the magnetization has reversed divided by the average of their phases, multiplied by a constant and by the value of the mean inner potential of each magnetic layer separately. Formally, this process can be written in the form

$$\left(\frac{C_E \hbar V(x)}{e}\right)\left\{\frac{\Delta[d\phi(x)/dx]}{\langle\phi(x)\rangle}\right\}$$
$$= \frac{\Delta[B_\perp(x)]}{\left(1 - (e/C_E\hbar V(x))\left\{\langle\int B_\perp(x)t(x)dx\rangle/t(x)\right\}\right)} \quad (56)$$

According to Eq. (56), by combining the phase profiles and phase gradients (evaluated in a direction perpendicular to the layers) from successive holograms between which the magnetization direction has been reversed, the specimen thickness profile is eliminated and the magnetization can be determined quantitatively. This process is equivalent to using the average phase to calculate the specimen thickness and then using this knowledge to eliminate the thickness

from the magnetic contribution to the phase gradient. Most importantly, both the magnitude and the sign of $\Delta[B_\perp(x)] = 2B_\perp(x)$ are obtained exactly using Eq. (56) if the magnetization reverses exactly everywhere in the sample between the two holograms. (The denominator on the right-hand side of the equation is then unity.) Furthermore, nonzero values are returned only in regions where the magnetization has changed.

Figure 31 illustrates the application of Eq. (56) to a cross-sectional sample of a magnetic tunnel junction that contains a layer sequence of 22 nm Co/4 nm HfO_2/36 nm CoFe on a Si substrate [258]. Two holograms were obtained, similar to that shown in Figure 31a, between which the magnetization directions of the Co and CoFe layers in the sample were reversed *in-situ* in the electron microscope. Figure 31b shows an unwrapped phase profile obtained from the hologram in Figure 31a by taking a line profile in the direction perpendicular to the layers. The phase profiles from the two holograms appeared almost identical irrespective of the direction of magnetization. The application of Eq. (56) to the two phase images (i.e., dividing the difference in the gradients of the two phase images obtained perpendicular to the layers by the average of the original phases) results in the image shown in Figure 31c, which represents $2B_\perp(x)$. The line profile in Figure 31d was obtained by averaging Figure 31c along the direction of the layers. As predicted, Figure 31d, which should by now be independent of variations in composition and sample thickness, is nonzero only in the magnetic layers and yields a value for the magnetization of Co of 1.5 T (assuming a mean inner potential of 25 V). (In a similar experiment, holograms of $La_{0.5}Ca_{0.5}MnO_3$ have

Figure 31. (a) Off-axis electron hologram obtained from a magnetic tunnel junction with a 4-nm HfO_2 tunnel barrier. (b) Measured phase profile across layers in tunnel junction structure. (c) Image formed by recording two holograms with opposite directions of magnetization in the sample, taking the difference between the recorded phase gradients (calculated in a direction perpendicular to the layers) and dividing by the average of the two phases. (d) Measured magnetic induction in the tunnel junction sample, generated by multiplying a line profile obtained from image (c) by a constant (see text for details), with the vertical scale now plotted in units of Tesla. Reprinted with permission from [258], M. R. McCartney and R. E. Dunin-Borkowski, in "Electron Microscopy 98" (H. A. Calderón Benavides and M. José Yacamán, Eds.), Vol. 2, p. 497. Paper presented at the 14th International Conference on Electron Microscopy, Cancun, Mexico, 31 August–4 September, 1998. recently been acquired both above and below the Curie temperature of the material to remove sample thickness and mean inner potential contributions from the measured phase [203].)

Artifacts may be present in a profile such as that shown in Figure 31d. The primary disadvantage of using Eq. (56) to determine the magnetization in a cross-sectional sample is that it utilizes differences between subtle changes in the phase gradient. Thus, holograms of high quality are required and it is important to register them to subpixel accuracy. The magnetic layers must be unbroken and uniform in cross-section along their length to minimize any magnetic fringing fields around them. If the sample is too thick or the image too far from focus, then Fresnel effects at the layers may cause additional oscillations in the phase images [211]. As a result, it is particularly important to record the two phase images both close to focus and at the same defocus. The accuracy with which the absolute magnetization can be inferred is limited by the degree to which the mean inner potential of the area of interest can be estimated. The approach is not affected by diffraction contrast if the local orientation of the sample is identical for the two holograms. However, surface contamination layers should be thin in order to validate multiplication by the local value of the mean inner potential. The sample should be sufficiently thick so that division by the average phase does not substantially increase the noise in the inferred magnetization profile.

Recently, electron holography has been used to examine spin valve structures containing oxide layers, and to infer a 3–4 V step in potential across a metal/oxide interface. This potential barrier was related to the magnetoresistive properties of the material [259].

3.3. Superconducting Thin Films

An external magnetic field can pass through a type-II superconductor in the form of thin filaments with a magnetic flux that is a multiple of $h/(2e) = 2 \times 10^{-15}$ Wb. These filaments are known as fluxons, or vortices. The critical current of the superconductor is determined by how tightly the fluxons are attached to pinning centers when a Lorentz force is exerted on them by a current passing through the sample. Electron holography allows fluxons to be observed directly, both in profile and in transmission. Dynamic observations of their motion are also possible.

Figure 32a illustrates the procedure used to study static fluxons in profile. In this case, lead was evaporated onto one side of a 30-μm-diameter tungsten wire that had been cleaned by flash-heating. (Lead is a type-I superconductor in bulk form and a type-II superconductor when it is in the form of a thin film.) The sample was examined with a magnetic field of a few Gauss applied in a direction perpendicular to the film. Whereas the Meissner effect excludes a weak magnetic field from the superconducting film, magnetic lines of force penetrate the superconductor as the strength of the applied field is increased. These magnetic lines of force can then be characterized directly using electron holography. Figure 32b shows a two-times-phase-amplified interference micrograph obtained from a 0.2-μm-thick superconducting lead film at a temperature of 4.5 K [260, 261]. The critical

Figure 32. (a) Electron-optical configuration used for recording a hologram of a superconducting Pb film evaporated onto one side of a tungsten wire. (b) and (c) Two-times-phase-amplified interference micrographs of magnetic flux penetrating superconducting Pb films of thickness 0.2 and 1.0 μm, respectively. The holograms were recorded at a temperature of 4.5 K. The critical temperature of the films is 7.2 K. Reprinted with permission from [260], T. Matsuda et al., *Phys. Rev. Lett.* 62, 2519 (1989). © 1989, American Physical Society.

temperature of the film is 7.2 K. In this figure, each fringe corresponds to a single fluxon, which is observed to have a diameter of approximately 150 nm at the sample surface. The image shows a single fluxon on the right and a fluxon pair on the left. The magnetic field at the position of a fluxon near the surface of the sample is as high as 1000 Gauss, even though the applied magnetic field is only a few Gauss. As expected, the magnetic lines of force outside the sample disappear above the critical temperature. Figure 32c shows corresponding magnetic lines of force recorded from a 1-μm-thick Pb film, again with two times phase amplification. In this image, the magnetic flux always emerges from the sample surface in integral multiples of $h/(2e)$. Observations similar to those shown in Figure 32 have been made "dynamically" as the sample temperature is raised and the fluxon diameters increase [262]. Using this approach, fluxons

were observed to move from one pinning center to the next. The dynamics of fluxons that are driven by the Lorentz force as a current is passed through the sample have also been studied [263], allowing the pinning force in the film to be measured. Computer simulations of the phase contours of fluxons observed in profile have highlighted the importance of including the effect of the perturbed reference wave on such calculations [264].

The experiment described in Figure 32 only reveals the magnetic lines of force *outside* the superconductor. A transmission geometry is required to visualize fluxon distributions inside a superconductor. In this mode, the superconducting film has to be tilted, as shown in Figure 33a, since the phase shift associated with a fluxon is too small to be detected when the electron beam is parallel to its axis [265, 266]. The TEM sample should have uniform thickness, so that changes in film thickness do not obscure small phase changes that arise from the presence of the fluxon. Figure 33b shows a 16-times-phase-amplified interference micrograph of a vortex lattice in a 100-nm-thick superconducting film of single-crystalline Nb, recorded at a temperature of 4.5 K with a 150 Gauss magnetic field applied horizontally and the sample tilted by 45° [267]. Regions where the contours are most closely spaced, which are circled in the image, correspond to the positions of fluxons. Figure 33c, d, and e illustrates measurements of changes in the sizes of vortices as the sample temperature is changed from 4.5 to 7.0 and 8 K, respectively [268]. The average vortex diameter at these temperatures is measured to be 150, 185, and 230 nm, respectively. As the vortices broaden with increasing temperature, the flux enclosed remains constant. Simulations of the holographic contrast observed at fluxons in transmission mode [269–275] have been performed. In contrast to electron holography, Lorentz microscopy, which reveals fluxons as pairs of bright and dark contrast features, can be used to observe fluxon dynamics in real time, including flux pinning as the sample temperature and the applied magnetic field are varied [276–284].

4. ELECTROSTATIC FIELDS IN NANOSTRUCTURED MATERIALS

The characterization of magnetic fields in nanostructured materials by electron holography, as described in Section 3, has been explored in considerable depth. Key issues and problems have been addressed, and many remaining challenges are either technical or else involve the further development of existing aspects of the technique. In contrast, the application of electron holography to the characterization of electrostatic fields in nanostructured materials (e.g., [285, 286]) is less developed and requires several basic technical and conceptual problems to be resolved. In this section, work that has already been carried out in this field is reviewed. Initial examples are taken from the characterization of electrostatic fringing fields outside charged particles and electrically biased carbon nanotubes. The considerable challenges that are associated with imaging dopant contrast at depletion layers in semiconductors are described, before proceeding to other more complicated systems such as the characterization of interfaces at which both charge redistribution and changes in chemistry are possible.

4.1. Charged Latex Particles

Latex spheres that become charged when exposed to a high-energy electron beam are often used as "standard" samples for studying electrostatic fields using electron holography (e.g., [41, 42, 285, 287]). Electron holography has also been used to measure charging effects due to electron irradiation in 250-nm-diameter SiO_2 particles [288]. For example, Figure 34 shows a simulation of equiphase contours
Figure 34. (a) Simulated (b) experimental equiphase lines for a charged 2.7-μm-diameter latex sphere, reconstructed using a reference hologram. Reprinted with permission from [289], B. Frost and T. L. Jenkins, *J. Microsc.* 187, 85 (1997). © 1997, Blackwell Science Ltd.

associated with a 2.7-μm-diameter latex sphere placed close to a Cu grid bar, together with the corresponding experimental phase image [289]. The simulation takes into account the image charge of the sphere in the grid bar and assumes that the charge is distributed uniformly throughout the particle. The match between the simulation and the measured phase profile in Figure 34 appears to be satisfactory, but changes in the measured phase distributions across latex spheres and other materials have been reported to depend on the condenser aperture size and the objective lens strength used when recording the holograms [290, 291]. These observations indicate the need for care when recording and interpreting such low resolution phase images. However, the origin of the differences remains to be explained. Possible reasons could include changes in the way in which either the sample or parts of the microscope have accumulated electrostatic charge as the electron optical conditions are varied.

4.2. Field-Emitting Carbon Nanotubes

Electron holography can be used *in-situ* in the TEM to measure the electrostatic potential in samples that have a voltage applied to them. Early experiments that demonstrated this capability were carried out on tungsten microtips, which exhibited a strong electrostatic fringing field [292], on pairs of parallel conducting (1-μm-diameter Pt) wires held at different potentials [293], and on single conducting wires [294]. Simulations have also been presented for electrostatic phase plates [295]. A more recent example involved the use of electron holography to map the electrostatic potential surrounding the end of a field-emitting, electrically biased, multiwalled carbon nanotube [296]. (The ability to bias carbon nanotubes in the TEM has also been demonstrated in other experiments, e.g., [297, 298].) The carbon nanotubes were mounted onto a piezo-driven three-axis manipulation electrode using conducting epoxy and positioned approximately 6 μm from a gold electrode, as shown in Figure 35a. Depending on the biasing conditions, electrons could be emitted from the nanotube to the gold collector plate, in a direction perpendicular to the incident high-energy electron beam. Electron holograms were acquired during this biasing experiment using a Philips CM200ST FEG-TEM

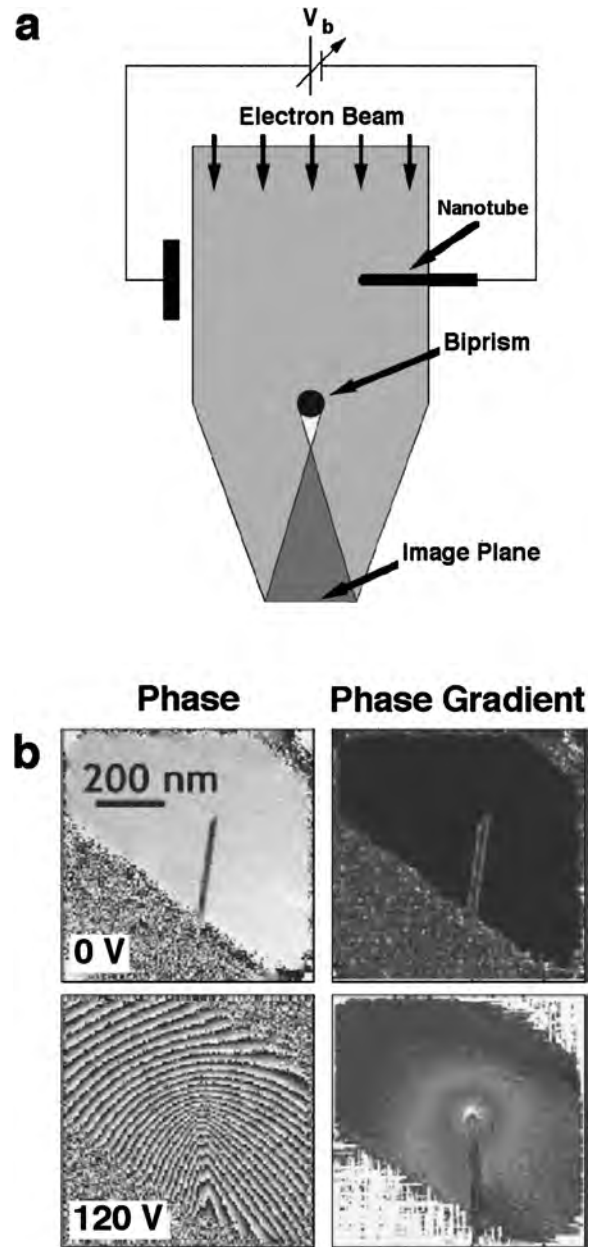

Figure 35. (a) Schematic diagram of the experimental setup used to record electron holograms of field-emitting carbon nanotubes. (b) Phase shift and phase gradient maps extracted from holograms of the same nanotube at bias voltages of 0 and 120 V. The phase gradient indicates where the electric field is strongest; note the concentration of the electric field at the nanotube tip when the bias voltage is 120 V. Reprinted with permission from [296], J. Cumings et al., *Phys. Rev. Lett.* 88, 056804 (2002). © 2002, American Physical Society.

operated at 200 kV and an interference fringe spacing of 4 nm. Figure 35b shows contoured phase images in the left hand column recorded both before any bias was applied to the sample and at a bias V_b above the threshold for electron field emission (approximately 70 V for this sample). The upper phase shift map (at $V_b = 0$) shows a featureless area around the nanotube, whereas the lower map (at $V_b = 120$ V) shows a striking distribution of closely spaced 2π

phase contours. The right hand column in Figure 35b shows the corresponding two-dimensional phase gradient for each phase image. (The phase gradients are much less affected by a perturbed reference wave than the original phase images.) When $V_b = 0$, the phase gradient is featureless around the nanotube, whereas the gradient is concentrated around the nanotube tip when $V_b = 120$ V. The phase and phase gradient images shown in Figure 35b were interpreted quantitatively by comparing them with simulated images, calculated on the assumption that the nanotube could be approximated by a line charge, on which the charge distribution was varied until a best fit to the data was found. The best fit to the 120 V phase data shown in Figure 35b gave a value of 1.22 V/nm for the electric field at the nanotube tip. This electric field was concentrated at the tip and was not observed at other defects such as sidewall imperfections. It was also stable over time, even when the field emission current varied. The fact that clear holograms could be recorded from a single field-emitting nanotube placed an upper limit on fluctuations in the electric field strength at the tip of 0.03 V/nm.

4.3. Dopant Potentials in Semiconductors

One of the most elusive but tantalizing problems for electron holography has been the quest for a reliable and quantitative approach for the characterization of electrostatic potentials associated with charge redistribution at depletion layers in doped semiconductors. Attempts to tackle this problem have been made since the 1960s using many forms of electron interferometry, both experimentally under reverse-bias conditions (e.g., [299–306]) and also theoretically (e.g., [307–312]). In most of these studies, in which chemically thinned samples were examined, virtually zero contrast was observed at the position of a p–n junction until it was reverse-biased *in-situ* in the TEM. Although it was predicted that external electrostatic fringing fields outside the TEM sample could, in principle, dominate the observed phase shift at the junction position, these fringing fields were rarely seen at any p–n junction until it was reverse-biased.

It has recently been recognized that TEM sample preparation can have a profound effect on the contrast seen in holographic phase images of doped semiconductors, either because of physical damage to the sample surface or because of the implantation of dopant ions such as Ar or Ga. Either an electrically inactive surface layer or a doped layer, with a thickness that varies depending on the sample preparation method, may then form at the sample surface. In addition, the sample may become charged during observation, to such an extent that all dopant contrast is lost. It is possible that the effects of sample preparation, and in particular the electrical state of the sample surface, could account for many of the anomalous results seen in early experiments, including the absence of electrostatic fringing fields outside unbiased p–n junctions. Recent studies, which are now reviewed, suggest that these problems are being successfully addressed.

4.3.1. Transistors

Following earlier experiments on one-dimensional dopant profiles (e.g., [313]), the first unequivocal demonstration of the two-dimensional mapping of the electrostatic potential

in an *unbiased* doped semiconductor using electron holography was achieved for metal-oxide-semiconductor (MOS) Si transistor structures [67, 314, 315]. Figure 36 shows electron holography results obtained from several 0.35-μm-channel-length MOS transistors, examined in cross-section at 200 kV using a Philips CM200 FEG-TEM. The samples were tilted by approximately 4° from Si $\langle 110 \rangle$ to minimize dynamical diffraction contributions to the contrast. Amplitude images from these samples are shown in Figure 36a and b, and corresponding phase images are shown in Figure 36c and d. The images shown in Figure 36a and c were obtained from an n-MOS transistor, while Figure 36b and d was obtained from a p-MOS transistor. The source and drain regions in each transistor structure (marked n^+ and p^+) are clearly visible in the phase images with a spatial resolution of 10 nm and an energy resolution of 0.10 V. The effect of differential thinning across the junctions was discounted as a possible cause of the observed phase shifts, and an optimal sample thickness of between 200 and 400 nm was identified for such experiments.

Two aspects of this study deserve further comment. First, the transistor structures were prepared for TEM examination using conventional mechanical polishing and Ar-ion milling. Although this approach proved successful here, it has since been found elsewhere to result in gross charging effects in other similar samples. Second, a 25-nm-thick electrically dead layer was identified on each surface of the sample, which resulted in a measured built-in voltage across each p–n junction of 0.9 ± 0.1 V. This value was lower than the value of 1.0 V predicted for the specified dopant concentrations. It should, however, be noted that the voltage profile is remarkably insensitive to changes in the charge density profile across the junction. As a

Figure 36. Electron holography results revealing the electrostatic potential distributions in metal-oxide-semiconductor transistors. Amplitude and phase images of 0.35 μm channel length (a) and (c) n-MOS and (b) and (d) p-MOS transistors, viewed in cross-section. The source and drain areas (marked n^+ and p^+) are clearly visible in the phase images. The holograms were recorded at 200 kV in a Philips CM200 FEG-TEM. Reprinted with permission from [67], W. D. Rau et al., *Phys. Rev. Lett.* 82, 2614 (1999). © 1999, American Physical Society.

result, partial deactivation of the dopant in the depletion region due to the TEM sample preparation may account for the lower than expected value of the built-in voltage, but without changing the position of each junction in the device appreciably. Further results have since been published on the examination of process-induced boron redistribution in Si/SiGe/Si heterostructures [316]. These results were compared with process simulations in order to measure parameters such as surface recombination lengths for self-interstitials.

More recently, electron holography studies of transistor structures have been compared with process simulation and secondary ion mass spectrometry results [317]. Figure 37a shows a contoured phase image of the electrostatic potential distribution in a 0.35 μm Si device structure, which was recorded at 200 kV in a Philips CM200 ST FEG-TEM. The contour step in this image corresponds to a potential step of 0.1 V. As in Figure 36, the B-doped source and drain regions in the device are clearly delineated in the phase image. In this study, the sample was prepared using tripod wedge-polishing followed by limited low-angle Ar ion milling at 3.5 kV. Significantly, no electrically dead layer needed to be taken into account to quantify the results. However, there was some evidence for charging in the near-surface regions under the sidewall spacers. Figure 37b and c shows a comparison between simulations and line profiles obtained from Figure 37a, both laterally across the junction and as a function of depth from the Si surface. Simulations for "scaled loss" and "empirical loss" models, which account for B-implant segregation into the adjacent oxide and nitride layers, are shown. The scaled-loss model, which leads to stronger B diffusion, assumes uniform B loss across the device structure, while the empirical loss model assumes segregation of the implanted B at the surface of the source and drain regions. In both Figure 37b and c, the empirical loss model provides a better match to the experimental results. Figure 37d shows a simulated electrostatic potential map for the same device structure based on the "empirical loss" model, with a contour step of 0.1 V, which matches closely with the experimental image in Figure 37a. Overall, this study demonstrated the successful two-dimensional mapping of the electrostatic potential in 0.13 and 0.35 μm device structures with a spatial resolution of 6 nm and a sensitivity of 0.17 V.

4.3.2. Sample Preparation and Charging

The results presented in Figure 36 and 37 highlight the fact that the nature and extent of the electrically dead layer on the sample surface of a doped semiconductor depend on the TEM sample preparation procedure. The ways in which the sample preparation technique of "wedge-polishing" affects both the dead layer thickness and sample charging are explored further in Figure 38, which shows results obtained from a one-dimensional p–n junction in Si [318]. This sample was prepared from a p-type wafer that had been subjected to a shallow B implant and a deeper P implant, resulting in the formation of an n-type well and a p-doped surface region. A 30-nm-thick $CoSi_2$ film and a further oxide (tetraethylorthosilicate—TEOS) layer were deposited onto the wafer surface before TEM sample preparation, which

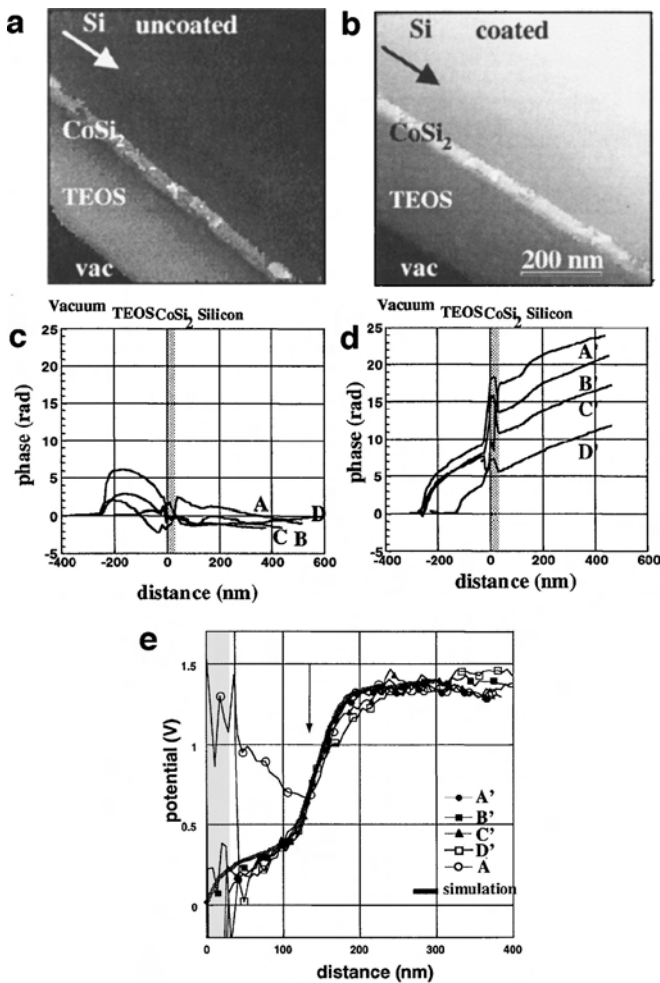
Figure 37. used wedge-polishing and brief Ar-ion milling to provide a continuous range of sample thicknesses for examination. Figure 38a and b shows typical reconstructed phase images from this sample, obtained both before and after coating one side of the sample with approximately 40 nm of carbon, respectively. The images were obtained with the sample


Figure 38. (a) Reconstructed phase image of a one-dimensional *p–n* junction sample prior to carbon coating. (b) Reconstructed phase image from a similar region after carbon coating. (c) Phase profiles for uncoated sample regions of decreasing thickness. At 180 nm from the top of the CoSi$_2$ (gray region), the thicknesses are A = 250 nm, B = 170 nm, C = 120 nm, and D = 50 nm, as measured from holographic amplitude images. (d) Phase profiles after carbon coating. At 180 nm, the thicknesses are A′ = 280 nm, B′ = 220 nm, C′ = 160 nm, and D′ = 85 nm. (e) Comparison of the electrostatic potential derived from simulations based on secondary ion mass spectrometry with measurements obtained using electron holography. Note the close agreement of profiles A′, B′, and C′. The position of the *p–n* junction is marked. The gray region is the CoSi$_2$ layer. Reprinted with permission from [318], M. R. McCartney et al., *Appl. Phys. Lett.* 80, 3213 (2002). © 2002, American Institute of Physics.

tilted by about 10° to a weakly diffracting orientation close to ⟨110⟩, and with the layers kept 1–2° from edge-on.

Figure 38c and d shows line profiles obtained perpendicular to the layers from the uncoated and carbon-coated sample, respectively, for a range of sample thicknesses (measured from the corresponding amplitude images). The phase profiles obtained from the uncoated sample (Fig. 38c) show an initial increase in the measured phase going from vacuum into the TEOS layer. However, the phase profiles then drop steeply and even become negative at the largest sample thicknesses. In contrast, after the sample surface was coated

with carbon (Fig. 38d), the phase profiles increase with sample thickness, suggesting that the anomalous behavior observed in Figure 38c is associated with sample charging. Such charging effects may result from the electron-beam-induced emission of secondary electrons, which is negated by carbon-coating. The sample would indeed need to be positively charged along its thin edge to reproduce the features visible in Figure 38c.

Figure 38e shows electrostatic potential profiles derived for four different sample thicknesses from the phase profiles shown in Figure 38d, displayed alongside a simulation based on a secondary ion mass spectrometry measurement of the dopant profile. The position of the *p–n* junction is marked with an arrow. Close agreement between the data and the simulation is obtained for all of the profiles apart from D′, which was obtained from the thinnest area after carbon-coating. Profile A was obtained by subtracting a linear ramp from the phase profile from the thickest uncoated sample and shows a distinct change in slope in the part of the sample that lies between the *p–n* junction and the silicon–silicide interface. Significantly, after carbon-coating, depleted surface layers did not need to be taken into account to obtain quantitative matches to simulations.

In addition to charging problems, an important issue associated with the preparation of a TEM sample for electron holography studies of dopant potentials is the need for uniformly thin areas [319]. This requirement is particularly demanding for focused ion beam milling of device structures since curtaining effects (thickness corrugations) result if substantial metallization is present on the wafer surface. One solution to this problem involves focused ion beam milling of the sample from several directions to form a freestanding electron-transparent membrane. The final milling is then carried out from the substrate side of the wafer to provide an electron-transparent site-specific TEM sample that exhibits minimal thickness variations [320].

4.3.3. In-situ Electrical Biasing Experiments

The experiments illustrated by Figure 36 to 38 involved the examination of unbiased semiconductor device structures, where some part of the TEM sample may have been grounded to the electron microscope sample holder, while some other part may have been subject to current flow or to charging as a result of the generation of positive charge caused by secondary electron emission. The effect on the contrast of examining an unbiased doped semiconductor may be assessed by comparing the results with samples that have been biased electrically *in-situ* in the TEM. Electrical biasing experiments may then provide the potential distribution in a semiconductor device under "working conditions," as well as allowing unwanted effects from variations in sample thickness and composition to be removed by making use of the difference between holographic phase images acquired at different sample voltages.

The earliest applications of electron holography to dopant delineation were carried out under conditions of reverse bias [305, 306]. In these experiments, which involved the examination of chemically thinned Si samples, difference images were recorded between phase images obtained at different

reverse-bias voltages. This procedure allowed an electro-static fringing field outside the sample to be visualized at the position of the *p*–*n* junction.

Electrostatic potential profiles have recently been measured from reverse-biased Si *p*–*n* junctions that were prepared for TEM examination using focused ion beam milling [321]. A significant aspect of these experiments is the fact that focused ion beam milling is the technique of choice for preparing TEM samples from site-specific regions of integrated circuits. It is therefore essential to establish whether results obtained from unbiased samples prepared by focused ion beam milling are reliable, as well as to develop a suitable sample geometry that allows currents to be passed through TEM samples prepared using this technique. Samples for electrical biasing were prepared for TEM examination by using a 30 kV FEI 200 focused ion beam workstation to machine parallel-sided electron-transparent membranes at the corners of 1 mm × 1 mm 90° cleaved squares of wafer, as shown schematically in Figure 39a. This sample geometry allowed electrical spring contacts to be made to the front and back surfaces of the cleaved wafer in a modified single-tilt sample holder, as shown in Figure 39b. Holograms were recorded at 200 kV in a Philips CM200 ST FEG-TEM operated in Lorentz mode, using a biprism voltage of 100 V. The samples were always tilted by 1–2° from the ⟨100⟩ zone axis, while keeping the *p*–*n* junction edge-on to better than 0.2°, in order to ensure that dynamical diffraction effects were minimized. Care was taken during sample preparation to minimize physical damage and implantation of Ga ions into the samples [322, 323]. The area of interest was exposed to the focused beam of Ga ions only at a glancing angle to its surface, and the final stage of milling was performed exactly parallel to the surface of the thin membrane using a small spot size of 10 nm and a low ion beam current of 150 pA.

Figure 39c shows a representative electron holographic phase image obtained from an unbiased Si *p*–*n* junction sample prepared by focused ion beam milling. The crystalline thickness of this sample was measured to be 550 nm using convergent beam electron diffraction. The *p*-type and *n*-type regions are delineated clearly as areas of dark and bright contrast, respectively. An additional "gray" band at the sample edge is presumably associated with the presence of an electrically dead layer, which is visible in cross-section in this image but is thought to run around the entire sample surface. No electrostatic fringing field is visible in vacuum outside the sample, indicating that its surface is an equipotential. Line profiles across the *p*–*n* junction were obtained from phase images acquired with different reverse-bias voltages applied to a sample with a crystalline thickness of 390 nm (Fig. 39d), as well as from several unbiased samples of different thickness. Each profile in Figure 39d is qualitatively consistent with the expected potential profile of a *p*–*n* junction contained in a sample of uniform thickness. The height of the potential step across the junction, $\Delta\phi$, increases linearly with reverse-bias voltage V_{appl}, as shown in Figure 39e. This behavior is described by the equation

$$\Delta\phi = C_E(V_{\text{bi}} + V_{\text{appl}})t_{\text{active}} \qquad (57)$$

where C_E is defined in Eq. (21) and the *p*–*n* junction is contained within an electrically active layer of thickness t_{active}

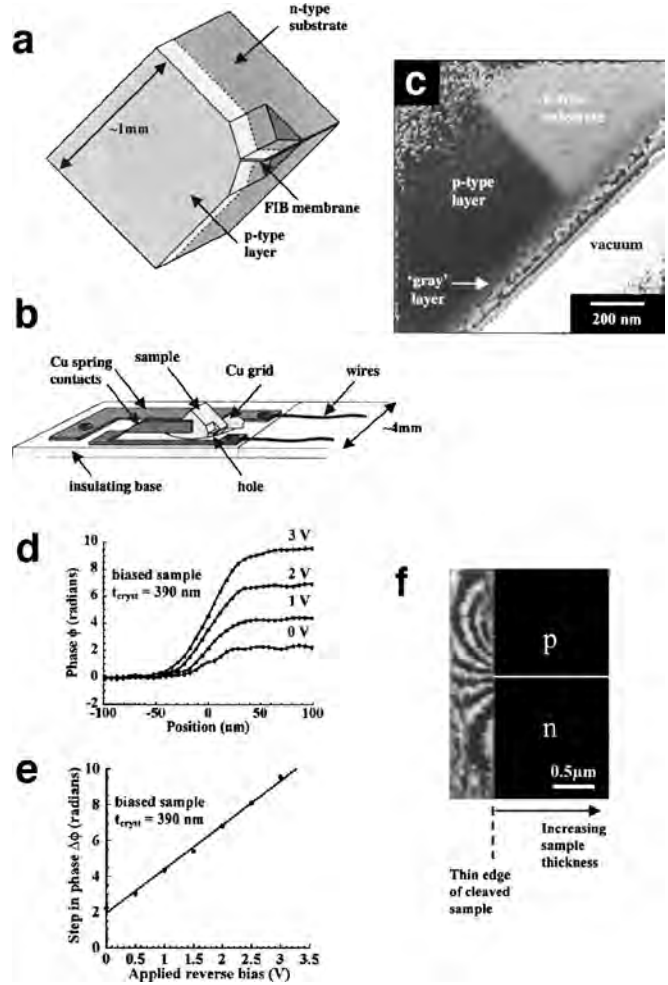

Figure 39. (a) Schematic diagram showing the sample geometry used for biasing experiments. Focused ion beam milling has been used to machine a membrane of uniform thickness that contains a *p*–*n* junction, at one corner of a 90° cleaved wedge. (b) Schematic diagram showing the sample position in a single tilt electrical biasing holder. The sample is glued to the edge of a Cu grid using conducting epoxy and then clamped between two spring contacts on an insulating base. (c) Reconstructed phase image of an unbiased Si sample containing a *p*–*n* junction. Note the "gray" layer running along the edge of the membrane, which is discussed in the text. No attempt has been made to remove the 2π phase "wraps" at the edge of the sample. (d) Phase (ϕ) measured across a *p*–*n* junction as a function of reverse bias for a single sample of crystalline thickness 390 nm (measured using convergent beam electron diffraction). (e) shows the height of the measured step in phase ($\Delta\phi$) across the junction as a function of reverse bias. (f) Four-times-amplified reconstructed phase image, showing the vacuum region outside a *p*–*n* junction in a 2 V reverse-biased cleaved wedge sample that had not been focused ion beam milled. within the total sample thickness *t*. Measurement of the gradient of Figure 3e, which is equal to $C_E t_{\text{active}}$ according to Eq. (67), provides a value to t_{active} of 340 ± 10 nm, indicating that 25 ± 5 nm of the crystalline sample thickness on each surface of the TEM sample is electrically inactive. Similarly, the intercept of the graph with the vertical axis is $C_E V_{\text{bi}} t_{\text{active}}$, which provides the expected value for the built-in voltage

across the junction of 0.9 ± 0.1 V. Depletion widths across the junction measured from the line profiles are higher than expected, suggesting that the electrically active dopant concentration in the sample is lower than the nominal value. However, these experiments also show that electrical biasing reactivates some of the dopant in the sample that has been passivated by sample preparation [324].

The electrical nature of the sample surface was investigated by examining the vacuum region just outside the edge of the sample in the recorded phase images. Figure 39f shows a four-times-amplified phase image obtained from a 90° cleaved wedge sample that had *not* been focused ion beam milled, for an applied reverse bias of 2 V, in which an external electrostatic fringing field similar to that predicted [325] is visible. Such fringing fields were never observed outside either *unbiased* cleaved wedges or any focused ion beam milled samples, indicating that the surface of a TEM sample prepared by focused ion beam milling is always an equipotential under applied bias.

The importance of minimizing and assessing damage, implantation, and curtaining problems when examining a focused ion beam milled TEM sample that contains a *p–n* junction has been highlighted by three recent papers that present results from unbiased samples [326–328]. The most elegant of these experiments involved the use of focused ion beam milling to form a 45° wedge, from which both the phase change across the junction and the absolute phase shift relative to vacuum on each side of the junction could be plotted as a function of sample thickness. The slopes of these phase change and phase profiles were then used to provide the built-in voltage across the junction and the mean inner potentials of the *p* and *n* sides of the junction, respectively, while the intercept of the phase change graph was used to determine the electrically dead layer thickness. Using this approach, the built-in voltage across a junction with a dopant concentration of approximately 10^{15} cm^{-3} was measured to be 0.71 ± 0.05 V, while the mean inner potentials of the *p* and *n* sides of the junction were measured to be 11.50 ± 0.27 and 12.1 ± 0.40 V, respectively. The electrically dead layer thickness was measured to be approximately 25 nm on each sample surface.

4.3.4. Simulations

The electrical state of the surface of a TEM sample that contains a doped semiconductor can be assessed by comparing experimental holographic results with computer simulations. Simulations have recently been performed using commercial semiconductor process simulation software [329]. These simulations considered the effect of surface states, charged surface oxide layers, and the generation of electron–hole pairs on the electrostatic potential in the sample. Figure 40a shows simulated equipotential contours for a Si sample of thickness 100 nm that has hole traps on its surfaces. The *n* and *p* sides have doping concentrations of 4.86×10^{15} and 9×10^{18} cm^{-3}, respectively. A sample with these doping concentrations has been studied experimentally [312] and has revealed anomalous contrast features in defocused images of the junction. The presence of surface states in the simulation leads to the formation of a surface depletion layer on the *p*-side of the junction, but the model cannot

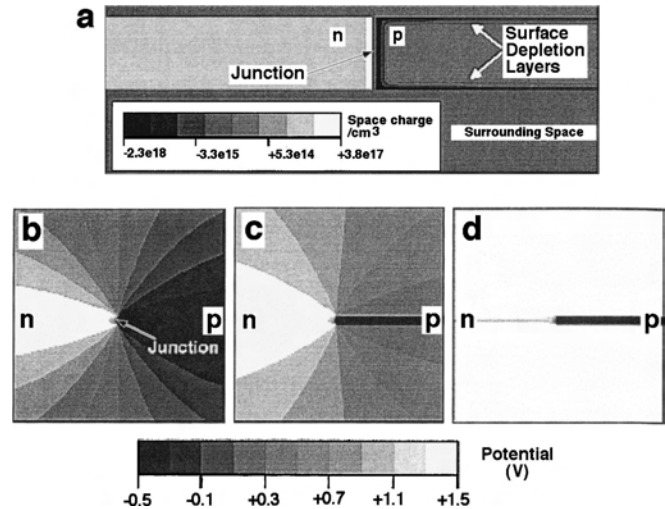

Figure 40. (a) Simulation showing equipotential contours that depict surface depletion layers on the *p*-side of a *p–n* junction in a Si sample of thickness 100 nm, created by the presence of hole traps on the sample surfaces. The *n*- and *p*-sides have doping concentrations of 4.86×10^{15} and 9×10^{18} cm^{-3}, respectively. (b), (c), and (d) Equipotential contours showing the effect of increasing positive surface charge concentrations of 1×10^{13}, 2.5×10^{13}, and 1×10^{14} cm^{-2}, respectively. The external electrostatic leakage field outside the sample is no longer present in (d). Reprinted with permission from [329], M. Beleggia et al., *Inst. Phys. Conf. Ser.* 169, 427 (2001). © 2001, Institute of Physics Publishing.

account for the experimental observations. A better model involves including electron-beam-induced charging of the silicon oxide layer that forms on the sample surfaces, at a level of approximately 10^{13} to 10^{14} cm^{-2}. The presence of this concentration of positive charge creates an inversion layer on the *p*-side of the junction, which eventually cancels out the surface potential and results in the absence of electrostatic fringing fields outside the sample surface, in agreement with observations for unbiased *p–n* junctions. (Such fringing fields, if present, would dominate the observed phase contrast [330].) The depletion width in the simulation varies with distance from the sample surfaces, in agreement with experimental measurements obtained as a function of sample thickness from a focused ion beam milled sample [321]. Figure 40b, c, and d shows the effect of increasing the surface charge concentration on the equipotential contours that form both within and surrounding the sample described in Figure 40a. The electrostatic fringing field disappears progressively with increasing surface charge density, until it is no longer visible at a concentration of 10^{14} cm^{-2}.

4.3.5. Layered Device Structures

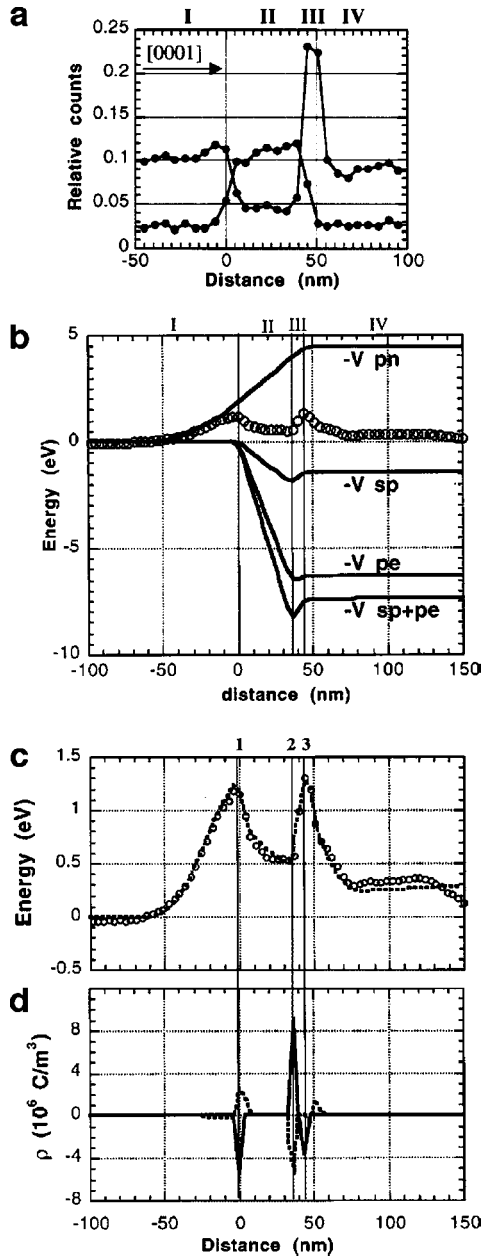
Although questions still remain about the phase contrast observed at a simple Si *p–n* junction, successful attempts have been made to interpret electron holographic data obtained from more complicated semiconductor device structures, where changes in composition as well as doping concentration were present. Figure 41 shows results obtained from a strained *n*-Al$_{0.1}$Ga$_{0.9}$N/In$_{0.1}$Ga$_{0.9}$N/*p*-Al$_{0.1}$Ga$_{0.9}$N heterojunction diode, in which large piezoelectric and polarization fields are used to induce high two-dimensional electron gas (2DEG) concentrations [331].


Figure 41. (a) Energy dispersive X-ray profiles showing the Al and In signals obtained from an n-$Al_{0.1}Ga_{0.9}N$/$In_{0.1}Ga_{0.9}N$/p-$Al_{0.1}Ga_{0.9}N$ structure with an additional thin barrier layer with an enhanced Al concentration of 30% grown on the InGaN. The n-AlGaN layer was nominally doped with 1×10^{18} cm^{-3} of Si, while the p-AlGaN layer was nominally doped with 1×10^{20} cm^{-3} of Mg. Integrated peak counts were normalized to the Ga signal. Regions I, II, III, and IV correspond to n-AlGaN, InGaN, the high concentration AlGaN barrier, and p-AlGaN, respectively. (b) Energy-profile across structure measured from an electron holographic phase image acquired at 200 kV using a Philips CM200 FEG-TEM (open circles). Calculated energy contributions for p-n junction V_{pn}, spontaneous polarization V_{sp}, and piezoelectric V_{pe} contributions to the energy are indicated. (c) Experimental (open circles) and simulated (dotted line) energy across structure, incorporating both spontaneous and piezoelectric polarization. (d) Bound polarization-induced interface charge (solid line) and additional charge (dotted line) used for energy simulation shown in (c). Reprinted with permission from [331], M. R. McCartney et al., *Appl. Phys. Lett.* 76, 3055 (2000). © 2000, American Institute of Physics.

The n-AlGaN layer in this sample was nominally doped with 1×10^{18} cm^{-3} of Si, while the p-AlGaN layer was nominally doped with 1×10^{20} cm^{-3} of Mg. An additional thin barrier layer with an enhanced Al concentration of 30% was grown on the InGaN. Figure 41a shows Al and In energy-dispersive X-ray profiles obtained from this sample, in which regions I, II, III, and IV correspond to n-AlGaN, InGaN, the high concentration AlGaN barrier, and p-AlGaN, respectively.

Electron holograms of a sample that had been prepared using conventional mechanical polishing and Ar-ion milling, and also lightly carbon-coated, were acquired at 200 kV using a Philips CM200 ST FEG-TEM operated in Lorentz mode. The open circles in Figure 41b show experimental measurements of the potential profile across the heterojunction, after correcting for changes in sample thickness (assuming a linear thickness profile and neglecting contributions to the measured phase from variations in mean inner potential). In order to interpret the experimental energy profile, simulations incorporated the effects of the p-n junction potential, the presence of both spontaneous and piezoelectric polarization, and additional charge accumulation. These contributions to the potential are shown in Figure 41b alongside the experimental data points. Additional charge had to be added to the simulations in order to account for discrepancies between the experimental data and the simulations in Figure 41b, within the constraint that the total charge in the model had to be zero. Figure 41c shows the best-fitting simulation, which incorporates both spontaneous and piezoelectric polarization, plotted alongside the experimental data. Figure 41d shows the magnitude of the bound polarization-induced interface charge and the additional charge required to obtain the match shown in Figure 41c. In particular, a sheet of negative charge was included at the bottom of the InGaN well, at a position consistent with the expected location of a 2DEG. The sheet charge density at this position was 2.1×10^{13} cm^{-2}.

Off-axis electron holography has also been used to characterize and to interpret electrostatic potentials within GaN-based quantum well structures [332–336] and to study charging effects at different types of threading dislocations in GaN [337–339].

4.4. Space Charge Layers at Grain Boundaries

Figure 41 demonstrated the use of electron holography to characterize interfaces in semiconductor devices where there were rapid changes in both composition and doping concentration. The technique has also been used to characterize space charge layers at doped and undoped grain boundaries in electroceramics such as $SrTiO_3$ and ZnO, where several possible contributions to the measured electron holographic phase complicate interpretation. The space charge distribution that is predicted to form at such a grain boundary [340, 341] is often described as a double (back-to-back) Schottky barrier, and the barrier height and width greatly influence the performance of the material in applications that include varistor devices for overvoltage protection.

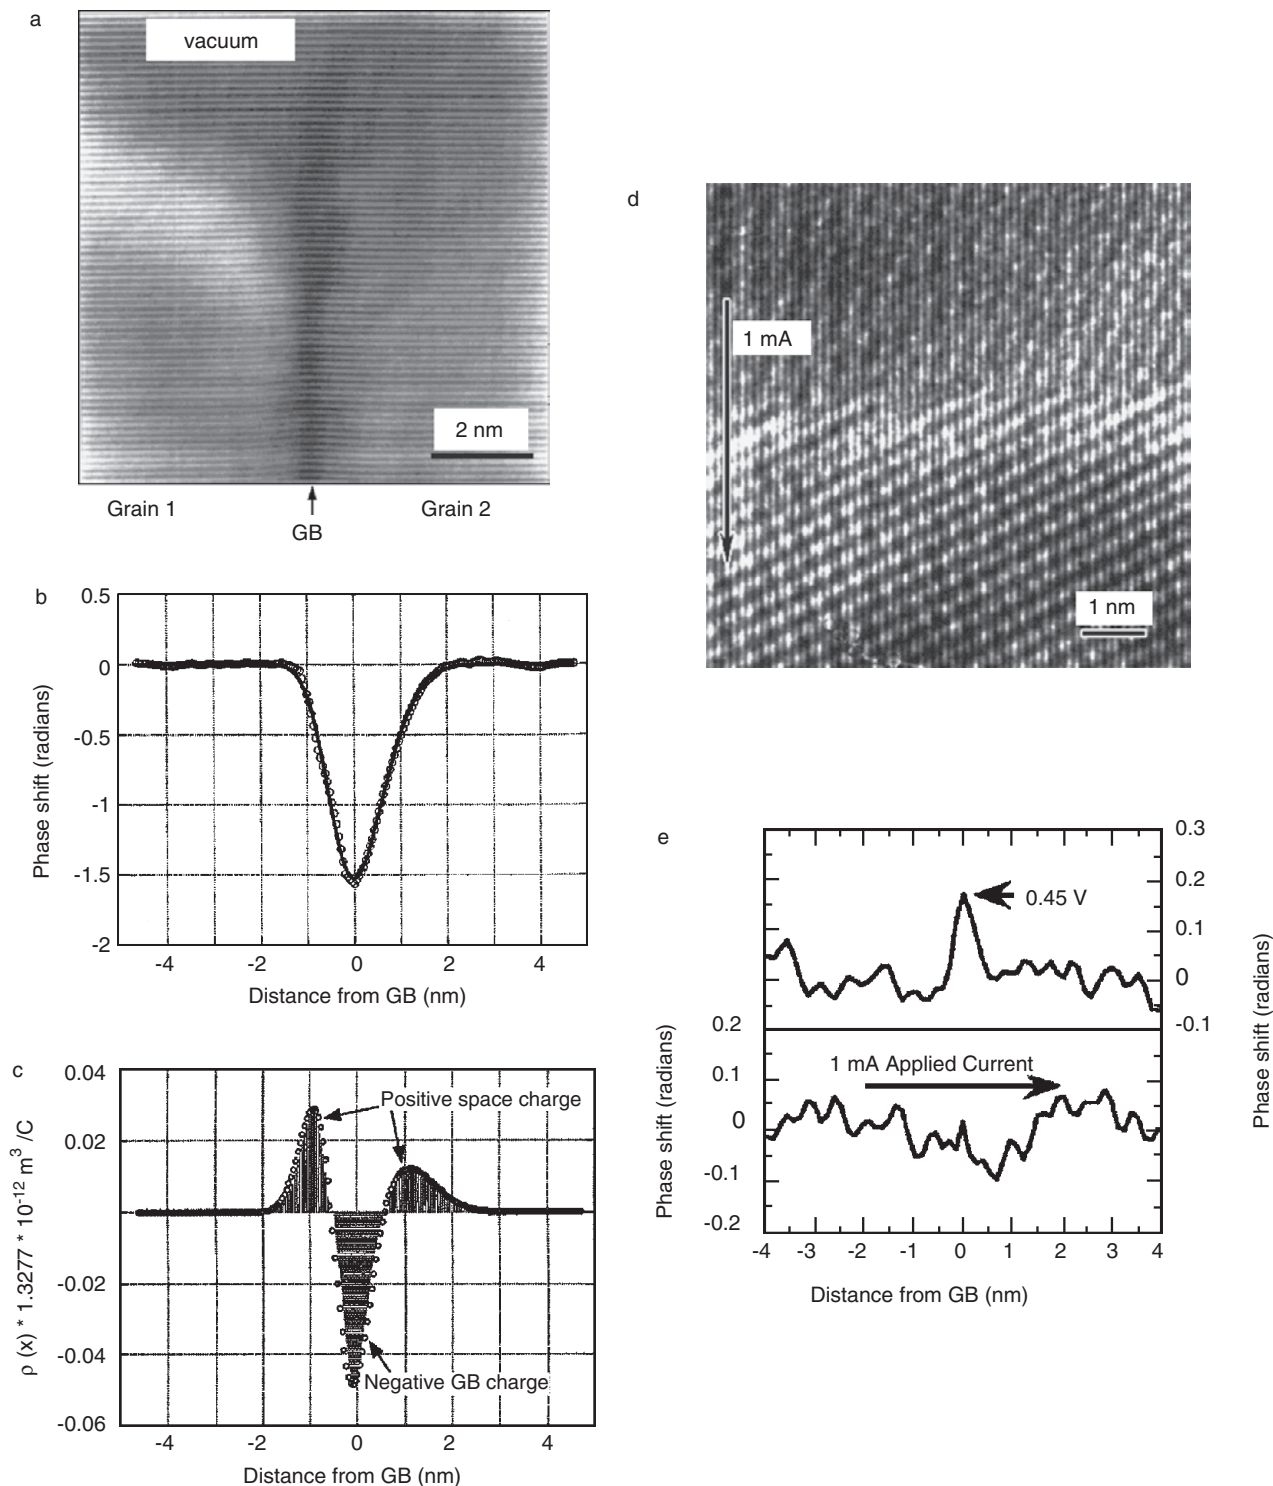
Figure 42a shows an electron hologram of a Mn-doped grain boundary in $SrTiO_3$, acquired at 200 kV in a Hitachi HF-2000 FEG-TEM using an interference fringe spacing of


Figure 42. (a) Electron hologram of a Mn-doped grain boundary in $SrTiO_3$ acquired using a Hitachi HF-2000 FEG-TEM. The interference fringe spacing is 0.14 nm. (b) Phase profile measured across grain boundary shown in (a). (c) Charge density profile inferred by applying Poisson's equation direction to the phase profile shown in (b). The charge density profile suggests the presence of negative grain boundary charge and compensating positive space charge. The spatial extent of the boundary charge is approximately 1.4 nm. (d) Electron hologram acquired from a Nb-doped grain boundary in $SrTiO_3$ that has a current flowing across it *in-situ* in the TEM. (e) Measured phase shift across the boundary shown in (d), both before applying a current and as a current is applied. The absence of contrast at the boundary when a current is flowing suggests barrier breakdown. Reprinted with permission from [357], K. D. Johnson and V. P. Dravid, *Appl. Phys. Lett.* 74, 621 (1999). © 1999, American Institute of Physics.

0.14 nm [342–348]. Similar holograms were obtained from several undoped and doped grain boundaries in SrTiO$_3$. All results showed a decrease in the measured phase shift at the boundary relative to that in the sample. However, the changes in phase measured at the doped boundaries were consistently larger in both magnitude and spatial extent than at similar undoped grain boundaries. Possible contributions to the contrast from changes in density, composition, sample thickness, dynamical diffraction, and electrostatic fringing fields [349, 350] were considered, and the remaining contributions to the measured phase shifts at the doped boundaries were attributed to space charge. The sign of this space charge contribution to the specimen potential was consistent with the presence of Mn^{2+} and Mn^{3+} ions on Ti sites at the boundaries. The phase profile and the corresponding charge density profile at a Mn-doped boundary, as inferred from the hologram in Figure 42a, are shown in Figure 42b and c, respectively. Both the force acting on the boundary as a result of the presence of the space charge layer and the resulting strain profile were calculated for these boundaries [345], presumably on the basis of equations published in an earlier study [351]. The results were finally interpreted in terms of a narrow (1–2 nm) region of negative grain boundary charge and a wider (3–5 nm) distribution of positive space charge.

A similar approach has recently been applied to the characterization of grain boundaries in ZnO, where a space charge layer width of approximately 150 nm has been measured [352]. In an earlier study, the defocus contrast recorded from delta-doped layers in Si and GaAs was also attributed to the presence of space charge [353]. Defocus contrast has been used to assess possible space charge contributions to electrostatic potential profiles across grain boundaries in mullite [354] and in both doped and undoped SrTiO$_3$ [355, 356]. In contrast to the results shown in Figure 42, the contrast observed in the latter experiments was not found to be consistent with a dominant contribution to the signal from space charge.

The electrical transport properties of Nb-doped and Mn-doped grain boundaries in SrTiO$_3$ bicrystals have recently been examined *in-situ* in the TEM by acquiring electron holograms while electric currents were passed across the boundaries [357–359]. In order to perform these experiments, Ni contact pads were evaporated onto the samples after they had first been prepared for TEM examination using dimpling and ion milling. Figure 42d shows an electron hologram acquired from a Nb-doped grain boundary in SrTiO$_3$ as a current of 1 mA flows across it. The measured phase shift across the boundary is shown in Figure 42e both before applying the current and as the current is applied. The absence of a detectable phase shift at the boundary when the current is flowing suggests that barrier breakdown then occurs. This suppression of the boundary potential is reversible as the current is applied and then removed.

Related experiments have been performed to measure the polarization distributions across domain boundaries in ferroelectric materials such as BaTiO$_3$ and PbTiO$_3$ [360–365] and the external electrostatic fringing fields [366]. The theory of electron holographic contrast from ferroelectric domain walls has also been presented [367]. Considerable further work is possible on this subject.

5. ALTERNATIVE FORMS OF ELECTRON HOLOGRAPHY

There are many different forms of electron holography that can be implemented both in the TEM and in the STEM [368]. Equally, there are several alternative ways in which the off-axis mode of TEM electron holography can be implemented. A full discussion of the various possible schemes that have been investigated, which include interferometry in the diffraction plane of the electron microscope [369, 370], reflection electron holography [371], and coherent convergent beam electron diffraction [372, 373], is beyond the scope of this chapter. Some developments that are historically or potentially most useful for examining nanostructured materials are reviewed.

5.1. Differential Form of TEM Electron Holography

The need for a vacuum reference wave is a major drawback of the normal off-axis mode of TEM holography since this requirement restricts the region that can be examined to the specimen edge. In many applications, the feature of interest is not so conveniently located. In addition, the presence of an edge may dominate the magnetic contribution to the measured phase shift for magnetic samples. The implementation of a differential phase contrast (DPC) mode of electron holography in the TEM enables this restriction to be overcome. DPC imaging is well established as a technique in the scanning transmission electron microscope, involving various combinations of detectors to obtain magnetic domain contrast [374–376]. It has also been shown [377] that DPC contrast can be obtained using far-out-of-focus STEM electron holography. An equivalent configuration can be achieved in the TEM by using an electrostatic biprism located in the condenser aperture plane of the electron microscope [378].

Figure 43a shows a schematic ray diagram that illustrates the electron-optical configuration of the microscope for the differential mode of off-axis TEM holography. The application of a positive voltage to the biprism wire results in the formation of two closely spaced, overlapping plane waves, which appear to originate from sources S$_1$ and S$_2$ to create an interference fringe pattern at the specimen level. When the observation plane is defocused by a distance Δz with respect to the specimen plane, the two coherent beams produced by the beamsplitter, which are labelled k$_1$ and k$_2$ in Figure 43a, impinge upon different parts of the specimen. For a magnetic material, the difference in the component of the magnetic induction parallel to the biprism wire between these two points in the specimen plane determines the relative phase shift of the holographic fringes, thus giving differential phase contrast. Since the hologram is acquired under out-of-focus conditions, it is in effect the superposition of a pair of Fresnel images. The biprism voltage must be adjusted so that the feature of interest or the desired spatial resolution is sampled by at least three interference fringes. An appropriate postspecimen magnification should be chosen to ensure that the interference fringes are properly sampled by the recording medium.

Figure 43b shows a composite phase image obtained from a series of eight DPC holograms of a 30-nm-thick Co film, where the fringe system was shifted progressively across the specimen plane between exposures. In addition to the holographic interference fringes, the image shows charac-

teristic black and white lines that delineate walls between magnetic domains, with magnetization ripple visible within the domains. All of the image features appear doubled due to the split incident beam. Figure 43c shows the final reconstructed DPC image obtained from Figure 43b, in which the contrast is proportional to the component of the magnetic induction parallel to the holographic fringes. The arrow below the image indicates the direction of the component of the magnetic induction analyzed in this experiment. Several magnetic vortices are visible, where the measured field direction circles an imperfection in the film. One such vortex is indicated by an arrow in the lower right corner of the image. For complete characterization of both components of the in-plane induction without removing the sample from the electron microscope, either a rotating biprism or a rotating sample holder is required.

5.2. Amplitude Division Electron Holography

A scheme that is conceptually similar to the differerential mode of electron holography in the TEM, but which does not require the use of either an electron biprism or a field emission electron gun, is termed amplitude division electron holography. Whereas conventional modes of electron holography involve splitting the wavefront of the incident illumination and thus require high spatial coherence in order to form interference fringes, this coherence requirement can be removed by dividing the amplitude of the incident electron wave instead of the wavefront. This division of the amplitude of the incident electron wave can be achieved by using a crystal film located before the sample. The lattice fringes of the crystal film are then used as carrier fringes. The original configuration for this scheme involved placing the specimen in the selected-area-aperture plane of the electron microscope [379, 380]. The specimen can also be inserted into the normal object plane by using the electron-optical configuration shown in Figure 44a [381, 382]. A single-crystal thin film and the sample of interest are placed on top of each other, in close proximity, in the electron microscope. The single-crystal film is then tilted to a strong Bragg condition and used as an electron beam splitter. As a result of the separation of the crystal and sample, the hologram plane contains two defocused images of the sample that are shifted laterally with respect to each other. One of these images is carried by the direct beam and the other by the Bragg-reflected beam, as indicated by the solid and dashed lines in Figure 44a, respectively. When the distance between the two images is greater than the object size, the images separate perfectly and interfere with adjacent plane waves to form an off-axis electron hologram. The distance between the two images is given by the expression

$$l = \frac{\lambda z}{d} \tag{58}$$

where λ is the electron wavelength, z is the distance between the crystal and the specimen, and d is the lattice spacing of the crystal. Because the single crystal is in focus and the object is out of focus, a Fresnel electron hologram of the object is obtained. The defocus of the object can
Figure 44. (a) Electron-optical setup for hologram formation using a single-crystal film as an electron beamsplitter. The solid lines indicate the direct electron rays, while the dashed lines indicate the Bragg-reflected rays. (b) Fresnel hologram of a polystyrene latex particle. Approximately 1500 Au lattice fringes are recorded. The left and right images are formed by the Bragg-reflected and direct beams, respectively. (c) Reconstructed phase map of a pair of (111) Au platelets grown epitaxially on MoS_2. Reprinted with permission from [381], Q. Ru et al., *Ultramicroscopy* 53, 1 (1994). © 1994, Elsevier Science.

be corrected at the reconstruction stage by using a phase plate, although high coherence of the incident illumination is then required. The coherence used when forming the image therefore determines the spatial resolution of the final reconstructed image. In addition, poor contrast in the lattice fringes will lead to noise in the reconstructed phase image. Although amplitude-division electron holography has several obvious disadvantages over wavefront-division holography, the final phase image is not affected by such effects as Fresnel diffraction from the edges of the biprism wire. The diffracting condition and the thickness of the crystal film also have little effect on the results [383].

Figure 42b shows a hologram of a 120-nm-diameter polystyrene latex particle, illuminated by an electron beam that has been split by a single crystal Au film with a lattice spacing of 0.204 nm. This image was recorded using convergent illumination, under conditions where no interference fringes would be produced in a conventional off-axis electron hologram. The image on the right of Figure 42b is formed by the direct beam, while the image on the left is formed by the Bragg-reflected beam. The crystal and the sample are separated by 10 nm, and approximately 1500 Au lattice fringes are recorded in the hologram. An enlarged area of the hologram, where the lattice fringes are visible, is shown at the bottom of Figure 44b. Figure 42c shows a reconstructed phase image obtained by amplitude division electron holography from a pair of (111) Au platelets grown epitaxially on a molybdenite (MoS_2) substrate.

5.3. Phase Shifting Electron Holography

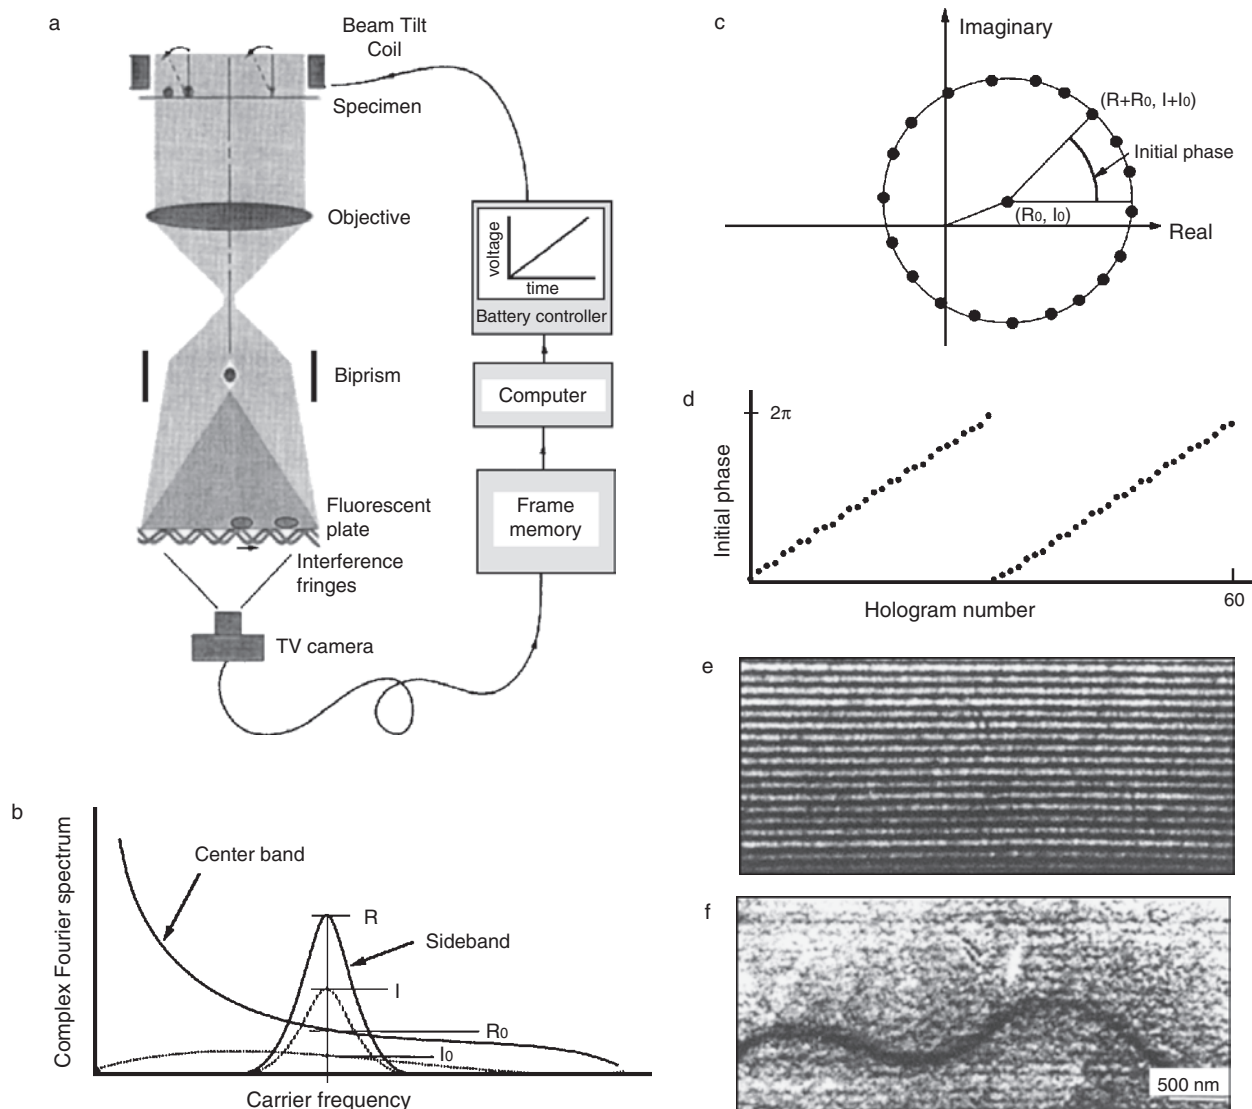
One approach that can be used to increase the phase sensitivity of electron holography is termed phase-shifting electron holography. This approach is based on the acquisition of several off-axis holograms while the phase offset (the initial phase) of the image is changed, either by tilting the incident electron beam or by shifting the biprism [384, 385]. The electron optics that are required for the scheme that involves tilting the incident beam are shown in Figure 45a. Electron holograms are recorded at successive values of the incident beam tilt, such that the phase is shifted by at least 2π over the image series. The fringe shift can be monitored in the complex Fourier spectra of the holograms. In Figure 45b, the real and imaginary components given by the center band are denoted R_0 and I_0, while those given by the sideband are denoted R and I. The real and imaginary parts of the complex Fourier spectrum are shown as solid and broken lines, respectively. Since shifting the initial phase does not change the complex spectrum of the center band nor the absolute amplitude of the sideband, the parameters R_0, I_0, and $(R^2 + I^2)^{0.5}$ do not change when the phase is shifted. A series of real–imaginary pair values obtained from holograms acquired with different initial phases therefore trace out a circular trajectory, with radius $(R^2 + I^2)^{0.5}$ and center located at (R_0, I_0), as shown schematically in Figure 45c. The values of R_0 and I_0 can be determined by fitting the trajectory with a circle, while R and I are given by subtracting R_0 and I_0 from the measured spectrum data. The initial phase of each hologram is determined by calculating the inverse tangent of the ratio I/R. A series of calculated


Figure 45. (a) Electron optics and equipment required for shifting the initial phase of an electron hologram. (b) Schematic diagram of the complex Fourier spectrum, with the real and imaginary parts shown as solid and broken lines, respectively. (c) Complex plane, illustrating the circular trajectory of the spectrum data at the carrier frequency. (d) Calculated initial phase data for a series of holograms. (e) Hologram of a thin flagellum filament. (f) The corresponding phase image, obtained from a series of 96 holograms with different initial phases from 0 to 4π. The maximum phase change due to the filament is $2\pi/40$. Reprinted with permission from [69], Q. Ru et al., *Ultramicroscopy* **55**, 209 (1994). © 1994, Elsevier Science.

initial phases is plotted in Figure 45d for a 4π shift in the initial phase.

For N holograms recorded in equal steps between phase shifts of 0 and 2π, the procedure involves multiplying the intensity in the nth hologram in the series by $\exp(2\pi in/N)$, and adding these images together in the form

$$C_3 = \left(\frac{1}{N}\right) \sum_{n=1}^{N} I(n) \exp\left(\frac{2\pi in}{N}\right) \qquad (59)$$

The desired phase distribution $\phi(x, y)$ is then given by the expression

$$\phi(x, y) = \tan^{-1}\left(\frac{\text{Im}[C_3]}{\text{Re}[C_3]}\right) - \frac{2\pi x}{T_x} - \frac{2\pi y}{T_y} \qquad (60)$$

where T_x and T_y are the fringe spacings in the x and y directions, respectively. Although three holograms can in principle be used to reconstruct the object wave, in practice as many holograms as possible are used to reduce noise in the reconstructed phase.

The advantages of the phase-shifting approach are greatly improved phase sensitivity and spatial resolution. Since the object wave is reconstructed from only the intensity data at each point, defects do not propagate into adjacent areas, and the spatial resolution is equal to that of the original image, independent of the fringe spacing. Objects that are smaller than one fringe width can therefore be reconstructed. Care is required if the object is out of focus, as tilting the beam will then induce an image shift between successive images. Shifting the biprism may then be required if

atomic resolution phase measurements are to be achieved. Figure 45e shows an individual hologram of a thin bacterial flagellum filament, and Figure 45f shows the corresponding phase image, obtained from a series of 96 holograms acquired with different initial phases ranging from 0 to 4π. The maximum phase change due to the filament is $2\pi/40$ [69]. Very small phase shifts have also been observed from individual unstained ferritine molecules [386] and both latex and iron particles [387].

5.4. Real-Time Electron Holography

Electron holograms can be acquired at video rate and subsequently digitized and processed individually to record dynamic events, but this procedure is very time-consuming. An alternative, real-time approach for acquiring and processing holograms has been demonstrated by using a liquid–crystal panel to reconstruct holograms in real time [388–390], in the configuration shown in Figure 46. The electron holograms are recorded at TV rate and then transferred to a liquid–crystal spatial light modulator, which is located at the output of a Mach–Zender interferometer. The liquid–crystal panel is illuminated using a He–Ne laser, and interference micrographs are observed and recorded at video rate on the monitor beside the microscope as the sample is examined. (In an alternative configuration, a liquid–crystal
panel can also be used as a computer-controlled phase plate to correct for aberrations [391].) Recently, an all-digital system that allowed reconstructed (wrapped) phase images to be displayed at approximately one frame per second has been facilitated by developments in computer speed, with the number of phase wraps across the field of view minimized automatically in each image [392]. This performance represents a substantial improvement over a time of 30 s per hologram reported in 1991 [47].

5.5. In-Line Electron Holography

Whereas an off-axis electron hologram is formed by the interference of an object and a reference wave that propagate in different directions in the electron microscope, as shown schematically in Figure 47a and b [35], the simplest way of recording an electron hologram without using an electron biprism involves using the transmitted wave as the reference wave to form an in-line electron hologram. Gabor's original paper [1] describes the reconstruction of an image by illuminating an in-line hologram with a parallel beam of light using a spherical aberration correcting plate and an astigmatism corrector. The reconstructed image is, however, disturbed by a "ghost" or "conjugate" twin image. If the hologram is recorded and subsequently illuminated by a plane wave, then both the reconstructed image and a

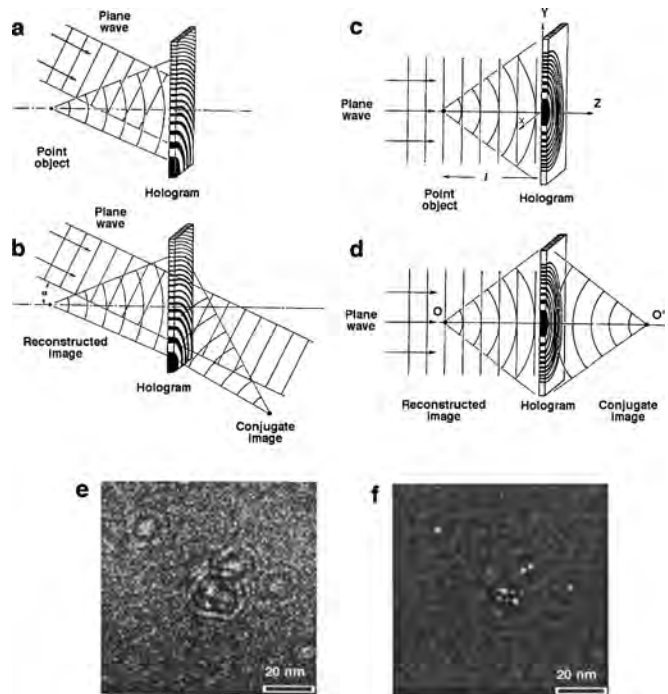

Figure 46. Schematic diagram of an on-line real-time electron holography system. The hologram formed in the microscope is transferred, as a video signal, to a liquid–crystal spatial light modulator located at the output part of a Mach–Zender interferometer. Interference micrographs are observed on the monitor beside the microscope. Reprinted with permission from [390], T. Hirayama et al., *Ultramicroscopy* 54, 9 (1994). © 1994, Elsevier Science.

(c) and (d) As for (a) and (b) but for in-line electron holography of a point object. Reprinted with permission from [35], A. Tonomura, "Electron Holography," pp. 4 and 7. Springer-Verlag, Berlin, 1999. © 1999, Springer-Verlag. (e) Fraunhofer in-line electron hologram of an undecagold cluster, at a defocus of 13.6 μm. The corresponding Fresnel number is 0.0155. (f) Phase image reconstructed from the hologram shown in (e). Reprinted with permission from [396], T. Matsumoto et al., *Ultramicroscopy* 54, 317 (1994). © 1994, Elsevier Science.

defocused conjugate image of the object are superimposed on top of each other since both images lie on the same axis, as shown schematically in Figure 47c and d. The most effective method for separating the twin images is to use Fraunhofer in-line holography [15]. Here, in-line holograms are recorded in the Fraunhofer diffraction plane of the object [393, 394], for which the defocusing distance

$$z \gg \frac{d^2}{\lambda} \tag{61}$$

where d is the object width and λ is the wavelength of the incident illumination. Under this condition, the conjugate image is so blurred that its effect on the reconstructed image is negligible [395].

An example of a Fraunhofer in-line electron hologram of an undecagold cluster, which is supported on a thin (<5 nm) carbon film, and recorded at a defocus of 13.6 μm, is shown in Figure 47e [396]. The Fraunhofer condition described by Eq. (61) is satisfied for this object. Figure 47f shows the phase image reconstructed from the hologram shown in Figure 47e. The Fraunhofer condition would no longer be satisfied if a considerably larger object were present in the field of view at this defocus. A maximum entropy approach has also been applied to the reconstruction of in-line electron holograms [397].

It should be noted that in-line electron holography also encompasses "Fresnel imaging," which has been used to measure the structure and composition of a variety of boundaries and interfaces [398–409], including magnetic domain boundaries [410, 411].

5.6. Differential Form of STEM Electron Holography

The STEM holographic mode used for DPC imaging, which has similarities with the TEM differential mode of electron holography described above, is a point projection technique in which a *stationary* illuminating beam in a STEM is split by a biprism preceding the sample so that two mutually coherent electron point sources are formed just above the sample. The electron-optical configuration for this mode of holography is shown schematically in Figure 48. In this operating mode, the objective lens is weakly excited so that the hologram is formed in the diffraction plane rather than the image plane [412]. By greatly defocusing the objective lens, a shadow image of the object is formed, which has the appearance of a TEM hologram, although it is distorted by spherical aberration and defocus. The image magnification and the separation of the sources relative to the sample are flexible in this configuration and can easily be adjusted by changing the biprism voltage and/or the objective or postspecimen lens settings. The far-out-of-focus mode of STEM holography has been applied to the characterization of a wide range of magnetic materials [377, 413–420], where the sample had to be displaced by ∼15 mm from the center of the objective lens so that it could be located in a field-free region of the electron microscope.

5.7. Double Exposure Electron Holography

A simple approach that can be used to visualize equiphase contours involves superimposing a hologram of the sample onto a reference hologram acquired under identical conditions, with the sample removed from the field of view [421]. Interference effects between the holographic fringes in the two images then provide widely spaced, low contrast bright and dark bands that reveal phase contours directly. Defocusing the combined image slightly can then be used to remove the unwanted, finely spaced holographic interference fringes. The technique has been applied to image both electrostatic and magnetic fields [41]. For example, Figure 49a shows an experimental double-exposure electron hologram of the magnetic leakage field outside the apex of a Ni magnetic force microscopy tip. The phase difference between neighboring black or white fringes is 2π. A computer simulation of the contrast, generated by assuming that the tip can be approximated by a single macroscopic magnetic dipole, is shown in Figure 49b. The simulation includes the effect of the perturbed reference wave on the recorded phase image [40]. Figure 49c shows a double-exposure electron hologram of crossed domain walls in a permalloy thin film [41]. A similar double-exposure hologram can be obtained after changing the biprism voltage by a small amount before recording the reference hologram [36].

A related approach involves the use of two parallel or perpendicular electron biprisms to generate an interference pattern between either three or four electron waves, respectively. Equiphase contours are displayed in the recorded hologram in the same manner as for double-exposure electron holography. This method has been used to form images of electric field lines outside charged latex and alumina particles, as well as magnetic fields outside barium ferrite particles [422–424], and even to expose a resist to fabricate a 100-nm-period two-dimensional grating lithographically [425]. Two parallel biprisms have also been used to
Figure 49. (a) Experimental double-exposure electron hologram of the magnetic leakage field outside the apex of a Ni magnetic force microscopy tip, recorded in a Philips EM 400T FEG-TEM. The overlap width is 4 μm. The phase difference between neighboring black or white fringes is 2π. (b) Computer simulation of the contrast in image (a), generated by assuming that the tip can be approximated by a single macroscopic magnetic dipole. The simulation includes the effect of the perturbed reference wave on the recorded phase image. Reprinted with permission from [40], G. Matteucci et al., *Phys. Rev. B* 50, 6823 (1994). © 1994, American Physical Society. (c) Double-exposure electron hologram of crossed domain walls in a permalloy film. Reprinted with permission from [41], G. Matteucci et al., *Appl. Phys. Lett.* 52, 176 (1988). © 1988, American Institute of Physics.

form a "trapezoidal" biprism, in order to record a double-exposure hologram with the biprism voltage changed [426], but the reference wave unaffected by the biprism voltage [427]. This scheme is similar conceptually to that presented by van Dyck [39].

6. CONCLUSIONS

The reconstruction of electron holograms using both optical and digital methods has been outlined, and the different types of information that can be obtained using the two approaches have been illustrated using results from a wide variety of nanostructured materials. A key point is that as nanostructured materials decrease in size so the magnetic and electrostatic signals from them also become progressively weaker. Of the different microscopy techniques that are available, it is easiest to measure these signals with high sensitivity from a phase image recorded using electron holography. For example, most other TEM techniques for measuring magnetic microstructure (such as the Fresnel and Foucault modes of Lorentz microscopy and DPC imaging) record signals that are proportional to either the first or the second differential of the phase shift, which inherently enhance contributions to the signal from rapid variations in sample thickness and composition, as compared to the weak and slowly varying magnetic signal.

Results have been presented from many different types of materials, including fine magnetic particles, the experimental confirmation of the Aharonov–Bohm effect, mag-

netic force microscopy tips, field-emitting carbon nanotubes, and a range of semiconductor device structures. *In-situ* experiments, which allow magnetization reversal processes to be followed and electrostatic fields in working semiconductor devices to be characterized, have been described. Although the results that are presented here are specific to the dimensions and the morphologies of the samples that are described, they illustrate the ways in which electron holography can be adapted to tackle different materials problems and the issues that remain to be answered, both about the technique and about the materials of interest.

Future developments in the field of electron holography of nanostructured materials are likely to follow several distinct paths: the development of new forms of electron holography and instrumentation, the development of new approaches that can enhance weak magnetic and electrostatic signals, the further examination of novel materials, the formulation of a complete understanding of the effect of different TEM sample preparation approaches on dopant contrast in semiconductors, and the combination of electron holography with electron tomography to record both electrostatic scalar fields and magnetic vector fields *inside* nanostructured materials (rather than simply the stray fields outside [428]) in *three* rather than just two dimensions [146]. The application of electron holographic tomography to the characterization of magnetic vector fields requires two high-tilt series of holograms to be recorded about orthogonal axes in order to reconstruct the three-dimensional distributions of two of the three components of the magnetic field in the sample B_x and B_y. The third component B_z could then be evaluated by making use of the criterion that div.**B** must equal zero everywhere, in the form

$$B_z(x, y, z) = -\int_{-\infty}^{z} \left[\frac{\partial}{\partial x} B_x(x, y, \zeta) + \frac{\partial}{\partial y} B_y(x, y, \zeta) \right] d\zeta$$

(62)

If this approach is ultimately successful, the primary difficulty may lie in the measurement and subtraction of the unwanted mean inner potential contribution to the measured phase shift at every one of the tilt angles required.

Electron holography has progressed through many generations of development. It has now evolved to the stage where the emphasis is shifting toward its optimization for specific challenging applications to diverse materials problems. This statement is particularly true for electron holography applications at medium resolution, for which the phase image provides information about magnetic and electric fields both in the sample and in the surrounding space. Such information is rarely available using other TEM imaging techniques.

The unique capability of the technique to provide quantitative information at resolutions approaching the nanometer scale, coupled with the increasing availability of field-emission-gun transmission electron microscopes and quantitative digital recording, suggests that the technique has a very promising future.

GLOSSARY

Electron holography An electron microscopy technique that can be used to record an interference pattern (an electron hologram) that contains information about changes in

the amplitude and phase shift of an electron wave scattered by a material. The hologram can be used to provide information about local variations in electrostatic and magnetic potential within and surrounding the material at a spatial resolution that can approach the atomic scale.

Transmission electron microscope (TEM)   An instrument that makes use of a beam of high energy (>50 kV) electrons, which are focused using electromagnetic lenses, to obtain information about the microstructure of a thin (<1 micrometer) sample, through which the electrons pass. Further electromagnetic lenses are used to magnify either an image or a diffraction pattern of the sample. Additional components such as spectrometers can be used to record a variety of signals from the sample in order to characterize its chemical composition and electrical and magnetic properties at a spatial resolution that can approach the atomic scale.

CONTENTS

1. INTRODUCTION

The study of the dispersion of light by the condensed matter constitutes a means of investigation of the substance. The theoretical investigations of Brillouin were the beginning of investigation of the inelastic dispersion of light, with the publication of a study about the interaction of light with liquids in 1922. One year later the work of Smekal continued, in atoms of two electron levels, foreseeing that the elementary excitements should produce a displacement in the frequency of the dispersed light. In 1928, Raman observed experimentally this effect, which is called the Smekal–Raman effect, now known as Raman scattering. In that same year, Landsberg and Mandelstam reported the same effect in quartz. The type of Raman scattering depends on the quasiparticles involved. In particular, if it is an electron, it is named electron Raman scattering.

Raman scattering allows the study of the vibrations and the structure of the molecules, which it makes possible the analysis of molecular complex mixtures, whose study by chemical means would be very complex and in some cases impossible to carry out. Also, it allows the investigation of the optical properties of the substance taking advantage of the growth of liquid crystals, fluorescent screens, optical memory, lasers, and other optical and electronic devices whose applications offer wide perspectives in the industry.

The study of Raman scattering is one of the most known methods of investigation of solids, with a very fast development. The employment of conventional sources of light, due to their low spectral density and their low coherence, has allowed the study of this phenomenon only in the region of small absorption, where the resonant effects are scarce, due to excitonic and impurities states. In 1962 Porto and Wood showed that the employment of a laser, as a substitute source of the solar light and lamps of gas discharges, could increase notably the experimental possibilities; this led to the discovery of phenomena whose detailed explanation is impossible in the frame of the traditional concepts of Raman scattering or luminescence in solids. The monochromatic, coherent and high spectral density character of the light laser allows one to explore the region of fundamental interest in the solids, that is, the region of strong absorption, which has allowed one to observe the phenomenon of multiphonon resonance Raman scattering.

The interest in the study of the nanostructured semiconductors is due to the possibility to observe phenomena such as the negative differential conductivity, the amplification of electromagnetic waves, the variation of the frequencies and intensities of the absorption and emission lines, and other nonlinear optical properties, which allows new applications in different branches of the science. In some cases these phenomena are impossible to observe in bulk materials. Thus,

such nanostructures might constitute the basis, in the near future, of an alternative class of solid-state lasers, transport, and optoelectronic devices.

The possibilities of fabrication of new electro-optical devices based in low dimensional systems have led to enormous interest in the investigation of semiconductor nanostructures such as quantum wells, superlattices, quantum wires, and quantum dots which are usually made from weakly ionic materials (for instance GaAs/AlAs). The nanostructured semiconductors can be synthesized by several methods, namely, porous silicon, zeolite cavities, molecular beam epitaxy with ionic attack, holographic nanolithography, etc. Such nanostructures might constitute the basis of an alternative class of solid-state lasers, transport, and optoelectronic devices, in the near future.

One of the most important processes in the physics of the condensed matter is the electron–phonon interaction, because it is involved in numerous phenomena such as the lifetime of the excitons, transport phenomena, etc. On the other hand, this theory is primordial for the analysis of the results of several experimental techniques like Raman scattering.

Polar optical oscillations in such systems play an important role in many physical processes, especially in the long-wavelength limit. One of the principal scattering mechanisms in these structures is through optical–phonon emission or absorption, which has led to many studies of the effects of the reduced dimensionality on the phonon modes. A continuum theory of optical phonons in quantum dot (QD), quantum well wire (QWW), and freestanding wire (FSW) was developed in [1–5], where the dispersion was illustrated for phonon modes with $l = 0$.

Raman scattering experiments are well known to provide a powerful tool for the investigation of different physical properties of semiconductor nanostructures [6–8]. In particular the electronic structure of semiconductor materials and nanostructures can be thoroughly investigated considering different polarizations for the incident and emitted radiation [6, 9]. In connection with this kind of experiment the calculation of the differential cross-section (DCS) for electron Raman scattering (ERS) remains a rather interesting and fundamental issue to achieve a better understanding of the manmade semiconductor nanostructures characterized by their mesoscopic dimensions [10–16].

The experiments of electron Raman scattering and resonant Raman scattering in nanostructures began to be carried out starting in the last five years. Some of the most recent works reported in the international literature are the following. Kohno et al. [17] studied chains of crystalline-Si nanospheres by means of Raman scattering spectroscopy. They found that the one-phonon Raman scattering peak from the chains was asymmetric and broader than that from bulk Si. This phenomenon can be attributed to phonon confinement in the silicon nanospheres. The phonon confinement became more obvious by decreasing the size of the silicon nanospheres in the chains. They also found that the Si nanospheres in the chains were under compressive stress by the covering oxide layers through the analysis of the Raman shift. Kaschner et al. [18] investigated ZnCdSe/ZnSe quantum dot structures which include planar and coherently strained three-dimensional islands with different sizes. They reported Raman scattering and photoluminescence investigations of ZnCdSe/ZnSe structures. Their results show that resonant Raman scattering can be used to investigate the stability of such structures under conditions of resonant excitation of the QDs. It was reported that resonant Raman scattering can be applied to the ZnSe material system to distinguish between the phonons ZnSe and the ZnSe-like longitudinal-optical (LO) phonons of $Zn_{0.8}Cd_{0.2}Se/ZnSe$ quantum wires presented in [19]. Artús et al. [20] provided direct experimental evidence of the existence of phonons arising from the QDs. To demonstrate this point they present a Raman scattering study of InAs/GaAs QDs for several coverage thicknesses L within the range of coherent three-dimensional island growth. For all the samples they detect a Raman peak at a frequency higher than the InAs LO frequency exhibits a dependence on L. Cazayous et al. [21] reported resonant Raman scattering by acoustical phonons in self-assembled QD structures. Most of the published Raman studies on self-assembled QDs were limited to the optical phonon frequency range [22–26]. It was demonstrated that valuable information about residual strain and chemical composition in the QD can be derived from the optical phonon Raman spectra [22, 24, 25]. Raman scattering by acoustic phonons in self-assembled QDs was reported very recently [27–29]. References [27, 28] deal with structures containing many QD layers, and the corresponding low frequency Raman spectra display features similar to the ones observed in SLs. Huntzinger et al. reported acoustic phonon Raman scattering in structures containing a single layer of InAs/InP QDs. Sobolev et al. [30] investigated the quenching of photoluminescence in InAs/GaAs quantum dots and quantum wells by 2 MeV electron irradiation. They demonstrate a much higher radiation hardness of the quantum dots. Possible mechanisms of this phenomenon are discussed in terms of the wavefunction localization and defect reactions. Heitz et al. [31] presented a time-integrated and time-resolved study of resonant Raman scattering for self-organized InAs/GaAs QDs yielding detailed information on the interaction of excitons with local phonon modes of the InAs QD layer. Kasuya et al. [32] presented experimental evidence on critical point structures in the electronic states found in resonant Raman scattering and optical absorption spectra. The recent Raman scattering measurements on single-wall nanotubes show evidence for the zone-folding effect in the phonon system [33, 34]. Jorio et al. [35] measured the resonant window for the resonant Raman scattering of one isolated single-wall carbon nanotube by using a frequency tunable laser E_l. They here report an asymmetric shape for the E_l dependent resonant window, showing the importance of including the detailed experimentally determined joint density of electronic states line shape in the resonant Raman theory for one-dimensional (1D) systems and considering incoherent scattering. Therefore, they show that resonant Raman scattering can be used to characterize the joint density of electronic states of a single-wall carbon nanotube with much better resolution than scanning tunneling spectroscopy measurements. In [36] it is shown that the Raman scattering technique can give complete structural information for one-dimensional systems, such as carbon nanotubes. Resonant confocal micro-Raman spectroscopy of an (n, m) individual

single-wall nanotube makes it possible to assign its chirality uniquely by measuring one radial breathing mode frequency ω_{RBM} and using the theory of resonant transitions. A unique chirality assignment can be made for both metallic and semiconductor nanotubes of diameter d, using the parameters $\gamma_0 = 2.9$ eV and $\omega_{RBM} = 248/d$. Kneipp et al. [37] studied polarization effects in surface-enhanced resonant Raman spectroscopy from single-wall carbon nanotubes on silver colloidal clusters. The authors use single-wall carbon nanotubes as a model molecule to understand the increase of the depolarization ratios [38] measured in many surface-enhanced resonant Raman spectroscopy experiments compared to "normal" (resonant) Raman scattering [39–42]. Benoit et al. [43] presented a detailed low frequency Raman study of arc discharge multiwalled carbon nanotubes, which are characterized by transmission electron microscopy. They clearly identify low frequency modes in purified samples. They presented a model to interpret these modes based on the coupling of the radial-breathing mode of each individual wall of the multiwall nanotube. Intensity calculations have been carried out as well. The low frequency spectrum of the multiwall nanotube is shown to be very sensitive to the internal diameter of multiwall nanotube. At the first time, a comprehensive simulation of the low frequency Raman spectrum of multiwall nanotube is given. Preliminary results have already been presented elsewhere [44]. Maciel et al. [45] have used Raman spectroscopy to measure phonons in GaAs v-groove quantum wire structures containing (001) and (111) GaAs/AlAs superlattice barrier regions. Resonance enhancement permits the identification of modes in different regions of the structure, and the measured phonon frequencies provide structural information, which shows clear evidence of GaAs migration during growth from (001) surfaces into the grooves. Confined and interface phonons with large in-(111) plane wavevectors are observed. In [46] resonant Raman scattering for one single-wall carbon nanotube spectroscopy is overviewed. First order resonance Raman spectra of the radial breathing mode of one carbon nanotube is of importance for assigning (n, m) values to the nanotube. The assignment of (n, m) values is confirmed by the chirality dependence of the other phonon modes. Second order, one phonon emission, and the intervalley scattering processes of two-dimensional graphite and of single-wall carbon nanotubes are relevant to disorder-induced D-band Raman spectra. The dispersive nature of the D-band Raman spectra is explained by double resonance processes. Many weak Raman spectra appearing in the intermediate frequency range, which have been observed for a long time but were never assigned, have recently been assigned as double resonance Raman peaks. The second order Raman phonon frequencies can be used as a new fundamental tool for determining the phonon energy dispersion relations, especially for disordered materials and for zone boundary phonons. Husberg et al. [47] reported further investigations of the luminescence of the phase separated In-rich structures in c-In$_x$Ga$_{1-x}$N/GaN DHs. The observation of luminescence line narrowing in resonant excitation experiments supports the QD-like structure of the In-rich phase. Annealing experiments were performed to gain insight into the process of formation of these inclusions. Toda et al. [48] have investigated the carrier relaxation

mechanism in InGaAs/GaAs quantum dots by photoluminescence excitation spectroscopy. Near-field scanning optical microscopy successfully shows that a photoluminescence excitation resonance at a relaxation energy of 36 meV can be seen in all single-dot luminescence spectra and thus can be attributed to resonant Raman scattering by a GaAs LO phonon to the excitonic ground state. In addition, a number of sharp resonances observed in single-dot photoluminescence excitation spectra can be identified as resonant Raman features due to localized phonons, which are observed in the conventional Raman spectrum. The results reveal the mechanism for the efficient relaxation of carriers observed in self-assembled quantum dots: the carriers can relax within the continuum states and make transitions to the excitonic ground state by phonon emission.

On the other hand, recently it has also been reported in the international literature some theoretical works related with the electron Raman scattering and resonant Raman scattering; between them, we could mention the following. Wang and Sarma [49] provide (within the resonant RPA scheme) a compellingly generic theory for resonant Raman scattering theory for resonant Raman scattering experiments by including the valence-band electrons during the scattering processes for one-, two-, and three-dimensional semiconductor systems, following their earlier short paper [50] on 1D systems. Scamarcio et al. [51] unambiguously demonstrate that the strength of the electron–LO-phonon coupling increases with increasing confinement (decreasing size) in the strong confinement limit. This conclusion results from the size dependence of the ratio between two-phonon and one-phonon Raman cross-sections in a prototype system: CdS$_x$Se$_{1-x}$ nanocrystals embedded in a glass matrix. It is important to stress that, in their experiments, the resonance condition has been kept constant (within <1 meV) for each investigated nanocrystal size. This has been achieved by fully exploiting the advantages of a Raman microprobe apparatus and a suitable sample in which the mean nanoparticle size increases monotonically along one direction. Due to the strong energy dependence of the Raman cross-section, keeping constant the resonance condition is mandatory for a meaningful comparison of spectra associated with nanocrystals having different sizes and hence different electronic transitions. Their approach represents an improvement with respect to previous resonant Raman scattering investigations in which the challenging experimental problem of keeping constant the resonance condition has not been properly solved [52–54]. Also, they report a polarization analysis of the Raman spectra in nanocrystals. Menéndez-Proupin and Cabo-Bisset [55] revised the adiabatic theory of resonance one-phonon Raman scattering in semiconductor nanocrystals and extended with perturbative nonadiabatic corrections, given by Albrecht's B term. This theory is confronted with the time-dependent perturbation approach, pointing at their differences and similarities. It is shown that both theories are equivalent in the limit of weak electron–phonon coupling and nondegenerate or uncoupled resonant states. Evaluations of the A and B terms for the confined LO phonon in CdSe and CdS nanocrystals are reported. These evaluations show that the B term can usually be neglected. Gonzalez and Menéndez-Proupin [56] studied interband

absorption and luminescence small quantum dots under conditions similar to the experiments reported in [57, 58] (i.e., quasi-two-dimensional motion, magnetic fields in the interval 8 T $\leq B \leq$ 60 T, and temperatures well below 2 K).

Very recent experimental works [59–86], related to the electron Raman scattering and resonant Raman scattering phenomena in nanostructured materials, can be used in order to verify the several theoretical models considered in the interpretation of these processes. In the same way we could find other recent theoretical works in [87–105].

Among the various Raman scattering processes involved in this kind of research, ERS seems to be a useful technique providing direct information about the energy band structure and the optical properties of the investigated systems. ERS is qualitatively explained as a three-step process: in the first step the system absorbs a photon from the incident radiation and an electron–hole pair (EHP) is created in a virtual state (after an interband electron transition); in the second step the electron and the hole move independently of each other and emit one optical phonon performing intraband transitions. In the last step the electron and the hole move independently of each other and emit photons of secondary radiation performing intraband or interband transitions [14–16]. In the final step an excited phonon of frequency ω and a photon of frequency ω_s appear as a real state of the system and an EHP is annihilated or created in another excited state. Moreover, the DCS for ERS, in the general case, usually shows singularities related to interband and intraband transitions. The latter result strongly depends on the scattering configurations; namely, the structure of the singularities is varied when the photon polarization changes [106]. This peculiar feature of ERS allows one to determine the subband structure of the system by direct inspection of the singularity positions in the spectra.

For bulk semiconductors ERS has been studied in the presence of the external applied magnetic and electric fields [7, 107, 108]. In this work we study ERS in QW, QWW, and FS Wire of cylindrical shapes and QDs of spherical shape, considering transitions assisted by photons and within or without phonons. We assume electron confinement within the system, as well as parabolic bands at $T = 0$ K [109]. The assumption of $T = 0$ K eliminates the possibility of absorption of phonons in the electron–phonon interaction Hamiltonian, but it does not change the optical properties. The parabolic band approximation is commonly used in the II–VI and III–V semiconductors when one works near the center of Brillouin's zone in the reduced zone scheme. Under these dynamical conditions, since the potential barriers do not imply interband transitions, the nanostructures can be treated within the envelope function and effective mass approximations.

Regarding the complex valence band of III–V and II–VI semiconductor compounds, the contribution of band mixing is small in the confinement regime assumed in this work and is consistent with previous treatments [110, 111]. When the excitation energy is close to the bandgap energy, the valence band structure is very important in the strong confinement regime and only a conduction band can be assumed since the electronic contribution to the process is negligible, as has been pointed out recently by Fomin et al. [112]; however, this is not the case of the present work because the excitation energy considered herein is much higher than the bandgap energy.

2. RAMAN CROSS-SECTION

The DCS for ERS in a volume V per unit solid angle $d\Omega$ for incoming light of frequency ω_l and scattered light of frequency ω_s is given by [109]

$$\frac{d^2\sigma}{d\omega_s\, d\Omega} = \frac{V^2\omega_s^2\eta(\omega_s)}{8\pi^3 c^4\eta(\omega_l)} W(\omega_s, \hat{\mathbf{e}}_s) \qquad (1)$$

where $\eta(\omega)$ is the refraction index as a function of the radiation frequency, $\hat{\mathbf{e}}_s$ is the unit polarization vector for the emitted secondary radiation, c is the light velocity in vacuum, and $W(\omega_s, \hat{\mathbf{e}}_s)$ is the transition rate for the emission of secondary radiation (with frequency ω_s and polarization $\hat{\mathbf{e}}_s$) calculated according to the Fermi golden rule,

$$W(\omega_s, \hat{\mathbf{e}}_s) = \frac{2\pi}{\hbar} \sum_f |M_1 + M_2|^2\, \delta(E_f - E_i) \qquad (2)$$

where, for an electron Raman scattering process without phonon-assisted transitions,

$$M_j = \sum_a \frac{\langle f|\widehat{H}_{js}|a\rangle\langle a|\widehat{H}_{jl}|i\rangle}{(E_i - E_a + i\Gamma_{a_j})} + \sum_b \frac{\langle f|\widehat{H}_{jl}|b\rangle\langle b|\widehat{H}_{js}|i\rangle}{(E_i - E_b + i\Gamma_{b_j})} \qquad (3)$$

and $j = 1, 2$ denotes electron or hole contributions, respectively.

In Eq. (3) $|i\rangle$ and $|f\rangle$ denote initial and final states of the system with their corresponding energies E_i and E_f. $|a\rangle$ and $|b\rangle$ are intermediate states with energies E_a and E_b. Γ_{aj} and Γ_{bj} are the corresponding lifetimes. In Figure 1 we show Feynman diagrams describing the considered processes.

The operator $\widehat{H}_{jl}$ is given in the form

$$\widehat{H}_{jl} = \frac{|e|}{\mu_0}\sqrt{\frac{2\pi\hbar}{V\omega_l}}\,\hat{\mathbf{e}}_l \cdot \hat{\mathbf{p}} \qquad \hat{\mathbf{p}} = -i\hbar\nabla \qquad j = 1, 2 \quad (4)$$

where μ_0 is the free electron mass. This operator describes the interaction with the incident radiation field in the dipole

Figure 1. Diagrams contributing to electron Raman scattering for intersubband transitions. (a) and (b) show contributions from the electron or the hole, respectively. (c) and (d) show interference processes.

approximation. The interaction with the secondary radiation field is described by the operator:

$$\widehat{H}_{js} = \frac{|e|}{\mu_j}\sqrt{\frac{2\pi\hbar}{V\omega_s}}\hat{\mathbf{e}}_s \cdot \hat{\mathbf{p}} \qquad (5)$$

This operator describes the photon emission by the electron (hole) after transitions between conduction (valence) subbands of the system. In Eq. (3) the intermediate state $|a\rangle$ represents an EHP virtual (after absorption of the incident photon), while the states $|b\rangle$ and $|c\rangle$ represent an EHP real (after the emission of a phonon and a secondary photon, respectively), and μ_j is the effective mass of the electron (hole).

In the initial state $|i\rangle$ we have a completely occupied valence band, an unoccupied conduction band, and an incident photon of energy $\hbar\omega_l$. Thus

$$E_i = \hbar\omega_l \qquad (6)$$

The final state $|f\rangle$ involves an EHP excited in a real state and a secondary radiation emitted photon of energy $\hbar\omega_s$. Hence

$$E_f = E_1 + E_2 + E_g + \hbar\omega_s \qquad (7)$$

For the intermediate state $|a\rangle$ the energies E_a are easily obtained from the previous discussion and using energy and momentum conservation laws we can evaluate the denominators in Eq. (3),

$$E_i - E_a = E_j - E_j' + \hbar\omega_s \qquad (8)$$

$$E_i - E_b = E_j - E_j' - \hbar\omega_l \qquad (9)$$

From the latter results it can be deduced that for semiconductors with large enough energy gap E_g (as is the case, for instance, with GaAs, CdTe, etc.) we have not considered the first term because $E_j - E_j' < E_g$ and considering that $\hbar\omega_l > E_g$, this corresponds to the "interference diagrams."

For an electron Raman scattering process with phonon-assisted transitions,

$$M_j = \sum_{a,b} \frac{\langle f|\widehat{H}_{js}|b\rangle\langle b|\widehat{H}_{jph}|a\rangle\langle a|\widehat{H}_{jl}|i\rangle}{(E_i - E_a + i\Gamma_{aj})(E_i - E_b + i\Gamma_{bj})}$$
$$+ \sum_{a,c} \frac{\langle f|\widehat{H}_{jph}|c\rangle\langle c|\widehat{H}_{js}|a\rangle\langle a|\widehat{H}_{jl}|i\rangle}{(E_i - E_a + i\Gamma_{aj})(E_i - E_c + i\Gamma_{cj})} \qquad (10)$$

$|a\rangle$, $|b\rangle$, and $|c\rangle$ are intermediate states with energies E_a, E_b, and E_c while Γ_{aj}, Γ_{bj}, and Γ_{cj} are the corresponding lifetime widths. The "interference diagrams" can be neglected. In Figure 2 we show Feynman diagrams describing the considered processes.

In the initial state $|i\rangle$ we have a completely occupied valence band, an unoccupied conduction band, and an incident photon of energy $\hbar\omega_l$. Thus
$$E_i = \hbar\omega_l \qquad (11)$$

Figure 2. Diagrams contributing to one phonon-assisted electron Raman scattering for intersubband transitions. (a) and (c) show contributions from the electron. (b) and (d) show contributions from the hole.

The final state $|f\rangle$ involves an EHP excited in a real state, a secondary radiation emitted photon of energy $\hbar\omega_s$, and one phonon of energy $\hbar\omega_q$; hence

$$E_f = E_1 + E_2 + E_g + \hbar\omega_s + \hbar\omega_q \qquad (12)$$

For the intermediate states $|a\rangle$, $|b\rangle$, and $|c\rangle$ the energies E_a, E_b, and E_c are easily obtained from the previous discussion and using energy and momentum conservation laws we can evaluate the denominators in Eq. (10):

$$E_i - E_a = E_j - E_j'' + \hbar\omega_s + \hbar\omega_q \qquad (13)$$

$$E_i - E_b = E_j - E_j' + \hbar\omega_s \qquad (14)$$

$$E_i - E_c = E_j - E_j' + \hbar\omega_q \qquad (15)$$

Considering that the energy of the $\hbar\omega_l$ radiation incident is such that upon the electron absorbing the same it could reach the first subbands, and from the latter results, the contribution of the second term of Eq. (10) can be neglected if it is compared with the contribution of the first one.

We thus should consider, for the determination of the DCS, the contribution of just the first term in the right-hand side of Eq. (10) during the calculation of M_j.

3. MODEL DESCRIPTION OF ELECTRON–PHONON INTERACTION IN NANOSTRUCTURED SEMICONDUCTORS

Let us briefly summarize some details concerning the optical phonons and electron–phonon interaction Hamiltonian in QDs, QWWs, and FSWs. In [1, 2], within the framework of a macroscopic continuum coupling model, the mechanical phonon displacement vector **u**, the electrostatic potential ϕ, and the optical vibrational modes were obtained. These results are in close agreement with both experiments and microscopic calculations [113–115]. The main points of this treatment are: (i) we should solve a system of coupled differential equations for the displacement field **u** and the electric potential ϕ; (ii) we should apply matching conditions at the interfaces in close consistency with both the differential

equations of the treatment and the involved physical principles; (iii) we are in general led to coupled oscillation modes involving a mixed character. For further details [113–115] should be consulted. The boundary conditions that need to be satisfied at the interface are the continuity of: (1) all the components of the displacement, $\mathbf{u}$; (2) the electrostatic potential, ϕ; (3) the normal component of the mechanical stress tensor, σ_N; and (4) the normal component of the electric displacement, D_N. For a GaAs/AlAs system the zone center optical phonon frequencies in the two bulk materials are separated by 100 cm^{-1}, which leads to virtually complete confinement of the GaAs vibrations in GaAs and of the AlAs vibrations in AlAs (in fact, the displacements of the modes of GaAs frequency are zero at the first Al atom after the interface). In order to simplify the algebra, the boundary condition (1) is modified from $\mathbf{u}$ continuous to $\mathbf{u} = 0$ at the interface. With this modification, the stress boundary condition (3) becomes redundant.

Other cases also considered in the literature are free oscillations for FSW. In such cases the active medium is surrounded by vacuum (or quartz), thus allowing free oscillations of the surface. In this case the matching boundary conditions are $\boldsymbol{\sigma} \cdot \mathbf{N}|_{r\epsilon S} = 0$ and $\mathbf{u}$ is defined for just one side of the structure.

We will use a model for the optical oscillations in ionic crystals where a Lagrangian density is postulated and the solid is considered like a continuous distribution with density being the mass reduced of the ions and the volume of the primitive cell. So the Lagrangian density is expressed through the expression

$$L = \frac{1}{2}\rho\dot{\mathbf{u}} \cdot \dot{\mathbf{u}} - \frac{1}{2}\mathbf{u} \cdot \overleftrightarrow{\gamma} \cdot \mathbf{u} + \frac{1}{2}\mathbf{E} \cdot \overleftrightarrow{\beta} \cdot \mathbf{E}$$
$$+ (-\mathbf{u}) \cdot \overleftrightarrow{\alpha} \cdot \mathbf{E} + \frac{1}{2}u_{ik}\lambda_{iklm}u_{lm} \qquad (16)$$

where $\mathbf{u}$ is the relative displacement between the ions and u_{ik} is the deformation tensor:

$$u_{ik} = \frac{1}{2}(\nabla_k u_i + \nabla_i u_k) \qquad (17)$$

The first term of Eq. (16) is the kinetic energy density; the second describes the elastic interaction between the ions. The third term is the electric interaction. The fourth term is the coupling of electric field with the field of the displacements. The fifth and last term is related to the internal efforts and is the one that leads to the dispersion.

Considering that the fields vary harmonically with the time, the system of equations for $\mathbf{u}$ and ϕ is obtained as

$$\rho(\omega^2 - \omega_T^2)\mathbf{u} = \alpha\nabla\phi + \rho B_L^2\nabla\nabla \cdot \mathbf{u} - \rho B_L^2\nabla \times \nabla \times \mathbf{u} \quad (18)$$

$$\nabla \cdot \nabla\phi = \frac{4\pi\alpha}{\epsilon_\infty}\nabla \cdot \mathbf{u} \qquad (19)$$

If the displacement is written as

$$\mathbf{u} = \mathbf{u}_T + \mathbf{u}_L \quad \text{where} \quad \nabla \cdot \mathbf{u}_T = 0 \quad \text{and} \quad \nabla \times \mathbf{u}_L = 0 \quad (20)$$

then

$$\rho(\omega^2 - \omega_T^2)\mathbf{u}_T = -\rho B_T^2\nabla \times \nabla \times \mathbf{u}_T \qquad (21)$$

$$\rho(\omega^2 - \omega_L^2)\mathbf{u}_L = \rho B_L^2\nabla\nabla \cdot \mathbf{u}_L \qquad (22)$$

$$\nabla\phi = \frac{4\pi\alpha}{\epsilon_\infty}\mathbf{u}_L \qquad (23)$$

$\omega_L = \sqrt{(\epsilon_0/\epsilon_\infty)}\omega_T$ is the Lydane–Sachs–Teller relation.

From this system of equations is easy to observe that the electric field originating from the media polarization is coupled only with the longitudinal oscillations. This field is also longitudinal and opposite to the displacement.

The Hamiltonian of the electron–phonon interaction is obtained considering that both functions $\mathbf{u}(r)$ and $\phi(r)$ form an orthogonal and complete system. The operators of creation and annihilation that satisfy the relation of commutation of the Bose statistical are introduced in order to obtain the quantized fields.

3.1. Electron–Phonon Interaction Hamiltonian for Quantum Well

The electron–LO-phonon interaction Hamiltonian is deduced in a systematic way from a model of dispersive polar optical vibrations for a double semiconductor heterostructure (DHS) as a QW. LO-phonon confinement effects are included in this model, which can be imagined as a jellium slab disposed between two rigid walls. The obtained Hamiltonian includes screening in the spirit of the static 3D Thomas–Fermi approximation and contains the 3D Fröhlich Hamiltonian as a limiting case. The case of a single heterostructure is also obtained as another limit.

3.1.1. Polarization Field

We are only concerned with the long wavelength LO-phonon and, therefore, a continuum approach along the lines of Born and Huang for the classical vibrational field is appropriated, which, afterward, must be properly quantized.

In the frame of this model the dynamical equations for the lattice are written in the form

$$\ddot{\mathbf{u}} = -\omega_T^2\mathbf{u} + \sqrt{\frac{\varepsilon_0 - \varepsilon_\infty}{4\pi}}\omega_T\mathbf{E} - v_a^2\nabla(\nabla \cdot \mathbf{u}) - v_b^2\nabla^2\mathbf{u} \quad (24)$$

$$\mathbf{P} = \sqrt{\frac{\varepsilon_0 - \varepsilon_\infty}{4\pi}}\omega_T\mathbf{u} + \frac{\varepsilon_\infty - 1}{4\pi}\mathbf{E} \qquad (25)$$

where $\mathbf{u}(\mathbf{r}, t)$ is the effective relative ionic displacement (the units are such that $\mathbf{u} = \sqrt{\rho}\mathbf{w}$, where ρ is the mass density and $\mathbf{w}$ is the real displacement field with length units), $\mathbf{E}$ is the electric field, $\mathbf{P}$ is the polarization field associated with the vibrations, and $\mathbf{v}_a$, $\mathbf{v}_b$ are vector parameters with dimensions of velocity. Equations (24) and (25) are analogous to those of Born and Huang for an isotropic continuum but they include dispersion effects through the terms proportional to $\mathbf{v}_a$ and $\mathbf{v}_b$; this dispersive modification of Born and Huang equations is especially appropriate to account for the boundary conditions at the interfaces of the double heterostructure.

For a charge-free (and current-free) system Eqs. (24) and (25) are supplemented by the Maxwell equations,

$$\nabla \cdot \mathbf{D} = 0 \quad \nabla \cdot \mathbf{H} = 0 \quad \nabla \times \mathbf{H} = \frac{1}{c}\frac{\partial \mathbf{D}}{\partial t} \quad \nabla \times \mathbf{E} = -\frac{1}{c}\frac{\partial \mathbf{H}}{\partial t} \tag{26}$$

where the medium is assumed nonmagnetic and $\mathbf{D} = \mathbf{E} + 4\pi\mathbf{P}$.

Assuming $\mathbf{u}(\mathbf{r}, t) = \mathbf{u}(\mathbf{r})e^{-i\omega t}$ we obtain

$$\mathbf{E} = \left[\frac{4\pi}{\omega_T^2}\left(\varepsilon_0 - \varepsilon_\infty\right)^{-1}\right]^{\frac{1}{2}}\left[\omega_T^2 - \omega^2 + v_a^2\nabla(\nabla\cdot) + v_b^2\nabla^2\right]\mathbf{u} \tag{27}$$

$$\mathbf{P} = \left[4\pi\omega_T^2\left(\varepsilon_0 - \varepsilon_\infty\right)\right]^{-\frac{1}{2}}\left\{\left(\varepsilon_0 - 1\right)\omega_T^2 - \left(\varepsilon_\infty - 1\right)\omega^2 \right. \\ \left. + \left(\varepsilon_\infty - 1\right)\left[v_a^2\nabla(\nabla\cdot) + v_b^2\nabla^2\right]\right\}\mathbf{u} \tag{28}$$

and

$$\mathbf{D} = \left[\frac{4\pi}{\omega_T^2}\left(\varepsilon_0 - \varepsilon_\infty\right)^{-1}\right]^{\frac{1}{2}} \\ \times \left\{\varepsilon_0\omega_T^2 - \varepsilon_\infty\omega^2 + \varepsilon_\infty \cdot \left[v_a^2\nabla(\nabla\cdot) + v_b^2\nabla^2\right]\right\}\mathbf{u} \tag{29}$$

Equations (24), (25), and (26) are satisfied by a displacement field decomposed in the form $\mathbf{u} = \mathbf{u}_T + \mathbf{u}_L$ where

$$\nabla \cdot \mathbf{u}_T = 0 \quad \nabla \times \mathbf{u}_T \neq 0 \quad \nabla \cdot \mathbf{u}_L \neq 0 \quad \nabla \times \mathbf{u}_L = 0 \tag{30}$$

For $\mathbf{u}_T$ the equation $\nabla \cdot \mathbf{D} = 0$ is satisfied with $\mathbf{D} \neq 0$ and the corresponding (dispersive) polariton modes are obtained. However, we are only interested in the longitudinal displacements $\mathbf{u}_L$ where equation $\nabla \cdot \mathbf{D} = 0$ is satisfied automatically because $\mathbf{D} = 0$. For $\mathbf{u}_L(\mathbf{r}, \omega)$ we obtain

$$\left(\nabla^2 + \frac{(\omega_{LO}^2 - \omega^2)}{v^2}\right)\mathbf{u}_L(\mathbf{r}, \omega) = 0 \tag{31}$$

where $v^2 = v_a^2 + v_b^2$. In the bulk case Eq. (31) leads us to a quadratic dispersion law

$$\omega_q^2 = \omega_{LO}^2 - v^2 q^2 \tag{32}$$

For the longitudinal electric and polarization fields we obtain

$$\mathbf{E}_L = -\left[\frac{4\pi\omega_{LO}^2}{\varepsilon^*}\right]^{\frac{1}{2}}\mathbf{u}_L \quad \text{and} \quad \mathbf{P}_L = \left[\frac{\omega_{LO}^2}{4\pi\varepsilon^*}\right]^{\frac{1}{2}}\mathbf{u}_L \tag{33}$$

where $(\varepsilon^*)^{-1} = \varepsilon_\infty^{-1} - \varepsilon_0^{-1}$ (and therefore $\mathbf{D}_L = 0$).

Let us now consider a DHS with interfaces at $z = 0$ and $z = d$ (the "z" axis is perpendicular to the interfaces). For $0 < z < d$ we have a given material (say, GaAs) and for $z < 0$ and $z > d$ we have another material (say, AlGaAs). The boundary conditions of continuous $\rho^{-1/2}\dot{u}_z$ and $v^2\rho^{1/2}\nabla \cdot \mathbf{u}$ at the interfaces are imposed in the spirit of a hydrodynamic (or jellium) model; the first quantity is the "z" component of the velocity field and the second quantity is the pressure. We will not discuss the more general solution of (31), but the one entailing complete confinement of the LO

vibrations. This particular form of vibrations should provide an appropriate description for the observed highly confined LO phonon. Therefore, we solve Eq. (31) under the requirements

$$u_z(\mathbf{r}, \omega) = 0 \qquad \text{for } z = 0 \quad \text{and} \quad z = d \tag{34}$$

From now the subscript "L" is avoided and $\mathbf{u}$ will describe purely longitudinal vibrations. Conditions (34) involve a "jellium" slab disposed between rigid walls at $z = 0$ and $z = d$ as a macroscopic model for completely confined LO vibrations, that is, a model excluding penetration of the polar optical vibrations from a given layer into the adjacent ones. We must emphasize that this kind of model is in good agreement with experimental facts and numerical simulations and also provides the possibility of working out analytical expressions for the displacement and polarization fields.

After substitution of $\mathbf{u}(\mathbf{r}) = \boldsymbol{\zeta}(z)e^{i\mathbf{q}_\perp \cdot \mathbf{r}_\perp}$ in (31) we obtain

$$\left(\frac{d^2}{dz^2} + q_z^2\right)\boldsymbol{\zeta}(z) = 0 \tag{35}$$

where

$$q_z^2 = \frac{1}{v^2}\left(\omega_{LO}^2 - \omega^2\right) - q_\perp^2 \geq 0 \quad \text{and} \quad \zeta_z(0) = \zeta_z(d) = 0 \tag{36}$$

For $q_z^2 > 0$ the solution of (35) is

$$\boldsymbol{\zeta}(z) = A\left[(\mathbf{q}_\perp + q_z\hat{\mathbf{e}}_z)e^{iq_z z} + (\mathbf{q}_\perp - q_z\hat{\mathbf{e}}_z)e^{-iq_z z}\right] \tag{37}$$

with $q_z = \frac{n\pi}{d}$, and $n = 1, 2, 3, \ldots$

Let us remark that (37) satisfies Eq. (34) with the given boundary conditions $\nabla \times \mathbf{u} = 0$ for the longitudinal displacements. It is easy to include the case $q_z = 0$ just allowing n to be zero in (37). For $q_z^2 < 0$ no solutions exist satisfying the given boundary conditions.

From (37) we obtain the general solution for $\mathbf{u}$,

$$\mathbf{u}(\mathbf{r}) = \sum_{\mathbf{q}_\perp}\sum_{n \geq 0} A_{\mathbf{q}_\perp, n}\left[(\mathbf{q}_\perp + q_z\hat{\mathbf{e}}_z)e^{iq_z z} + (\mathbf{q}_\perp - q_z\hat{\mathbf{e}}_z)e^{-iq_z z}\right]e^{i\mathbf{q}_\perp \cdot \mathbf{r}_\perp} \tag{38}$$

where q_z and $A_{\mathbf{q}_\perp, n}$ are constant parameters. Let us note that the sums over $\mathbf{q}_\perp$ and n can be infinite. We must require $\omega^2 = \omega_{LO}^2 - v^2 q^2 > 0$ (only if $v \to 0$ we obtain infinite sums). We should agree to sum in the following ways: n will be summed in the interval $0 < n < N(q_\perp)$ where $N(q_\perp)$ is the higher integer less than $((\omega_{LO}^2/v^2) - q_\perp^2)^{1/2}$ for a fixed $q_\perp$; after that $\mathbf{q}_\perp$ will be summed for all values inside the circle limited by $q_\perp^2 = q_x^2 + q_y^2 = (\omega_{LO}/v)^2$. Notice that the change $\mathbf{q}_\perp$ by $-\mathbf{q}_\perp$ does not alter the latter summation. Expression (38) can be transformed into

$$\mathbf{u}(\mathbf{r}) = \sum_{\mathbf{q}_\perp}\sum_{n=-N(\mathbf{q}_\perp)}^{N(\mathbf{q}_\perp)} \mathbf{q}\left[A_{\mathbf{q}_\perp, |n|}e^{iq_z z} + A_{\mathbf{q}_\perp, |n|}^*e^{-iq_z z}\right] \tag{39}$$

with $\mathbf{q} = \mathbf{q}_\perp + q_z\hat{\mathbf{e}}_z$ and $A_{\mathbf{q}_\perp, |n|}^* = -A_{-\mathbf{q}_\perp, |n|}$, the latter condition ensuring that $\mathbf{u}$ is a real quantity.

Obviously, (38) and (39) are completely identical expressions, but (39) is more convenient in the following. Substitution of (39) in (33) yields $\mathbf{P}(\mathbf{r}, t)$, the polarization field,

while the corresponding canonical conjugate momentum is given by

$$\Pi(\mathbf{r}, t) = \frac{4\pi\varepsilon^*}{\omega_{\text{LO}}^2} \frac{\partial}{\partial t} \mathbf{P}(\mathbf{r}, t) \qquad (40)$$

The parameters $A_{\mathbf{q}_\perp, |n|}^*$ must be chosen appropriately in order that the corresponding quantized fields $\mathbf{P}$ and Π could satisfy adequate commutation relations.

We just report the final expression for $\mathbf{P}(\mathbf{r})$,

$$\mathbf{P}(\mathbf{r}) = \sum_{\mathbf{q}_\perp} \sum_{n=-N(\mathbf{q}_\perp)}^{N(\mathbf{q}_\perp)} \left[\frac{\hbar\omega_{\text{LO}}^2}{8\pi\varepsilon^*\omega_q V}\right]^{1/2} \frac{\mathbf{q}}{|\mathbf{q}|} \left[e^{i\mathbf{q}\cdot\mathbf{r}}\hat{b}_{\mathbf{q}} + e^{-i\mathbf{q}\cdot\mathbf{r}}\hat{b}_{\mathbf{q}}^+\right] \tag{41}$$

where $\hat{b}_{\mathbf{q}}$, $\hat{b}_{\mathbf{q}}^+$ are second-quantization Bose operators such that

$$[\hat{b}_{\mathbf{q}}, \hat{b}_{\mathbf{q}'}] = [\hat{b}_{\mathbf{q}}^+, \hat{b}_{\mathbf{q}'}^+] = 0 \qquad [\hat{b}_{\mathbf{q}}, \hat{b}_{\mathbf{q}'}^+] = \delta_{\mathbf{q}, \mathbf{q}'} \qquad (42)$$

Expression (41) is the fundamental result of this section, which must be used to derive the electron–LO-phonon Hamiltonian for a DHS. The main difference with respect to the usual (bulk) polarization field is the discrete nature of $q_z = \frac{n\pi}{d}$ and the fact that $\mathbf{P}(\mathbf{r})$ is defined just for the layer $0 < z < d$.

3.1.2. Interaction Hamiltonian

The interaction Hamiltonian can be deduced from

$$\widehat{H}_I(\mathbf{r}) = \int \frac{e[-\nabla'\cdot\mathbf{P}(\mathbf{r}')]}{|\mathbf{r}-\mathbf{r}'|} e^{-\frac{|\mathbf{r}-\mathbf{r}'|}{\lambda}} d^3 r' \qquad (43)$$

where, for the sake of generality, we have included a screening λ in the spirit of the (bulk) Thomas–Fermi static approximation. Let us remark, however, that the obtained results are perfectly valid in the limit $\lambda \to \infty$.

Substitution of (41) in (43) yields, after straightforward integrations, the Hamiltonian for the DHS

$$\widehat{H} = \sum_{\mathbf{q}_\perp} \sum_{n=-N(\mathbf{q}_\perp)}^{N(\mathbf{q}_\perp)} \left[\Phi_{\mathbf{q}, \lambda}^{\text{DHS}}(z) C_{\mathbf{q}, \lambda} e^{i\mathbf{q}\cdot\mathbf{r}} \hat{b}_{\mathbf{q}} + HC\right] \qquad (44)$$

where

$$C_{\mathbf{q}, \lambda} = i\left[\frac{\omega_L}{\omega_q}\right]^{\frac{1}{2}} \frac{qC_F}{q^2+1/\lambda^2} \quad \text{and} \quad C_F = -\sqrt{\frac{2\pi e^2\hbar\omega_L}{V}(\epsilon_{a\infty}^{-1} - \epsilon_{a0}^{-1})} \qquad (45)$$

is the usual (screened) coupling factor of the bulk theory and

$$\Phi_{\mathbf{q}, \lambda}^{\text{DHS}}(z) = \begin{cases} \frac{1}{2}e^{(Q-iq_z)z}[1-(-1)^n e^{-Qd}] & \text{for } z < 0 \\ 1-\frac{1}{2}e^{-iq_z z}[e^{-Qz}+(-1)^n e^{Q(z-d)}] & \text{for } 0 < z < d \\ \frac{1}{2}e^{-(Q+iq_z)z}[(-1)^n e^{Qd}-1] & \text{for } z > d \end{cases} \qquad (46)$$

where $Q^2 = q_\perp^2 + 1/\lambda^2$. $\epsilon_{a\infty}(\epsilon_{a0})$ is the high frequency (static) dielectric constant; the index a refers to the interior of the nanostructure.

The structure of $\widehat{H}$ is very clear from the physical point of view. Due to LO-phonon confinement the "z" component of the phonon wavevector $\mathbf{q}$ bears a discrete nature. The coupling factor $C_{\mathbf{q}, \lambda}$ is the same as in the bulk (screened) Fröhlich Hamiltonian, but now a certain modulation function $\Phi_{\mathbf{q}, \lambda}^{\text{DHS}}(z)$ is present describing the effect of confinement. In fact, we must notice that $\Phi_{\mathbf{q}, \lambda}^{\text{DHS}}(z)$ is evanescent for $z < 0$ or $z > d$; for $0 < z < d$, $\Phi_{\mathbf{q}, \lambda}^{\text{DHS}}(z)$ has two terms: the first term (equal to unity) is just the bulklike contribution, while the second term involves two contributions coming from the interface at $z = 0$ and $z = d$. The unscreened limit ($\lambda \to \infty$) is obtained without difficulties just taking $Q \to q_\perp$ in (46) and the corresponding expression for (45). A more realistic screening theory can be obtained from the unscreened $\widehat{H}$ just dividing $C_{\mathbf{q}}$ by a proper dielectric function $\varepsilon(\mathbf{q}, \omega)$ (see, for instance, [116]).

One important feature of the obtained expressions (44), (45), and (46) is that the 3D (bulk) limiting can be achieved if we first shift the coordinate origin by means of $z = z' + d/2$ and afterward take the limit $d \to \infty$. Hence we obtain the well-known screened Fröhlich Hamiltonian. Another important limiting case can be deduced from the expressions if we directly take $d \to \infty$ in (44), (45), and (46). This is the case of the single heterostructure (SHS) where

$$\Phi_{\mathbf{q}, \lambda}^{\text{SHS}}(z) = \begin{cases} \frac{1}{2}e^{(Q-iq_z)z} & \text{for } z < 0 \\ 1-\frac{1}{2}e^{-(Q+iq_z)z} & \text{for } z > 0 \end{cases} \qquad (47)$$

Substitution of (47) in place of $\Phi_{\mathbf{q}, \lambda}^{\text{DHS}}$ in (44) provides the given Hamiltonian for SHS.

3.2. Electron–Phonon Interaction Hamiltonian for QWW and FSW

In the frame of the present treatment we shall restrict ourselves to the case of oscillations perpendicular to the wire axis (i.e., $q_z = 0$ and hence $U_z = 0$). We are thus considering a particular case, which, however, entails a direct interest for the study of certain physical processes (one phonon Raman scattering configuration [6], for instance) and gives us insight into the nature of the oscillations. It has been shown that the corresponding eigensolutions constitute a complete orthonormal basis of eigenvectors $\mathbf{U}_{nm}$ and the electron–phonon interaction Hamiltonian is derived using the second-quantization formalism and can be written as [2]

$$\widehat{H} = \sum_{n, m} C_{nm}[F_{nm}(r)e^{in\theta}\hat{b}_{nm} + HC] \qquad (48)$$

where

$$C_{nm} = \left[\frac{\pi\omega_L\rho}{\omega_q}\right]^{\frac{1}{2}} r_0^2 C_F \qquad (49)$$

where ρ is the reduced mass density, ω_q is the frequency of the nm mode, and the functions $F_{nm}(r)$ have different forms for the QWW and the FSW. For a QWW, we have that

$$F_{nm}^{\text{QWW}} = B_{nm} \begin{cases} \dfrac{1}{x} f_n\left(\mu \dfrac{r}{r_0}\right) - S_n(\mu)\left(\dfrac{r}{r_0}\right)^n & \text{for } r \le r_0 \\[3mm] \left[\dfrac{1}{x} f_n(\mu) - S_n(\mu)\right]\left(\dfrac{r_0}{r}\right)^n & \text{for } r > r_0 \end{cases}$$

(50)

being

$$S_n(\mu) = \frac{\epsilon_{a\infty}}{\epsilon_{a\infty} + \epsilon_{b\infty}}\left[\frac{1}{n}f_{n-1}(\mu) + \frac{1}{x}\left(\frac{\epsilon_{b\infty} - \epsilon_{a\infty}}{\epsilon_{a\infty}}\right)f_n(\mu)\right]$$

(51)

while for a FSW

$$F_{nm}^{\text{FSW}} = B_{nm} \begin{cases} f_n\left(\mu \dfrac{r}{r_0}\right) - t_n(\mu, \nu)\left(\dfrac{r}{r_0}\right)^n & \text{for } r \le r_0 \\[3mm] [f_n(\mu) - t_n(\mu, \nu)]\left(\dfrac{r_0}{r}\right)^n & \text{for } r > r_0 \end{cases}$$

(52)

where

$$t_n(\mu, \nu) = \left[y^2 f_n(\mu)f_{n+2}(\nu) + \frac{\epsilon_{a\infty}}{\epsilon_{b\infty}} g_n(\mu)f_n(\nu)\right]$$
$$\times \left[\left(\frac{\epsilon_{a\infty}}{\epsilon_{b\infty}}\left(\frac{\beta_L}{\beta_T}\right)^2 \mu^2 + \nu^2\right)f_{n+2}(\nu)\right]^{-1}$$

(53)

and

$$g_n(\mu) = \frac{\beta_L^2}{\beta_T^2}\mu^2 f_n(\mu) - 2(n+1)\mu f_{n+1}(\mu)$$

(54)

where $\epsilon_{b\infty}(\epsilon_{b0})$ is the high frequency (static) dielectric constant, the index b refers to the exterior of the nanostructure, and B_{nm} is a normalization constant that can be determined from Eq. (34) of [2]. In this constant we may include the term ρ from Eq. (16) of same reference and this term will not appear later. $\beta_L(\beta_T)$ is a parameter describing the dispersion of the oscillations longitudinal (transverse).

On the other hand

$$\mu = qr_0 \quad \nu = Qr_0 \quad \left(\frac{r_0}{\beta_L}\right)^2(\omega_L^2 - \omega_T^2) = R = \mu^2 - \left(\frac{\beta_T}{\beta_L}\right)^2 \nu^2$$

(55)

$$q^2 = \frac{\omega_L^2 - \omega_q^2}{\beta_L^2} \quad Q^2 = \frac{\omega_T^2 - \omega_q^2}{\beta_T^2}$$

(56)

and $f_n(x)$ represents a solution of the Bessel equation of order n (this function should be bounded in its domain of definition) and m is the order of the zero, obtained in the secular equations Eq. (57), for the QWW, and (58) for the FSW. It must be noticed that $\omega_q < \omega_L$ for all the frequencies involved; thus, q_z is always a real quantity. On the contrary, Q is real for $\omega_q < \omega_T$, but a pure complex quantity for $\omega_T < \omega_q < \omega_L$. The eigenfrequencies of the oscillation modes for

this case are reported in [4]; they can be obtained by solving the secular equation

$$\frac{\epsilon_{a\infty} + \epsilon_{b\infty}}{2}\left[f_{n-1}(\mu)f_{n+1}(\nu) + f_{n-1}(\nu)f_{n+1}(\mu)\right]$$
$$+ \left(\frac{\beta_L}{\beta_T}\right)^2 \frac{\epsilon_{a\infty}}{\nu^2}R^2\left[f_{n-1}(\mu) + \frac{n}{\mu}f_n(\mu)\left(\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}} - 1\right)\right]f_{n+1}(\nu) = 0$$

(57)

and for the FSW case are given by solving the secular equation

$$2n(n-1)\left(\frac{\beta_L}{\beta_T}\right)^2 R^2 t_n(\mu, \nu)f_{n+2}(\nu)$$
$$+ 2n\nu^2 f_{n+2}(\nu)\left[\mu f_n'(\mu) - f_n(\mu)\right] + g_n(\mu)$$
$$\times \left[2\nu f_n'(\nu) + (\nu^2 - 2n^2)f_n(\nu)\right] = 0$$

(58)

for what $\omega_q = \omega_{nm}$.

3.3. Electron–Phonon Interaction Hamiltonian for QD

It has been shown that the corresponding eigensolutions constitute a complete orthonormal basis of eigenvectors $\mathbf{U}_{lnm}$ and the electron–phonon interaction Hamiltonian is derived using the second-quantization formalism and can be written as in Ref. [1],

$$\widehat{H} = \sum_{l=0}^{\infty} \sum_n \sum_{m=-l}^{l} r_0 C_F \sqrt{\frac{4\pi}{3}} \Phi_{l,n} Y_l^m(\theta, \varphi)[\hat{b}_{lnm} + \hat{b}_{lnm}^+]$$

(59)

where the functions $\Phi_{l,n}(r)$ are given as

$$\Phi_{l,n}(r) = \frac{\sqrt{r_0}}{|\mathbf{u}|}\begin{cases} j_l\left(\mu_n \dfrac{r}{r_0}\right) - \dfrac{\mu_n j_l'(\mu_n) + (l+1)\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}j_l(\mu_n)}{l + (l+1)\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}}\left(\dfrac{r}{r_0}\right)^l \\[3mm] \qquad \text{for } r \le r_0 \\[3mm] -\dfrac{\mu_n j_l'(\mu_n) + l\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}j_l(\mu_n)}{l + (l+1)\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}}\left(\dfrac{r}{r_0}\right)^l \\[3mm] \qquad \text{for } r > r_0 \end{cases}$$

(60)

where j_l is the spherical Bessel function, and μ and ν can be determined using Eqs. (55) and (56). The eigenfrequencies of the oscillation modes are reported in [1]; they can be obtained by solving the secular equation

$$\nu j_l'(\mu)F_l(\nu) = l(l+1)j_l(\mu)G_l(\nu)$$

(61)

where

$$F_l(\nu) = \frac{\omega_L^2 - \omega_T^2}{\beta_T^2}\left(\frac{r_0}{\nu}\right)^2 l\left[\nu g_l'(\nu) - lg_l(\nu)\right]$$
$$+ \left(l + (l+1)\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}\right)\left[\nu g_l'(\nu) + g_l(\nu)\right]$$

(62)

$$G_l(\nu) = \frac{\omega_L^2 - \omega_T^2}{\beta_T^2}\left(\frac{r_0}{\nu}\right)^2 \frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}\left[lg_l(\nu) - \nu g_l'(\nu)\right]$$
$$+ \left(l + (l+1)\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}\right)g_l(\nu)$$

(63)

Here l represents the order of the spherical Bessel function and n is the order of the zero obtained in the secular equations (61). It can be appreciated that the energy of the modes, $\hbar\omega_q = \hbar\omega_{ln}$, does not depend on m.

In Eq. (60) the term $|\mathbf{u}|$ represents the norm of the vibrational amplitude and is equal to

$$|\mathbf{u}|^2 = \int_0^{r_0} \left\{ \left[-\frac{d}{dr} j_l\left(\mu\frac{r}{r_0}\right) + \frac{l(l+1)}{r} p_l g_l\left(\nu\frac{r}{r_0}\right) \right. \right.$$
$$\left. - \frac{t_l}{r_0} l\left(\frac{r}{r_0}\right)^{l-1} \right]^2 + \frac{l(l+1)}{r^2}$$
$$\times \left[-j_l\left(\mu\frac{r}{r_0}\right) + \frac{p_l}{l}\frac{d}{dr}\left[r g_l\left(\nu\frac{r}{r_0}\right)\right] - t_l\left(\frac{r}{r_0}\right)^l \right]^2 \right\} r^2 \, dr \quad (64)$$

with

$$p_l = \frac{\mu_k j_l'(\mu) - l j_l(\mu)}{l g_l(\nu) - \nu g_l'(\nu)} \qquad t_l = \frac{\gamma_0}{\nu_k^2} \frac{\left[\mu_k j_l'(\mu) + (l+1)\frac{\epsilon_{b\infty}}{\epsilon_{a\infty}} j_l(\mu)\right]}{1 + \frac{\epsilon_{b\infty}}{\epsilon_{a\infty}}(l+1)} \quad (65)$$

$$\gamma_0 = \frac{\omega_L^2 - \omega_T^2}{\beta_T^2} r_0^2 \quad (66)$$

and the function $g_l(z)$ is defined as

$$g_l(z) = \begin{cases} j_l(z) & \text{for } z^2 > 0 \\ i_l(z) & \text{for } z^2 < 0 \end{cases} \quad (67)$$

$i_l(z)$ is the modified spherical Bessel function.

Different modes of oscillation, with frequencies ω, contribute to the solution of the system of equations. These modes have several features; some of them are purely transverse and they are uncoupled to the electric field, and this is the reason because they do not interact via Fröhlich. The other oscillation modes are coupled to the electric field; these can have a longitudinal part and a transverse part. However, in this framework, the oscillation modes are purely longitudinal or purely transverse, for the QW. Also $n = 1$ for the QWW and the FSW, and $l = 0$ for the QD, where there are purely longitudinal modes. This can be observed in the Figure 3 where coupled modes $l = 0$ and $l = 1$ for the QD are shown.

4. DIFFERENTIAL CROSS-SECTION FOR QUANTUM WELL (QW)

Let us briefly describe the model and fundamental theory applied in our calculations. The problem of determining the stationary states of motion of a particle of mass μ in an external potential field leads to the solution of the equation

$$\left\{ \nabla^2 + \frac{2\mu}{\hbar^2}[E - V(r)] \right\} \Psi = 0 \quad (68)$$

In our model we assume a z-direction grown semiconductor QW with interfaces located at $z = -\frac{d}{2}, z = \frac{d}{2}$. We also assume the quantum well with finite potential barriers

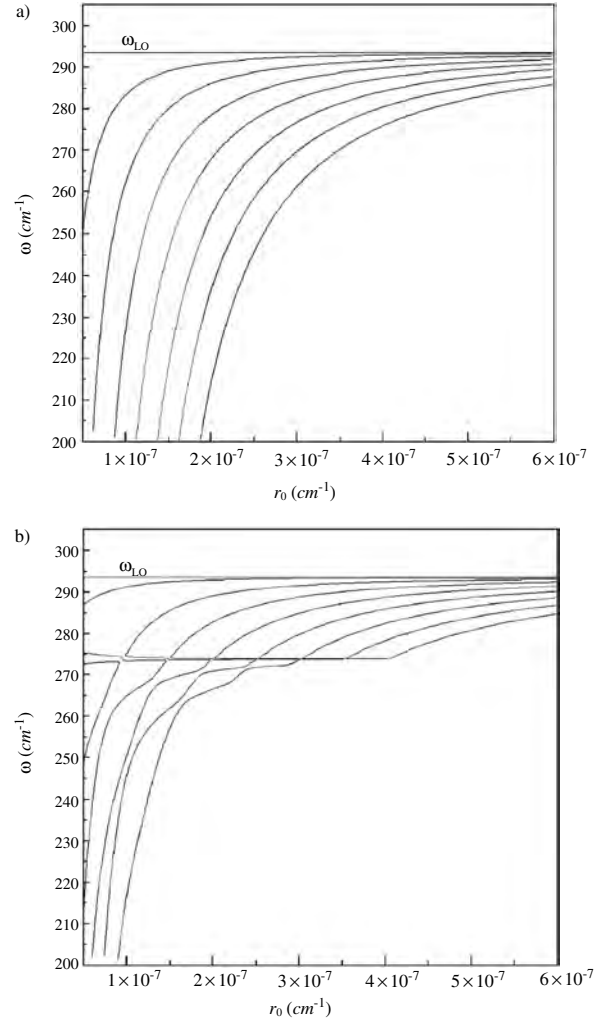

Figure 3. Coupled modes for: (a) $l = 0$, (b) $l = 1$.

at the interfaces. The solution of Schrödinger's equation, in the envelope function approximation, leads to

$$\varphi_{n_j}(r) = \left(\frac{2}{V}\right)^{\frac{1}{2}} \exp[-(i\mathbf{k}_{j\perp} \cdot \mathbf{r}_\perp)]$$
$$\times A_j \begin{cases} \cos(k_{n_j} z) & n_j \text{ odd} \quad \text{for } |z| \leq \frac{d}{2} \\ \sin(k_{n_j} z) & n_j \text{ even} \\ B_j e^{-\gamma_j |z|} & \text{for } |z| > \frac{d}{2} \end{cases} \quad (69)$$

and

$$\Psi_{n_j}(r) = \varphi_{n_j}(r) u_j(r) \quad (70)$$

where

$$A_j = \frac{1}{\sqrt{1 - \frac{2}{d}\cos\left(\frac{k_{n_j} d}{2}\right)\left[\frac{1}{\gamma_{n_j}} + (-1)^{n_j}\frac{\sin\left(\frac{k_{n_j} d}{2}\right)}{k_j}\right]}} \quad (71)$$

and

$$B_j = \exp\left(\frac{\gamma_{n_j} d}{2}\right) \begin{cases} \cos\left(\dfrac{k_{n_j} d}{2}\right) & \text{for } n_j \text{ odd} \\[2mm] \sin\left(\dfrac{k_{n_j} d}{2}\right) & \text{for } n_j \text{ even} \end{cases} \tag{72}$$

with

$$k_{n_j} d = n_j \pi - 2\arcsin\left(\frac{1}{\sqrt{\frac{2\mu_{jo} V_j}{\hbar^2 k_{n_j}^2} - \frac{\mu_{jo}}{\mu_{ji}} + 1}}\right) \quad \text{and}$$

$$\gamma_{n_j} = \sqrt{\frac{2\mu_{jo} V_j}{\hbar^2} - \frac{\mu_{jo}}{\mu_{ji}} k_{n_j}^2} \tag{73}$$

The energies are given by

$$E_j = \frac{\hbar^2}{2\mu_{ji}}\left[k_{j\perp}^2 + k_{n_j}^2\right] \qquad n_j = 1, 2, \ldots \tag{74}$$

where $j = 1, 2$ denotes electron or hole quantities, V_j represents the band offset, μ_{ji} is the electron or hole effective mass in the nanostructures, V is the volume, and $u_j(r)$ is the Bloch function taken at $\mathbf{k} = 0$, where (by assumption) the band extrema are located. Label "$\perp$" means "perpendicular to the z axis." The energy bands are unfolded in a system of subbands, where n_j is the order of the zero of Eq. (73).

4.1. Raman Scattering Intensities

From Eqs. (69) and (4) we can obtain the matrix element

$$\langle a|\widehat{H}_{jl}|i\rangle = \frac{|e|}{\mu_0}\sqrt{\frac{2\pi\hbar}{V\omega_l}}\,\hat{\mathbf{e}}_l \cdot \langle a|\hat{\mathbf{p}}|i\rangle \tag{75}$$

where $\hat{\mathbf{p}} = -i\hbar\nabla$ for the electron contribution and

$$\langle a_1|\hat{\mathbf{p}}|i\rangle = \int \bar{\varphi}_{n_1'}(r)\bar{u}_1'(r)u_2(r)\hat{\mathbf{p}}\varphi_{n_2}(r)\,dV$$
$$+ \int \bar{\varphi}_{n_1'}(r)\bar{u}_1'(r)\varphi_{n_2}(r)\hat{\mathbf{p}}u_2(r)\,dV \tag{76}$$

Consider that:

(1) The crystal possesses a volume $V = N_0\Omega_0$, in which N_0 and Ω_0 are the number of unitary cells and their volume, respectively.
(2) The function $u_j(r)(\varphi_{n_j}(r))$ varies quickly (slowly) in the volume.

Then Eq. (76) comes in,

$$\langle a_1|\hat{\mathbf{p}}|i\rangle = \sum_{\text{cells}} \bar{\varphi}_{n_1'}(r)\hat{\mathbf{p}}\varphi_{n_2}(r)\int_{\Omega_0}\bar{u}_1'(r)u_2(r)\,dV$$
$$+ \sum_{\text{cells}} \bar{\varphi}_{n_1'}(r)\varphi_{n_2}(r)\int_{\Omega_0}\bar{u}_1'(r)\hat{\mathbf{p}}u_2(r)\,dV \tag{77}$$

upon considering the orthogonal character of the functions of Bloch. The first sum of expression (77) is annulled. The

aforementioned and the definition of the moment between the bands of valence and conduction leads to the expression

$$\mathbf{p}_{cv}(0) = \int_{\Omega_0} \bar{u}_1'(r)\hat{\mathbf{p}}u_2(r)\,dV \tag{78}$$

where $\mathbf{p}_{cv}(0)$ is the interband momentum matrix element (evaluate at $\mathbf{k} = 0$). This allows us to write Eq. (75) as

$$\langle a|\widehat{H}_{jl}|i\rangle = \frac{|e|}{\mu_0}\sqrt{\frac{2\pi\hbar}{V\omega_l}}\,\hat{\mathbf{e}}_l \cdot \mathbf{p}_{cv}(0)\int \bar{\varphi}_{n_1'}(r)\varphi_{n_2}(r)\,dV \tag{79}$$

obtaining finally the expression for the matrix element

$$\langle a|\widehat{H}_{jl}|i\rangle = \frac{|e|}{\mu_0}\sqrt{\frac{2\pi\hbar}{V\omega_l}}\,\hat{\mathbf{e}}_l \cdot \mathbf{p}_{cv}(0) \begin{cases} T_{n_1', n_2}\delta_{\bar{k}_{1\perp}', -\bar{k}_{2\perp}} & \text{for } j = 1 \\[2mm] T_{n_2', n_1}\delta_{-\bar{k}_{2\perp}', \bar{k}_{1\perp}} & \text{for } j = 2 \end{cases} \tag{80}$$

where

$$T_{n_a, n_b} = A_a A_b \Bigg\{ \frac{[1 + (-1)^{n_a + n_b}]}{d}$$
$$\times \left[\frac{\sin[(k_{n_a} - k_{n_b})\frac{d}{2}]}{k_{n_a} - k_{n_b}} - (-1)^{n_a}\frac{\sin[(k_{n_a} + k_{n_b})\frac{d}{2}]}{k_{n_a} + k_{n_b}}\right]$$
$$+ \frac{4B_a B_b}{(\gamma_{n_a} + \gamma_{n_b})d}\exp\left[-(\gamma_{n_a} + \gamma_{n_b})\frac{d}{2}\right]\Bigg\} \tag{81}$$

where a (b) indicates the electron (hole) state. T_{n_a, n_b} represents the creation of an electron–hole pair due to a transition interband, where a photon of energy $\hbar\omega_l$ of incident radiation is annihilated.

If we applied the same treatment to the calculation of the other matrix elements of the expression (3), we obtain

$$\langle f|\widehat{H}_{jl}|a\rangle = (-1)^{j+1}\frac{|e|}{\mu_j}\sqrt{\frac{2\pi\hbar}{V\omega_s}}\,\hat{\mathbf{e}}_s \cdot \langle f|\hat{\mathbf{p}}|a\rangle \tag{82}$$

In a similar way we obtain that

$$\langle f|\hat{\mathbf{p}}|a\rangle = \int \bar{\varphi}_{n_j}(r)\bar{u}_j(r)\hat{\mathbf{p}}\varphi_{n_j'}(r)u_j'(r)\,dV$$
$$+ \int \bar{\varphi}_{n_j}(r)\bar{u}_j(r)\varphi_{n_j'}(r)\hat{\mathbf{p}}u_j'(r)\,dV \tag{83}$$

Then

$$\langle f|\hat{\mathbf{p}}|a\rangle = \sum_{\text{cells}} \bar{\varphi}_{n_j}(r)\hat{\mathbf{p}}\varphi_{n_j'}(r)\int_{\Omega_0}\bar{u}_j(r)u_j'(r)\,dV$$
$$+ \sum_{\text{cells}} \bar{\varphi}_{n_j}(r)\varphi_{n_j'}(r)\int_{\Omega_0}\bar{u}_j(r)\hat{\mathbf{p}}u_j'(r)\,dV \tag{84}$$

In this expression the second sum is equal to zero because the integral is calculated between symmetrical limits of an odd operator between functions of equal parity. Upon keeping in mind that the Bloch's functions are orthonormal, the integral of the first sum is equal to the unit. Then

$$\langle f|\widehat{H}_{js}|a\rangle = (-1)^{j+1}\frac{|e|}{\mu_j}\sqrt{\frac{2\pi\hbar}{V\omega_s}}\,\hat{\mathbf{e}}_s \cdot \int \bar{\varphi}_{n_j}(r)\hat{\mathbf{p}}\varphi_{n_j'}(r)\,dV \tag{85}$$

From here we obtain that

$$\langle f|\widehat{H}_{js}|a\rangle = (-1)^{j+1}\frac{|e|}{\mu_j}\sqrt{\frac{2\pi\hbar^3}{V\omega_s}}$$

$$\times\left[\hat{\mathbf{e}}_s\cdot\mathbf{k}_{j\perp}I_{n_j,n'_j} + 2i\frac{\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_z}{d}II_{n_j,n'_j}\right]\delta_{\mathbf{k}_{j\perp},\mathbf{k}'_{j\perp}} \quad (86)$$

being

$$I_{n_j,n'_j} = \begin{cases} A_jA'_j\left\{\dfrac{[1+(-1)^{n_j+n'_j}]}{d}\right. \\ \quad\times\left[\dfrac{\sin\left[(k_{n_j}-k_{n'_j})\frac{d}{2}\right]}{k_{n_j}-k_{n'_j}} - (-1)^{n_j}\dfrac{\sin\left[(k_{n_j}+k_{n'_j})\frac{d}{2}\right]}{k_{n_j}+k_{n'_j}}\right] \\ \quad\left. +\dfrac{4B_{n_j}B_{n'_j}}{(\gamma_{n_j}+\gamma_{n'_j})d}\dfrac{\mu_{jo}}{\mu_{ji}}\exp\left[-(\gamma_{n_j}+\gamma_{n'_j})\frac{d}{2}\right]\right\} \\ \qquad\qquad\qquad\text{for } n_j\neq n'_j \\ A_j^2\left\{\left[2-(-1)^{n_j}\dfrac{\sin(k_{n_j}d)}{k_{n_j}d}\right] + \dfrac{2B_{n_j}^2}{\gamma_{n_j}d}\dfrac{\mu_{jo}}{\mu_{ji}}\exp(-\gamma_{n_j}d)\right\} \\ \qquad\qquad\qquad\text{for } n_j=n'_j \end{cases} \tag{87}$$

$$II_{n_j,n'_j} = (-1)^{n_j}A_jA'_j\left(1-(-1)^{n_j+n'_j}\right)k_{n'_j}$$

$$\times\left[\frac{\sin\left[(k_{n_j}-k_{n'_j})\frac{d}{2}\right]}{k_{n_j}-k_{n'_j}}\right.$$

$$\left. -(-1)^{n_j}\frac{\sin\left[(k_{n_j}+k_{n'_j})\frac{d}{2}\right]}{k_{n_j}+k_{n'_j}}\right] \tag{88}$$

This expression represents a intersubband transition, where a photon of secondary radiation was created, with energy $\hbar\omega_s$. In this calculation the photon wavevector in comparison with the electron wavevector has been neglected. Hence, in the final state we have $\mathbf{k}_e + \mathbf{k}_h = 0$.

Considering that

$$|M_1+M_2|^2 = |M_1|^2+|M_2|^2+2\,\mathrm{Re}(M_1)\mathrm{Re}(M_2)$$

$$+2\,\mathrm{Im}(M_1)\mathrm{Im}(M_2) \tag{89}$$

we have three different contributions.

After substitution of Eqs. (80) and (86), in Eq. (3) we have

$$M_j = (-1)^{j+1}\beta_j\frac{A_0}{\mu_rE_0d}\sum_{n'_j}\frac{T_{n'_j,n_2\delta_{j1}+n_1\delta_{j2}}}{\frac{\hbar\omega_s}{E_0}+\beta_j\left[(k_{n_j}d)^2-(k_{n'_j}d)^2\right]+i\delta_{aj}}$$

$$\times[d(\hat{\mathbf{e}}_s\cdot\mathbf{k}_{j\perp})I_{n_j,n'_j}+2i(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_z)II_{n_j,n'_j}] \tag{90}$$

where

$$A_0 = \frac{e^2}{\mu_0}\frac{2\pi\hbar^2}{V}\sqrt{\frac{1}{\omega_s\omega_l}}(\hat{\mathbf{e}}_l\cdot\mathbf{p}_{cv}(0)) \tag{91}$$

and

$$E_0 = \frac{\hbar^2}{2\mu_rd^2} \quad \mu_r^{-1}=\mu_{1i}^{-1}+\mu_{2i}^{-1} \quad \beta_j=\frac{\mu_r}{\mu_{ji}} \quad \delta_{aj}=\frac{\Gamma_{aj}}{E_0} \tag{92}$$

After the substitution of Eq. (90) in Eqs. (2) and (1) we obtain that

$$\frac{d^2\sigma}{d\Omega\,d\omega_s} = \frac{V^2\omega_s^2\eta(\omega_s)}{8\pi^3c^4\eta(\omega_l)}\left|\frac{A_0}{\mu E_0d}\right|^2\frac{2\pi}{\hbar}\frac{1}{E_0}\sum_{k_{1\perp}}\sum_{n_1n_2}|\overline{M}_1+\overline{M}_2|$$

$$\times\delta\left(\frac{\hbar\omega_l-E_g}{E_0}-\frac{\hbar\omega_s}{E_0}-\beta_1(k_{n_1}d)^2\right.$$

$$\left.-\beta_2(k_{n_2}d)^2-(k_{1\perp}d)^2\right) \tag{93}$$

where

$$\overline{M}_j = (-1)^{j+1}\beta_j\sum_{n'_j}\frac{T_{n'_j,n_2\delta_{j1}+n_1\delta_{j2}}}{\frac{\hbar\omega_s}{E_0}+\beta_j\left[(k_{n_j}d)^2-(k_{n'_j}d)^2\right]+i\delta_{aj}}$$

$$\times[d(\hat{\mathbf{e}}_s\cdot\mathbf{k}_{j\perp})I_{n_j,n'_j}+2i(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_z)II_{n_j,n'_j}] \tag{94}$$

and considering that

$$\sum_{\mathbf{k}_\perp}\cdots\cdots \implies \frac{L_xL_y}{(2\pi)^2}\int_0^\infty\cdots\cdots\mathbf{k}_\perp\,d\mathbf{k}_\perp \tag{95}$$

we obtain

$$\frac{d^2\sigma}{d\Omega\,d\omega_s} = \left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_0 + \left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_\perp + \left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_z \tag{96}$$

where

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_0 = \sigma_0\frac{9}{2\sqrt{2}}\left(\frac{\hbar\omega_s}{E_0}\right)^2\sum_{n_1n_2}[\mathrm{Re}(M_{1p})\mathrm{Re}(M_{2p})$$

$$+\mathrm{Im}(M_{1p})\mathrm{Im}(M_{2p})]S_0 \tag{97}$$

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_\perp = \sigma_0\frac{9}{4\sqrt{2}}\left(\frac{\hbar\omega_s}{E_0}\right)^2\sum_{n_1n_2}[|M_{1\perp}|^2+|M_{2\perp}|^2]$$

$$\times\left(\frac{\hbar\omega_l-E_g}{E_0}-\frac{\hbar\omega_s}{E_0}-\beta_1(k_{n_1}d)^2-\beta_2(k_{n_2}d)^2\right)S_\perp \tag{98}$$

and

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_z = \sigma_0\frac{9}{4\sqrt{2}}\left(\frac{\hbar\omega_s}{E_0}\right)^2\sum_{n_1n_2}[|M_{1z}|^2+|M_{2z}|^2]S_z \tag{99}$$

Here

$$M_{jp} = M_{j\perp}\left(\frac{\hbar\omega_l-E_g}{E_0}-\frac{\hbar\omega_s}{E_0}\right.$$

$$\left.-\beta_1(k_{n_1}d)^2-\beta_2(k_{n_2}d)^2\right)^{\frac{1}{2}}+iM_{jz} \tag{100}$$

and

$$M_{j\perp} = (-1)^{j+1}\beta_j \sum_{n'_j} \frac{T_{n'_j, n_2\delta_{j1}+n_1\delta_{j2}}}{\frac{\hbar\omega_s}{E_0} + \beta_j\left[(k_{n_j}d)^2 - (k_{n'_j}d)^2\right] + i\delta_{aj}} I_{n_j, n'_j} \tag{101}$$

$$M_{jz} = (-1)^{j+1}\beta_j \sum_{n'_j} \frac{2T_{n'_j, n_2\delta_{j1}+n_1\delta_{j2}}}{\frac{\hbar\omega_s}{E_0} + \beta_j\left[(k_{n_j}d)^2 - (k_{n'_j}d)^2\right] + i\delta_{aj}} II_{n_j, n'_j} \tag{102}$$

besides

$$S_0 = |\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_\perp||\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z| \qquad S_\perp = |\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_\perp|^2 \qquad S_z = |\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z|^2 \tag{103}$$

and

$$\sigma_0 = \frac{4\sqrt{2}Ve^4|\hat{\mathbf{e}}_l \cdot \mathbf{p}_{cv}(0)|^2\eta(\omega_s)\mu_r^{\frac{1}{2}}E_0^{\frac{3}{2}}}{9\pi^2\mu_0^2\hbar^4c^4\eta(\omega_l)\omega_l\omega_s} \tag{104}$$

The contribution of the polarization S_0 can be neglected if it is compared with the contribution $S_\perp$ or S_z, if the electron effective mass is different from the hole effective mass.

Summation over the subband label must be done under the following requirements:

$$\frac{\hbar\omega_l - E_g}{E_0} - \frac{\hbar\omega_s}{E_0} - \beta_1(k_{n_1}d)^2 - \beta_2(k_{n_2}d)^2 \geq 0 \tag{105}$$

The differential cross-section for a semiconductor QW presents singular peaks for secondary radiation frequency ω_s such that

$$(s, e)(n_1, n'_1) = \beta_1\left[(k_{n'_1}d)^2 - (k_{n_1}d)^2\right] \tag{106}$$

$$(s, h)(n_2, n'_2) = \beta_2\left[(k_{n'_2}d)^2 - (k_{n_2}d)^2\right] \tag{107}$$

$$(n_1, n_2) = \frac{\hbar\omega_l - E_g}{E_0} - \beta_1(k_{n_1}d)^2 - \beta_2(k_{n_2}d)^2 \tag{108}$$

The intersubband transitions obey a selection rule requiring $n_1 + n_2$ to be odd for the polarization S_z, but for $S_\perp$ this is not a rule.

We have computed the scattering efficiency

$$\frac{1}{\sigma_0}\frac{d^2\sigma}{d\Omega\,d\omega_s} \qquad \text{vs} \qquad \frac{\hbar\omega_s}{E_0}$$

the so-called "emission spectra" of the electron raman scattering process for a given polarization $\hat{\mathbf{e}}_s$ of the emitted radiation. The physical parameters entering in our formulas were taken for the GaAs case: $E_g = 1.5177$ eV, $\varepsilon_{a\infty} = 10.90$, $\mu_{1i} = 0.0665\mu_0$, $\mu_{2i} = 0.45\mu_0$ (the heavy-hole band) and $\varepsilon_{b\infty} = 8.16$. We have set $\Gamma_f = 3$ meV, $\Gamma_{aj} = \Gamma_{bj} = 1$ meV, $V_1 = 0.968$ eV, and $V_2 = 0.6453$ eV.

In Figure 4 are shown two emission spectra for two wide $d = 3.5$ nm and $d = 5.0$ nm, and the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_z)Z$ of a QW. The incident radiation energy is $\hbar\omega_l = 2.4$ eV and several singularities are observed. The peaks position depends on the width in such a way that with the increase of width more peaks appear, because more energy levels

Figure 4. The emission spectra of the electron Raman scattering in QW for the polarization $\overline{Z}(\mathbf{e}_l, S_z)Z$ and for several widths.

exit from the interior of the QW. The intensity of the different singularities depends on the subbands involved in the transition.

In Figure 5 emission spectra for a QW with width $d = 5.0$ nm, incident radiation $\hbar\omega_l = 2.8$ eV, and polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_z)Z$ are shown. The increasing of the width of QW allows the appearance of new singularities, but the previous ones are kept. This is due to the fact that with the increase of the width the energy levels descend, making it possible that the EHP can reach new subbands. If we increase the energy of the incident radiation, new peaks appear, and the previous ones are kept. This behavior is due to the fact that new subbands can be reached by the EHP. This can also be observed in the dispersion assisted or not by phonons in QDs and in QWWs. The intensity of the different singularities does not depend on the incident radiation for the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_z)Z$.

4.2. Raman Scattering Intensities with One Phonon-Assisted Transition in QWs

In this case we begin from Eqs. (69) and (44), taking into account the same previous treatment. The calculation of the matrix element is given by

$$\langle b|\widehat{H}_{jph}|a\rangle = \int \bar{\varphi}_{n'_j}(r)\bar{u}'_j(r)\widehat{H}_{jph}\varphi_{n''_j}(r)u''_j(r)\,dV \tag{109}$$

**Figure 5.** The emission spectra of the electron Raman scattering in QW for the polarization $\overline{Z}(\mathbf{e}_l, S_z)Z$.

From here we obtain that

$$\langle b|\widehat{H}_{jph}|a\rangle = \sum_{\text{cells}} \bar{\varphi}_{n'_j}(r)\widehat{H}_{jph}\varphi_{n''_j}(r)\int_{\Omega_0} \bar{u}'_j(r)u''_j(r)\,dV \quad (110)$$

considering the orthonormality of the functions of Bloch, it can be obtained that

$$\langle b|\widehat{H}_{jph}|a\rangle = \int \bar{\varphi}_{n'_j}(r)\widehat{H}_{jph}\varphi_{n''_j}(r), \quad (111)$$

which is given by

$$\langle b|\widehat{H}_{jph}|a\rangle = (-1)^{j+1}C_q\Xi_{n,n'_j,n''_j}(q_\perp)\delta(k'_{j\perp}-k''_{j\perp}-q_\perp) \quad (112)$$

$$\Xi_{n,n'_j,n''_j}(q_\perp) = A'_j A''_j[\Pi_1(n,q_\perp)+\Pi_2(q_\perp)] \quad (113)$$

with

$$\Pi_1(n,q_\perp) = \frac{(1+(-1)^{n'_j+n''_j})}{d}$$
$$\times \left[\exp\left(iq_z\frac{d}{2}\right)[I'_-(iq_z)-(-1)^{n'_j}I'_+(iq_z)]\right.$$
$$- \exp\left(q_\perp\frac{d}{2}\right)\{[I'_-(-q_\perp)+I'_-(q_\perp)]-(-1)^{n'_j}$$
$$\times [I'_+(-q_\perp)+I'_+(q_\perp)]\}\right] + \frac{(1-(-1)^{n'_j+n''_j})}{d}$$
$$\times \left[\exp\left(iq_z\frac{d}{2}\right)[I''_-(iq_z)-(-1)^{n'_j}I''_+(iq_z)]\right.$$
$$- \exp\left(q_\perp\frac{d}{2}\right)\{[I''_-(-q_\perp)+I''_-(q_\perp)]$$
$$\left.- (-1)^{n'_j}[I''_+(-q_\perp)+I''_+(q_\perp)]\}\right] \quad (114)$$

where

$$I'_\pm(q) = \cosh\left(q\frac{d}{2}\right)\frac{(k_{n'_j}\pm k_{n''_j})\sin[(k_{n'_j}\pm k_{n''_j})\frac{d}{2}]}{(k_{n'_j}\pm k_{n''_j})^2+q^2}$$
$$+ \sinh\left(q\frac{d}{2}\right)\frac{q\cos[(k_{n'_j}\pm k_{n''_j})\frac{d}{2}]}{(k_{n'_j}\pm k_{n''_j})^2+q^2} \quad (115)$$

$$I''_\pm(q) = \cosh\left(q\frac{d}{2}\right)\frac{q\sin[(k_{n'_j}\pm k_{n''_j})\frac{d}{2}]}{(k_{n'_j}\pm k_{n''_j})^2+q^2}$$
$$- \sinh\left(q\frac{d}{2}\right)\frac{(k_{n'_j}\pm k_{n''_j})\cos[(k_{n'_j}\pm k_{n''_j})\frac{d}{2}]}{(k_{n'_j}\pm k_{n''_j})^2+q^2} \quad (116)$$

$$\Pi_2(q_\perp) = 4B'_j B''_j \sinh\left(q_\perp\frac{d}{2}\right)\frac{\exp[-(\gamma_{n'_j}+\gamma_{n''_j}+q_\perp)\frac{d}{2}]}{(\gamma_{n'_j}+\gamma_{n''_j}+q_\perp)d} \quad (117)$$

Here a quantum transition is realized and the hole or the electron emits a phonon of energy $\hbar\omega_q$. As can be observed, there exists a mixture between the confined part and the free

part of the phonon $\Pi_1(n,q_\perp)$, although the contribution of this diminishes upon increasing $q_\perp$.

The first intermediate state, a, is indicated by the quantum numbers n''_j and $k''_{j\perp}$, and for the second intermediate state, b, n'_j, and $k'_{j\perp}$ will be used. The notation of a $''$ for the state a and a $'$ for the second intermediate state b will be used for the one phonon-assisted dispersion.

Substituting Eqs. (80), (86), and (112) in Eq. (3) the following expression is obtained:

$$M_j = \beta_j\frac{A_0 C_q}{\mu_r E_0 d}\sum_{n'_j,n''_j}\frac{(\delta_{k_{2\perp},k'_{1\perp}}\delta_{j1}+\delta_{k_{1\perp},k'_{2\perp}}\delta_{j2})}{\frac{\hbar\omega_s}{E_0}+\beta_j[(k_{n_j}d)^2-(k_{n''_j}d)^2]+i\delta_{aj}}$$
$$\times \frac{T_{n'_j,n_2\delta_{j1}+n_1\delta_{j2}}\Xi_{n,n'_j,n''_j}(q_\perp)\delta(k_{j\perp}-k'_{j\perp}-q_\perp)}{\left[\frac{\hbar\omega_s}{E_0}+\frac{\hbar\omega_q}{E_0}+\beta_j[(k_{n_j}d)^2-(k_{n'_j}d)^2+(k_{j\perp}d)^2-(k'_{j\perp}d)^2]+i\delta_{aj}\right]}$$
$$\times [d(\hat{\mathbf{e}}_s\cdot\mathbf{k}_{j\perp})I_{n_j,n''_j}+2i(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_z)II_{n_j,n''_j}] \quad (118)$$

If we substitute Eq. (118) into Eqs. (2) and (1), we obtain

$$\frac{d^2\sigma}{d\Omega\,d\omega_s} = \left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_0 + \left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_\perp + \left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_z \quad (119)$$

with

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_0 = \sigma_{ph}\frac{1}{2\pi}\left(\frac{V}{d^3}\right)^2\left(\frac{\hbar\omega_s}{E_0}\right)^2\sum_n\sum_{n_1 n_2}\int_0^\infty\frac{q_\perp\,dq_\perp}{q_\perp^2+\left(\frac{n\pi}{d}\right)^2}$$
$$\times [\text{Re}(M_{1p}^{ph})\text{Re}(m_{2p}^{ph})+\text{Im}(M_{1p}^{ph})\text{Im}(M_{2p}^{ph})]S_0 \quad (120)$$

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_\perp = \sigma_{ph}\frac{1}{4\pi}\left(\frac{V}{d^3}\right)^2\left(\frac{\hbar\omega_s}{E_0}\right)^2\sum_n\sum_{n_1 n_2}\int_0^\infty\frac{q_\perp\,dq_\perp}{q_\perp^2+\left(\frac{n\pi}{d}\right)^2}$$
$$\times [|M_{1\perp}^{ph}|^2+|M_{2\perp}^{ph}|^2]GS_\perp \quad (121)$$

and

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_z = \sigma_{ph}\frac{1}{4\pi}\left(\frac{V}{d^3}\right)^2\left(\frac{\hbar\omega_s}{E_0}\right)^2\sum_n\sum_{n_1 n_2}\int_0^\infty\frac{q_\perp\,dq_\perp}{q_\perp^2+\left(\frac{n\pi}{d}\right)^2}$$
$$\times [|M_{1z}^{ph}|^2+|M_{2z}^{ph}|^2]S_z \quad (122)$$

where

$$M_{jz}^{ph} = \beta_j\sum_{n'_j,n''_j}II_{n_j,n'_j}\Xi_{n,n'_j,n''_j}\frac{T_{n''_j,n_2\delta_{j1}+n_1\delta_{j2}}}{\left[\frac{\hbar\omega_s}{E_0}+\beta_j[(k_{n_j}d)^2-(k_{n''_j}d)^2]+i\delta_{bj}\right]}$$
$$\times \frac{2}{\left[\frac{\hbar\omega_s}{E_0}+\frac{\hbar\omega_q}{E_0}+\beta_j\{[(k_{n_j}d)^2-(k_{n'_j}d)^2]-(-1)^j[(q_\perp d)^2-2k_{1\perp}q_\perp d^2]\}+i\delta_{aj}\right]} \quad (123)$$

$$M_{j\perp}^{ph} = \beta_j\sum_{n'_j,n''_j}I_{n_j,n'_j}\Xi_{n,n'_j,n''_j}\frac{T_{n''_j,n_2\delta_{j1}+n_1\delta_{j2}}}{\left[\frac{\hbar\omega_s}{E_0}+\beta_j[(k_{n_j}d)^2-(k_{n''_j}d)^2]+i\delta_{bj}\right]}$$
$$\times \frac{(k_{1\perp}d-\delta_{j2}q_\perp d)}{\left[\frac{\hbar\omega_s}{E_0}+\frac{\hbar\omega_q}{E_0}+\beta_j\{[(k_{n_j}d)^2-(k_{n'_j}d)^2]-(-1)^j[(q_\perp d)^2-2k_{1\perp}q_\perp d^2]\}+i\delta_{aj}\right]} \quad (124)$$

$$M_{jp}^{ph} = M_{j\perp}^{ph} + iM_{jz}^{ph} \quad \text{and}$$
$$k_{1\perp}d = \beta_2 q_\perp d + \sqrt{G^2-\beta_1\beta_2(q_\perp d)^2} \quad (125)$$

with

$$\delta_{bj} = \frac{\Gamma_{bj}}{E_0} \qquad \sigma_{ph} = \frac{e^4 \hbar |\hat{\mathbf{e}}_l \cdot \mathbf{p}_{cv}(0)|^2 \eta(\omega_s)}{\pi \mu_0^2 \mu_r^2 c^4 \eta(\omega_l) E_0^3 \omega_l \omega_s} |C_F|^2 \qquad (126)$$

and

$$G^2 = \frac{\hbar\omega_l - E_g}{E_0} - \frac{\hbar\omega_q}{E_0} - \frac{\hbar\omega_s}{E_0} - \beta_1 (k_{n_1} d)^2 - \beta_2 (k_{n_2} d)^2 \tag{127}$$

We have computed the scattering efficiency

$$\left(\frac{d^3}{V}\right)^2 \frac{1}{\sigma_{ph}} \left(\frac{d^2\sigma}{d\Omega\, d\omega_s}\right)_z \qquad \text{vs} \qquad \frac{\hbar\omega_s}{E_0}$$

As can be observed in Figure 6, in this case the one phonon-assisted dispersion does not produce new peaks associated with the emission of the phonon. This is due to the fact that the position and the intensity of these peaks, for the QW, depend on the phonon momentum, which takes continuous values [see Eq. (123)].

5. DIFFERENTIAL CROSS-SECTION FOR QUANTUM WELL WIRES (QWWs) AND FREESTANDING WIRES (FSWs)

The QWW geometry is cylindrical with circular cross-section of radius r_0 and length L. As explained, we consider a single conduction (valence) band, which is split into a subband system due to electron confinement within the structure:

$$\Psi_{l_j n_j} = (2\pi L)^{-\frac{1}{2}} \exp(-i(l_j \phi + k_j z)) u_j$$

$$\times \begin{cases} A_j J_{l_j}\left(x_{l_j n_j} \dfrac{r}{r_0}\right) & \text{for } r \leq r_0 \\[2mm] B_j K_{l_j}\left(y_{l_j n_j} \dfrac{r}{r_0}\right) & \text{for } r > r_0 \end{cases} \tag{128}$$

Figure 6. The emission spectra of the electron Raman scattering in QW for the polarization $\overline{Z}(\mathbf{e}_l, S_z)Z$. The transitions assisted by one phonon are considered.

with

$$B_j = \frac{J_{l_j}(x_{l_j n_j})}{K_{l_j}(y_{l_j n_j})} A_j \quad \text{and}$$

$$A_j = \left\{ \left\| J_{l_j}(x_{l_j n_j}) \right\|^2 + \left[\frac{J_{l_j}(x_{l_j n_j})}{K_{l_j}(y_{l_j n_j})}\right]^2 \left\| K_{l_j}(y_{l_j n_j}) \right\|^2 \right\}^{-\frac{1}{2}} \tag{129}$$

where

$$y_{l_j n_j} = \sqrt{\frac{2\mu_{jo} r_0^2 V_j}{\hbar^2} - \frac{\mu_{jo}}{\mu_{ji}} x_{l_j n_j}}$$

J_{l_j} and K_{l_j} are the Bessel and modified Bessel functions, and μ_{jo} is the effective mass in the surrounding medium. The states are described by the quantum numbers: $l_j = 0, 1, \ldots$; $n_j = 1, 2, \ldots$; k_j. Taking as matching boundary conditions the continuity of the function Ψ and the current $(1/\mu_i)\frac{\partial \Psi}{\partial r}$ at the interface, the confinement energies are determined by the secular equation

$$\mu_{ji} y_{l_j n_j} K'_{l_j}(y_{l_j n_j}) J_{l_j}(x_{l_j n_j}) = \mu_{jo} x_{l_j n_j} J'_{l_j}(x_{l_j n_j}) K_{n_j}(y_{l_j n_j}) \tag{130}$$

The total energies are

$$E_j = \frac{\hbar^2}{2\mu_{ji}} \left[k_j^2 + \left(\frac{x_{l_j n_j}}{r_0}\right)^2 \right] \tag{131}$$

The FSW can be modeled as a QWW with a infinitely high potential barrier; the wave function becomes

$$\Psi_j = \left[\sqrt{\pi L} r_0 J'_{l_j}(x_{l_j n_j}) \right]^{-1} J_{l_j}\left(x_{l_j n_j} \frac{r}{r_0} \right) \exp(-i(l_j \phi + k_j z)) u_j \tag{132}$$

Here, $x_{l_j n_j}$ denotes the zeros of Bessel functions, $J_{l_j}(x_{l_j n_j}) = 0$. Thus, there will be an infinite number of states completely confined in the interior of the FSW. As we can observe the bands are unfolded in a system of subbands, l_j, which themselves are also unfolded in a system of subbands, n_j, and all of them are parabolic.

5.1. Raman Scattering Intensities

From Eqs. (128), (4), and (5), applying the same procedure, it can be obtained that

$$\langle a|\widehat{H}_{jl}|i\rangle = \frac{|e|}{\mu_0} \sqrt{\frac{2\pi\hbar}{V\omega_l}} \hat{\mathbf{e}}_l \cdot \mathbf{p}_{cv}(0)$$

$$\times \begin{cases} T^0_{l'_1, n'_1, n_2} \delta_{l'_1, l_2} \delta_{k'_1, -k_2} & \text{for } j = 1 \\[2mm] T^0_{l'_2, n'_2, n_1} \delta_{l'_2, l_1} \delta_{-k'_2, k_1} & \text{for } j = 2 \end{cases} \tag{133}$$

where

$$T^v_{l, n_a, n_b} = A_a A_b \int_0^{r_0} J_{l+v}\left(x_{l n_a} \frac{r}{r_0}\right) J_{l+v}\left(x_{l n_b} \frac{r}{r_0}\right) r\, dr$$

$$+ B_a B_b \int_{r_0}^{\infty} K_{l+v}\left(y_{l n_a} \frac{r}{r_0}\right) K_{l+v}\left(y_{l n_b} \frac{r}{r_0}\right) r\, dr \tag{134}$$

with a (b) indicating the electron (hole) state. This term is similar to the obtained for the QW and it represents a interband transition, due to the emission of a photon and the creation of an EHP; but, in contrast with the QW, here the transition takes place between subbands with the same quantum number l_j.

In the solution of the second matrix element is convenient with the introduction of a new base,

$$\hat{\mathbf{e}}_{\pm} = \hat{\mathbf{e}}_x \pm i\hat{\mathbf{e}}_y \quad \hat{\mathbf{e}}_r \pm i\hat{\mathbf{e}}_\phi = e^{\mp i\phi}(\hat{\mathbf{e}}_x \pm i\hat{\mathbf{e}}_y) = e^{\mp i\phi}\hat{\mathbf{e}}_{\pm} \quad (135)$$

Thus, considering

$$\hat{\mathbf{p}} = -i\hbar\nabla \qquad \nabla = \hat{\mathbf{e}}_r \frac{\partial}{\partial r} + \frac{\hat{\mathbf{e}}_\phi}{r}\frac{\partial}{\partial \phi} + \hat{\mathbf{e}}_z \frac{\partial}{\partial z} \quad (136)$$

and after several operations and calculations we obtain that for $r < r_0$

$$\nabla J_l\left(x_{ln}\frac{r}{r_0}\right)e^{-i(l\phi + kz)}$$
$$= e^{-i(l\phi+kz)}\left\{-ikJ_l\left(x_{ln}\frac{r}{r_0}\right)\hat{\mathbf{e}}_z - \frac{x_{ln}}{2r_0}J_{l+1}\left(x_{ln}\frac{r}{r_0}\right)(\hat{\mathbf{e}}_x + i\hat{\mathbf{e}}_y)\right.$$
$$\left. + \frac{x_{ln}}{2r_0}J_{l-1}\left(x_{ln}\frac{r}{r_0}\right)(\hat{\mathbf{e}}_x - i\hat{\mathbf{e}}_y)\right\} \quad (137)$$

and for $r > r_0$

$$\nabla K_l\left(y_{ln}\frac{r}{r_0}\right)e^{-i(l_j\phi + k_j z)}$$
$$= e^{-i(l_j\phi+k_j z)}\left\{-ik_z K_l\left(y_{ln}\frac{r}{r_0}\right)\hat{\mathbf{e}}_z - \frac{y_{ln}}{2r_0}K_{l+1}\left(y_{ln}\frac{r}{r_0}\right)(\hat{\mathbf{e}}_x + i\hat{\mathbf{e}}_y)\right.$$
$$\left. - \frac{y_{ln}}{2r_0}K_{l-1}\left(y_{ln}\frac{r}{r_0}\right)(\hat{\mathbf{e}}_x - i\hat{\mathbf{e}}_y)\right\} \quad (138)$$

With these results it is obtained that

$$\langle f|\widehat{H}_{js}|b\rangle = i\hbar(-1)^j \frac{|e|}{\mu_j}\sqrt{\frac{2\pi\hbar}{V\omega_s}}$$
$$\times \left\{\frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)}{r_0}Y_{j1}\delta_{n'_j, n_j-1} + \frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)}{r_0}Y_{j2}\delta_{n'_j, n_j+1}\right.$$
$$\left. - ik'_j Y_{j3}(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)\delta_{l_j l'_j}\right\}\delta_{k_j k'_j} \quad (139)$$

where

$$Y_{jp} = \frac{1}{2}\left[(-1)^p A_a A_b \int_0^{r_0} J_{l_a}\left(x_{l_a n_a}\frac{r}{r_0}\right)J_{l_b}\left(x_{l_b n_b}\frac{r}{r_0}\right)r\,dr\right.$$
$$\left. - B_a B_b \int_{r_0}^{\infty} K_{l_a}\left(y_{l_a n_a}\frac{r}{r_0}\right)K_{l_b}\left(y_{l_b n_b}\frac{r}{r_0}\right)r\,dr\right]$$
$$\text{for } p = 1, 2 \quad (140)$$

and

$$Y_{j3} = A_a A_b \int_0^{r_0} J_{l_a}\left(x_{l_a n_a}\frac{r}{r_0}\right)J_{l_b}\left(x_{l_b n_b}\frac{r}{r_0}\right)r\,dr$$
$$+ B_a B_b \int_{r_0}^{\infty} K_{l_a}\left(y_{l_a n_a}\frac{r}{r_0}\right)K_{l_b}\left(y_{l_b n_b}\frac{r}{r_0}\right)r\,dr \quad (141)$$

Here we obtain three independent polarizations.

After substitution of Eqs. (133) and (139) into Eqs. (3) it can be obtained that

$$M_1 = -A_0\beta_1\delta_{k_1 k'_2}\sum_{l'_1, n'_1} \frac{T^0_{l'_1, n'_1, n_2}\delta_{l'_1, l_2}}{\frac{\hbar\omega_s}{E_0} + \beta_1[(x_{l_1 n_1})^2 - (x_{l'_1 n'_1})^2] + i\delta_{a1}}$$
$$\times \left[\frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)}{r_0}Y_{11}\delta_{l'_1, l_1-1} + \frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)}{r_0}Y_{12}\delta_{l'_1, l_1+1}\right.$$
$$\left. + ik'_1 Y_{13}(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)\delta_{l'_1 l_1}\right] \quad (142)$$

$$M_2 = A_0\beta_2\delta_{k_1 k'_2}\sum_{l'_2, n'_2} \frac{T^0_{l'_2, n'_2, n_1}\delta_{l'_2, l_1}}{\frac{\hbar\omega_s}{E_0} + \beta_2[(x_{l_2 n_2})^2 - (x_{l'_2 n'_2})^2] + i\delta_{a2}}$$
$$\times \left[\frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)}{r_0}Y_{21}\delta_{l'_2, l_2-1} + \frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)}{r_0}Y_{22}\delta_{l'_2, l_2+1}\right.$$
$$\left. + ik'_2 Y_{23}(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)\delta_{l'_2 l_2}\right] \quad (143)$$

After substitution of Eqs. (142) and (143) into Eqs. (2) and (1) we obtain

$$\frac{d^2\sigma}{d\Omega\,d\omega_s} = \sum_{p=0}^{3}\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_p \quad (144)$$

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_0 = \frac{9}{4\sqrt{2}}\sigma_0\left(\frac{\hbar\omega_s}{E_0}\right)^2 \sum_{l_1, n_1, l_2, n_2}\{\text{Re}(M_{12})\text{Re}(M_{21})$$
$$+ \text{Re}(M_{22})\text{Re}(M_{11}) + \text{Im}(M_{12})\text{Im}(M_{21})$$
$$+ \text{Im}(M_{22})\text{Im}(M_{11})\}\sqrt{\frac{g^2 + \sqrt{g^4 + \delta_f^2}}{\sqrt{g^4 + \delta_f^2}}}S_0$$
$$\quad (145)$$

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_p = \frac{9}{4\sqrt{2}}\sigma_0\left(\frac{\hbar\omega_s}{E_0}\right)^2 \sum_{l_1, n_1, l_2, n_2}|M_{1p} + M_{2p}|^2$$
$$\times S_p\begin{cases}\sqrt{\dfrac{g^2 + \sqrt{g^4 + \delta_f^2}}{\sqrt{g^4 + \delta_f^2}}} & \text{for } p \neq 3 \\[4mm] \sqrt{g^2 + \sqrt{g^4 + \delta_f^2}} & \text{for } p = 3 \\[2mm] p = 1, 2, 3\end{cases} \quad (146)$$

where

$$M_{1p} = -\beta_1\sum_{l'_1, n'_1} \frac{T^0_{l'_1, n'_1, n_2}\delta_{l'_1, l_2}}{\frac{\hbar\omega_s}{E_0} + \beta_1[(x_{l_1 n_1})^2 - (x_{l'_1 n'_1})^2] + i\delta_{a1}}$$
$$\times Y_{1p}\begin{cases}\delta_{l'_1, l_1-1} & \text{for } p = 1 \\ \delta_{l'_1, l_1+1} & \text{for } p = 2 \\ \delta_{l'_1, l_1} & \text{for } p = 3\end{cases} \quad (147)$$

$$M_{2p} = \beta_2 \sum_{l'_2, n'_2} \frac{T^0_{l'_2, n'_2, n_1} \delta_{l'_2, l_1}}{\frac{\hbar \omega_s}{E_0} + \beta_2[(x_{l_2 n_2})^2 - (x_{l'_2 n'_2})^2] + i\delta_{a2}}$$

$$\times Y_{2p} \begin{cases} \delta_{l'_2, l_2 - 1} & \text{for } p = 1 \\ \delta_{l'_2, l_2 + 1} & \text{for } p = 2 \\ \delta_{l'_2, l_2} & \text{for } p = 3 \end{cases} \quad (148)$$

and

$$S_0 = |\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+||\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-| \quad S_p \begin{cases} |\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+|^2 & p = 1 \\ |\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-|^2 & p = 2 \\ |\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z|^2 & p = 3 \end{cases} \quad (149)$$

Besides

$$g^2 = \frac{\hbar \omega_l - E_g}{E_0} - \frac{\hbar \omega_s}{E_0} - \beta_1 (x_{l_1 n_1})^2 - \beta_2 (x_{l_2 n_2})^2 \quad (150)$$

for the QWW, FSW, and QD

$$E_0 = \frac{\hbar^2}{2\mu_r r_0^2} \quad (151)$$

In the deduction of Eqs. (146) and (145) we have taken

$$\delta(E_f - E_i) \to \frac{1}{\pi} \frac{\Gamma_f}{(E_f - E_i)^2 + \Gamma_f^2} \quad \text{and} \quad \delta_f = \frac{\Gamma_f}{E_0} \quad (152)$$

assuming a finite lifetime, Γ_f, for the EHP in the final state. We have four contributions; three of them (S_1, S_2, S_3) are independent of each other, but the contribution of the polarization S_0 can be neglected if it is compared with the contribution S_1 or S_2.

The differential cross-section for a semiconductor QWW presents singular peaks for secondary radiation frequency ω_s such that

$$(s, e)(l_1, n_1, l'_1, n'_1) = \beta_1[(x_{l'_1 n'_1})^2 - (x_{l_1 n_1})^2] \quad (153)$$

$$(s, h)(l_2, n_2, l'_2, n'_2) = \beta_2[(x_{l'_2 n'_2})^2 - (x_{l_2 n_2})^2] \quad (154)$$

$$(l_1, n_1, l_2, n_2) = \frac{\hbar \omega_l - E_g}{E_0} - \beta_1 (x_{l_1 n_1})^2 - \beta_2 (x_{l_2 n_2})^2 \quad (155)$$

As can be seen from Eqs. (153) or (154), these frequencies correspond to electron transitions connecting the subbands edges for a process involving just the conduction or just the valence band (i.e., intraband transitions). The values of frequencies reported in Eqs. (153) and (154) are associated with the emission of a photon by the electron or hole in intersubband transitions. The selection rules are $l_1 = l_2 \pm 1$ for the electron transitions and $l_2 = l_1 \pm 1$ for the hole transitions; this selection rule corresponds to $(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_\mp)$ polarization and $l_2 = l_1$ to $(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)$ polarization. The singularities involved in Eq. (155) are dependent on ω_l and correspond to interband transitions.

We have computed the scattering efficiency

$$\frac{1}{\sigma_0} \frac{d^2\sigma}{d\Omega\, d\omega_s} \quad \text{vs} \quad \frac{\hbar \omega_s}{E_0}$$

In Figure 7 we show emission spectra for the QWW and the QD with the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$. If we compare the spectrum obtained for the QWW with $r_0 = 2.0$ nm with the one obtained for $r_0 = 2.5$ nm a displacement is observed to the right of peaks $(s, h)(1, 1, 0, 1)$ and $(s, e)(1, 1, 0, 1)$, which is of bigger magnitude for the peaks related to the electron, because for the finite potential barriers at the interface the states depend on r_0 and the effective mass for the QWW and QD [see Eqs. (130), (131), (187), and (188)]. The decrease of the intensity of the peaks can also be appreciated. This is due to the fact that with the increase of the radius the difference of energy of the subbands increases too.

This figure also shows that the peaks related to the electron transitions are bigger than those related to the hole transitions, because the hole possesses a bigger effective mass than the electron and also a lesser band offset. This can also be observed in the dispersion assisted or not assisted by phonons in QDs and in QWWs.

5.2. Raman Scattering Intensities with One Phonon-Assisted Transition for QWWs

From Eqs. (128) and (50) it can be obtained that

$$\langle b|\hat{H}_{jph}|a \rangle = C_{nm} J^{l'_j n'_j}_{l''_j n''_j} \delta_{l'_j,\, l''_j - n} \delta_{k'_j,\, k''_j} \quad (156)$$

being

$$J^{l'_j n'_j}_{l''_j n''_j} = \sqrt{\frac{V\rho}{r_0}} \left\{ A'_j A''_j \int_0^{r_0} J_{l'_j}\left(x_{l'_j n'_j} \frac{r}{r_0}\right) F^{\text{QWW}}_{nm}(r) \right.$$

$$\times J_{l''_j}\left(x_{l''_j n''_j} \frac{r}{r_0}\right) r\, dr + B'_j B''_j \int_{r_0}^{\infty} K_{l'_j}\left(y_{l'_j n'_j} \frac{r}{r_0}\right)$$

$$\left. \times F^{\text{QWW}}_{nm}(r) K_{l''_j}\left(y_{l''_j n''_j} \frac{r}{r_0}\right) r\, dr \right\} \quad (157)$$

As can be observed the emission of the phonon of energy $\hbar \omega_q$ follows the rule of selection $l'_j - l''_j = n$. This means that the transition takes place between subbands with quantum numbers separated by n, which is a phonon quantum number.

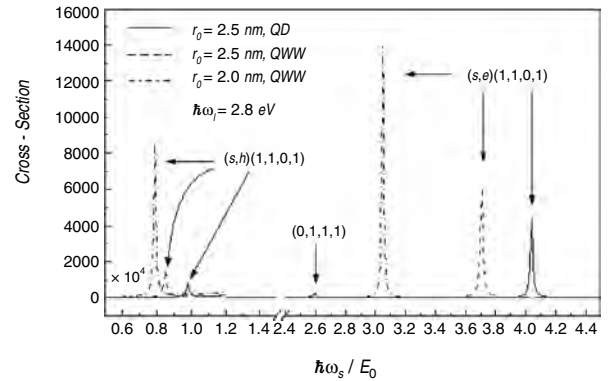

Figure 7. The emission spectra of the electron Raman scattering in QWWs and QDs for the polarization $\overline{Z}(\mathbf{e}_l, S_2)Z$. The left side of the figure was multiplied by 10^4.

After substitution of Eqs. (133), (156), and (139) into Eq. (10) it can be obtained that

$$M_1 = A_0 C_{nm} \beta_1 \sum_{l_1'', n_1'', l_1', n_1'} \frac{T_{l_1'', n_1'', n_2}^0 \delta_{l_1'', l_2} \delta_{k_1'', -k_2} \delta_{k_1, k_1''} \delta_{k_1', k_1''}}{\left[\frac{\hbar\omega_s}{E_0} + \beta_1\left[(x_{l_1 n_1})^2 - (x_{l_1' n_1'})^2\right] + i\delta_{b1}\right]}$$

$$\times \frac{J_{l_1'' n_1''}^{l_1' n_1'} \delta_{l_1', l_1''-n}}{\left[\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_1\left[(x_{l_1 n_1})^2 - (x_{l_1'' n_1''})^2\right] + i\delta_{a1}\right]}$$

$$\times \left[\frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)}{r_0} Y_{11} \delta_{l_1', l_1-1} + \frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)}{r_0} Y_{12} \delta_{l_1', l_1+1}\right.$$

$$\left. + i k_1' Y_{13} (\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z) \delta_{l_1', l_1}\right] \quad (158)$$

$$M_2 = A_0 C_{nm} \beta_2 \sum_{l_2'', n_2'', l_2', n_2'} \frac{T_{l_2'', n_2'', n_1}^0 \delta_{l_2'', l_1} \delta_{-k_2'', k_1} \delta_{k_2, k_2''} \delta_{k_2', k_2''}}{\frac{\hbar\omega_s}{E_0} + \beta_2\left[(x_{l_2 n_2})^2 - (x_{l_2' n_2'})^2\right] + i\delta_{b2}}$$

$$\times \frac{J_{l_2'' n_2''}^{l_2' n_2'} \delta_{l_2', l_2''-n}}{\left[\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_2\left[(x_{l_2 n_2})^2 - (x_{l_2'' n_2''})^2\right] + i\delta_{a2}\right]}$$

$$\times \left[\frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)}{r_0} Y_{21} \delta_{l_2', l_2-1} + \frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)}{r_0} Y_{22} \delta_{l_2', l_2+1}\right.$$

$$\left. + i k_2' Y_{23} (\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z) \delta_{l_2', l2}\right] \quad (159)$$

If we substitute Eqs. (158) and (159) into Eqs. (2) and (1) we obtain

$$\frac{d^2\sigma}{d\Omega \, d\omega_s} = \sum_{p=0}^{3} \left[\frac{d^2\sigma}{d\Omega \, d\omega_s}\right]_p \quad (160)$$

$$\left[\frac{d^2\sigma}{d\Omega d\omega_s}\right]_0 = \frac{\sqrt{2}}{4} \sigma_{ph} \left(\frac{\hbar\omega_s}{E_0}\right)^2 \sum_{nm} \sum_{l_1, n_1, l_2, n_2} \left\{\mathrm{Re}(M_{12}^{ph})\mathrm{Re}(M_{21}^{ph})\right.$$

$$+ \mathrm{Re}(M_{22}^{ph})\mathrm{Re}(M_{11}^{ph}) + \mathrm{Im}(M_{12}^{ph})\mathrm{Im}(M_{21}^{ph})$$

$$\left. + \mathrm{Im}(M_{22}^{ph})\mathrm{Im}(M_{11}^{ph})\right\} \sqrt{\frac{G^2 + \sqrt{G^4 + \delta_f^2}}{\sqrt{G^4 + \delta_f^2}}} S_0 \delta_{n,0}$$

$$(161)$$

$$\left[\frac{d^2\sigma}{d\Omega d\omega_s}\right]_p = \frac{\sqrt{2}}{4} \sigma_{ph} \left(\frac{\hbar\omega_s}{E_0}\right)^2 \sum_{nm} \sum_{l_1, n_1, l_2, n_2} \left|M_{1p}^{ph} + M_{2p}^{ph}\right|^2$$

$$\times S_p \begin{cases} \sqrt{\dfrac{G^2 + \sqrt{G^4 + \delta_f^2}}{\sqrt{G^4 + \delta_f^2}}} & \text{for } p \neq 3 \\[2em] \sqrt{G^2 + \sqrt{G^4 + \delta_f^2}} & \text{for } p = 3 \\ p = 1, 2, 3 \end{cases} \quad (162)$$

where

$$M_{1p}^{ph} = \beta_1 \frac{\omega_L}{\omega_q} \sum_{l_1'', n_1'', l_1', n_1'} Y_{1p} \frac{J_{l_1'' n_1''}^{l_1' n_1'}}{\left[\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_1\left[(x_{l_1 n_1})^2 - (x_{l_1'' n_1''})^2\right] + i\delta_{a1}\right]}$$

$$\times \frac{T_{l_1'', n_1'', n_2}^0 \delta_{l_1'', l_2} \delta_{l_1', l_1''-n}}{\left[\frac{\hbar\omega_s}{E_0} + \beta_1\left[(x_{l_1 n_1})^2 - (x_{l_1' n_1'})^2\right] + i\delta_{b1}\right]} \begin{cases} \delta_{l_1', l_1-1} & \text{for } p=1 \\ \delta_{l_1', l_1+1} & \text{for } p=2 \\ \delta_{l_1', l_1} & \text{for } p=3 \end{cases} \quad (163)$$

$$M_{2p}^{ph} = \beta_2 \frac{\omega_L}{\omega_q} \sum_{l_2'', n_2'', l_2', n_2'} Y_{2p} \frac{J_{l_2'' n_2''}^{l_2' n_2'}}{\left[\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_2\left[(x_{l_2 n_2})^2 - (x_{l_2'' n_2''})^2\right] + i\delta_{a2}\right]}$$

$$\times \frac{T_{l_2'', n_2'', n_1}^0 \delta_{l_2'', l_1} \delta_{l_2', l_2''-n}}{\left[\frac{\hbar\omega_s}{E_0} + \beta_2\left[(x_{l_2 n_2})^2 - (x_{l_2' n_2'})^2\right] + i\delta_{b2}\right]} \begin{cases} \delta_{l_2', l_2-1} & \text{for } p=1 \\ \delta_{l_2', l_2+1} & \text{for } p=2 \\ \delta_{l_2', l_2} & \text{for } p=3 \end{cases} \quad (164)$$

being

$$\delta_{aj} = \frac{\Gamma_{aj}}{E_0} \qquad \delta_{bj} = \frac{\Gamma_{bj}}{E_0} \quad (165)$$

and

$$G^2 = \frac{\hbar\omega_l - E_g}{E_0} - \frac{\hbar\omega_q}{E_0} - \frac{\hbar\omega_s}{E_0} - \beta_1(x_{l_1 n_1})^2 - \beta_2(x_{l_2 n_2})^2 \quad (166)$$

The differential cross-section for a semiconductor QWW presents singular peaks for secondary radiation frequency ω_s:

$$(s, e)(l_1, n_1, l_1', n_1') = \beta_1\left[(x_{l_1' n_1'})^2 - (x_{l_1 n_1})^2\right] \quad (167)$$

$$(s, h)(l_2, n_2, l_2', n_2') = \beta_2\left[(x_{l_2' n_2'})^2 - (x_{l_2 n_2})^2\right] \quad (168)$$

$$(f, e)(l_1, n_1, l_1'', n_1'') = \beta_1\left[(x_{l_1'' n_1''})^2 - (x_{l_1 n_1})^2\right] - \frac{\hbar\omega_q}{E_0} \quad (169)$$

$$(f, h)(l_2, n_2, l_2'', n_2'') = \beta_2\left[(x_{l_2'' n_2''})^2 - (x_{l_2 n_2})^2\right] - \frac{\hbar\omega_q}{E_0} \quad (170)$$

$$(l_1, n_1, l_2, n_2) = \frac{\hbar\omega_l - E_g}{E_0} - \frac{\hbar\omega_q}{E_0} - \beta_1(x_{l_1 n_1})^2 - \beta_2(x_{l_2 n_2})^2 \quad (171)$$

We can see that the Eqs. (167) and (168) represent the same frequencies as (153) and (154) and have the same selection rule $l_j'' = l_j \pm 1$. As can be seen from (169) or (170), these frequencies correspond to electron transitions connecting the subband edges for a process involving just the conduction or just the valence band (i.e., intraband transitions). The values of frequencies reported in (169) and (170) are associated with the emission of a phonon by the electron or hole in intersubband transitions. The selection rules are $l_1' = l_1 \pm n + 1$ for the electron transitions and $l_2' = l_2 \pm n + 1$ for the hole transitions; this selection rule corresponds to $(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_\mp)$ polarization and $l_j' = l_j + n$ to $(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)$ polarization. The singularities involved in (171) depend on ω_l and correspond to interband transitions.

In Figure 8 the emission spectra for the QWW and the FSW for different phonon modes with $n = 0$ and a polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$ are presented. As is shown, the intensity of the peaks in the mode $m = 1$ is bigger than $m = 2$ and this is bigger than $m = 3$; this means that we only need to consider the contribution of the first phonon modes in the differential cross-section. On the other hand, the magnitude of the
Figure 8. The emission spectra of the electron Raman scattering in QWW and FSW for the polarization $\overline{Z}(\mathbf{e}_l, S_2)Z$ for $n = 0$, varying the phonons mode of the system.

differential cross-section is bigger for the FSW than for the QWW, which is due to the fact that the boundary conditions make the form factor for the FSW bigger than for the QWW. A displacement to the right of peaks related to the emission of the phonon is also observed, in both spectra, due to the fact that $\hbar\omega_q$ diminishes with the increase of m [2].

In Figure 9 the emission spectra for a QWW with $n = 0$, $r_0 = 2.5$ nm, and $\hbar\omega_l = 3.2$ eV for the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_1)Z$ are presented. As can be observed if we compare with the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$ (see Fig. 8) the change of the polarization affects the position of the peaks. This is due to the fact that the polarization change implies a change in the selection rules; that is to say, they change the subbands involved in the transitions, which also produces a decrease of the intensity of the DCS for the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_1)Z$. In this figure only singularities produced by holes transitions are shown, which is due to the fact that the number of electron states is very small (the electron tunneling is small), but its contribution increases with the increase of the radius. The decrease of the intensity of DCS for the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_1)Z$ is due to the fact that it is more probable that the electron or the hole makes a transition to a subband with a lesser l_j when emitting a photon.
Figure 9. The emission spectra of the electron Raman scattering in QWW for the polarization $\overline{Z}(\mathbf{e}_l, S_1)Z$ for $n = 0$.

5.3. Raman Scattering Intensities with One Phonon-Assisted Transition for FSWs

From Eqs. (132) and (52) it can be obtained that

$$T^0_{l, n_a, n_b} = \delta_{n_a, n_b} \tag{172}$$

The aforementioned implies that electron and hole have the same quantum numbers,

$$Y_{j3} = \delta_{n_a, n_b}, \; Y_{jp} = (-1)^p \frac{x_{l_j n_j} x_{l'_j n'_j}}{(x_{l'_j n'_j})^2 - (x_{l_j n_j})^2} \tag{173}$$

Then, by using Eqs. (52) and (157),

$$
\begin{aligned}
J^{l'_j n'_j}_{l''_j n''_j} = & \sqrt{\frac{V\rho}{r_0}} \frac{1}{r_0^2 J'_{l'_j}(x_{l'_j n'_j}) J'_{l'_j}(x_{l''_j n''_j})} \\
& \times \int_0^{r_0} J_{l'_j}\left(x_{l'_j n'_j}\frac{r}{r_0}\right) F^{\mathrm{FSW}}_{nm}(r) J_{l'_j}\left(x_{l''_j n''_j}\frac{r}{r_0}\right) r \, dr
\end{aligned} \tag{174}
$$

This means that in this case the creation of EHP is direct.

With these results Eqs. (158) and (159) remain in the form

$$
\begin{aligned}
M_1 = & A_0 C_{nm} \beta_1 \sum_{l''_1, n''_1, l'_1, n'_1} \frac{\delta_{n''_1, n_2}\delta_{l''_1, l_2}\delta_{k''_1, -k_2}\delta_{k_1, k''_1}\delta_{k'_1, k''_1}}{\left[\frac{\hbar\omega_s}{E_0} + \beta_1\left[(x_{l_1 n_1})^2 - (x_{l'_1 n'_1})^2\right] + i\delta_{b1}\right]} \\
& \times \frac{J^{l'_1 n'_1}_{l''_1 n''_1}\delta_{l'_1, l''_1-n}}{\left[\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_1\left[(x_{l_1 n_1})^2 - (x_{l''_1 n''_1})^2\right] + i\delta_{a1}\right]} \\
& \times \left[\frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)}{r_0} Y_{11}\delta_{l'_1, l_1-1} + \frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)}{r_0} Y_{12}\delta_{l'_1, l_1+1} \right. \\
& \left. + ik'_1 Y_{13}(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)\delta_{l'_1, l_1}\right]
\end{aligned} \tag{175}
$$

$$
\begin{aligned}
M_2 = & A_0 C_{nm} \beta_2 \sum_{l''_2, n''_2, l'_2, n'_2} \frac{\delta_{n''_2, n_1}\delta_{l''_2, l_1}\delta_{-k''_2, k_1}\delta_{k_2, k''_2}\delta_{k'_2 k''_2}}{\frac{\hbar\omega_s}{E_0} + \beta_2\left[(x_{l_2 n_2})^2 - (x_{l'_2 n'_2})^2\right] + i\delta_{b2}} \\
& \times \frac{J^{l'_2 n'_2}_{l''_2 n''_2}\delta_{l'_2, l''_2-n}}{\left[\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_2\left[(x_{l_2 n_2})^2 - (x_{l''_2 n''_2})^2\right] + i\delta_{a2}\right]} \\
& \times \left[\frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)}{r_0} Y_{21}\delta_{l'_2, l_2-1} + \frac{(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)}{r_0} Y_{22}\delta_{l'_2, l_2+1} \right. \\
& \left. + ik'_2 Y_{23}(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)\delta_{l'_2, l2}\right]
\end{aligned} \tag{176}
$$

We just write the final results,

$$\frac{d^2\sigma}{d\Omega \, d\omega_s} = \sum_{p=0}^{3}\left[\frac{d^2\sigma}{d\Omega \, d\omega_s}\right]_p \tag{177}$$

$$
\begin{aligned}
\left[\frac{d^2\sigma}{d\Omega \, d\omega_s}\right]_0 = & \frac{\sqrt{2}}{4}\sigma_{ph}\left(\frac{\hbar\omega_s}{E_0}\right)^2 \sum_{nm}\sum_{l_1, n_1, l_2, n_2}\left\{\mathrm{Re}(M^{ph}_{12})\mathrm{Re}(M^{ph}_{21})\right. \\
& + \mathrm{Re}(M^{ph}_{22})\mathrm{Re}(M^{ph}_{11}) + \mathrm{Im}(M^{ph}_{12})\mathrm{Im}(M^{ph}_{21}) \\
& \left. + \mathrm{Im}(M^{ph}_{22})\mathrm{Im}(M^{ph}_{11})\right\} \sqrt{\frac{G^2 + \sqrt{G^4 + \delta_f^2}}{\sqrt{G^4 + \delta_f^2}}} S_0 \delta_{n,0}
\end{aligned} \tag{178}
$$

$$\left[\frac{d^2\sigma}{d\Omega\, d\omega_s}\right]_p = \frac{\sqrt{2}}{4}\sigma_{ph}\left(\frac{\hbar\omega_s}{E_0}\right)^2 \sum_{nm}\sum_{l_1,n_1,l_2,n_2}\left|M_{1p}^{ph}+M_{2p}^{ph}\right|^2$$

$$\times S_p \begin{cases} \sqrt{\dfrac{G^2+\sqrt{G^4+\delta_f^2}}{\sqrt{G^4+\delta_f^2}}} & \text{for } p\neq 3 \\[4mm] \sqrt{G^2+\sqrt{G^4+\delta_f^2}} & \text{for } p=3 \\[2mm] \qquad p=1,2,3 \end{cases} \tag{179}$$

where

$$M_{1p}^{ph} = \beta_1 \frac{\omega_L}{\omega_q}\sum_{l_1'',n_1'',l_1',n_1'} Y_{1p}\frac{J_{l_1''n_1''}^{l_1'n_1'}}{\left[\frac{\hbar\omega_s}{E_0}+\frac{\hbar\omega_q}{E_0}+\beta_1\left[(x_{l_1n_1})^2-(x_{l_1''n_1''})^2\right]+i\delta_{a1}\right]}$$

$$\times \frac{\delta_{l_1'',l_2}\delta_{n_1'',n_2}\delta_{l_1',l_1''-n}}{\left[\frac{\hbar\omega_s}{E_0}+\beta_1\left[(x_{l_1n_1})^2-(x_{l_1'n_1'})^2\right]+i\delta_{b1}\right]}\begin{cases}\delta_{l_1',l_1-1} & \text{for } p=1 \\ \delta_{l_1',l_1+1} & \text{for } p=2\end{cases} \tag{180}$$

$$\times \frac{\delta_{l_2'',l_1}\delta_{n_2'',n_1}\delta_{l_2',l_2''-n}}{\left[\frac{\hbar\omega_s}{E_0}+\beta_2\left[(x_{l_2n_2})^2-(x_{l_2'n_2'})^2\right]+i\delta_{b2}\right]}\begin{cases}\delta_{l_2',l_2-1} & \text{for } p=1 \\ \delta_{l_2',l_2+1} & \text{for } p=2\end{cases} \tag{181}$$

$$M_{13}^{ph} = \beta_1 \frac{\omega_L}{\omega_q}\frac{J_{l_2n_2}^{l_1n_1}\delta_{l_1,l_2-n},\delta_{n_1',n_2}}{\left[\frac{\hbar\omega_s}{E_0}+i\delta_{b1}\right]\left[\frac{\hbar\omega_s}{E_0}+\frac{\hbar\omega_q}{E_0}+\beta_1\left[(x_{l_1n_1})^2-(x_{l_2n_2})^2\right]+i\delta_{a1}\right]} \tag{182}$$

$$M_{23}^{ph} = \beta_2 \frac{\omega_L}{\omega_q}\frac{J_{l_1n_1}^{l_2n_2}\delta_{l_2,l_1-n}}{\left[\frac{\hbar\omega_s}{E_0}+i\delta_{b2}\right]\left[\frac{\hbar\omega_s}{E_0}+\frac{\hbar\omega_q}{E_0}+\beta_2\left[(x_{l_2n_2})^2-(x_{l_1n_1})^2\right]+i\delta_{a2}\right]} \tag{183}$$

The differential cross-section for a semiconductor FSW presents singular peaks for the secondary radiation frequency ω_s. This could be calculated with Eqs. (167), (168), (169), (170), and (171), and it has the same properties.

In Figure 8 also observed are a displacement to the right and more intensity of peaks for the FSW in comparison with the QWW, which is due to the different conditions of confining. The increment of the potential barrier is the cause of this displacement and also the increasing number of energy levels [117]. It also can be observed that the differences of intensity of DCS for $n=0$ and the other phonons made in the FSW are bigger than in the QWW, because the FSW and the QWW have different dispersion laws for the phonon modes.

In Figure 10 the emission spectra for a FSW considering only $n=0$ and for a polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$ are presented. The emission spectra for $r_0 = 2.5$ nm and $r_0 = 3.0$ nm can be observed. Then, a comparison between both radii illustrates that an increase of the radius causes a displacement of the peaks (associated to the emission of a phonon) toward the left. This fact is justified when the dispersion law and Eqs. (169) and (170) are analyzed; the displacement is influenced fundamentally by the energy of formation of the electron–hole pair, E_0. Also, the increase of the radius produces a decrease of the intensity of the DCS (fundamentally the transitions that involve the holes) due to the fact that the energy levels diminish. This also is observed in the one phonon-assisted dispersion in any nanostructures.

In Figure 11 the emission spectra of a FSW with $n=0$, $r_0 = 2.5$ nm, and $\hbar\omega_l = 10.0$ eV for the polarization

Figure 10. The emission spectra of the one phonon-assisted electron Raman scattering in FSW for the polarization $\overline{Z}(\mathbf{e}_l, S_2)Z$ for $n=0$ and several radii.

$\overline{Z}(\hat{\mathbf{e}}_l, S_1)Z$ are presented. As can be observed if we compare with the polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$ (see Fig. 10), also in this case the change of polarization affects the position of the peaks; however, a bigger increase of the energy of incident radiation is required in order for the bands involved in transitions to be reached by the EHP. This is due to the fact that a change in the polarization changes the selection rules, which it means a change in the involved subbands in the transitions. This is observed in the QW and QWW.

If we compare with Figure 9 we can observe that in the case of the QWW the increment of energy cannot be very large, because of the finite height of the barrier. Thus, is enough to consider that the energy of the incident photon be equal to the gap of the external material in order for all the energy levels to be reached by the EHP. Also, due to the fact that the number of energy levels is finite, the selection rules will not always be completed, so that the peaks will not appear. In the case of the FSW peaks always can be obtained, because in this case we consider that the potential barriers are infinite and there exists an infinite number of energy levels.

In Figure 12 the emission spectrum is also observed for the FSW with $r_0 = 2.5$ nm, $\hbar\omega_l = 10.0$ eV, with polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$ for $n=0$ and $n=1$. It can be observed that the peak associated with the emission of a photon does not vary

Figure 11. The emission spectra of the electron Raman scattering in FSW for the polarization $\overline{Z}(\mathbf{e}_l, S_1)Z$ for $n=0$.
Figure 12. The emission spectra of the electron Raman scattering in FSW for the polarization $\bar{Z}(\mathbf{e}_l, S_2)Z$ for $n = 0$ and $n = 1$.

its position with the increase of the order of the phonon mode. The peak associated to the emission of a phonon (see Fig. 10) varies its position in accordance with the selection rule $l_2 = l_1 + n + 1$ [see Eqs. (180) and (181)]. It can also be appreciated that the intensity of the DCS diminishes with the increase of n. From the physical point of view this is due to the fact that for the emission of a phonon a transition intrasubband is less favorable for $n = 0$ than a transition serial intersubbands, for $n = 1$. This demonstrates that the fundamental contribution carries out the phonon mode $n = 0$.

6. DIFFERENTIAL CROSS-SECTION FOR QUANTUM DOT (QD)

We will consider a spherical QD of radius r_0 with single conduction (valence) band. This band is split in a system of subbands due to a complete confinement of the electrons in all directions. The solution of the Schrödinger equation, in the envelope function approximation, leads to

$$\Psi_{l_j m_j n_j} = Y_{n_j}^{m_j}(\theta, \varphi) u_j \begin{cases} \dfrac{A_j}{\sqrt{r}} J_{l_j + \frac{1}{2}}\left(x_{l_j n_j} \dfrac{r}{r_0}\right) & \text{for } r \le r_0 \\[3mm] \dfrac{B_j}{\sqrt{r}} K_{l_j + \frac{1}{2}}\left(y_{l_j n_j} \dfrac{r}{r_0}\right) & \text{for } r > r_0 \end{cases}$$

(184)

with

$$B_j = \frac{J_{l_j + \frac{1}{2}}\left(x_{l_j n_j}\right)}{K_{l_j + \frac{1}{2}}\left(y_{l_j n_j}\right)} A_j$$

(185)

and

$$A_j = \left\{ \left\| J_{l_j + \frac{1}{2}}\left(x_{l_j n_j}\right) \right\|^2 + \left[\frac{J_{l_j + \frac{1}{2}}\left(x_{l_j n_j}\right)}{K_{l_j + \frac{1}{2}}\left(y_{l_j n_j}\right)} \right]^2 \left\| K_{l_j + \frac{1}{2}}\left(y_{l_j n_j}\right) \right\|^2 \right\}^{-\frac{1}{2}}$$

(186)

In Eq. (184) $Y_{n_1}^{m_1}(\theta, \varphi)$ are the spherical harmonics. We use spherical coordinates r, θ, φ.

The confinement energies are determined by the secular equation

$$\mu_{ji} y_{l_j n_j} K'_{n_j + \frac{1}{2}}\left(y_{l_j n_j}\right) J_{l_j + \frac{1}{2}}\left(x_{l_j n_j}\right)$$
$$= \mu_{jo} x_{l_j n_j} J'_{l_j + \frac{1}{2}}\left(x_{l_j n_j}\right) K_{n_j + \frac{1}{2}}\left(y_{l_j n_j}\right)$$

(187)

The energy is given by

$$E_j = \frac{\hbar^2}{2\mu_{ji} r_0^2}\left(x_{l_j n_j}\right)^2$$

(188)

where $x_{l_j n_j}$ denotes the zeros of Eq. (187). In this case the bands remain completely quantized, due to the total confinement to which they are subjected; however, due to the symmetry, this is $2l_j + 1$ times degenerate.

6.1. Raman Scattering Intensities

From Eqs. (184), (4), and (5) it can be obtained that

$$\langle a|\widehat{H}_{jl}|i\rangle = \frac{|e|}{\mu_0}\sqrt{\frac{2\pi\hbar}{V\omega_l}}\,\hat{\mathbf{e}}_l \cdot \mathbf{p}_{cv}(0) \begin{cases} T_{l'_1, n'_1, n_2}^{\frac{1}{2}} \delta_{l'_1, l_2} \delta_{m'_1, m_2} & \text{for } j = 1 \\[2mm] T_{l'_2, n'_2, n_1}^{\frac{1}{2}} \delta_{l'_2, l_1} \delta_{m'_2, m_1} & \text{for } j = 2 \end{cases}$$

(189)

This is the same as that obtained for the QWW. It represents an interband transition due to the emission of a photon and the creation of an EHP, but additionally the transition takes place between subbands with the same quantum number l_j and m_j.

In the solution of the second matrix element the introduction of a new base is convenient:

$$\hat{\mathbf{e}}_{\pm} = \frac{1}{\sqrt{2}}(\hat{\mathbf{e}}_x \pm i\hat{\mathbf{e}}_y) \quad \text{and} \quad \hat{\mathbf{e}}_z$$

(190)

$$\hat{\mathbf{e}}_r = \sin\theta\cos\phi\,\hat{\mathbf{e}}_x + \sin\theta\sin\phi\,\hat{\mathbf{e}}_y + \cos\theta\,\hat{\mathbf{e}}_z$$
$$= \frac{\sin\theta}{\sqrt{2}}\left(e^{-i\phi}\hat{\mathbf{e}}_+ + e^{i\phi}\hat{\mathbf{e}}_-\right) + \cos\theta\,\hat{\mathbf{e}}_z$$

(191)

Then, by considering

$$\hat{\mathbf{p}} = -i\hbar\nabla \qquad \nabla = \hat{\mathbf{e}}_r\frac{\partial}{\partial r} + \frac{i}{\hbar r}\hat{\mathbf{e}}_r \times \widehat{\mathbf{L}}$$

(192)

applying the base given in Eq. (190) and introducing the operators

$$\widehat{L}_{\pm} = \frac{1}{\sqrt{2}}\left(\widehat{L}_x \pm \widehat{L}_y\right)$$

(193)

and considering that

$$\hat{\mathbf{e}}_r \times \widehat{\mathbf{L}} = i\frac{\sin\theta}{\sqrt{2}}\left(e^{i\phi}\widehat{L}_- - e^{-i\phi}\widehat{L}_+\right)\hat{\mathbf{e}}_z$$
$$+ i\left(\cos\theta\widehat{L}_+ - \frac{\sin\theta}{\sqrt{2}}e^{-i\phi}\widehat{L}_z\right)\hat{\mathbf{e}}_-$$
$$+ i\left(\frac{\sin\theta}{\sqrt{2}}e^{-i\phi}\widehat{L}_z - \cos\theta\widehat{L}_-\right)\hat{\mathbf{e}}_+$$

(194)

we obtain for the matrix element

$$\langle f|\hat{H}_{js}|b\rangle = \langle f|\hat{H}_{js}|b\rangle_1 + \langle f|\hat{H}_{js}|b\rangle_2 + \langle f|\hat{H}_{js}|b\rangle_3 \quad (195)$$

where

$$\langle f|\hat{H}_{js}|b\rangle_p = i\hbar(-1)^j \frac{|e|}{r_0\mu_j}\sqrt{\frac{2\pi\hbar}{V\omega_s}}\left[\Pi_{j1p}\delta_{l'_j,l_j+1} + \Pi_{j2p}\delta_{l'_j,l_j-1}\right]$$

$$\times I_{l_j n_j}^{l'_j n'_j}\begin{cases}\delta_{m'_j,m_j+1}(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_+) & \text{for } p=1\\\delta_{m'_j,m_j-1}(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_-) & \text{for } p=2 \quad (196)\\\delta_{m'_j,m_j}(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_z) & \text{for } p=2\end{cases}$$

and

$$\Pi_{j11} = -\sqrt{\frac{(l_j+m_j+2)(l_j+m_j+1)}{2(2l_j+1)(2l_j+3)}} \quad \Pi_{j21} = \sqrt{\frac{(l_j-m_j-1)(l_j-m_j)}{2(2l_j-1)(2l_j+1)}}$$

$$\Pi_{j12} = \sqrt{\frac{(l_j-m_j+2)(l_j-m_j+1)}{2(2l_j+1)(2l_j+3)}} \quad \Pi_{j22} = -\sqrt{\frac{(l_j+m_j-1)(l_j+m_j)}{2(2l_j-1)(2l_j+1)}}$$

$$\Pi_{j13} = \sqrt{\frac{(l_j-m_j+1)(l_j+m_j+1)}{(2l_j+1)(2l_j+3)}} \quad \Pi_{j23} = \sqrt{\frac{(l_j-m_j)(l_j+m_j)}{(2l_j-1)(2l_j+1)}}$$

$$(197)$$

$$I_{l_j n_j}^{l'_j n'_j} = A_j A'_j \int_0^{r_0} J_{l_j+\frac{1}{2}}\left(x_{l_j n_j}\frac{r}{r_0}\right)J_{l'_j+\frac{1}{2}}\left(x_{l'_j n'_j}\frac{r}{r_0}\right)r\,dr$$

$$+ B_j B'_j \int_{r_0}^{\infty} K_{l_j+\frac{1}{2}}\left(y_{l_j n_j}\frac{r}{r_0}\right)K_{l'_j+\frac{1}{2}}\left(y_{l'_j n'_j}\frac{r}{r_0}\right)r\,dr \quad (198)$$

This shows that in the emission of a photon, $\hbar\omega_s$, three independent polarizations appear in which the transitions occur between states that fulfill that $l'_j, l_j \pm 1$.

After substitution of Eqs. (189) and (195) into Eqs. (3) we will have that

$$M_1 = -A_0\beta_1 \sum_{l'_1, m'_1, n'_1} \frac{\left[\Pi_{11p}\delta_{l'_1,l_1+1} + \Pi_{12p}\delta_{l'_1,l_1-1}\right]\delta_{l'_1,l_2}}{\frac{\hbar\omega_s}{E_0}+\beta_1\left[(x_{l_1 n_1})^2 - (x_{l'_1 n'_1})^2\right]+i\delta_{a1}}$$

$$\times I_{l_1 n_1}^{l'_1 n'_1} T_{l'_1 n'_1, n_2}^{\frac{1}{2}}\delta_{m'_1,m_2}\begin{cases}(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_+)\delta_{m'_1,m_1+1} & \text{for } p=1\\(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_-)\delta_{m'_1,m_1-1} & \text{for } p=2 \quad (199)\\(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_z)\delta_{m'_1,m_1} & \text{for } p=3\end{cases}$$

$$M_2 = A_0\beta_2 \sum_{l'_2, m'_2, n'_2} \frac{\left[\Pi_{21p}\delta_{l'_2,l_2+1} + \Pi_{22p}\delta_{l'_2,l_2-1}\right]\delta_{l'_2,l_1}}{\frac{\hbar\omega_s}{E_0}+\beta_2\left[(x_{l_2 n_2})^2 - (x_{l'_2 n'_2})^2\right]+i\delta_{a2}}$$

$$\times I_{l_2 n_2}^{l'_2 n'_2} T_{l'_2 n'_2, n_1}^{\frac{1}{2}}\delta_{m'_2,m_1}\begin{cases}(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_+)\delta_{m'_2,m_2+1} & \text{for } p=1\\(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_-)\delta_{m'_2,m_2-1} & \text{for } p=2 \quad (200)\\(\hat{\mathbf{e}}_s\cdot\hat{\mathbf{e}}_z)\delta_{m'_2,m_2} & \text{for } p=3\end{cases}$$

After substitution of Eqs. (199) and (200) into Eqs. (2) and (1) we obtain

$$\frac{d^2\sigma}{d\Omega\,d\omega_s} = \sum_{p=0}^{3}\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_p \quad (201)$$

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_0 = \frac{27}{4}\sigma_0\left(\frac{\hbar\omega_s}{E_0}\right)^2\delta_f$$

$$\times \sum_{l_1,n_1,m_1}\sum_{l_2,n_2,m_2}\{\text{Re}(M_{11})\text{Re}(M_{22})$$

$$+ \text{Re}(M_{12})\text{Re}(M_{21}) + \text{Im}(M_{11})\text{Im}(M_{22})$$

$$+ \text{Im}(M_{12})\text{Im}(M_{21})\}\frac{S_o}{g^4+\delta_f^2} \quad (202)$$

$$\left[\frac{d^2\sigma}{d\Omega\,d\omega_s}\right]_p = \frac{27}{4}\sigma_0\left(\frac{\hbar\omega_s}{E_0}\right)^2\delta_f \sum_{l_1,n_1,m_1}\sum_{l_2,n_2,m_2}|M_{1p}+M_{2p}|^2$$

$$\times \frac{S_p}{g^4+\delta_f^2} \quad p=1,2,3 \quad (203)$$

where

$$M_{1p} = -\beta_1 \sum_{l'_1,m'_1,n'_1} \frac{\left[\Pi_{11p}\delta_{l'_1,l_1+1} + \Pi_{12p}\delta_{l'_1,l_1-1}\right]\delta_{l'_1,l_2}}{\frac{\hbar\omega_s}{E_0}+\beta_1\left[(x_{l_1 n_1})^2 - (x_{l'_1 n'_1})^2\right]+i\delta_{a1}}$$

$$\times I_{l_1 n_1}^{l'_1 n'_1} T_{l'_1 n'_1, n_2}^{\frac{1}{2}}\delta_{m'_1,m_2}\begin{cases}\delta_{m'_1,m_1+1} & \text{for } p=1\\\delta_{m'_1,m_1-1} & \text{for } p=2\\\delta_{m'_1,m_1} & \text{for } p=3\end{cases}$$

$$(204)$$

$$M_{2p} = \beta_2 \sum_{l'_2,m'_2,n'_2} \frac{\left[\Pi_{21p}\delta_{l'_2,l_2+1} + \Pi_{22p}\delta_{l'_2,l_2-1}\right]\delta_{l'_2,l_1}}{\frac{\hbar\omega_s}{E_0}+\beta_2\left[(x_{l_2 n_2})^2 - (x_{l'_2 n'_2})^2\right]+i\delta_{a2}}$$

$$\times I_{l_2 n_2}^{l'_2 n'_2} T_{l'_2 n'_2, n_1}^{\frac{1}{2}}\delta_{m'_2,m_1}\begin{cases}\delta_{m'_2,m_2+1} & \text{for } p=1\\\delta_{m'_2,m_2-1} & \text{for } p=2\\\delta_{m'_2,m_2} & \text{for } p=3\end{cases}$$

$$(205)$$

The contribution of the polarization S_0 can be neglected if it is compared with the contribution S_1 or S_2.

The differential cross-section for a semiconductor QD presents singular peaks for secondary radiation frequency ω_s such that

$$(s,e)(l_1,n_1,l'_1,n'_1) = \beta_1\left[(x_{l'_1 n'_1})^2 - (x_{l_1 n_1})^2\right] \quad (206)$$

$$(s,h)(l_2,n_2,l'_2,n'_2) = \beta_1\left[(x_{l'_2 n'_2})^2 - (x_{l_2 n_2})^2\right] \quad (207)$$

$$(l_1,n_1,l_2,n_2) = \frac{\hbar\omega_l - E_g}{E_0} - \beta_1(x_{l_1 n_1})^2 - \beta_2(x_{l_2 n_2})^2 \quad (208)$$

As can be seen from Eqs. (206) or (207) these frequencies correspond to electron transitions connecting the subbands edges for a process involving just the conduction or just the valence band (i.e., intraband transitions). The values of frequencies in Eqs. (206) and (207) are associated with the emission of a photon by the electron or hole intersubband transitions. The selection rules are $l_1 = l_2 \pm 1$ for the electron transitions and $l_2 = l_1 \pm 1$ for the hole transitions. The singularities involved in Eq. (208) depend on ω_l and correspond to interband transitions.

If the spectra of the QWW are compared with those obtained for the QD with $r_0 = 2.5$ nm (see Fig. 7), it can be

observed that the peaks are displaced to the right. This is due to the fact that the subbands of the QD are more separated that those of the QWW; the intensity of the peaks of QD is also smaller, since the QD has a smaller state density.

6.2. Raman Scattering Intensities with One Phonon-Assisted Transition

From Eqs. (184) and (59) it can be obtained that

$$\langle b|\widehat{H}_{jph}|a\rangle = r_0 C_F \sqrt{\frac{4\pi}{3}} II^{l'_j n'_j}_{l''_j n''_j} \Lambda^{l'_j n'_j}_{l''_j n''_j} \tag{209}$$

being

$$II^{l'_j n'_j}_{l''_j n''_j} = A'_j A''_j \int_0^{r_0} J_{l'_j+\frac{1}{2}}\left(x_{l'_j n'_j}\frac{r}{r_0}\right)\Phi_{l,n}(r) J_{l''_j+\frac{1}{2}}\left(x_{l''_j n''_j}\frac{r}{r_0}\right) r\, dr$$

$$+ B'_j B''_j \int_{r_0}^0 K_{l'_j+\frac{1}{2}}\left(x_{l'_j n'_j}\frac{r}{r_0}\right)\Phi_{l,n}(r)$$

$$\times K_{l''_j+\frac{1}{2}}\left(x_{l''_j n''_j}\frac{r}{r_0}\right) r\, dr \tag{210}$$

$$\Lambda^{l'_j n'_j}_{l''_j n''_j} = \int Y^{m'_j}_{l'_j} Y^m_l Y^{m''_j}_{l''_j}\, d\Omega$$

$$= (-1)^{l'_j}\left[\frac{(2l'_j+1)(2l+1)(2l''_j+1)}{4\pi}\right]^{\frac{1}{2}}\Sigma_1\Sigma_2 \tag{211}$$

and Σ are the $3j$ symbols given by

$$\Sigma_1 = \begin{pmatrix} l'_j & l & l''_j \\ -m'_j & m & m''_j \end{pmatrix} \quad \text{and} \quad \Sigma_2 = \begin{pmatrix} l'_j & l & l''_j \\ 0 & 0 & 0 \end{pmatrix} \tag{212}$$

which are different from zero if they fulfill the following selection rules:

1. $l'_j + l + l''_j$ is even,
2. $-m'_j + m_p + m''_j = 0$.

By applying the properties of the $3j$ symbols we can demonstrate that for $l = 0$ the transitions obey the selection rule $l'_j = l''_j$; that is to say, there will be intrasubband transitions. For $l = 1$ we have that $l'_j = l''_j \pm 1$; that is to say, there will be intersubband transitions. As it happens for the QWW and the FSW, the increase of l implies that the differential cross-section diminishes. This shows that the fundamental contribution is carried out by the phonon modes $l = 0$.

After substitution in Eq. (10) we obtain

$$M_1 = \frac{A_0 r_0 C_F}{E_0}\sqrt{\frac{4\pi}{3}}\beta_1$$

$$\times \sum_{l'_2, m'_2, n'''_{22}} \sum_{l''_2, m''_2, n''_2} \frac{I^{l'_1 n'_1}_{l_1 n_1} T^{\frac{1}{2}}_{l''_1 n''_1, n_2}}{\frac{\hbar\omega_s}{E_0} + \beta_1[(x_{l_1 n_1})^2 - (x_{l'_1 n'_1})^2] + i\delta_{b1}}$$

$$\times \frac{[\Pi_{11p}\delta_{l'_1, l_1+1} + \Pi_{12p}\delta_{l'_1, l_1-1}]\delta_{l''_1, l_2}}{\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_1[(x_{l_1 n_1})^2 - (x_{l''_1 n''_1})^2] + i\delta_{a1}} II^{l'_1 n'_1}_{l''_1 n''_1} \Lambda^{l'_1 n'_1}_{l''_1 n''_1}$$

$$\times [(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)\delta_{m'_1, m_1+1} + (\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)\delta_{m'_1, m_1-1}$$

$$+ (\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)\delta_{m'_1, m_1}]\delta_{m''_1, m_2} \tag{213}$$

$$M_2 = \frac{A_0 r_0 C_F}{E_0}\sqrt{\frac{4\pi}{3}}\beta_2$$

$$\times \sum_{l'_2, m'_2, n'''_{22}} \sum_{l''_2, m''_2, n''_2} \frac{I^{l'_2 n'_2}_{l_2 n_2} T^{\frac{1}{2}}_{l''_2 n''_2, n_1}}{\frac{\hbar\omega_s}{E_0} + \beta_2[(x_{l_2 n_2})^2 - (x_{l'_2 n'_2})^2] + i\delta_{b2}}$$

$$\times \frac{[\Pi_{21p}\delta_{l'_2, l_2+1} + \Pi_{22p}\delta_{l'_2, l_2-1}]\delta_{l''_2, l_1}}{\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_2[(x_{l_2 n_2})^2 - (x_{l''_2 n''_2})^2] + i\delta_{a2}} II^{l'_2 n'_2}_{l''_2 n''_2} \Lambda^{l'_2 n'_2}_{l''_2 n''_2}$$

$$\times [(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_+)\delta_{m'_2, m_2+1} + (\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_-)\delta_{m'_2, m_2-1}$$

$$+ (\hat{\mathbf{e}}_s \cdot \hat{\mathbf{e}}_z)\delta_{m'_2, m_2}]\delta_{m''_2, m_1} \tag{214}$$

Finally

$$\frac{d^2\sigma}{d\Omega\, d\omega_s} = \sum_{p=0}^{3}\left[\frac{d^2\sigma}{d\Omega\, d\omega_s}\right]_p \tag{215}$$

$$\left[\frac{d^2\sigma}{d\Omega\, d\omega_s}\right]_0 = \frac{8}{3}\sigma_{ph}\left(\frac{\hbar\omega_s}{E_0}\right)^2\delta_f$$

$$\times \sum_{l,n,m}\sum_{l_1,n_1,m_1}\sum_{l_2,n_2,m_2}\{\text{Re}(M^{ph}_{11})\text{Re}(M^{ph}_{22})$$

$$+ \text{Re}(M^{ph}_{12})\text{Re}(M^{ph}_{21}) + \text{Im}(M^{ph}_{11})\text{Im}(M^{ph}_{11})$$

$$+ \text{Im}(M^{ph}_{12})\text{Im}(M^{ph}_{21})\}\frac{S_0}{G^4 + \delta^2_f}\delta_{m,0} \tag{216}$$

$$\left[\frac{d^2\sigma}{d\Omega\, d\omega_s}\right]_p = \frac{8}{3}\sigma_{ph}\left(\frac{\hbar\omega_s}{E_0}\right)^2\delta_f$$

$$\times \sum_{l,n,m}\sum_{l_1,n_1,m_1}\sum_{l_2,n_2,m_2}\left|M^{ph}_{1p} + M^{ph}_{2p}\right|^2$$

$$\times \frac{S_p}{G^4 + \delta^2_f} \quad p = 1, 2, 3 \tag{217}$$

where

$$M^{ph}_{1p} = \beta_1 \sum_{l'_2, m'_2, n'''_{22}}\sum_{l''_2, m''_2, n''_2}\frac{[\Pi_{11p}\delta_{l'_1, l_1+1} + \Pi_{12p}\delta_{l'_1, l_1-1}]\delta_{l''_1, l_2}}{\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_1[(x_{l_1 n_1})^2 - (x_{l''_1 n''_1})^2] + i\delta_{a1}}$$

$$\times \frac{II^{l'_1 n'_1}_{l''_1 n''_1}\Lambda^{l'_1 n'_1}_{l''_1 n''_1}I^{l'_1 n'_1}_{l_1 n_1}T^{\frac{1}{2}}_{l''_1 n''_1, n_2}}{\frac{\hbar\omega_s}{E_0} + \beta_1[(x_{l_1 n_1})^2 - (x_{l'_1 n'_1})^2] + i\delta_{b1}} \begin{cases} \delta_{m'_1, m_1+1} & \text{for } p = 1 \\ \delta_{m'_1, m_1-1} & \text{for } p = 2 \\ \delta_{m'_1, m_1} & \text{for } p = 3 \end{cases}$$

$$\tag{218}$$

$$M^{ph}_{2p} = \beta_2 \sum_{l'_2, m'_2, n'''_{22}}\sum_{l''_2, m''_2, n''_2}\frac{[\Pi_{21p}\delta_{l'_2, l_2+1} + \Pi_{22p}\delta_{l'_2, l_2-1}]\delta_{l''_2, l_1}}{\frac{\hbar\omega_s}{E_0} + \frac{\hbar\omega_q}{E_0} + \beta_2[(x_{l_2 n_2})^2 - (x_{l''_2 n''_2})^2] + i\delta_{a2}}$$

$$\times \frac{II^{l'_2 n'_2}_{l''_2 n''_2}\Lambda^{l'_2 n'_2}_{l''_2 n''_2}I^{l'_2 n'_2}_{l_2 n_2}T^{\frac{1}{2}}_{l''_2 n''_2, n_1}}{\frac{\hbar\omega_s}{E_0} + \beta_2[(x_{l_2 n_2})^2 - (x_{l'_2 n'_2})^2] + i\delta_{b2}} \begin{cases} \delta_{m'_2, m_2+1} & \text{for } p = 1 \\ \delta_{m'_2, m_2-1} & \text{for } p = 2 \\ \delta_{m'_2, m_2} & \text{for } p = 3 \end{cases}$$

$$\tag{219}$$

The differential cross-section for a semiconductor QWW and FSW presents singular peaks for secondary radiation frequency ω_s:

$$(s, e)(l_1, n_1, l'_1, n'_1) = \beta_1[(x_{l'_1 n'_1})^2 - (x_{l_1 n_1})^2] \tag{220}$$

$$(s, h)(l_2, n_2, l_2', n_2') = \beta_1\left[(x_{l_2'n_2'})^2 - (x_{l_2n_2})^2\right] \quad (221)$$

$$(f, e)(l_1, n_1, l_1'', n_1'') = \beta_1\left[(x_{l_1''n_1''})^2 - (x_{l_1n_1})^2\right] - \frac{\hbar\omega_q}{E_0} \quad (222)$$

$$(f, h)(l_2, n_2, l_2'', n_2'') = \beta_1\left[(x_{l_2''n_2''})^2 - (x_{l_2n_2})^2\right] - \frac{\hbar\omega_q}{E_0} \quad (223)$$

$$(l_1, n_1, l_2, n_2) = \frac{\hbar\omega_l - E_g}{E_0} - \frac{\hbar\omega_q}{E_0} - \beta_1(x_{l_1n_1})^2 - \beta_2(x_{l_2n_2})^2$$
$$(224)$$

We can see that Eqs. (220) and (221) represent the same frequencies as Eqs. (206) and (207). As can be seen from Eq. (222) or (223) these frequencies correspond to electron transitions connecting the subbands edges for a process involving just the conduction or just the valence band (i.e., intraband transitions). The values of frequencies in Eqs. (222) and (223) are associated with the emission of a phonon by the electron or hole intersubband transitions. The selection rules depend on the phonon oscillation modes. The singularities involved in (171) depend on ω_l and correspond to interband transitions.

In Figure 13 the emission spectra for a QD when varying the phonon mode of the system, for $n = 0$ and a polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$, are presented. It can be observed that the peaks associated with the emission of a phonon are lightly displaced to the right. The aforementioned is justified when analyzing the law of dispersion of the photon mode (see [1, 2]). However, when the peaks are due to the emission of photons, this situation does not occur; that is to say, the position of peaks is invariable under any oscillation modes [see Eqs. (220) and (222)]. On the other hand, the intensity of the effective differential cross-section diminishes with the increase of the order of the phonon modes. This is due to the fact that the intensity of the oscillator diminishes with the increase of the order of the phonon mode. If we observe the total contribution (see Fig. 14), the sum of the contribution of all the modes, we cannot appreciate the peaks corresponding to each phonon mode. This is due to the fact that the difference of energy between the phonon modes is very small.

In Figure 15 we can observe the emission spectra for one phonon-assisted electron Raman scattering in QDs and

Figure 14. The emission spectra of the electron Raman scattering in QDs for the polarization $\overline{Z}(\mathbf{e}_l, S_2)Z$ for $n = 0$.

QWWs considering only the modes $n = 0$, for a polarization $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$. If we compare these with those of Figure 7 we can appreciate the difference of intensity of the singularities; from here we can deduce that the electron–phonon interaction for this kind of dispersion is weak. It can be appreciated that the position of singularities does not change and peaks related to the emission of a phonon appear. If we compare with Figure 14 we can observe that the increase of the energy of the incident radiation produces a decrease of the intensity of the DCS.

In Figure 16 the emission spectra for a QD with $n = 0$, $r_0 = 2.5$ nm, and $\hbar\omega_l = 3.2$ eV for the polarizations $\overline{Z}(\hat{\mathbf{e}}_l, S_1)Z$ and $\overline{Z}(\hat{\mathbf{e}}_l, S_3)Z$ are presented. It can be observed that the polarization change does not affect the position of the peaks, but it only causes a decrease of the intensity of the DCS for $\overline{Z}(\hat{\mathbf{e}}_l, S_3)Z$. If we compare the spectrum for $\overline{Z}(\hat{\mathbf{e}}_l, S_1)Z$ with $\overline{Z}(\hat{\mathbf{e}}_l, S_2)Z$ we can observe that small changes take place in the intensity of the DCS. The aforementioned is due to the fact that only the polarization change implies changes in the degenerated states involved in the transitions.

If we compare the one phonon-assisted electron Raman scattering with the electron Raman scattering without the phonon participation, we can observe that, for the QD,

Figure 13. The emission spectra of the electron Raman scattering in QDs for the polarization $\overline{Z}(\mathbf{e}_l, S_2)Z$ for $n = 0$, varying the phonons mode of the system.

Figure 15. The emission spectra of the one phonon-assisted electron Raman scattering in QWWs and QDs for the polarization $\overline{Z}(\mathbf{e}_l, S_2)Z$ for $n = 0$. The left part of the curves that corresponding to the QD are multiplied by 10^2.
Figure 16. The emission spectra of the electron Raman scattering in QDs for the polarizations $\overline{Z}(\mathbf{e}_l, S_1)Z$ and $\overline{Z}(\mathbf{e}_l, S_3)Z$ for $n = 0$.

the quantum efficiency $\left(\frac{1}{V}\frac{d\sigma}{d\Omega}\right)$ of the system it is much less in the first one, but it is similar for the other nanostructures. From here we can conclude that the electron–phonon interaction is weak for this case. Therefore, the fundamental contributions to the spectrum are the singularities given by the emission of a photon of secondary radiation, which coincide in both dispersion types. The singularities described here correspond to intersubband transitions with smaller energy values than the gap. In this work we have showed that the EHP can be dispersed by any phonon mode, except the purely "transverse" [1, 2], because they are uncoupled from the electric field, because they do not interact via Fröhlich.

When we compare the dispersion assisted by one phonon in the three systems we can notice that for the QW the peaks corresponding to the emission of the phonon cannot be appreciated, which is due to the fact that their positions depend on the phonon and electron momenta, which vary in a very large range, so that the peaks cannot be observed. This same occurs with the QWW and the FSW because their contribution is very small in comparison with the QW; however, we cannot observe it because we worked with particles of $q_z = 0$.

The number of singularities in the case of QD and QWW will be determined by the radius and the energy of the incident radiation. We know that radius determines the number of subbands appearing, but we have supposed that QWs and FSWs have potential barriers of infinite height; therefore the number of subbands in this case is infinite. The energy of the incident radiation determines the number of singularities that should complete the law of conservation of the energy.

Finally, in the present work we have applied a simplified model for the electronic structure of system. In a more realistic case we should consider coupled band structure using a calculation model like that of Luttinger–Kohn or the Kane model. We also assumed an infinite potential barrier for the electron at the FSW interface. A calculation assuming a finite barrier would be better, but it is also possible to introduce a certain redefined effective mass for the infinite barrier case leading to the correct energy levels for the electrons and holes. The aforementioned assumptions would lead to better results but entail more complicated calculations. However, within the limits of our simple model we are

able to account for the essential physical properties of the discussed problem. The fundamental features of the DCS, as described here, should not change very much in the real QWW case. It can be easily proved that the singular peaks in the DCS will be present irrespective of the model used for the subband structure and may be determined for the values of $\hbar\omega_s$ equal to the energy difference between two subbands: $\hbar\omega_s^{e(h)} = E_\alpha^{e(h)} - E_\beta^{e(h)}$, where $E_\alpha^{e(h)}(E_\beta^{e(h)})$ are the respective electron (hole) energies in the subbands. Similarly, we shall have a steplike dependence in the DCS for $\hbar\omega_l = \hbar\omega_s + \hbar\omega + E_g + E_\alpha + E_\beta$. This type of dispersion gives information about the contribution of the electrons and holes of separate form, and of the electron–phonon interaction. It also allows one to determine the structure of phonon subbands.

7. ONE PHONON RESONANT RAMAN SCATTERING IN QUANTUM WIRE, FREESTANDING WIRE, AND QUANTUM DOTS

Nanometer-scale confinements of the band electrons (band holes) in semiconductor materials provide varieties of quantum phenomena, such as low-dimensional electron states (hole states), dynamics of carriers in the systems, and increased exciton binding energies.

In previous sections the one phonon-assisted electron Raman scattering via Fröhlich interaction has been presented. The investigations for quantum well wires, freestanding wires, and quantum dots appear in [14, 118].

Within the strong-confinement regime and disregarding the exciton contribution, the electron intermediate states were considered as uncorrelated electron–hole pairs.

The present section is devoted to a model of the first order resonant Raman scattering in QWW, FSW, and QDs, in which electron–hole correction effects via Coulomb interaction are not taken into account.

7.1. One Phonon Resonant Raman Scattering in Quantum Wires and Freestanding Wires

7.1.1. Model and Applied Theory

In these calculations, the QWW geometry is cylindrical with circular cross-section of radius r_0 and length L. As was explained, we consider again a single conduction (valence) band, which is split into a subband system due to electron confinement within the structure. The solution of the Schrödinger equation in the envelope function approximation has been obtained in the previous sections where the envelope function and the energy states were presented.

7.1.2. Raman Cross-Section

The differential Raman cross-section $d^2\sigma/d\omega_s\,d\Omega$ of a volume V per unit solid angle $d\Omega$ for incoming light of frequency ω_l and scattered light of frequency ω_s is given by Eq. (1).

In this case

$$W(\omega_s, \hat{\mathbf{e}}_s) = \frac{2\pi}{\hbar} \sum_f |M_{fi}|^2 \delta(\hbar\omega_l - \hbar\omega_s - \hbar\omega_{ph}) \quad (225)$$

being

$$M_{fi} = \sum_{a, b} \frac{\langle f|\widehat{H}_r^+|b\rangle \langle b|\widehat{H}_{ph}|a\rangle \langle a|\widehat{H}_r^-|i\rangle}{(\hbar\omega_l - E_a + i\Gamma_a)(\hbar\omega_s - E_b + i\Gamma_b)} \quad (226)$$

In Eq. (226) $|a\rangle$ and $|b\rangle$ are intermediate states with energies E_a and E_b, Γ_a and Γ_b are the corresponding lifetime broadening, and $\widehat{H}_r^{\pm}$ and $\widehat{H}_{ph}$ are the electron–photon and electron–phonon interaction Hamiltonians, respectively. The sign $+(-)$ corresponds to the emission (absorption) of a photon.

The initial state $|i\rangle$ of the system consists of an incident photon of frequency ω_l and polarization $\hat{\mathbf{e}}_l$. In this case we have a completely occupied valence band and unoccupied conduction band. The final state $|f\rangle$ of the system consists of a photon of frequency ω_s and an excited phonon of frequency ω_p. Following Eqs. (1) and (225) the Raman scattering efficiency per unit solid angle can be obtained as

$$\frac{1}{V}\frac{d\sigma}{d\Omega} = \frac{V(\omega_l - \omega_{ph})^2 \eta(\omega_s)}{8\pi^3 c^4 \eta(\omega_l)} \frac{2\pi}{\hbar^2} \sum_f |M_{fi}(\omega_l - \omega_{ph}, \hat{\mathbf{e}}_s, \omega_l, \hat{\mathbf{e}}_l)|^2$$

$$(227)$$

The operator $\widehat{H}_r^+$ is given by Eqs. (4) and (5). This operator describes the interaction of the EHP with the incident and secondary radiation field in the dipole approximation.

In previous sections we summarized some details concerning the optical phonons and electron–phonon interaction Hamiltonian for QWW and FSW.

7.1.3. Calculation of Raman Scattering Intensities

If we consider direct allowed electron transitions between conduction (c) and valence (v) bands, Eqs. (128), (132), and (227), then the matrix element $\langle a|\widehat{H}_r^-|i\rangle$ (or $\langle f|\widehat{H}_r^+|b\rangle$), in the envelope function approximation, can be written as

$$\langle a|\widehat{H}_r^-|i\rangle = \frac{|e|}{\mu_0}\sqrt{\frac{2\pi\hbar}{V\omega_l}}\hat{\mathbf{e}}_l \cdot \hat{\mathbf{p}}_{cv}(0) T_{n_1, m_1', m_2} \delta_{n_1', n_2} \delta_{k_1', -k_2} \quad (228)$$

$$\langle f|\widehat{H}_r^+|b\rangle = \frac{|e|}{\mu_0}\sqrt{\frac{2\pi\hbar}{V\omega_s}}\hat{\mathbf{e}}_s \cdot \hat{\mathbf{p}}_{vc}(0) T_{n_1, m_1, m_2} \delta_{n_1, n_2} \delta_{k_1, -k_2}$$

$$(229)$$

where

$$T_{n, m_a, m_b} = A_{nm_a}^{(e)} A_{nm_b}^{(h)} \int_0^{r_0} J_n\left(x_{nm_a}^{(e)}\frac{r}{r_0}\right) J_n\left(x_{nm_b}^{(h)}\frac{r}{r_0}\right) r\, dr$$

$$+ B_{nm_a}^{(e)} B_{nm_b}^{(h)} \int_{r_0}^{\infty} K_n\left(y_{nm_a}^{(e)}\frac{r}{r_0}\right) K_n\left(y_{nm_b}^{(h)}\frac{r}{r_0}\right) r\, dr$$

and for the FSW

$$T_{n, m_a, m_b} = \delta_{m_a, m_b}$$

where $\hat{\mathbf{p}}_{cv}$ and $\hat{\mathbf{p}}_{vc}$ are the momenta matrix elements between the v and c bands (evaluated at $\mathbf{k} = \mathbf{0}$).

For the electron–phonon interaction matrix elements, we have

$$\langle b|\widehat{H}_{ph}|a\rangle = C_{nm}\big[\delta_{a_h, b_h}\langle c; n_1, m_1'|F_{nm}(r)e^{in\theta}|n_1, m_1; c\rangle$$

$$- \delta_{a_e, b_e}\langle v; n_2, m_2'|F_{nm}(r)e^{in\theta}|n_2, m_2; v\rangle\big]$$

where

$$\langle i; n_j, m_j'|F_{nm}(r)e^{in\theta}|n_j, m_j; i\rangle$$

$$= I_{n_j m_j m_j'}\delta_{n, 0}\delta_{k_j, k_j'} \quad i = c, v \quad (230)$$

being

$$I_{n_j m_j m_j'} = \sqrt{\frac{V\rho}{r_0}}\left\{ A_{n_j m_j'} A_{n_j m_j} \int_0^{r_0} J_n\left(x_{n_j m_j'}\frac{r}{r_0}\right)\right.$$

$$\times F_{0m}^{\text{QWW}}(r) J_n\left(x_{n_j m_j}\frac{r}{r_0}\right) r\, dr$$

$$+ B_{n_j m_j'} B_{n_j m_j} \int_{r_0}^{\infty} K_n\left(y_{n_j m_j'}\frac{r}{r_0}\right)$$

$$\left. \times F_{0m}^{\text{QWW}}(r) K_n\left(y_{n_j m_j}\frac{r}{r_0}\right) r\, dr\right\} \quad (231)$$

and for the FSW

$$I_{n_j m_j m_j'} = \delta_{m_j m_j'}\sqrt{\frac{V\rho}{r_0}}\big[r_0 J_{l_j}'(x_{n_j m_j})\big]^{-2}$$

$$\times \int_0^{r_0} J_n^2\left(x_{n_j m_j'}\frac{r}{r_0}\right) F_{0m}^{\text{FSW}}(r) r\, dr \quad (232)$$

Here, the phonon modes are restricted to $n = 0$ when the dipole approximation is used [7, 15, 110–112, 115, 119, 120].

The probability amplitude is given by

$$M_{fi} = M_1 - M_2 \quad (233)$$

$$M_j = \sum_{n_j m_j m_j'} \sum_{k_j} \left(\frac{e}{\mu_0}\right)^2 \frac{2\pi\hbar}{\sqrt{\omega_s\omega_l}} \frac{\hat{\mathbf{e}}_s \cdot \hat{\mathbf{p}}_{vc}(0)\hat{\mathbf{e}}_l \cdot \hat{\mathbf{p}}_{cv}(0)}{V} C_{0m}$$

$$\times \frac{(T_{n_1, m_1, m_2} I_{n_1 m_1 m_1'} T_{n_1, m_1', m_2} \delta_{j, 1} + T_{n_2, m_1, m_2} I_{n_2 m_2 m_2'} T_{n_2, m_1, m_2'}\delta_{j, 2})}{(\hbar\omega_l - E_a + i\Gamma_a)(\hbar\omega_l - \hbar\omega_{0m} - E_b + i\Gamma_b)}$$

$$(234)$$

After substitution of Eqs. (231) and (232) in Eq. (1) we obtain

$$\Phi_1(\hbar\omega_l, \hbar\omega_s) = \beta_1 \sum_{n_1 m_1 m_2} T_{n_1, m_1, m_2}$$

$$\times \sum_{m_1'} \frac{I_{n_1 m_1 m_1'} T_{n_1, m_1', m_2}}{\big[\hbar\omega_{0m} + E_{n_1, m_1, m_2} - E_{n_1, m_1', m_2} + i(\Gamma_a - \Gamma_b)\big]}$$

$$\times \big[Z_1(n_1, m_1', m_2) - Z_2(n_1, m_1, m_2)\big] \quad (235)$$

$$\Phi_2(\hbar\omega_l, \hbar\omega_s) = \beta_2 \sum_{n_2 m_1 m_2} T_{n_2, m_1, m_2}$$

$$\times \sum_{m_2'} \frac{I_{n_2 m_2 m_2'} T_{n_2, m_1, m_2'}}{[\hbar\omega_{0m} + E_{n_2, m_1, m_2} - E_{n_2, m_1, m_2'} + i(\Gamma_a - \Gamma_b)]}$$

$$\times [Z_1(n_2, m_1, m_2') - Z_2(n_2, m_1, m_2)] \qquad (236)$$

where

$$Z_1(n, m_a, m_b) = \frac{1}{\left[\hbar\omega_l - E_{n, m_a, m_b} + i\Gamma_a\right]^{\frac{1}{2}}} \qquad (237)$$

$$Z_2(n, m_a, m_b) = \frac{1}{\left[\hbar\omega_s - E_{n, m_a, m_b} + i\Gamma_b\right]^{\frac{1}{2}}} \qquad (238)$$

$$\beta_j = \sqrt{\frac{\mu_{ji}}{\mu_r}} \quad \text{and} \quad \frac{1}{\mu_r} = \frac{1}{\mu_{1i}} + \frac{1}{\mu_{2i}}$$

with

$$E_{n, m_a, m_b} = \frac{\hbar^2}{2\mu_{1i} r_0^2}(x_{nm_a}^{(e)})^2 + \frac{\hbar^2}{2\mu_{2i} r_0^2}(x_{nm_b}^{(h)})^2 + E_g \qquad (239)$$

where the expressions

$$\frac{\hbar^2}{2\mu_{1i} r_0^2}(x_{nm_a}^{(e)})^2 \quad \text{and} \quad \frac{\hbar^2}{2\mu_{2i} r_0^2}(x_{nm_b}^{(h)})^2$$

are the "confined" part of the electron and hole energies, respectively [see Eqs. (131)].

Finally, substitution of Eqs. (235) and (236) into Eq. (1) gives

$$\frac{d^2\sigma}{d\Omega\, d\omega_s} = \frac{V\mu_r P}{2\pi^2}\left(\frac{e}{\mu_0 c}\right)^4 \frac{\eta(\omega_s)}{\eta(\omega_l)}\frac{\omega_s}{\omega_l} C_F^2$$

$$\times \sum_m \frac{\omega_L}{\omega_{0m}}|\Phi_1(\hbar\omega_l, \hbar\omega_s) - \Phi_2(\hbar\omega_l, \hbar\omega_s)|^2$$

$$\times \frac{\Gamma_p}{(\hbar\omega_l - \hbar\omega_s - \hbar\omega_{0m})^2 + \Gamma_p^2} \qquad (240)$$

with $P = |(\hat{\mathbf{e}}_l \cdot \hat{\mathbf{p}}_{cv})(\hat{\mathbf{e}}_s \cdot \hat{\mathbf{p}}_{vc})|^2$. In Eq. (240), the substitution

$$\delta(E_f - E_i) \rightarrow \frac{1}{\pi}\frac{\Gamma_p}{(E_f - E_i)^2 + \Gamma_p^2}$$

has been used in order to take into account the phonon linewidth Γ_p in the Raman shift spectrum. The Raman scattering efficiency is given by

$$\frac{1}{V}\frac{d\sigma}{d\Omega} = \frac{\mu_r P}{2\pi^2}\left(\frac{e}{\mu_0 c}\right)^4 \frac{\eta(\omega_s)}{\eta(\omega_l)}C_F^2 \sum_m \frac{\omega_l - \omega_{0m}}{\omega_l}\frac{\omega_L}{\omega_{0m}}$$

$$\times |\Phi_1(\hbar\omega_l, \hbar\omega_l - \hbar\omega_{0m}) - \Phi_2(\hbar\omega_l, \hbar\omega_l - \hbar\omega_{0m})|^2$$

$$(241)$$

where the incoming and outgoing resonances are due to intersubband electron or hole transitions and are located at energies [see Eqs. (235)–(239)]

$$\hbar\omega_l = E_{n_1, m_a, m_b} \quad \text{and} \quad \hbar\omega_s = E_{n_1, m_a, m_b}$$

Figure 17 illustrates the behavior of ω_{om} frequency with radius r_0 and m optical phonon modes of the QWW (Fig. 17a) and FSW (Fig. 17b) using the parameters given in Table 1. These ω_{om} frequencies for $n = 0$ modes are simple confined modes of a purely longitudinal nature and they contain no surface mode contribution. In Figure 17a and b we can observe that the frequency decreases with the increase of the optical phonon mode for a fixed radius value and increases with the enlargement of the radius. Moreover, the ω_{om} frequency values tend to the ω_L value limit ($r_0 > 50$ Å, although, for clarity, it has not been shown). In all cases the frequency of the FSW is larger than the QWW. These results are explained with the formalism given in Section 7.1.

In Figure 18 the Raman scattering efficiency as a function of the incident energy for the FSW (Fig. 18a) and QWW (Fig. 18b) cases are shown. In both figures the solid (dashed) line corresponds to $r_0 = 15$ Å (20 Å). In order to indicate which subbands are included in the intersubband transitions, the subindex n_1, m_a, m_b is used. $m_a(m_b)$ belongs to the conduction (valence) subband. In all cases, when the radius is increased, the energy values associated with intersubbands transitions will be shifted to the left [see Eqs. (237) and (238)]. From the free boundary conditions we can see that the scattering intensity of the FSW is larger than the QWW. In each energy level, E_{n_1, m_a, m_b}, two peaks appear, which correspond to incoming and outgoing resonance separated by the energy of one phonon.

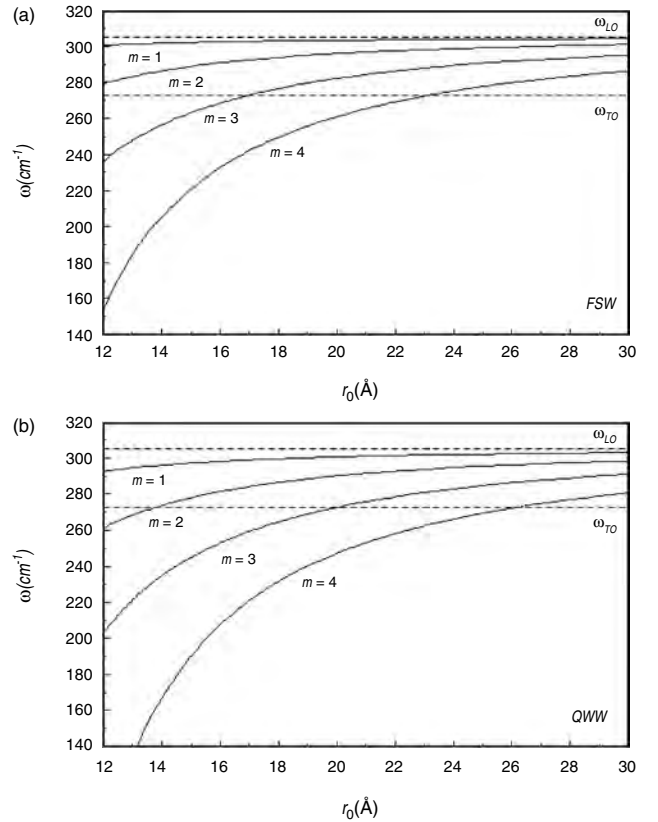

Figure 17. Oscillation modes of (a) freestanding wire and (b) quantum well wire.

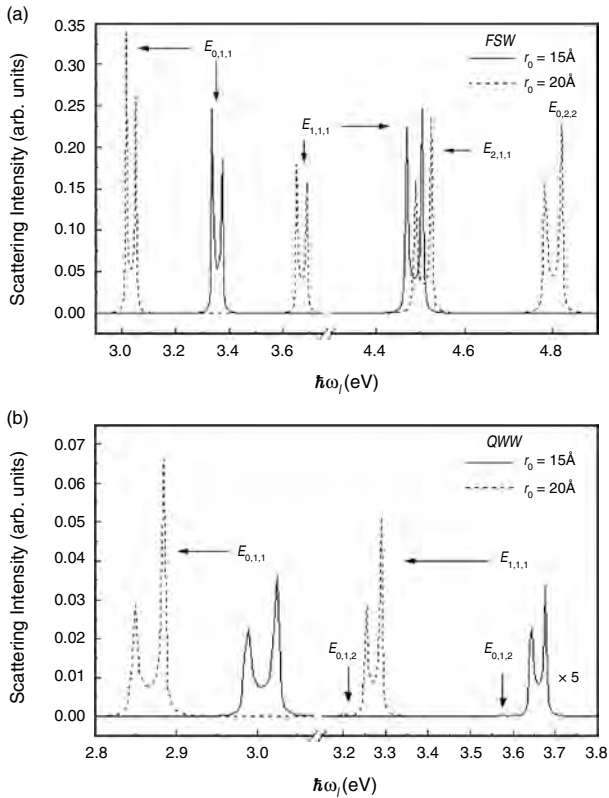
Table 1. Values of the material parameters used for the numerical calculations illustrated in the figures [110].

	E_g (eV)	ω_L (cm^{-1})	ω_T (cm^{-1})	$\frac{\mu_e}{\mu_0}$	$\frac{\mu_h}{\mu_0}$	ε_∞	β_L (ms^{-1})	β_T (ms^{-1})	V_0^e (eV)	V_0^h (eV)
CdS	2.6	305	238	0.18	0.51	5.3	5.04×10^3	1.58×10^3	2.5	1.9
Glass	7	—	—	1	1	4.64	—	—	—	—

In Figure 19 the Raman cross-section as a function of frequency shift for different energies is shown. The $r_0 = 15$ Å radius has been chosen for FSW and QWW, respectively. The spectrum for $\hbar\omega_l = 3.34$ eV (Fig. 19a) corresponds to an incoming resonance with $n_1 = 0, m_1 = 1$ electron and $n_1 = 0, m_2 = 1$ hole states. There is a big contribution due to the $n = 0, m = 1$ phonon mode at 301 cm^{-1}. In this case the laser frequency fulfills the resonance condition. As in Figure 18, the Raman cross-section of the FSW is bigger than the QWW (see Fig. 19b). Figure 19b shows the spectra corresponding to QWW for different laser energies. The spectrum for $\hbar\omega_l = 2.99 + \hbar\omega_{01}$ eV belongs to an outgoing resonance with $n_1 = 0, m_1 = 1$ electron and $n_1 = 0, m_2 = 1$ hole states. There is a big contribution due to the $n = 0, m = 1$ phonon mode at 297 cm^{-1}. On the other hand, we can see that when the $\hbar\omega_l$ value increases the Raman intensity decreases, which can be justified from Eqs. (237) and (238) where the cross-section is inversely proportional to ω_l. Figure 19c shows the spectra for different energies of the QWW. We can see contributions from the three phonon modes $n = 0, m = 1$ to 3 with the biggest contribution from

the $m = 2$ mode at 279 cm^{-1}, when the energy is $3.57 + \hbar\omega_{02}$ eV. This is mainly because the laser frequency has been chosen to be in outgoing resonance with the emission of a phonon of the $n = 0, m = 2$ mode frequency. The other contributions come from the $m = 1$ mode at 297 cm^{-1} and $m = 3$ at 245 cm^{-1}. Moreover, when the $3.57 + \hbar\omega_{01}$ eV energy is chosen, the biggest contribution corresponds to

Figure 19. Differential cross section for (a) incoming resonance with $n_1 = 0, m_1 = 1$ electron $n_1 = 0, m_2 = 1$ hole states, (b) outgoing resonance with $n_1 = 0, m_1 = 1$ electron $n_1 = 0, m_2 = 1$ hole states for FWS, (c) outgoing resonance with $n_1 = 0, m_1 = 1$ electron $n_1 = 0, m_2 = 2$ hole states for QWW.



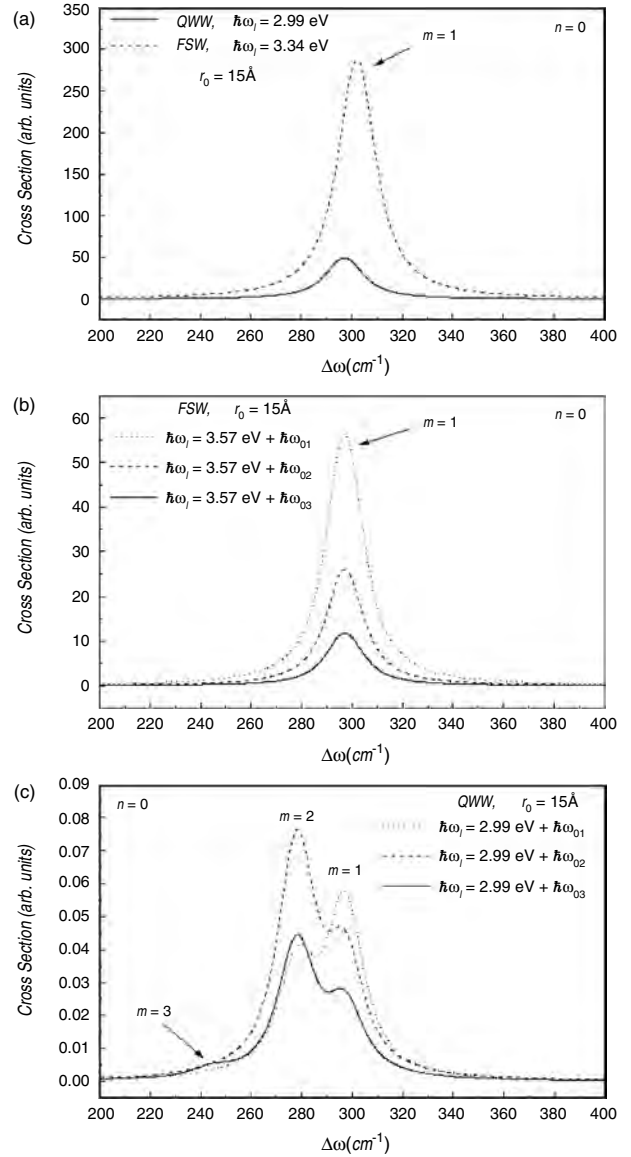


Figure 18. (a) Raman spectra for 20 and 15 Å radius CdS freestanding wire at two different laser energies. (b) Raman spectra for 20 and 15 Å radius CdS quantum wire embedded in glass at two different laser energies. The graph for 20 Å is multiplied by 5.

the $n = 0$, $m = 1$ mode frequency because in this case the laser frequency is in outgoing resonance with the emission of a phonon of this frequency. For $3.57 + \hbar\omega_{03}$ eV energy we can see situation similar to the $3.57 + \hbar\omega_{02}$ eV one, but the electron and hole subbands involved are $n_1 = 0$, $m_1 = 1$ and $n_1 = 0$, $m_2 = 2$, respectively. In the latter case, the laser frequency is in incoming resonance with the emission of a phonon of $n = 0$, $m = 1$ mode frequency.

A formalism for calculating Raman scattering intensities due only to the Fröhlich interaction from optical phonons in semiconductor QWW and FSW has been presented. A continuum model for the phonons which satisfies both electrostatic and mechanical boundary conditions at the interface has been used, in accordance with physical principles and differential equations. The case of oscillation perpendicular to the wire axis (i.e, $q_z = 0$ and hence $v_z = 0$) has been regarded. Here, only the phonon dispersions for $n = 0$ modes have been considered. In this case the modes of the systems are longitudinal and transverse in nature, but in other cases ($n \neq 0$) they are a mixture of LO, TO, and surface mode components.

When Raman intensities are being considered, it has been found that the only contribution comes from the dipole approximation term, which interacts only with $n = 0$ phonons, assuming cylindrical systems and neglecting valence band mixing, and is mainly responsible for the resonant intrasubband term. One band effective mass model with a finite potential for the conduction and valence bands has been considered. The phonon selection rules given early are strict for cylindrical system.

7.2. One Phonon Resonant Raman Scattering in Quantum Dots

In this section the analytical expressions for the dispersion of the $l_p = 0, 1, 2$ modes, with illustration for CdS spherical microcrystallites embedded in glass, are determined, following the work of [110]. The theory is somewhat more appropriate to the case of the microcrystallites since they can have sizes as low as 13 Å in radius, whereas quantum dots in the GaAs/AlAs system are normally fabricated by applying electric potentials to quantum wells or growth along terraces where the confining sizes in one or more directions are usually greater than 100 Å. A formalism for calculating the Raman scattering intensities from optical phonons in QDs via the Fröhlich interaction applied to CdS microcrystallite is also presented. In this section it is found that the dipole approximation interaction, which for perfectly spherical structures where valence band mixing is neglected couples only to $l_p = 0$ phonon modes, there also exists a contribution that is proportional to the wavevector of the light $\boldsymbol{\kappa}$ (electrical quadrupole approximation). This additional contribution takes place by $l_p = 1$ phonon mode emission. Although it is generally much smaller than the dipole approximation term, especially when in intrasubband resonance, it dominates when one is resonant with an intersubband transition.

In previous sections were presented the electron states, so as the envelope function for spherical QDs.

In [110] are presented some details concerning the optical phonons and electron–phonon interaction Hamiltonian where dispersion relation for optical phonon is given by

$$\tan \mu = \mu$$

for $l_p = 0$, while for $l_p = 1$ and phonon frequencies ω above the TO phonon frequency ω_T it is neccesary to solve the secular equation

$$[2\mu \cos \mu + (\mu^2 - 2)\sin \mu]\left\{\left[-\frac{\gamma_0}{\nu^2}\left(\frac{3}{\nu^2} - 1\right) + \left(1 + 2\frac{\epsilon_\infty^{(2)}}{\epsilon_\infty^{(1)}}\right)\right.\right.$$
$$\left.\times \left(1 - \frac{1}{\mu^2}\right)\right]\sin \nu + \left[-\frac{3\gamma_0}{\nu^3} + \frac{1}{\nu}\left(1 + 2\frac{\epsilon_\infty^{(2)}}{\epsilon_\infty^{(1)}}\right)\right]\cos \nu\right\}$$
$$= 2[\sin \mu - \mu \cos \mu]\left\{\frac{1}{\nu}\left[-1 - 2\frac{\epsilon_\infty^{(2)}}{\epsilon_\infty^{(1)}} + 3\frac{\gamma_0}{\nu^2}\frac{\epsilon_\infty^{(2)}}{\epsilon_\infty^{(1)}}\right]\cos \nu\right.$$
$$\left. + \frac{1}{\nu^2}\left[\frac{\epsilon_\infty^{(2)}}{\epsilon_\infty^{(1)}}\gamma_0\left(1 - \frac{3}{\nu^2}\right) + \left(1 + \frac{\epsilon_\infty^{(2)}}{\epsilon_\infty^{(1)}}\right)\right]\sin \nu\right\}$$

with

$$\gamma_0 = \frac{\omega_L^2 - \omega_T^2}{\beta_T^2}R_0^2 \quad \omega^2 = \omega_L^2 - \beta_L^2\left(\frac{\mu}{R_0}\right)^2 \quad \omega^2 = \omega_T^2 + \beta_T^2\left(\frac{\nu}{R_0}\right)^2$$

and $\beta_L(\beta_T)$ is a parameter describing the dispersion, assumed to be parabolic, of the LO (TO) phonon in the bulk.

7.2.1. Calculation of the Raman Scattering Intensities in Quantum Dots

Considering direct allowed electron transitions between conduction and valence bands the matrix element $\langle a|H_{E-R}^-|I\rangle$ (or $\langle F|H_{E-R}^-|b\rangle$) can be written as

$$\langle \mu|H_{E-R}^-|I\rangle = \frac{e}{\mu_0}\sqrt{\frac{2\pi\hbar}{\omega_l\eta_l^2}}\frac{\hat{\mathbf{e}}_l \cdot \hat{\mathbf{p}}_{cv}}{\sqrt{V}}\int \Psi_c^* e^{i\boldsymbol{\kappa}_l \cdot \mathbf{r}}\Psi_v\, d^3r$$

$\Psi_c(\Psi_b)$ being the electron (hole) wave function in the quantum dot. Since the photon wavevectors are small, the expansion of $e^{i\boldsymbol{\kappa}_l \cdot \mathbf{r}}$ up to terms proportional to $\boldsymbol{\kappa}$ can be made:

$$\langle \mu|H_{E-R}^-|I\rangle = \frac{e}{\mu_0}\sqrt{\frac{2\pi\hbar}{\omega_l\eta_l^2}}\frac{\hat{\mathbf{e}}_l \cdot \hat{\mathbf{p}}_{cv}}{\sqrt{V}}[\langle c; n_e, l_e, m_e|m_h, l_h, n_h; v\rangle$$
$$+ i\boldsymbol{\kappa}_l \cdot \langle c; n_e, l_e, m_e|\mathbf{r}|m_h, l_h, n_h; v\rangle] \quad (242)$$

For the electron–phonon interaction matrix elements they have

$$\langle \mu_2|H_{E-P}|\mu_1\rangle = \frac{C_F}{\sqrt{R_0}}\{\delta_{\mu'_h, \mu_h}\langle c; n'_e, l'_e|\Phi_{\mu, l_p}|l_e, n_e; c\rangle$$
$$\times \langle Y_{l'_e, m'_e}|Y_{l_p, m_p}|Y_{l_e, m_e}\rangle$$
$$- \delta_{e'_h, \mu_e}\langle v; n'_h, l'_h|\Phi_{\mu, l_p}|l_h, n_h; v\rangle\}$$
$$\times \langle Y_{l'_h, m'_h}|Y_{l_p, m_p}|Y_{l_h, m_h}\rangle \quad (243)$$

where $\mu_e(\mu_h) = n_e, l_e, m_e(n_h, l_h, m_h)$ represents the set of quantum numbers for the electron (hole) state. The amplitude probability was found as

$$M_{FI} = \left(\frac{e}{m_0}\right)^2 \frac{2\pi\hbar}{\sqrt{\omega_l \omega_s \eta_l^2 \eta_s^2}} \frac{\hat{\mathbf{e}}_s^* \cdot \hat{\mathbf{p}}_{vc} \hat{\mathbf{e}}_l \cdot \hat{\mathbf{p}}_{cv}}{V} \frac{C_F}{\sqrt{R_0}} \left[M_{FI}^{(0)} + M_{FI}^{(1)}\right]$$

(244)

where

$$M_{FI}^{(0)} = \sum_{n_e, n_h} \sum_{l'=0}^{\infty} \sum_{m'=-l'}^{l'} \langle Y_{l',m'} | Y_{l_p,m_p} | Y_{l',m'} \rangle$$

$$\times \frac{F_0(n_e, n_h)}{\left[\hbar\omega_l - E_g - E_e(n_e, l') - E_h(n_h, l') + i(\Gamma_e + \Gamma_h)\right]}$$

$$\times \left\{ \sum_{n'} \frac{F_0(n_e', n_h)\langle c; n', l' | \Phi_{\mu, l_p} | l_e, n_e; c\rangle}{\left[\hbar\omega_s - E_g - E_e(n_e', l') - E_h(n_h, l') + i(\Gamma_e' + \Gamma_h)\right]} \right\}$$

$$\times \left\{ \sum_{n'} \frac{F_0(n', n_e)\langle v; n', l' | \Phi_{\mu, l_p} | l, n_h; v\rangle}{\left[\hbar\omega_s - E_g - E_e(n_e, l') - E_h(n', l') + i(\Gamma_e' + \Gamma_h')\right]} \right\}$$

(245)

Here, the incoming light with a wavevector $\boldsymbol{\kappa}_l \approx 0$ creates an electron–hole pair of energy $E_e(n_e, l') + E_h(n_h, l')$ via the dipole transition $F_0(n_e, n_h)$. Subsequently, as the electron (or hole) emits an LO phonon of frequency $\omega(\mu, l_p)$ an electron transition from (n_e, l', m') to (n', l', m') takes place [or from (n_h, l', m') to (n', l', m') hole states]. Finally, a scattered photon of frequency ω_s and wavevector $\boldsymbol{\kappa}_l \approx 0$ is created due to the electron–hole recombination with a probability given by the overlap integral $F_0(n_h, n')$ [or $F_0(n', n_e)$ if the phonon is emitted by a hole]. From the previous equation, a set of incoming and outgoing resonances follows at the frequencies:

$$\hbar\omega_l = E_g + E_e(n_e, l') + E_h(n_h, l')$$

$$\hbar\omega_s = E_g + E_e(n', l') + E_h(n_h, l') \quad l' = 0, 1, 2, \ldots$$

The second term in Eq. (244) is given by

$$M_{FI}^{(1)} = i \sum_{n, l'} \sum_{m'=-l'}^{l'} a_{l'-\frac{1}{2}\pm\frac{1}{2}} \langle Y_{l'\pm 1, m'} | Y_{l_p, m_p} | Y_{l', m'} \rangle$$

$$\times \sum_{n'} F_1(n', l\pm 1, n, l')\langle n', l'\pm 1 | \Phi_{\mu, l_p} | l', n\rangle$$

$$\times \left\{ \frac{\kappa_l}{[\hbar\omega_l - E_g - E_e(n, l') - E_h(n', l'\pm 1) + i(\Gamma_e + \Gamma_h')]} \right.$$

$$\times \left(\frac{1}{[\hbar\omega_s - E_g - E_e(n', l'\pm 1) - E_h(n', l'\pm 1) + i(\Gamma_e' + \Gamma_h')]} \right.$$

$$\left. - \frac{1}{[\hbar\omega_s - E_g - E_e(n, l') - E_h(n, l') + i(\Gamma_e + \Gamma_h)]} \right)$$

$$+ \frac{\kappa_s}{[\hbar\omega_l - E_g - E_e(n, l') - E_h(n, l') + i(\Gamma_e + \Gamma_h)]}$$

$$\times \left(\frac{1}{[\hbar\omega_s - E_g - E_e(n', l'\pm 1) - E_h(n, l') + i(\Gamma_e' + \Gamma_h)]} \right.$$

$$\left. \left. - \frac{1}{[\hbar\omega_s - E_g - E_e(n, l') - E_h(n', l'\pm 1) + i(\Gamma_e + \Gamma_h')]} \right) \right\}$$

(246)

where the wave function has been used to evaluate the matrix elements (242) and (243). The functions F_1 and a_l

are given in an appendix of [110]. Here, the physical picture is similar to that given above for $M_{FI}^{(0)}$ but now the incoming and outgoing resonances are due to intersubband electron or hole transitions and are located at energies

$$\hbar\omega_s = E_g + E_e(n, l') + E_h(n', l' \pm 1)$$

$$\hbar\omega_s = E_g + E_e(n, l') + E_h(n, l')$$

$$\hbar\omega_l = E_g + E_e(n, l') + E_h(n', l' \pm 1)$$

$$\hbar\omega_l = E_g + E_e(n, l') + E_h(n, l') \quad l' = 0, 1, \ldots$$

7.3. Selection Rules

The Fröhlich interaction coupling [Eq. (245)] of the dipole approximation (the wavevector of the light $\boldsymbol{\kappa} = 0$) conserves the electron angular momentum $\Delta l' = l_e' - l_h' = 0$ and obviously $\Delta m' = m_e' - m_h' = 0$. A simple inspection of the angular matrix element $\langle Y_{l',m'} | Y_{l_p,m_p} | Y_{l',m'}\rangle$ determines that $l_p = 0, 2, 4, \ldots$ and $m_p = 0$; the function $Y_{l_p,0}$ needs to be even for a nonzero Raman scattering cross-section in Eq. (245) because the electron–phonon coupling must conserve the parity of the quantum dot functions. The degeneracy of the electron state due to the l_Z' component, where z is the quantization axis, has been considered in $M_{FI}^{(0)}$ through the indicated m' sum in Eq. (245). Now, this sum can be obtained using the addition theorem

$$\frac{2l'+1}{4\pi} P_{l'}(\cos\alpha) = \sum_{m'=-l'}^{l'} Y_{l',m'}^*(\theta_1, \phi_1) Y_{l',m'}(\theta_2, \phi_2)$$

(247)

where α is the angle between directions (θ_1, ϕ_1) and (θ_2, ϕ_2). Taking $\theta_1 = \theta_2 = \theta$ and $\phi_1 = \phi_2 = \phi$ Eq. (247) is transformed into

$$\frac{2l'+1}{4\pi} = \sum_{m'=-l'}^{l'} \left| Y_{l',m'}(\theta, \phi) \right|^2$$

(248)

Thus, the term

$$I_\Omega = \sum_{m'=-l'}^{l'} \int_0^{2\pi} \int_{-\pi}^{\pi} \left| Y_{l',m'}(\theta, \phi) \right|^2 Y_{l_p, m_p}(\theta, \phi)\, d\Omega$$

of Eq. (245) is reduced to

$$I_\Omega = \frac{2l'+1}{4\pi} \int_0^{2\pi} \int_{-\pi}^{\pi} Y_{l_p, m_p}(\theta, \phi)\, d\Omega$$

Using the orthonormalization condition for the spherical harmonics,

$$I_\Omega = \frac{2l'+1}{4\pi} \delta_{p,0} \delta_{m_p,0}$$

Hence, the phonon modes are restricted to $l_p = 0$ for a spherical quantum dot when one uses the dipole approximation $\boldsymbol{\kappa} = 0$. One could have anticipated this selection rule since in the dipole approximation where $\boldsymbol{\kappa}_l, \boldsymbol{\kappa}_s = 0$, $m_p = 0$ for any axis of quantization. This implies for this most significant term in the Raman scattering cross-section, $M_{FI}^{(0)}$, that none of the higher order l_p phonons contribute and so

no interaction with modes containing surface components is seen.

For the matrix element $M_{FI}^{(1)}$, which is proportional to $\boldsymbol{\kappa}$, the quantization axis z is chosen to be parallel to the light wavevector $\boldsymbol{\kappa}_l$. The selection rules are

$$\Delta l' = \pm 1 \quad \Delta m' = 0$$
$$m_p = 0 \quad \text{and} \quad l_p = 1, 3, 5, \ldots$$

The restriction $\Delta l' = \pm 1$ comes from the first order dipole transition which connects electron states of different parity implying that only phonons of odd parity give nonzero matrix elements. For the coefficient,

$$I_\Omega^{(1)}(l'+1, l'; l_p) = \sum_{m'=-l'}^{l'} a_{l'} \langle Y_{l'+1, m'} | Y_{l_p, m_p} | Y_{l', m'} \rangle$$

the following functional relation is obtained according to Eqs. (B3) and (B5) of [110]:

$$I_\Omega^{(1)}(l'+1, l'; l_p) = \sum_{m'=-l'}^{l'} \int_0^{2\pi} \int_{-\pi}^{\pi} \left| Y_{l', m'}(\theta, \phi) \right|^2$$
$$\times Y_{l_p, m_p}(\theta, \phi) \, d\Omega - I_\Omega^{(1)}(l'-1, l'; l_p)$$

Using Eq. (248) this expression is transformed to

$$I_\Omega^{(1)}(l'+1, l'; l_p) = \frac{2l'+3}{\sqrt{12\pi}} \delta_{l_p, 1} \delta_{m_p, 0} - I_\Omega^{(1)}(l'-1, l'; l_p)$$

where it can be shown that

$$I_\Omega^{(1)}(0, 1; l_p) = \frac{\delta_{l_p, 1} \delta_{m_p, 0}}{\sqrt{12\pi}}$$

From the two last relations it immediately follows the phonon selection rule $l_p = 1$. The other odd modes ($l_p = 3, 5, \ldots$) are forbidden in the scattering matrix element $M_{FI}^{(1)}$. This $l_p = 1$ selection rule breaks down when one considers configurations other than backscattering (i.e., when there is an angle between the incoming and scattered light directions). According to these selection rules the Raman cross-section for the Fröhlich interaction contribution in a spherical quantum dot or microcrystallite can be written as

$$\frac{\partial^2 \sigma}{\partial \Omega \, \partial \omega_s} = S_0 \sum_\mu \sum_{l_p} \left\{ \left| M_{FI}^{(0)} \right|^2 \delta_{l_p, 0} + \left| M_{FI}^{(1)} \right|^2 \delta_{l_p, 1} \right\}$$
$$\times \frac{\Gamma_p}{[\hbar\omega_l - \hbar\omega_s - \hbar\omega_p(\mu, l_p)]^2 + \Gamma_p^2}$$

where the δ function in the calculation of the probability has been substituted by a Lorentzian in order to take into account the phonon linewidth Γ_p in the Raman shift spectrum. The coefficient S_0 is equal to

$$S_0 = \left(\frac{e}{m_0}\right)^4 \left(\frac{2P^2}{3c^2}\right) \hbar \left(\frac{\omega_s}{\omega_l}\right)^2 \frac{\eta_s}{\eta_l} \frac{|C_F|^2}{R_0}$$

with $P = \langle X | P_x | S \rangle$ [106].

The dispersion relations and scattering intensities for electron, hole, and lattice for a CdS microcrystallite embedded in glass in Figures 1, 2, and 3 of [110] can be appreciated.

In this section the one phonon Raman scattering cross-section using the band structure and phonon dispersions described previously has been calculated. It is important to remember the phonon selection rules already derived for the electron–phonon Fröhlich interaction. For the dipole approximation, with the wavevector of the light considered to be zero, there exist only intrasubband transitions. Due to the symmetry of the initial and final carrier states the phonons must be even in l_p and, furthermore, due to the degeneracy in energy for the carrier states of different m the only nonzero matrix element is for $l_p = 0$ phonon modes. The interaction term which is proportional to the carrier states and a nonzero matrix element, when summing over the m of the electrons or holes, only arises when $l_p = 1$ for the phonon modes.

In Figure 20 Raman scattering intensities as a function of frequency shift for different laser energies are shown.

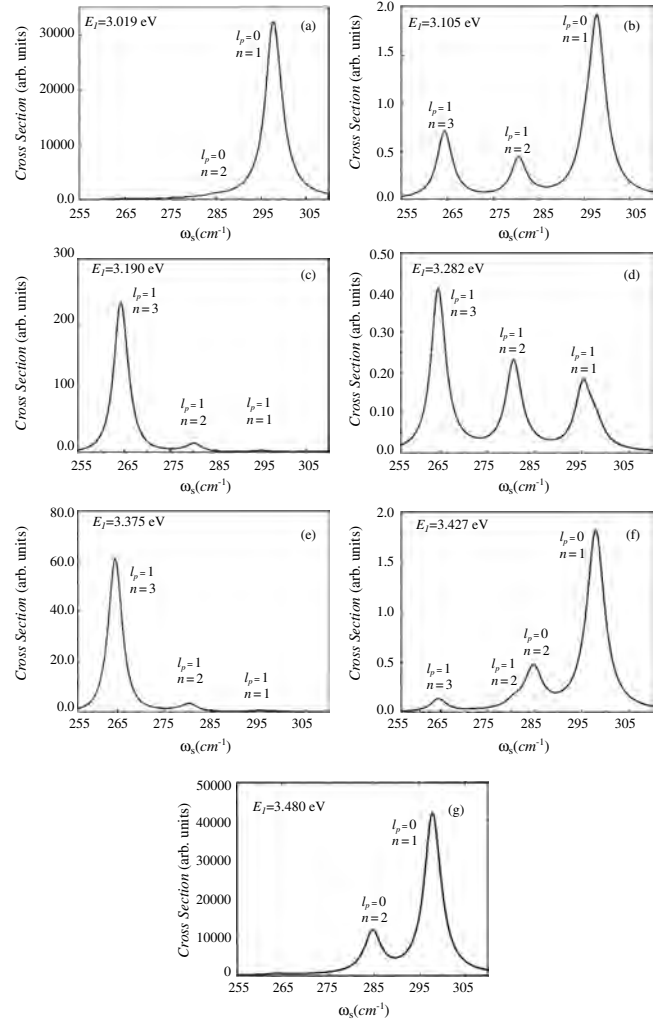

Figure 20. Raman spectra for a 20 Å radius CdS microcrystallite embedded in glass at different laser energies E_l. Reprinted with permission from [110], M. P. Chamberlain et al., *Phys. Rev. B* 51, 1680 (1995). © 1995, American Physical Society.

For the dipole approximation contribution to the matrix elements, $M_{FI}^{(0)}$ Eq. (245), the intrasubband contributions due to the $l = 0, 1$, and 2 electron and hole subbands have been considered. The contributions from higher electron and hole subbands have been neglected, but for laser energies away from the respective resonances these are effectively zero. For the matrix element proportional to the light wavevector, $M_{FI}^{(1)}$ Eq. (246), intersubband hole and electron transitions between the $l = 0$ and 1 carrier states (and vice versa) were considered. All the spectra have been broadened to have a full width at half maximum of 4 cm^{-1}. Since the TO component of the phonon modes does not couple to the electrons and holes via the Fröhlich interaction no interesting features are seen in the Raman spectra due to the LO and TO mode anticrossing between 238 and 255 cm^{-1} of Figures 2 and 3 of [110].

The Raman intensities in this region for a 20 Å radius crystallite are due to the higher order modes of the LO component and are much smaller than those due to the $n = 1$ to 3 modes shown in Figure 20. The spectrum for $E_l = 3.0193$ eV (Fig. 20a) corresponds to an incoming resonance with the $l = 0$ electron and $l = 0$ hole states. It is almost exclusively due to the $l = 0$ electron and hole intrasubband transition contributions arising from interaction with the $l_p = 0$ phonons, although intrasubband transitions for $l = 1$ and 2 carrier states and intersubband transitions are also included in the spectra. The latter are several orders of magnitude smaller and cannot be seen in the scale of Figure 20a. There is a big contribution due to the $l_p = 0, n = 1$ phonon mode at 298 cm^{-1} with a very small contribution due to the $l_p = 0, n = 2$ phonon at 284 cm^{-1} since the n dependent part of the matrix element drops off rapidly as n increases. On the other hand, the spectrum for $E_l = 3.1900$ eV (Fig. 20c) corresponds to outgoing resonance with the $l = 0$ electron state and the $l = 1$ hole state. This is the resonance case for the $l = 0$ to 1 hole intersubband transition which takes place via $l_p = 1$ phonon emission. One can see contributions from the three phonon modes $l_p = 1, n = 1$ to 3 with the biggest contribution from the $n = 3$ mode at 264 cm^{-1}. This is mainly because the laser frequencies are chosen to be in outgoing resonance with the emission of a phonon of the $l_p = 1, n = 3$ mode frequency. However, it should be noted that if the outgoing resonance corresponding to the emission of a phonon with a frequency of the $l_p = 1, n = 1$, or $n = 2$ modes is taken, then the biggest contribution is still from the $n = 3$ mode. If one looks back at the dispersion relation for the $l_p = 1$ modes in Figure 2 of [110], it can be seen that the $n = 3$ mode is very close to the Fröhlich mode frequency for a 20 Å radius microcrystallite and so has a strong electrostatic contribution. The electrostatic contribution is evident from the bending in the phonon dispersion around the Fröhlich frequency and thus the interaction with electrons and holes will always be dominant for a mode around this frequency. Once again, the intrasubband spectra due to the $l = 0, 1$, and 2 electron and hole states have been included, but since the region considered is far from resonance for these transitions their contributions do not show up in Figure 20c.

It should also be pointed out that the intensity units for each of the spectra in Figure 20 are the same and so the intensity for $E_l = 3.1900$ eV is much smaller than

for $E_l = 3.0193$ eV. The spectrum at the higher laser energy comes from the term which is proportional to κ_l or κ_s explaining the reduction in intensity by two orders of magnitudes. The laser energy $E_l = 3.1047$ eV of the spectrum in Figure 20b is halfway between that in Figure 20a and c. The spectrum shows a peak at 298 cm^{-1} due to the $l_p = 0, n = 1$ phonon mode and then two more peaks at 280 and 264 cm^{-1} due to the $l_p = 1$ phonon modes with $n = 2$ and 3, respectively. The highest frequency peak comes from the $\kappa = 0$ contribution to the matrix element $M_{FI}^{(0)}$ and the other two from the κ dependent term $M_{FI}^{(1)}$. With the laser energy being out of resonance with the intersubband and intrasubband transitions both are visible in the spectrum. One can see that the $l_p = 1$, $n = 3$ phonon mode peak is bigger than the $l_p = 1$, $n = 2$ peak as it contains a larger electrostatic interaction due to the Fröhlich mode component at this frequency. The overall intensities are also smaller than the two previous cases because the laser frequency does not fulfill any resonance condition.

The spectra for $E_l = 3.3745$ eV (Fig. 20e) are for outgoing resonance with the $l = 0$ hole state and the $l = 1$ electron state. It is virtually identical to that for $E_l = 3.1900$ eV (Fig. 20c) since we are in resonance with an intersubband transition when only the κ dependent term involving $l_p = 1$ phonons has a significant contribution. At the lower energy of $E_l = 3.2823$ eV (Fig. 20d), we are not in outgoing resonance with the $l_p = 1, n = 3$ phonon mode so the $l_p = 1$, $n = 1$ and 2 mode peaks are of similar intensity, but the $n = 3$ phonon mode scattering is still the strongest because it contains a significant electrostatic Fröhlich component. We are further away from an intrasubband resonance than from an intersubband one so the κ dependent term is larger. However, a shoulder appears at the right-hand side of the $l_p = 1, n = 1$ mode peak at 298 cm^{-1} which is due to the contribution of the $l_p = 0, n = 1$ phonon from the intrasubband term. For $E_l = 3.4796$ eV (Fig. 20g) there exists incoming resonance for the $l = 1$ electron and hole states. Thus, only the intrasubband terms appear in the spectra. One should note that the $l_p = 0, n = 2$ mode at 285 cm^{-1} is much stronger in relation to the $l_p = 0, n = 1$ mode than was the case for a laser energy in resonance with the $l = 0$ electron and hole states (Fig. 20a). For the higher l carrier state the n-dependent part of the matrix element is not as for the $l = 0$ case and the drop off with increasing n is not as great. One might also expect that the overall intensities for the $l = 1$ intrasubband resonance would be smaller than for the $l = 0$ intrasubband resonance. The electron–phonon interaction for an $l = 1$ intrasubband is about 40% of that for the $l = 0$ intrasubband transition. However, the $l = 1$ electron (or hole) has three energy degeneracy m states which then implies a 120% increase for the $l = 1$ transition. Hence the intensities for $E_l = 3.4796$ eV are bigger than for $E_l = 3.0193$ eV. Finally, the spectrum for $E_l = 3.4271$ eV (Fig. 20f) is similar to that for $E_l = 3.4796$ eV. The intensities are much reduced as we are away from intrasubband resonance. The $l = 1$ intersubband resonance at 3.3745 eV has also been moved and so the $l_p = 1$ modes from the intersubband transitions begin to appear. This is clearly visible for the $l_p = 1, n = 3$ mode at 264 cm^{-1} and also the $l_p = 1, n = 2$ mode appears as a shoulder at 280 cm^{-1}.

Klein et al. [52] have investigated electron–phonon coupling in CdSe microcrystallites both theoretically and experimentally. In considering the phonon modes of the nanospheres they have neglected the dispersion of the LO modes and calculated an independent set of internal modes (degenerate at the LO frequency due to lack of dispersion) and surface modes. These have been derived by applying electrostatic boundary conditions with the formalism of Mori and Ando [121] that was applied to quantum wells. Neglecting the mechanical boundary conditions and the LO dispersion means they were unable to describe the mixing of the confined and surface modes along with the mixed transverse longitudinal nature of the modes in general. When treating the Raman scattering they have only considered the dipole approximation which allows coupling to just $l_p = 0$ phonons. In the experiments, shoulders are seen on the spectra at the positions of the surface phonon frequency, which are disallowed for perfect spheres in the dipole approximation. The observation of the surface modes was explained by the relaxation of the $l_p = 0$ selection rule for monocrystals with a nonspherical shape. Although this is a possible explanation, the surface or Fröhlich mode shoulder could be due to $l_p = 1$ mode scattering from the κ dependent matrix element $M_{FI}^{(1)}$ from the intersubband electron (hole) transitions.

Finally in this section we have presented, following [110], a formalism for calculating Raman scattering intensities, due to the Fröhlich interaction, from optical phonons in semiconductor quantum dots and microcrystallites. In this treatment, the authors do not consider Raman scattering via the deformation potential interaction, which is important for laser energies that are far from the electron hole resonances. In particular, they used a continuum model for the phonons which satisfies both electrostatic and mechanical boundary conditions at the dot interface in accordance with the differential equations and physical principles involved. They also considered the CdS microcrystallite system and illustrated the phonon dispersions for $l_p = 1$ and 2 modes. It is seen that the modes of the system are generally both longitudinal and transverse in nature, being a mixture of LO, TO, and surface mode components as opposed to separate sets of confined and surface modes which have previously been assumed. Also they discussed the phonon properties of the CdS dots in glass, which is particularly interesting because of the positive phonon dispersion of the bulk TO mode which intermixes with LO and surface modes in the dot (for the GaAs/AlAs system both the TO and the LO mode frequencies decrease with increasing wavevector). When considering the Raman intensities, it has been found that the strongest contribution comes from the dipole approximation term which interacts only with $l_p = 0$ phonons, assuming perfectly spherical microcrystals and neglecting valence band mixing, and is mainly responsible for the resonant intrasubband term. They have shown that although the quadrupole contribution, proportional to the light wavevector κ, is generally much smaller than the dipole interaction term it dominates for intersubband scattering. This intersubband interaction occurs only via $l_p = 1$ phonons.

In treating the electron–phonon interaction, they considered a one band effective mass model with a finite potential for the conduction and valence bands. Using this approach,

the phonon selection rules given are strict for perfect spherical microcrystals. However, experiments performed by a number of authors give evidence for interaction with $l_p = 2$ phonons, implying a breakdown of these selection rules. It has been proposed elsewhere that this is either due to the nonspherical shape of the crystals [52] or mixing of the valence bands [122]. They believe that this is probably due to the hole subband mixing and propose to develop the formalism described here to calculate the magnitude of these effects using the same phonon model but increasing the complexity of the band structure description.

8. APPLICATIONS OF THE ELECTRON RAMAN SCATTERING AND RESONANT RAMAN SCATTERING PROCESSES IN NANOSTRUCTURES

A tunable intersubband Raman laser in multiple nanostructures can be designed theoretically as a new tunable source of infrared radiation based on intersubband electron Raman scattering in semiconductor nanostructures. The structure consists of three levels in two coupled quantum wells, quantum well wires, or quantum dots. A theoretical work on tunable intersubband Raman lasers in GaAs/AlGaAs multiple quantum well appears in [123].

8.1. Introduction

Following the work of Sun et al. [123] we can see there is a need for efficient sources of coherent mid-infrared radiation for applications such as remote sensing, laser radar, and wide-band communications. Rapidly evolving epitaxial growth techniques now allow the development of fundamentally new types of semiconductor lasers utilizing transitions between subbands in quantum wells and superlattices. With bandgap engineering, it is possible to adjust the intersubband transition energies over a wide range. The successful demonstration of the injection-pumped intersubband quantum-cascade laser operating in the 5-μm range has opened up the possibility of achieving coherent mid-to-far infrared light sources with high efficiency and compactness [124]. Although the quantum-cascade laser has been refined since its first demonstration nearly two years ago [125, 126], room-temperature continuous wave (cw) operation has not been achieved. This is primarily because intersubband lasers rely on elaborate pumping and relaxation schemes with multiple quantum wells to reach population inversion. The lifetime difference between the upper and the lower laser state in intersubband lasers can be artificially engineered but comes at the expense of the stimulated emission cross-section, as suggested in the optimization process of a four-level optically pumped intersubband laser [127]. An alternative scheme aimed at providing independent control of the intersubband lasing lifetimes has been proposed by use of the technique of electron Raman scattering [128]. Such a technique has previously been used in the investigation of transitions in confined systems [129]. In fact, a number of infrared sources based on stimulated Raman scattering in liquids [130] and semiconductors [131–135] have been successfully operated. It is

therefore reasonable to consider a stimulated intersubband electron Raman oscillator (SIERO) based on intersubband transitions.

The proposed stimulated intersubband electron Raman oscillator has several advantages over the conventional stimulated Raman lasers made of bulk semiconductors. It allows the independent control of the lifetimes of laser states and the stimulated emission cross-section. It offers a wide tuning range in lasing wavelengths by the design of proper quantum well parameters, whereas the tuning of electron Raman lasers of bulk semiconductors is mainly achieved by variance of pump wavelength. For a given quantum well Raman laser structure, the lasing wavelength can be further tuned by the application of an electric field, whereas that of conventional Raman lasers requires a magnetic field.

8.2. Analysis

Any optically pumped intersubband laser (OPIL) can be practically represented by a three-level model, as shown in Figure 21a in which three subbands are confined within two coupled quantum wells, incorporating the ground state $|g\rangle$, the upper laser state $|u\rangle$, and the lower laser state $|l\rangle$. The optically pumped intersubband laser operating cycle consists of the absorption of one photon of pump frequency $\hbar\omega_p$, resonant with the energy separation between the upper laser and the ground states, and the subsequent emission of a photon of lasing frequency $\hbar\omega_{out}$, determined by the energy separation between the upper and the lower laser states. The necessary condition for cw lasing operation in this optically pumped intersubband laser structure is that the lifetime of the upper laser state τ_u be longer than that of the lower laser state τ_l. In comparison the stimulated intersubband electron Raman oscillator using the electron Raman scattering process can be operated between two levels as shown in Figure 21b. The Stokes intersubband electron Raman scattering can be described as an electron in the ground state $|g\rangle$ absorbing a photon of pump frequency $\hbar\omega_p$, re-emitting

a photon of Stokes frequency $\hbar\omega_{out}$, and making a transition directly from the ground state $|g\rangle$ to the lower state $|l\rangle$. In fact, the transition is not entirely direct: The electron can be considered to arrive at its final destination via a virtual state $|u'\rangle$. In other words, it spends an extremely short time in the state $|u\rangle$, determined by the uncertainty principle associated with the upper state $|u\rangle$.

A complete operating cycle of the stimulated intersubband electron Raman oscillator can therefore be described by the following processes: (a) an electron at the ground state $|g\rangle$ absorbs one photon with energy $\hbar\omega_p$, detuned from the energy separation $E_u - E_g$, and reaches the virtual state $|u'\rangle$; (b) it emits one photon of Stokes frequency ω_{out} and arrives at the lower laser state $|l\rangle$; and (c) it then relaxes back to the ground state $|g\rangle$ through nonradiative intersubband processes such as phonon scattering. There is clearly a similarity between the stimulated intersubband electron Raman oscillator and the optically pumped intersubband laser, with the only difference being that instead of the virtual state $|u'\rangle$, a real state $|u\rangle$ is used as the upper laser state in the optically pumped intersubband laser. Obviously, resonant pumping between the ground $|g\rangle$ and the upper laser state $|u\rangle$ is necessary in the optically pumped intersubband laser, while in the stimulated intersubband electron Raman oscillator, the pumping is below resonance with a detuning of $\delta = E_u - E_g - \hbar\omega_p$. The Stokes frequency $\hbar\omega_{out}$ is detuned by the same amount from the $|u\rangle$ to the $|l\rangle$ transition: $E_u - E_l = \hbar\omega_{out} + \delta$. Thus the electron Raman scattering energy conservation $E_l - E_g = \hbar\omega_p - \hbar\omega_{out}$ is satisfied.

The nonlinear susceptibility that is due to the electron Raman scattering is calculated in [123, 136]. The coefficient of linear off-resonant absorption by the detuned $|u\rangle$ to $|l\rangle$ transition also is obtained in [123].

To focus on the issue of tunability in [123] is considered a minimal configuration consisting of two coupled quantum wells as shown in Figure 21b and c, with the GaAs wells being confined by $Al_{0.3}Ga_{0.7}As$ barriers. The wide well is designed to have two confined states, whereas the narrow well has only one state when isolated. The two quantum wells form a three-level system when coupled. The energy levels of the confined states are primarily determined by the well widths. The dipole matrix elements, however, are controlled by the barrier width separating the two wells.

Figure 21. Conduction-band diagram of the laser states and the transitions in two coupled GaAs/AlGaAs quantum wells for (a) OPIL, (b) SIERO under zero bias, and (c) SIERO under nonzero bias. Indicated are well and barrier widths, subband levels, pump detuning, and pumping and lasing transitions.

GLOSSARY

Carrier   An electron, a hole or an exciton.

Conduction band   Energy band in a crystalline solid partially filled.

Effective mass   The mass of a particle which is moving through a crystalline solid.

Electron–phonon interaction   The coupling between electrons and the oscillations of ions.

Exciton   Electron-hole pair correlated by a coulomb-like interaction.

Free standing wire   An isolated quantum well wire.

Gap   Forbidden region for the electrons, which it is determined by the difference of energies between conduction and valence bands.

Hole Its the absence of an electron in the valence band.

Nanostructure Material medium whose size is of the order of few nanometers.

Phonon Collective elemental excitation which describes the oscillations of ions in solids.

Quantum dot A quantum system, in which the carriers are confined in all directions.

Quantum well A quantum system, in which the carriers are confined in only one direction, the other dimensions remain free.

Quantum well wire A quantum system, in which the carriers are confined in two directions, the other remains free.

Raman cross-section The probability of Raman scattering occurs.

Raman scattering A process in which the light is inelastic scattered by a material.

Selection rules The rules that describe the allowed and forbidden transitions for a given process.

Valence band Energy band in a crystalline solid completely filled.

CONTENTS

1. INTRODUCTION

1.1. General Properties

The interest in organic, that is, carbon based, compounds as electronically and optically active materials has increased with an accelerating pace since the 1970s. With the emergence of the nanotechnology frontier in research, single organic molecules were often the focus of interest. With the discovery of the fullerene (C_{60}) in 1986 and especially the carbon nanotubes, all-carbon molecules are receiving a larger portion of the interest. Carbon nanotubes were discovered in 1991 by Sumio Iijima at the NEC laboratories in Japan rather accidentally during his TEM studies of fullerene material synthesized in an arc-discharge between graphite electrodes [1]. Although the interest in the fullerene molecule had been substantial, there were no widespread expectations of tubular extensions of the molecule. The carbon nanotube consists of one or multiple concentric shells of seamless graphite sheets; see Figure 1. A single wall nanotube (SWNT) has a diameter of around 1 nm, while the multiwalled nanotube (MWNT) may have any diameter in the range of 2–100 nm, with 10–20 nm being typical. Single nanotubes, even SWNTs, with lengths approaching 1 mm have been observed, giving astonishing aspect ratios (length/diameter). The typical length, however, is about 1 μm. As will be apparent from our brief discussion on nanotube synthesis in Section 2, there are various methods to produce nanotubes, some of which are related to the production of carbon fibers, an activity that well predates the discovery of the carbon nanotube. After the discovery, old research material on carbon fibers was given a second look, and indeed some old TEM images do show nanotubes [2]. Some methods of synthesis are especially developed with applications of molecular-level electronics in mind.
Figure 1. Carbon nanotubes can be either SWNT or MWNT.

Carbon nanotubes have several interesting physical and chemical properties that have attained much attention from both the basic and applied science communities. Depending on the wrapping angle of the graphite sheet, an individual nanotube can be either metallic or semiconducting. A fact of fundamental importance for this review is that the charge carriers in nanotubes of all sizes are truly delocalized. Ballistic conduction over μm-sized distances have been measured in carbon nanotubes. The axial Young's modulus of an individual nanotube sheet is approximated by the in-plane modulus of graphite ($\cong$1 TPa), which makes the carbon nanotube one of the stiffest materials that exists. A single carbon nanotube is an excellent freestanding electrical conductor. Chemically, the nanotube is perfectly stable in ambient conditions. In a vacuum, it can withstand temperatures far above 1000 °C without structural changes. These properties make it the ideal one-dimensional (1D) system. For technological applications, the major drawback is perhaps the insufficient control over the synthesis process. Presently the wrapping angle of the graphitic wall of the nanotube, which determines the electrical properties, can not be predetermined by the synthesicist. Nevertheless, the number of possible applications that have been forwarded within just ten years from the surprising discovery of the first nanotubes is substantial. Some of these already have been taken quite far toward realization (e.g., field emission displays), which is certainly promising for the future of the carbon nanotube.

In this chapter we will use the term nanotube to mean exclusively the carbon nanotube. However, nanotubes based on other elements besides carbon have also recently been synthesized. Most notable among these are boronitride (BN) tubes [3], which have a large energygap, and various metal chalcogenide tubes such as WS_2 [4] and MoS_2 [5]. In addition to nanotubes that are hollow and consist of concentric tubular shells, nanowires exist with diameters of about 10 nm. These nanowires are neither hollow nor are they derived from anisotropic layered materials. They have recently been synthesized from traditional semiconductor materials (Si, GaAs, InP) [6] as well as from certain metals (e.g., W [7]). Interesting electronic applications already have been demonstrated with semiconductor nanowires. It is possible that in the future the study and applications of nanotubes and nanowires will expand far beyond those made of carbon.

1.2. The Basic Geometry of Carbon Nanotubes

In the following section, we will define the basic geometries of the carbon nanotube. We will follow the presentation in Saito et al. [2]. The electronic properties in particular of a carbon nanotube are dependent on the geometry of the tube. A sheet of graphite can be wrapped in many different ways to make the wall of a carbon nanotube. Figure 2 illustrates the established nomenclature of three different types of nanotubes: (a) the armchair, (b) the zigzag, and (c) the chiral nanotube. The chiral nanotube obviously incorporates in principle an unlimited number of types with different wrapping angles relative to the tube axis. To define more precisely the lattice configuration of a single shell nanotube, we take a closer look on the honeycomb lattice of graphite in Figure 3. Vectors $\mathbf{C}$ and $\mathbf{T}$ are the chiral and translational vectors of a nanotube, respectively. They are defined by the unit vectors $\mathbf{a}_1$ and $\mathbf{a}_2$. Thus, for example, $\mathbf{C} = n\mathbf{a}_1 + m\mathbf{a}_2$. $\mathbf{T}$ points in the direction of the nanotube axis. To construct the nanotube, the graphite sheet is rolled so that the beginning and the end of $\mathbf{C}$ coincide. Thus the rectangle spanned by $\mathbf{C}$ and $\mathbf{T}$ is the unit cell of the nanotube lattice. The wrapping angle of the nanotube, or chiral angle θ, is given by the angle between $\mathbf{a}_1$ and $\mathbf{C}$. Because of the hexagonal symmetry of the lattice, θ is limited to the range $0° \leq \theta \leq 30°$. The special cases are $\theta = 0°$, the zigzag nanotube, and $\theta = 30°$, the armchair nanotube. The chiral vector $\mathbf{C}$, or in other words, the integer pair (n, m) defines the single shell nanotube. The tube diameter d_t and θ are given as

$$d_t = |\mathbf{C}|/\pi = a\sqrt{(n^2 + m^2 + nm)} \qquad (1)$$

$$\cos(\theta) = \mathbf{C}\cdot\mathbf{a}_1/|\mathbf{C}||\mathbf{a}_1| = 2n + m/(2\sqrt{(n^2 + m^2 + nm)}) \quad (2)$$

where a is the length of the unit vectors. The armchair nanotubes are of the form (n, n) while the zigzag tubes are

Figure 2. The different ways in which the graphitic wall of an individual carbon nanotube shell can be wrapped are generally presented as follows: (a) the armchair, (b) the zig-zag, and (c) the chiral nanotube. of the form $(n, 0)$. Furthermore, it follows from symmetry considerations that the restriction $0 < |m| < n$ can be imposed.

1.3. Various Forms of Carbon Nanotubes

Next we will discuss the different sizes and shapes a carbon nanotube can have. The variety that has already been observed is most impressive. As already mentioned, the carbon nanotube is a generic term that includes both single- and multiwalled nanotubes (SWNTs and MWNTs). The smallest nanotube reported to date has a diameter of only 4 Å [8]. Since increasing the curvature of the graphite wall increases the strain energy, this is also predicted to be the smallest possible diameter a nanotube can have. Typical diameters for SWNTs are between 1 and 2 nm, corresponding to n and m numbers of around 10. In MWNTs, the distance between the adjacent layers is about 0.34 nm, which is much more than the atomic separation (1.42 Å) within the individual layers. While typical values for the outer diameter are 10–20 nm, the inner diameter is typically 3–5 nm. Thus an ordinary MWNT has 10–30 layers, each of which are SWNTs of different diameters. The shell structure of MWNTs has not been studied thoroughly yet, but from geometrical considerations it is concluded that adjacent layers will generally be incommensurate [2]. Also, the larger the diameter of a MWNT is, the more likely the outer layers are disordered and noncircular.

The ends of nanotubes are generally closed in the growth process. While the wall of a carbon nanotube is made up of an exclusively hexagonal pattern, pentagons are needed to cap the tubes, as a close inspection of Figure 2 reveals [9]. More generally, pentagonal and heptagonal (5- and 7-cornered polygons, respectively) defects enable the graphitic sheet to take up more complicated structures than a simple tube, as we will discuss below. Unless special setups are used for the growth of SWNTs, they are usually assembled into ropes by their mutual van der Waals attraction. For example, a rope of a typical diameter of about 10 nm contains ∼100 SWNTs. Since multiwalled nanotubes have a much higher bending stiffness, they do not arrange similarly.

Nanotubes grown under suitable conditions have a very low concentration of defects over μm-distances, that is, over hundreds or even thousands of interatomic spacings. However, if one were able to control the occurrence

of defects, very useful and interesting nanotube structures would emerge. We will next show what kind of modified SWNTs and MWNTs have already been observed due to the occurrence of defects within the nanotubes. A single, stable defect structure in the hexagonal lattice of a graphite sheet is made up of a pentagon-heptagon pair, that is 5- and 7-sided polygons. One such defect can cause a sharp bend in a SWNT [10]. Figure 4 shows a SWNT with a sharp bend that is most likely caused by one or a few such simple defect structures. Defective nanotubes are especially interesting for electronic applications where the defect site may act as a tunneling barrier. In the case of MWNTs, highly defective tubes may be obtained with certain synthesis conditions, for example with relatively low growth temperatures. While high-quality MWNTs are very straight and stiff, very defective ones have a continuous and smooth curvature as seen in Figure 5. On the other hand, the curvature can be highly regular and so result in helices, such as is shown in Figure 6 [11]. An SWNT, or a single shell of a MWNT, can have a second nanotube branching out. The beginning point of the branch has similarly to the end sections pentagons dispersed among the hexagons to accommodate the necessary curvature. Such branching has been observed in a few cases to date [12].

As mentioned earlier, the ends of carbon nanotubes are usually closed. It is, however, possible to open nanotubes by a suitable chemical treatment. This is due to the stronger chemical reactivity of the end section with its larger curvature and pentagon structures. The opened nanotubes can be utilized for creating yet another side branch in the science of nanotubes, namely filled tubes [13]. Both SWNTs and MWNTs have been filled with various materials, such as fullerenes, simple metals, and molecular compounds. Nanotubes with fullerenes inside are called peapods, and are presently intensively investigated [14]. The study of the electronic properties of filled nanotubes is still in its infancy, and will not be considered in this review.

Finally, we will mention the μm-sized rings that were observed both in SWNT- and MWNT-based material rather early on. Figure 7 shows rings observed in MWNT material

Figure 4. An AFM image of a SWNT with a sharp bend caused by a single defect site.
Figure 5. AFM images of MWNTs produced by different synthesis conditions: (a) by the arc-discharge method and (b) by the CVD method. The curved appearance of the latter is seen to be due to a higher density of defects.

by SEM. Some claims were made for the SWNT rings to be genuine toroids, that is, seamless ring structures. Later research has, however, shown that ring structures are readily formed by the van der Waals force–mediated attraction between the two ends of a nanotube [15]. The curvature is in this case therefore not caused by defects but is determined by the competition between the strain energy of a bent nanotube and the van der Waals attraction energy. In fact, especially in the case of SWNTs, the ring may be composed of several turns of the nanotube (or a nanotube rope). Recently, it was claimed that a well defined single-turn ring can be made by the attraction between chemical groups attached to both ends of a nanotube [16].

1.4. Concluding Remarks

The prospects for widespread applications for carbon nanotubes in electronics (and elsewhere) are good for several reasons: As already discussed, the carbon nanotube is stable and durable both chemically and mechanically, and in addition is an excellent conductor. Furthermore, the previous discussion has made it clear that an impressive variability
Figure 6. A SEM image of a coiled MWNT produced by the CVD method.
Figure 7. A SEM image of a carbon nanotube ring obtained from CVD grown MWNT material. The scale bar is 0.5 μm.

exists in the possible different nanotube structures, ranging from the single SWNT with its different chiralities to complex branched and filled nanotubes. To date the control over the synthesis process is very poor but there are no known fundamental obstacles to efficient and controlled production of nanotubes for technological applications. Meanwhile, the impact of carbon and noncarbon nanotubes in the physical sciences has already been important and continues to enrichen scientific research.

2. SYNTHESIS AND CHEMICAL PROPERTIES

2.1. Introduction

The formation of filamentous carbon from the decomposition of carbonaceous gases was reported in the 19th century [17]. There has been quite a lot of work since then on the topic, notably since the 1960s, and the formation mechanisms have been particularly discussed (see Rodriguez [18] for a review). Most authors observe the presence of a catalyst particle at the tip of each carbon filament and therefore propose a formation mechanism close to the vapor-liquid-solid (VLS) mechanism [19]. This involves four main steps.

1. Gas adsorption at the surface of the particle and decomposition producing surface carbon species.
2. Bulk and/or surface diffusion toward the other side (rear side) of the particle.
3. Carbon precipitation on the rear side and lift-off of the particle.
4. Migration of surface carbon species until the catalyst surface is totally covered and thus deactivated.

Transmission electron microscopy (TEM) images showing very small hollow nanofilaments were published in 1976 [20], but neither the nanometric dimension nor the notion of nanotube were stressed. However, looking back with today's knowledge reveals that these nanofilaments indeed are Iijima–type nanotubes. This shows that it is possible to prepare nanotubes with the relatively simple techniques used for the production of filamentous carbon, known as catalytic chemical vapor deposition (CCVD). It was proposed [21] that the crystallographical arrangement adopted

by the metal particle will direct the precipitation of carbon toward the formation of filaments with different morphologies, that is, either with graphene planes perpendicular to the growth direction (nontubular fiber), with the so-called herringbone structure (hollow fiber), or as several concentric cylinders (thus forming what is now called a MWNT). For the latter case, a noteworthy growth model was proposed by Tibbetts [22].

However, it is the groundbreaking report by Iijima [1] on the obtaining of nanotubes with a diameter in the nanometer range and on their relation to the recently discovered fullerenes that triggered a worldwide research effort devoted to improving their synthesis, notably that of SWNTs. The most common synthesis methods (arc discharge, laser-vaporization, and CCVD) will be presented in the following section. First, the formation mechanisms will be briefly examined (see [23] for an early review).

Several authors using arc-discharge without a metal catalyst [24, 25] have proposed a growth mechanism for MWNTs based on the repeated incorporation of carbon dimers into an empty fullerene cage. Lengthening results from rearranging the carbon bonds to incorporate additional dimers near a pentagonal ring. Other researchers [26–28] have proposed that carbon atoms (C1, C2, C3) are adsorbed at the active dangling bond edge sites, thus always maintaining the tubes open during the growth. It was suggested [26, 27] that nanotube thickening occurs by the island growth of graphene basal planes on existing surfaces.

In the presence of metal catalyst, SWNTs are produced by arc-discharge, laser vaporization, and CCVD. Several nanotube formation mechanisms have been proposed but whatever the synthesis route, they basically fall into one of two categories: "one particle–one nanotube" or "one particle–many nanotubes," and they bear a certain relation with the VLS mechanism. In the case "one particle–one nanotube," observed when using CCVD, the diameter of the SWNTs is in the range 0.5–5 nm and is directly related to that of the catalyst particle. The critical diameter above which the formation of concentric carbon layers around the particle is favored was found to be about 3 nm [29, 30]. TEM images of both ends of isolated SWNTs support a base-growth mechanism [31]. In the "one particle–many nanotubes" mechanism, a large number of SWNTs bundles (or ropes) originate from the surface of a metal particle several tens of nm in diameter [32–34]. A narrow catalyst particle distribution centered on 15 nm appears to give the highest SWNT yields [35].

Whatever the synthesis route, research efforts on the synthesis and formation mechanisms have enabled the preparation of nanotubes samples of better as-produced purity and with an improved control on the diameter and number of walls. However, most importantly for the field of electronic properties, it is to be noted that an absolute control of the diameter and therefore of the helicity has so far not been found possible.

2.2. Most Common Synthesis Methods

In the following sections, we will only briefly describe the principal synthesis methods (arc-discharge, laser vaporization, and CCVD) and the characteristics of the so-prepared nanotubes. Each method could be the subject of a review on its own, which is beyond the scope of the present review. However, it is important to note some information that was not fully appreciated at the beginning of the development of the "nanotube" field, that is that each method produces different nanotube samples, that differences subsist depending on the experimental conditions for a given method, and that even different batches from a single source may not be exactly identical. A review, with 282 references, on the main synthesis methods and others (resistivity vaporization, electron- or ion-beam vaporization, sunlight-induced vaporization, flame synthesis, molten-salt electrolysis, chlorination of carbides and more) was published by Rakov [36].

2.2.1. Arc-Discharge

The arc-discharge method for the preparation of nanotubes is similar to that used for the synthesis of fullerenes. Following Iijima's report [1], modifications were proposed for the large-scale synthesis of nanotubes [37]. An inert gas atmosphere (typically He or Ar) is flown through a reaction vessel at a controlled pressure. Two graphite rods constitute the electrodes, between which a potential difference is applied. As the rods are brought close together, a discharge occurs, resulting in the formation of a plasma. A deposit, which may contain nanotubes under certain conditions, forms on the larger negative electrode (cathode) while the smaller positive electrode (anode) is consumed. Typically, the outer diameter of MWNTs prepared by the arc-discharge method ranges between 2 and 20 nm and the inner diameter ranges between 1 and 3 nm [38–41]. The length is of the order of one to several micrometers. MWNTs form regularly organized bundles, which may contain tens or hundreds of individual tubes. The bundles in turn are combined into fibers with a diameter of about 50 μm, which themselves form threads with a diameter of about 1 mm. It was furthermore noted that the arc-discharge MWNTs do contain many defects [42–44].

Using a metal catalyst was reported to produce SWNTs [45, 46]. A hole drilled in the anode is filled with a mixture of metal and graphite powder. The diameter distribution is very narrow: 0.7–1.6 nm [45] and 1.2 nm [46]. Ni-Y in particular emerged as a very good catalyst allowing a large-scale production of SWNTs [47]. Carbon deposits may be found in different places of the reaction chamber: as a soot deposited on the wall, as a hard shell at the surface of the cathode, as a soft belt (sometimes referred to as "collaret") around the cathode deposit, and as a web-like precipitate decorating the chamber walls. Various carbon species are found in the deposits including SWNTs, MWNTs, amorphous carbon, spherical metallic nanoparticles, empty or filled graphitic nanoparticles, and a few graphitic sheets, as well as round spherical metallic particles. The density of SWNTs is particularly high in the collaret. Purification procedures usually involving thermal and acidic treatments are required to eliminate the residual metal catalyst (the amount of which can reach 50 wt%) and the nontubular carbon species. The SWNT yield and diameter distribution depend on several other parameters including inert (He, Ar) or reactive (H_2, CH_4) gas nature, pressure and flow rate, electrodes nature, purity, diameter and position (vertical or horizontal),

reactor geometry, arc-discharge variable (voltage, current plasma temperature), process duration, and configuration of cooling devices. DWNTs were also prepared by a hydrogen arc discharge method [48].

The SWNTs are mostly organized in bundles consisting of a few to a few tens of individual tubes forming a triangular lattice and more or less covered with some carbon soot. The diameter distribution of the SWNTs is very narrow (1.2–1.4 nm) and lengths reach up to several μm. The tube tips are generally seen closed, in agreement with observations for MWNTs, without any trace of catalyst species at the end. MWNTs filled with Sn, Te, Bi, Ge, Sb, Pb, Al, In, S, Se, Cd, Gd, or Hf have been observed [49–51].

2.2.2. Laser Vaporization

Guo et al. [52] proposed an original method in which a mixture of carbon and transition metal is vaporized by a laser impinging on a metal-graphite composite target. The reactor tube is placed inside a furnace (typical temperature 1200 °C, flowing Ar). It is claimed that in contrast to the arc method, direct vaporization allows far greater control over growth conditions, permits continuous production, and produces SWNTs in higher yield (70–90%) and of better quality. The SWNTs are about 1–1.6 nm in diameter, a very narrow distribution, and are arranged in large bundles (ropes) that may be 100 μm long, with a similar spacing between adjacent SWNTs. It is claimed that no amorphous coating is observed. Bimetallic catalysts (Co-Ni and Co-Pt mixtures) have a SWNT yield 10–100 times that for single metals alone. It was suggested that the principal effect of a mixture is to increase the mobility of carbon on and/or within the metal particle, resulting in a greater rate of SWNT precipitation from the particle.

Optimizations of the method using pulsed laser [53], separate carbon and metal-alloy targets [54], or without a furnace [55] have been reported. The diameter distribution can be slightly changed by varying the process temperature [56] and gas pressure or flow velocity [57] and by changing the chemical composition of the gas and of the target. The introduction of hydrogen (as admixture to Ar), sulfur (as a FeS additive to the carbon target), or, particularly, both leads to the efficient formation of SWNTs with large diameters from 2 to 5.6 nm [58]. In some conditions, laser vaporization SWNTs were also found [14] to contain C_{60} fullerenes (referred to as a "peapod"), which may coalesce, thus forming a second tube inside the first one [59].

2.2.3. CCVD

The CCVD methods basically consist of passing a gaseous flow containing a certain proportion of hydrocarbon (mostly CH_4, C_2H_2, C_2H_4, and C_6H_6 usually as a mixture with N_2 or H_2) or CO over small transition metal particles. Many parameters, including the temperature and duration of the treatment, the gas composition and flow rate, and the catalyst nature and size, will affect the nature of the carbon species in the resulting material. Indeed, as observed for studies on filamentous carbon and vapor-grown carbon fibers [18], several species may be obtained in addition to Iijima-type nanotubes, including amorphous carbon, carbon particles either connected or not to the metal or carbide particles and carbidic carbon particles. Here we will

only consider a few post-1991 studies on the formation of MWNTs and SWNTs.

The decomposition of C_2H_2 and H_2-C_2H_2 on well-dispersed metal (Fe, Co, Ni, Cu) particles strongly adsorbed on a support (graphite flakes, SiO_2) produces MWNTs and graphitic filaments, sometimes covered by amorphous carbon [60, 61]. Co-SiO_2 was reported to be the best catalyst-support combination for the production of MWNTs. Straight and coiled tubes were obtained with inner and outer diameters of 3–7 and 15–20 nm, respectively, and up to 30 μm in length. The precipitation-ion-exchange method was found to provide a better dispersion of metals on SiO_2 than the impregnation technique [61]. The length of the MWNTs was found to depend on the duration of the catalytic process. However, the longest ones are also the thickest. The use of a zeolite as a support [62, 63] results in more finely dispersed metal particles (1–50 nm). Only on this Co-zeolite catalyst could thin tubes (4 nm, 2–3 walls) be observed, however in a very small amount. The influence of the addition of H_2 to CO on the MWNT or herringbone morphology was reported [64, 65]. The pyrolysis of metallocenes [66, 67], which act as a feedstock for both the transition metal and carbon, produces short MWNTs sometimes filled with the corresponding metal particles and coated with amorphous carbon.

For the preparation of SWNTs, it is of utmost importance that the metal particles are in the nanometer size range at the appropriate temperature. As previously noted, the critical size of the catalyst particles is $\sim$3 nm. Achieving this is obviously related to experimental conditions such as reaction atmosphere, temperature, and duration, but also, most importantly, to the way the catalyst material is prepared. The first CCVD SWNTs were prepared by CO disproportionation catalyzed by preformed Mo particles a few nanometers in diameter [68] and by CH_4 decomposition on Fe nanoparticles formed *in-situ* by elective reduction of an oxide solid solution [69]. Several groups have reported progresses in the yield, control of the diameter, and of the number of walls. Indeed, detailed HREM observations often reveal the presence of DWNTs and small MWNTs in addition to SWNTs [29, 30]. As noted above, a mechanism such as the "yarmulke" [68] accounts for the formation of both SWNTs and DWNTs. The HiPCO method [70] involving CO and $Fe(CO)_5$ allows the production of large quantities of SWNTs. The diameter of the CCVD CNTs, in the range 1–5 nm, is closely correlated with the size of the catalytic particle. Co, Fe/Co, Fe/Mo, and Co/Mo appear to be the best catalysts for the formation of SWNTs, although the role of molybdenum has not yet been totally explained. Length is ranging between $\sim$100 nm and several micrometers, and the surface is free of the amorphous carbon coating typically observed in catalytically produced MWNTs. The SWNTs are quite flexible and in general contain more defects than those produced by arc-discharge and laser vaporization.

CCVD methods are becoming increasingly attractive, owing to their great potential for the production of large quantities of nanotubes at a low cost, using standard technology. Moreover, one key advantage is the possibility to perform the oriented or localized growth of nanotubes.

2.3. Oriented or Localized Growth

The term "oriented" is used here to describe the formation of large quantities of CNTs aligned perpendicularly to the substrate surface, usually MWNTs of controlled dimensions (diameter 20–400 nm, length 0.1–60 μm). The key steps are substrate patterning, catalyst deposition, and the appropriate use of different CVD routes. The description of the numerous studies on this topic is well beyond the scope of this review. (see Huczko [71] and references therein).

The term "localized" describes the self-assembled nano-interconnections made by CNTs between islands on prepatterned substrate. The directed growth of SWNTs parallel to the plane of a silicon substrate was reported [72]. The SWNTs are suspended bridges grown from catalyst material placed on top of regularly patterned silicon tower structures. The key synthetic step in this approach involves developing a series of liquid-phase catalyst precursor materials, allowing for uniform film formation and large-scale catalyst patterning. Contact printing techniques were used to selectively deposit catalyst precursors on top of the silicon tower arrays. Calcination led to the formation of catalyst particles confined on the tower tops and subsequent CVD (CH$_4$, 900 °C, 20 min) growth yielded SWNTs emanating from the towers. Directed free-standing SWNT networks were formed by nanotubes growing to adjacent towers and becoming suspended above the surface. It is noted that a rational design of tower arrangements could lead to a variety of directed SWNT architectures. The liquid-phase catalyst precursors consist of three general components: inorganic chloride precursors, a removable triblock copolymer serving as the structure-directing agent for the chlorides, and an appropriate alcohol for dissolution of the inorganic and polymer compounds. The increase in yield was achieved through a so-called conditioning step that uses bulk amounts of catalysts placed near (upstream) the catalyst-patterned substrate in the CVD growth environment [73]. The influence of the CH$_4$ "wind" on the directional growth of the nanotubes was discussed [73, 74]. A hot-filament CVD technique was also reported [75]. SWNTs were grown onto more than 90% of 375 Si tips prefabricated on a wafer [76].

2.4. Chemistry of Carbon Nanotubes

The chemistry of carbon nanotubes, which encompasses the aspects of purification and functionalization, is a very important field for tailoring their structural and electronic properties and thus for the development of future applications. (see Rakov [77] and references therein). Purification aims at removing the nontubular material in raw nanotube samples. Several techniques, more or less complex, have been proposed, including solvent treatment followed by ultrafiltration [78], flocculation using aqueous surfactants [79, 80], oxidation and acid washing coupled with centrifugation, resuspension in surfactant solution, and cross-flow filtration steps [80–82]. These methods however lead to a mixture of nanotubes of differing lengths and still containing potential contamination with nontubular material. Polymer suspensions [83, 84] and chromatographic purification [85, 86] are useful to remove nontubular material. Field-flow fractionation on

purified, shortened nanotubes [87], and size-exclusion chromatography on raw nanotubes [88, 89] have demonstrated some success at producing fractions separated by length. Capillary electrophoresis was reported to allow separation based on tube length [90].

An early paper by Ebbesen et al. [91] reported that a thermal oxidation treatment eliminates all nanoparticles and SWNTs caps so that open SWNTs can be obtained free of other carbon species. However, only ca. 1 wt.% of the initial material remained after oxidation. As noted by Chen et al. [92], the chemical reactions that selectively attack the sites of preferential reactivity in nanotubes (the caps where the pyramidalization and curvature is greatest) are not satisfactory for the production of processable materials, because this type of transformation is too localized to bring about the necessary change in bulk properties. In contrast, one needs to selectively attack a few of the π-bonds in a controlled manner without bringing about a total destruction of the graphene electronic structure. This presents a further challenge to experiment, because the reduced strain in the walls lessens the reactivity. Chemical functionalization was reviewed by Sinnott [93].

Several methods for attachment of oxygen-containing groups to the nanotube surfaces have been developed [94, 95]. Carboxylic, carbonyl, and hydroxyl groups were found covering the nanotube walls [96]. The concentration of acid groups on the surfaces of HNO$_3$-treated nanotubes was higher than that found for graphite treated under the same conditions [97]. Sonication of nanotubes prior to the functionalization in acids increases the concentration of acid groups. Oxidation of nanotubes with a H$_2$SO$_4$-HNO$_3$ mixture also leads to a higher concentration of functional groups on the surface [98]. Long-term acid treatment of nanotubes also induces modifications. Functional groups can be removed from the surface of nanotubes by heating. It should be noted that SWNTs obtained by different methods exhibit different behavior in the course of acid treatment and subsequent oxidation. The sensitivity of SWNTs to chemical processing was investigated by TEM [99].

To enhance the possibilities of atomic force microscopes with nanotube probe tips, the tip ends were functionalized using both solutions [87, 100, 101] and gases [102–104]. Modification of tips using a discharge in N$_2$ results in the formation of nitrogen-containing heterocycles at the tip ends. High degree of saturation of nanotube tips with functional groups is achieved by treatment with a low-pressure ammonia plasma followed by oxidation with a NaClO$_3$ solution [103].

Studies on fluorination of nanotubes were reviewed by Rakov [77] and Touhara and Okino [105]. Fluorination was found to have a strong effect on the electronic properties of nanotubes: untreated nanotubes were conductors while fluorinated nanotubes were insulators [106]. Fluorination below 325 °C appeared to be reversible. The interaction between fluorinated nanotubes with a composition close to C$_2$F and anhydrous hydrazine resulted in removal of the fluorine atoms and in recovery of the initial structure of the nanotubes. This was accompanied by recovery of many of their initial properties. Fluorinated nanotubes membranes are potentially interesting materials for electrochemical batteries or capacitors [105].

The reactions with silicon of individual nanotubes or nanotube bundles at 970 °C in ultrahigh vacuum resulted in the formation of Si-β-SiC(nanorod)-nanotube hetero-junctions [107].

3. ELECTROMECHANICAL PROPERTIES

3.1. Introduction

Along with their electronic properties, carbon nanotubes have been praised for their mechanical properties. The praise is based on high strength, flexibility, and large aspect ratio. A carbon nanotube is a freestanding conductor and its mechanical properties are highly relevant for the electronic properties and the potential technological applications of the tube. For example, nanotube-based mechanical oscillators may have applications in high-frequency electronic circuits, and carbon nanotubes are already used in scanning probe microscopy both as STM and AFM tips. Thin, strong, and durable nanotubes come extremely close to an ideal scanning tip.

Mechanical properties of carbon nanotubes are closely related to the properties of a graphite sheet, but the tubular anisotropic form affects the mechanical behavior. The basis is the graphite sp^2 bond, which is the strongest of chemical bonds. In nanotubes the overall density of defects can be extremely low depending on the synthesizing method and prevailing synthesizing parametres. This has led to predictions of a very high axial strength.

3.2. Basic Mechanical Properties

Theoretical calculations of Young's modulus for individual SWNTs center around 1 TPa or slightly higher [108, 109], but values as high as 5.5 TPa [110] have been presented. The spread is due to different interaction models and, also to differing values of nanotube wall thickness—the wall thickness of an isolated nanotube is not a well-defined quantity. Most of the theoretical attention has been on SWNTs because modeling the interlayer interaction in MWNTs is a complicated matter. Lu [109] presents Young's modulus values for multiwalled tubes as well as SWNTs and obtains values from 0.97 TPa to 1.11 TPa with the value increasing slightly with the number of layers.

The small size of carbon nanotubes presents challenges also for experimental characterization. Nevertheless measurements have been performed. The first Young's modulus measurement [111] related thermal vibration amplitudes of MWNTs to their Young's modulus and obtained an average value of 1.8 TPa with a large spread. After that, with AFM techniques, values such as 1.28 ± 0.59 TPa for arc-discharge–produced tubes [112] have been obtained. The latest measuring technique by Poncharal et al., who induced vibrations on MWNTs by alternating potential and have measured the vibration frequencies [113]. Young's modulus values between 0.7 TPa and 1.3 TPa for tubes with a diameter less than 12 nm and between 0.1 TPa and 0.3 TPa for thicker tubes were reported. The drop is explained by an onset of a wave-like bending mode of the nanotube wall at the inner arc of the bending [113]. Measuring SWNTs is more complicated than measuring MWNTs due to their small diameters and the tendency to bundle. Krishnan et al. [114] report a measurement of individual SWNTs using the thermal vibrations method of Ref. [111], and they obtain an average value of 1.25 TPa. Although the current measurements suffer from inaccuracies due to vibration amplitude measurement and assumptions made on AFM tip characteristics, the current agreement is that defect-free nanotubes, both SWNTs and MWNTs, have a Young's modulus value around or slightly above 1 TPa, which is extremely high and sets nanotubes as the strongest known material albeit challenged by other nanotubular structures such as boronnitride tubes.

Theoretically, nanotube tensile strength is high, and this is supported by calculations in which SWNTs support as high as 30% of axial strain before brittle failure [115] and by more recent kinetic activation based calculations that give a yield strain of 17% with a chirality and temperature-dependent defect formation activation energy barriers [116]. Experimentally nanotube tensile strength has been measured for MWNTs by Yu et al. [117]. In the measurement, the contact is only to the outmost layer, and a sword-and-sheath type of failure of this outermost layer is reported. Tensile strength values ranging from 11 GPa to 63 GPa are reported [117]. The role of the inner layers is not, however, clear, and the failure process may be more complicated than has been proposed. For individual SWNTs, the experimental value of tensile strength is still an open question, but for bundles of SWNTs tensile strength values ranging between a few GPa and several tens of GPa depending on the bundle and measurement characteristics have been reported [118–120].

As a result of the high tensile strength, nanotubes can bear large strain before plastic deformation or brittle failure. The tubes buckle, flatten, form ripples, and generally deform under strain [110, 115, 121], but plastic deformation and relaxation occur only at elevated strain levels and temperatures [122–124]. An example of simulated nanotube behavior under strain is presented in Figure 8.

3.3. Defects in Carbon Nanotubes

As in any material, defects play an important role in nanotube properties. Structurally, defects make the tube less strong and thus in general defects are not desirable from the purely mechanical point of view. However, they alter the electronic properties locally, which can be utilized in the creation of single-tube devices. Defects are generated in the synthesizing process, and they can also be caused by mechanical manipulation, or, for example, by ion or electron beam bombardment of the tube. The most typical structural defects are fivefold (pentagon) and sevenfold (heptagon) rings in the sixfold (hexagonal) lattice. Other types of typical defects are vacancies and miscellaneous bonding configurations such as amorphous diamond. Noncarbon-based defects include substitutional atoms or atom groups. In addition to these, MWNTs exhibit diverse defects based on discontinuous inner layers. Defects may alter the tube form from a straight tube to a bulging, kinked, spiral, or even more miscellaneous form.

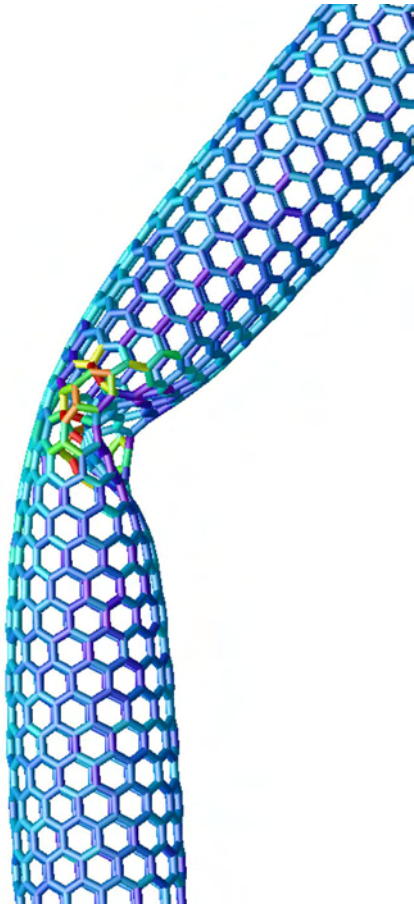
The effect of defects and deformations on nanotube conductivity has been studied in many reviews [125–131]. Defects and deformations induce scattering and localization,


Figure 8. A molecular dynamics simulations based example of nanotube behavior under strain. The image shows a portion of a $(14, 0)$ nanotube of 2632 atoms (tube length is 20 nm) bent 36 degrees with a constant bending rate in 300 K temperature and then, to enhance structural reconstruction, annealed in an elevated 3300 K temperature for a sequence of three 130 ps annealing and cooling simulation runs. In the bending process the tube buckled but remained hexagonally bonded. The defects visible in the image relax the strain and are a result of the third annealing [M. Huhtala, K. Mogami, A. Kuronen, and K. Kaski, to be published].

which result in conductivity drops, symmetry breaking based gap opening, and conductivity barriers. The scattering effects of isolated point defects are averaged over the circumference, and therefore their influence decreases with an increasing diameter and is small for all but the very thinnest tubes. However, if the defects or deformations accumulate locally, a tunneling barrier may form. AFM manipulation has been used to make sharp bends in SWNTs, which has resulted in the formation of tunnelling barriers [130–133]. The created changes are not, however, necessarily permanent. Another AFM based method for creating permanent tunneling barriers has been reported by Park et al. [134]. Nanotube defect manipulation offers interesting prospects both for devices with permanent characteristics and for devices with tunable properties, but a breakthrough requires more accurate and flexible mass manipulation of tube properties than is currently available.

3.4. Carbon Nanotubes as Mechanical Oscillators

Due to their small size, combined with a low mass density and high Young's modulus, nanotubes are predicted to have characteristic vibration frequencies in the gigahertz regime, which is extremely high for a mechanical vibrator [135, 136]. Such frequencies are not attainable with the current silicon-based micromechanical oscillator production techniques with which eigenfrequencies in the 10 MHz to 100 MHz regime can be attained [137]. A first approximation for the fundamental modes of a nanotube vibrator can be obtained from elasticity theory and is for a thin cylindrical transversally vibrating rod that is clamped from one end [138]

$$f_1 = 0.28 \frac{d_t}{L^2} \sqrt{\frac{Y}{\rho}} \qquad (3)$$

If values for tube diameter $d_t = 1$ nm, Young's modulus $Y = 1$ TPa, and density $\rho = 750$ kg/m^3 are used (The mass density of a SWNT is not a well-defined quantity; the value presented here is a rough estimate based on the nanotube atomic spacial density and the volume encompassed by a tubular cylinder depicting the tube of 1 nm radius, to compare with graphite mass density is 1900–2300 kg/m^3 [139]), a frequency of 10 MHz is obtained for a tube length of 1 μm and a frequency of 1 GHz for a length of 100 nm. For a rod clamped from both ends, the constant in front of the equation is altered according to the boundary conditions, but the overall dependency on d_t, L, Y, and ρ remains [138]. Based on the discussion above, nanotubes, and especially SWNTs, are capable of significantly smaller dimensions and higher frequencies than conventional silicon-based vibrators.

Currently, only a few studies of excited mechanical vibrations in nanotubes exist. Poncharal et al. apply alternating potentials to MWNTs and measure Young's modulus [113], and Reulet et al. [135] have performed a basic study of acoustoelectric coupling in ropes of SWNTs, and they report that depending on the excitation power, either electron heating or phase coherence breaking is observed.

To conclude, there are many things in the mechanical properties that have not been measured, and the measurements that exist suffer from a degree of inaccuracy. Most theory concentrates on SWNTs, and although the SWNTs often show more clearly the nanotube characteristic and desirable electronic properties, the theoretical aspects due to multiple layers still have many questions to answer, as do defectous-structure related matters. However, in nanoscale science and technology, electronic and mechanical will become more intimately connected, and therefore in the future the electromechanical properties of carbon nanotubes will play an important role.

4. ELECTRONIC STRUCTURE AND PROPERTIES

4.1. Tight Binding Model

The carbon atoms in nanotubes are sp^2-hybridized, thus each atom contributes one unpaired π-electron to the tube. Carbon nanotubes are electronically active materials due to

these π-electrons. The basic electronic properties of the carbon nanotube are calculated by extending the tight-binding approach of 2D graphite to the geometrical configuration of the 1D nanotube system. The crystal momentum vector perpendicular to the nanotube axis is quantized due to the periodic boundary condition imposed by the finite circumference of the nanotube. This relatively simple model has been proven, mainly by low temperature STM spectroscopy, to explain well the basic electronic structure of the carbon nanotube. According to this model, the chirality of the carbon nanotube determines its division into metallic and semiconducting tubes. In the model, the curvature of graphitic wall of the nanotube is ignored. This has lately been shown to bring about important modifications to the model [140]. Still the model survives well enough to continue to serve as a basis for classification of the nanotubes into metallic and semiconducting ones.

In the following brief presentation of the basic tight-binding model of the single shell carbon nanotube, we use the nomenclature of Saito et al. [2]. The different geometric shapes that a carbon nanotube can have and the (n, m) indices used for their identification were introduced in Section 1. Due to the tubular 1D structure, the nanotube has N separate 1D energy bands. In a general form these are derived from the graphite energy levels by the general formula

$$E_\mu(k) = E_{g2D}\left(k \frac{\mathbf{K_2}}{|\mathbf{K_2}|} + \mu \mathbf{K_1} \right)$$

$$\left(\mu = 0, \ldots, N-1, -\frac{\pi}{T} < k < \frac{\pi}{T} \right) \quad (4)$$

E_{g2D} denotes the energy eigenvalues of a 2D graphite sheet, $\mathbf{K_1}$ and $\mathbf{K_2}$ are reciprocal lattice vectors corresponding to $\mathbf{C}$ and $\mathbf{T}$, respectively. Figure 9 shows how the carbon nanotube k-vectors are projected to the graphite momentum space lattice. In graphite the conduction and valence bands meet at the so called K points in the momentum space, which is responsible for its semimetallic behavior. In the tight-binding picture, the metallicity of a carbon nanotube is determined by whether the 1D lines of allowed k-vectors run through these points. The dispersion relations for the
armchair tube $(5, 5)$ are shown in Figure 10 as an example. In an energy diagram, whether the energybands will cross the Fermi energy or leave an energy gap depends on the (n, m), that is the chirality, as follows: The armchair nanotubes, with indices (n, n), have two bands that cross each other and the Fermi energy at the points $k = \pm 2\pi/3a$; they are thus always metallic, while only some of the zig-zag tubes are so. The general condition for the metallicity of a nanotube is that the factor $2n + m$ is a multiple of 3, a condition that indeed is fulfilled for the armchair tubes. As a further result, the theory predicts that one-third of all nanotubes are metallic while two-thirds are semiconducting. These rates of occurrence have not been confirmed by the presently performed experiments, which however is not surprising considering doping effects and the fact that almost nothing is known about the possible preference in the growth processes for certain nanotube symmetries over others.

As a general result, in all metallic 1D systems with half-filled bands, the so-called Peierls distortion will, by an atomic displacement, change the unit cell so that the band becomes filled and a gap opens up at the Fermi energy. The phenomenon is well known among conducting polymers, charge transfer salts, etc. [141]. In carbon nanotubes, however, it has been shown theoretically that the effect very quickly diminishes as a function of nanotube radius [2].

4.2. Experimental Studies: STM Imaging and Spectroscopy

The electronic structure of the SWNT that is predicted by the tight-binding calculations described above was put to test at first primarily by scanning tunneling spectroscopy, done with low temperature STM [142, 143]. In such experiments, it is possible to image the nanotube with atomic resolution along the length of the tube and with a width of a few unit cells. The width of the imaging is of course limited by the curvature of the nanotube. This imaging reveals (in the best cases) the structure and diameter of the nanotube, enabling one to determine the (n, m) indices of the nanotube with some confidence. Furthermore, the STM tip can be positioned at any point along the nanotube, separated by
Figure 9. Allowed k-vectors of carbon nanotubes are formed by the vectors $\mathbf{K_1}$ and $\mathbf{K_2}$ in the reciprocal lattice space of graphite. The nanotube is metallic if the ratio of $\mathbf{YK}$ to $\mathbf{K_1}$ is an integer. Reprinted with permission from [2], R. Saito et al., "Physical Properties of Carbon Nanotubes," Imperial College Press, London, 1998. © 1998, Imperial College Press.

a tunneling distance from the nanotube surface, and spectroscopic measurements be performed by taking the current-voltage characteristics. The I–V characteristics reveal the metallic or semiconducting character of the tube since the measured current is proportional to its density of states (DOS). This experimental technique thus addresses the fundamental question of the relation between the structure and the basic electronic properties of the individual nanotube. Figure 11 shows the principal differences between the DOS of a metallic and a semiconducting tube. As seen by STM spectroscopy, in the zero-bias region the metallic tube (Fig. 11a) has a finite conductance while the semiconducting tube has zero, corresponding to the basic Fermi surface properties. At higher voltages asymmetric peaks in the conductance appear. These are the Van Hove peaks due to the 1D DOS. The low-temperature STM experiments were carried out with SWNTs, and thus they cover only a very limited range of diameters, between 1 and 2 nm. For this range, the measured E_g for semiconducting nanotubes followed roughly the predicted $1/d_t$ dependence, being in the range 0.3–0.7 eV [142].

In the presentation above, the effects of nanotube curvature on the tight-binding model were not addressed. In more recent scanning tunneling spectroscopy measurements on SWNTs, a curvature-induced "extra" gap was found in zig-zag type metallic nanotubes, but not in tubes of armchair type [140]. This gap is also inversely dependent on the nanotube radius. The measured results were theoretically anticipated in refined calculations (see [140] and refs. therein). The curvature-induced gap has a size of a few 10s of meV for subnanometer tube diameters. From this energy scale we see that for all but the very smallest of possible tubes, the effect is washed out at room temperature.

Other scanning tunneling spectroscopy experiments have been performed that explore other topics such as individual quantum states in short SWNTs [144, 145], MWNTs [146],

doped nanotubes [147], crossing nanotubes [148], defects and junctions in SWNTs [149, 150], and peapods (SWNTs filled with C_{60}) [151].

4.3. Experimental Studies: Raman Spectroscopy

Another important tool for nanotube characterization is Raman spectroscopy. Particularly, the strong, so-called radial breathing mode is derived from the tubular structure of the nanotube and is absent from all other 2D graphitic forms of carbon. It is widely utilized to give a measure on the nanotube diameter [2]. Due to the singularities in the DOS of the 1D nanotubes and the electron-phonon coupling, very strong resonant Raman effects are observable in studies on carbon nanotubes. This enables the use of Raman spectroscopy to investigate the electronic structure of carbon nanotubes, particularly the occurrence of semiconducting and metallic properties. A possibly very important recent development is the ability to measure the Raman signal from individual nanotubes with the so-called micro-Raman technique. It was claimed to be possible to determine the (n, m) indices of the isolated nanotube with this technique [152]. This of course opens up the possibility of transport measurements on a nanotube of known symmetry.

4.4. Optical Properties

The optical physics of nanotubes has not moved forward in pace with the other developments in the field. This is due to unability to make samples consisting of nanotubes of a single symmetry. (A more recent exception to this statement was reported in [153].) Thus all optical signals are a mixture of signals from a very large variety of nanotubes. Furthermore, since nanotubes tend to aggregate together, especially SWNTs, any signal from semiconducting tubes is easily hidden by interaction with neighboring metallic tubes. Unlike transport measurements, optical measurements on single nanotubes are experimentally less feasible. On the other hand, however, the 1D singularities in the optical response of nanotubes give strong signals, just as in the case of Raman spectroscopy. Also, if aligned assemblies of nanotubes can be produced, the optical anisotropy of such a system is potentially huge. In a recent development, SWNTs were processed by sonication and surface-active chemicals to produce solutions of truly individually solvated tubes, coated with the surface-active hydrocarbon molecules. These SWNTs were rather short (due to the strong sonication), with an average length of only 130 nm. For perhaps the first time, photoexcited luminescence from nanotube solutions were observed in this case [154]. The luminescence spectrum was closely associated with the measured absorption spectrum, with only a minor red-shift. At the moment of writing, this work is intensively being pursued and is likely to significantly widen research in carbon nanotube systems. Photoconductivity measurements on single nanotubes have so far not been successful.

The research on the optical properties of carbon nanotube may in the near future bring forward a number of potential applications within optoelectronics, thus adding to the list that already exists within other fields of nanotube-based nanotechnology.
5. ELECTRONIC TRANSPORT PROPERTIES

5.1. Introduction

Within the realm of electronic transport physics, the carbon nanotube offers exciting possibilities both as a testing ground in basic research as well as in nanotechnology. In the case of the former, the near perfection in structure for lengths exceeding 1 μm makes the nanotube the best concrete example of a 1D quantum wire. On the other hand, in nanotechnology the prospect of devices made from a single nanotube, that is, intrananotube devices, offer the possibility of truly molecular-level electronics. Even if molecular electronics is eventually pursued with smaller molecules, carbon nanotubes may be used as connecting wires between metal structures of ~100 nm size and molecules of ~1 nm size.

Although the carbon nanotube is mainly "marketed" as a perfect 1D object, this is not always the case. In fact, depending on the circumstances one may have to treat the nanotube as anything from a 0D to a 3D object. Obviously, if a SWNT is short enough, it becomes a 0D object, or a quantum dot. If only the outer shell of a MWNT is considered, and the diameter of the tube is large enough with respect to some critical length scale of the particular situation, this outer shell becomes a 2D object. Finally, if we again consider a larger MWNT (in diameter), and the charge carrier coupling between the layers is strong enough, then we may have at hand an anisotropic 3D object. We can thus see that even without considering nanotubes of different chiralities and more elaborate topologies than the simple tubular one, the subject of electron transport in carbon nanotubes can be rather complicated.

As was discussed in the previous chapter, the energy gap in semiconducting SWNTs is ~0.5 eV, which is high enough with a good margin for the nanotube to function at room temperature as the active component for example, in field effect transistors. Other effects, such as the energy-level quantization in short nanotubes ($L = 10–100$ nm), require cryogenic temperatures for the effects to be observable. Roughly it can be said that in metallic nanotubes the interesting transport phenomena occur at low temperatures, while in semiconducting tubes much of the work is carried out at room temperature.

5.2. Bulk Transport

In this section we review work on the transport physics of single SWNTs, SWNT ropes, and MWNTs. This is clearly more significant than the subject of transport in macroscopic amounts of carbon nanotubes. However, the carbon nanotube may offer interesting applications as the conductive component in composites, when mixed together with an insulating host material. In order to have a composite conducting, the volume fraction of the conductive component has to exceed some critical value. Typically the conductive material consists of μm-sized particles of a more or less rounded shape. For conduction to occur, the particles have to touch each other frequently enough so that the conductive channels are formed over macroscopic distances. As prescribed by percolation theory, this occurs at a volume

fraction of 16%, whereby the conductivity of the composite rises very sharply (as a function of filling percentage) with several orders of magnitude. However, it has already been demonstrated with conductive material consisting of 1D objects, for example fibrils of polyaniline [141], a conducting polymer, that there is no apparent sharp threshold for the onset of conduction, and more importantly, the composite becomes conducting at a much lower volume fraction of the conductive component. Obviously, this should also be achievable with nanotubes as the conductive components. In fact nanotube-based composite systems are already being considered for commercial applications.

5.3. Developments in Carbon Nanotube Transport

The theory of the basic electronic properties of carbon nanotubes was formed quickly after their discovery [155]. In the decade since then, the experimental investigations of carbon nanotube transport properties have been thorough but are still in a very dynamical phase. We will next review chronologically the development in experimental carbon nanotube transport physics. Larger amounts of carbon nanotubes were available two years after their discovery in 1991. The first experiments where electrodes were fabricated on single MWNTs were published in 1996 by Ebbesen et al. [156] and Langer et al. [157]. These groups used rather elaborate methods: The former deposited tungsten by focused ion beam deposition with direct writing of the electrodes, and the latter deposited a gold film on the MWNT and then removed it after patterning the excess gold with Ar ion-milling, leaving gold electrodes to the MWNT. The results in Ref. [156] were highly varying, showing two terminal resistances from ~100 Ω to ~100 MΩ. It is likely that the ion beams damaged excessively some of the nanotube sections between the electrodes. In the work by Langer et al. a rather low resistance (~10 kΩ) was achieved, and the group demonstrated quantum effects in the transport in the form of universal conductance fluctuations in the magnetoresistance.

Later, other groups undertook much more systematic investigations, concentrating either on SWNTs (often, in fact, SWNT ropes) or MWNTs. Basically, two methods have since been used to connect individual nanotubes to metal electrodes: Nanotubes can be deposited from a solution, such as by spinning, on top of prefabricated electrodes. Many electrode structures are needed due to the low success rate of getting just one tube on the electrodes. The alternative method is to deposit nanotubes on a substrate with alignment markers, to locate a tube with AFM or SEM, and then to fabricate electrodes on the tube with e-beam lithography. The main difference between the methods is thus that in the former the tube is on top of the electrodes, while in the latter the electrode covers the nanotube. The methods may result in different transport properties. It has, for example, been claimed that the metal evaporated on top of a tube effectively cuts it for charge carrier motion. More recently, the growth of SWNTs has been incorporated with the fabrication process. Single-walled nanotubes are grown from catalyst particles deposited on a wafer (see Section 2) with alignment markers. Thereafter metal electrodes are fabricated with e-beam lithography just as in the

previous method. This latest method has enabled fabrication of samples in very large numbers. Some experimentation has already been undertaken where the principles of self-assembly are employed to deposit nanotubes onto electrodes in a more controlled and repeatable fashion [158]. Perhaps in the future it will also be possible to select between nanotubes of different chirality in the deposition process, if a single-chirality synthesis procedure does not arise. Despite all the experimental work done so far, the issue of contact resistance is not firmly understood [159].

With these methods, large numbers of carbon nanotubes have been investigated since the mid-90s. At first the contact resistances were typically in the range from several tens of kΩs to several MΩs (if conducting at all). The conductances were thus clearly smaller than the quantum of conductance ($G_0 = 1/13 \, \text{k}\Omega^{-1}$), and the nanotube was isolated by tunneling barriers from the electrodes. This led to a situation with the Coulomb blockade dominating the transport of metallic nanotubes at low temperatures. Both metallic and semiconducting tubes were found. With an effective gate electrode present, the latter could be driven on and off a conducting state at room temperature with a current modulation by a factor of 10^5 at best. Later contact resistances were improved to such a degree that the intrinsic resistance of the tube would dominate over the former. This has enabled the study of one-dimensional charge transport in both the ballistic and diffusive limits. Furthermore, a few reports have emerged about either proximity-driven or intrinsic superconductivity in SWNTs or SWNT ropes, although only two groups have made such claims so far [160, 161]. SWNTs were eventually made available almost to the same extent as MWNTs, so the studies on transport physics have emphasized these, since intershell interactions can be ignored. This has been the case in particular since the emergence of the individually grown SWNTs from catalytical particles, which evades the problem of coalescence of SWNTs into ropes. A major breakthrough that is pursued at this point is the complete physical characterization of SWNTs of known chirality. To date this has been possible only in STM studies with nanotubes dispersed on conducting surfaces.

In the last few years, a number of experiments relevant to transport properties have emerged in which individual nanotubes are manipulated with physical means for the purpose, for example, of making tunneling barriers within the tube. In the majority of these experiments, the AFM has been utilized for this goal. Single-walled tubes with tunneling barriers can also be obtained by searching for tubes with pre-existing kinks (sharp bends), but especially the manipulated kinks are important since it has been possible to place these very close to each other in a SWNT, separated by just a few tens of nanometers. This has enabled the fabrication of room-temperature SETs [132, 133]. In MWNTs on the other hand, it is less plausible to induce well-defined tunneling barriers at one point due to the complications from multiple shells. However, it is possible to remove the layers by different means one-by-one [162]. This may in the near future enable the study of interlayer transport properties. In another set of experiments, the conducting tip of an AFM is used as a local gate in close proximity with the tube to be investigated. This has enabled observation of individual scattering sites in a carbon nanotube [163].

5.4. Metallic Tubes

5.4.1. Ballistic Conduction

One of the most exciting aspects of transport in metallic carbon nanotubes is their ability for ballistic transport over relatively large distances, exceeding 1 μm. Ballistic transport implies a large mean free path τ_m for the electrons. This large τ_m was estimated on theoretical grounds by White et al. [164]. Again, the tubular structure plays a role in that the disorder is expected to be averaged over the circumference of the nanotube. A ballistic conductor has a conductance given by the Landauer formula:

$$G = N_{\text{ch}} T_m G_0, \, G_0 = 2e^2/h \tag{5}$$

Where N_{ch} is the number of conducting channels, T_m is the transmission factor and G_0 the quantum of conductance in the noninteracting approximation. The factor 2 is due to spin degeneracy. In a much debated experiment by Frank et al. [165], an arc-discharge synthesized MWNT was sunk from the tip of a STM into a liquid metal (Hg,Ga) at room temperature. A conductance of $1G_0$ was measured repeatedly and independently of the distance that the tube penetrated into the liquid metal. However, a metallic carbon nanotube has two crossing 1D energy bands at the Fermi level, which yields a conductance of $2G_0$ for a single nanotube. Some of the more recent measurements on SWNTs have in fact, in accord with theory, approached but not exceeded this value, while all other transport experiments on MWNTs point toward a picture of more diffusive transport behavior. Therefore the controversy over the experiment by Frank et al. remains unsolved.

Two recent experiments [166, 167] in single SWNT samples grown by CVD have achieved the previously mentioned high conductances, a little below $2G_0$, in a fairly large number of samples. The temperature dependence of the conductance between 1 K and room temperature was weak, and even exhibited increasing conductance upon cooling. The ballisticity of the nanotubes, together with the fact that the contact resistances are large enough to cause reflections of the propagating modes at the nanotube-metal interfaces but weak enough to strongly suppress Coulomb blockade effects, results in a situation where the nanotube forms a resonant cavity for the charge carriers. If the wavelength of the conduction electrons is an integer fraction of the nanotube length, the wavefunctions form standing waves due to constructive interference between propagating and reflected electron waves. The wavelength can be tuned by changing the Fermi energy with a gate voltage (V_g). These effects can thus be seen as weak oscillations in I vs. V_g data at low temperatures. The work mentioned earlier demonstrated ballistic conduction over distances below 1 μm. Some recent work reports ballistic conduction for distances on the orders of tens of μms. The upper practical limit for the mean free path in SWNTs has thus not been established.

5.4.2. Luttinger Liquid

In the discussion above on ballistic conduction in carbon nanotubes we ignored e–e interaction effects. These do not necessarily affect the Landauer formula for ballistic conduction. The single-wall carbon nanotube in particular has been

forwarded as a prime candidate for hosting the so-called Luttinger liquid (LL), which is formed by interacting electrons in a 1D system [168]. In a normal 3D metal, the effect of e–e interactions to the independent electron approximation is limited; the noninteracting electrons change to independent quasiparticles in a one-to-one correspondence, as described by the Fermi liquid theory. In a strictly 1D system, however, the Fermi liquid picture breaks down and is replaced by the LL. In the LL, the e–e interactions dominate, and the electrons are in a highly correlated state. The primary excitations are not single quasiparticles above the Fermi level, but plasmons, which are analogous to electromagnetic pulses in a transmission line. However, the LL requires a high degree of order, since disorder destroys the correlated ground state. Therefore, a clean, strictly 1D system is difficult to realize and to investigate. In a LL, the DOS at the Fermi level is suppressed in a power law fashion, and spin and charge excitations are separated. Dating the observations of LL behavior is limited to edge states in 2D electron gases, to certain compounds with 1D substructure, and to single-walled carbon nanotubes. In transport measurements, the LL behavior is seen in the tunneling conductance from a normal electrode over a tunneling barrier to the LL, which has a tunneling DOS that is suppressed at the Fermi level according to a power law: DOS $\sim (E - E_\mathrm{F})^\alpha$. The parameter α is determined by the strength of the interaction between the electrons. It follows from the energy dependence of the tunneling DOS, that, at small voltages the tunneling conductance becomes

$$eV \ll k_B T \quad G(T) \sim T^\alpha \qquad (6)$$

and at large voltages

$$eV \gg k_B T \quad G(V) = dI/dV \sim V^\alpha \qquad (7)$$

The T dependent conductance has to be observed at some intermediate temperature range, since Coulomb blockade always dominates at low temperatures if the contacts have a low transparency. Measurements of conductance with tunneling contacts have been undertaken with SWNTs both as a function of T and V [169, 170]. Scaling of the experimental data as a function of $eV/k_B T$ gave limiting behavior that supports the LL picture as given by Eqs. (6) and (7). In particular, different types of contacts give different values for α: Tunneling over a nanotube bend is said to correspond to an "end-contact," that is, the charge carriers tunnel to an end section of a carbon nanotube and have only one way to propagate, while a carbon nanotube laid onto a metal electrode gives a "bulk-contact" with two possible (opposite) propagation directions. The α differs theoretically by a factor of 2 between the two cases, which also was roughly observed in the experiments.

However, if restricted to $I(V, T)$ measurements, the differences to other models are usually very small. An experiment that could provide a strong proof would be, for example, one that would demonstrate the spin-charge separation inherent in a LL. Such work has not been reported to date.

5.4.3. Coulomb Blockade

Coulomb blockade effects are rather central in mesoscopic physics [171]. In the experimental studies on low temperature transport processes in single-carbon nanotubes, they have been almost always present. They occur most prominently in a situation where a mesoscopic scale conductor is isolated by tunneling barriers between two electrodes, and thus form an "island" between the electrodes. The island has a capacitance C, and if the charging energy of a single electron $E_c = e^2/C$, is larger than the thermal energy ($E_c \gg k_B T$), then the system will not conduct due to the e–e repulsion. The other fundamental requirement is the that the contact resistances have to be large enough to form tunneling barriers: $R_c \gg R_k = h/e^2$. Such a system forms a single electron transistor (SET). Coulomb blockade may also occur in a single junction system, which, however, requires a very high impedance in one of the conductors. The Coulomb blockade in a SET can be modulated by a gate electrode from full blocking to a conducting state limited only by the tunneling barriers.

When nanotube-based SETs are discussed, it should be noted that up to now the tunneling barriers from metal electrodes to the nanotube have been formed without the intentional deposition of an insulating layer between the metal and the tube, unlike in other SET systems. The tunneling barriers are said to form from unavoidable impurities or, especially in the case of SWNTs, from the bending of the tube on the electrodes. The capacitance between the electrode and the tube is formed from the self-capacitance of the tube and the barrier capacitance at the nanotube-electrode junctions. With a typical junction length of 200 nm and a nanotube length of 1 μm, the capacitance is $\sim 10^{-17}$ F. This gives an E_c of ~ 10 meV, and thus the Coulomb blockade of a typical nanotube SET occurs at temperatures below 10 K ($k_B T$ should be $<0.1\ E_c$).

Nanotube SETs have been realized to date in different versions. In the simplest case, two metal electrodes are attached to the nanotube so that a tunneling barrier is formed between the tube and the metal (this easily happens unintentionally). The electrode spacing varies in the range 0.1–1 μm. This gives the spacing between the energy levels, ΔE, in the nanotube section to be measured, in the range 1–10 meV. That is, ΔE and E_c can be of the same order of magnitude. Energy-level quantization in the Coulomb blockade of SWNTs was for the first time measured in Refs. [172, 173].

A pure SET requires tunneling resistances much larger than R_K. As this condition is gradually relaxed, other effects are present alongside the Coulomb blockade, such as Kondo effects [174] and shell filling of individual quantum states [175]. As the tunneling resistance becomes small compared to R_K, and if the tube is ballistic, we recover the situation with ballistic conduction, already described.

More elaborate SETs can be built with nanotubes than the simple metal-nanotube systems described above. Figure 12 shows two crossing arc-discharge MWNTs; the lower one is contacted at both ends with gold electrodes and the upper tube with one electrode [176]. The lower tube acts as the island of a SET while the upper tube functions as a highly proximate gate electrode. Figure 13a shows the I–V
Figure 12. A SET made from two arc-discharge MWNTs. The horizontally directed (lower) tube forms the island, connected to source and drain electrodes, and the upper tube forms a highly proximate gate. Reprinted with permission from [176], M. Ahlskog et al., *Appl. Phys. Lett.* 77, 4037 (2000). © 2000, American Institute of Physics.

curves at different temperatures and Figure 13b shows current modulation using the nanotube gate. The close proximity of the nanotube gate translates into a small Coulomb oscillation period. It is of course also possible to place several tubes on the "island-tube" and thus create several local potential barriers on the tube. Two groups have used AFM manipulation to make two sharp bends very close to each other (<100 nm) on a single SWNT [132, 133]. In a SWNT, a sharp bend creates a tunneling barrier, thus two next to each other results in an intra-tube SET. The main advantage, besides the miniaturization aspect, is the very high Coulomb energy, due to the ultrasmall capacitances, resulting in a SET that works at temperatures close to room temperature. In another approach [177], single semiconducting nanotubes were covered with PMMA resist and small (∼100 nm) openings developed into the resist, which allowed selective doping to be done on small sections of the tube, thus creating local islands separated by *p–n* junctions.

5.4.4. Superconductivity

Concerning the study of intrinsic transport phenomena in metallic carbon nanotubes, two other lines of development have appeared that we will briefly mention here, namely superconductivity and highly disordered tubes.
Figure 13. (a) The *I–V* curves at different temperatures of the SET of Figure 12 and (b) current modulation at 150 mK using the nanotube gate. Notice the small magnitude of the gate voltage (V_g) required to produce Coulomb oscillations. Reprinted with permission from [176], M. Ahlskog et al., *Appl. Phys. Lett.* 77, 4037 (2000). © 2000, American Institute of Physics.

Superconducting phenomena in connection with the single carbon nanotube were first observed as the proximity effect with SWNTs or SWNT ropes connecting two superconducting electrodes [178, 179]. Later, a smooth superconducting transition was observed at sub-Kelvin temperatures in a few SWNT rope samples that were connected to normal electrodes (Pt/Au) [160]. These SWNT ropes were suspended with a unique technique developed earlier. The observed transition was gradual rather than abrupt as is the case for 1D systems. The Meissner effect could not be checked in this case due to residual metallic impurities present in macroscopic amounts of the material. Superconductivity was also reported in bulk samples of ultrasmall diameter SWNTs grown inside zeolites [161]. A smooth transition at around 10–15 K was observed with a squid magnetometer, that is, the Meissner effect.

5.4.5. Transport in Disordered Tubes: MWNTs

One of the advantages of carbon nanotubes is the very high degree of structural perfection often seen in them. As was noted above, transport measurements often indicate ballistic behavior among SWNTs, while among MWNTs, with diameters in the 10–20 nm range, diffusive behavior is more the norm. The density of defects in MWNTs depends strongly on the synthesis conditions, and especially, it is believed, on the growth temperature. Arc-discharge tubes are grown at temperatures approaching 2000 °C while in the CVD growth the temperature is well below 1000 °C. The resulting structural difference is immediately apparent as can be seen in Figure 5. With present knowledge, the mean free path is rather small even in the arc-discharge MWNTs. Axial magnetoresistance measurements on such tubes revealed Aharonov–Bohm oscillations with a period that matched the nanotube circumference [180]. Transport measurements on highly disordered CVD grown tubes were undertaken recently [181]. These measurements probed the intrinsic behavior of the tubes since contact resistances were very low. A typical resistivity of 80 kΩ/μm was reached. At low temperatures (<10 K) a zero-bias anomaly developed that was not due to Coulomb blockade, since the contact resistances were low. Possible explanations are disorder-induced *e–e* interaction effects or raised electron gas temperature due to Joule heating in a diffusive conductor.

5.5. Semiconducting Tubes

Semiconducting nanotubes are especially important for device-oriented applications. To date, semiconducting behavior has been observed in single SWNTs. In MWNTs and SWNT ropes, there usually exists individual shells of both the metallic and semiconducting kinds, as has been demonstrated by the IBM group [162]. Therefore pure semiconducting behavior in MWNTs has rarely been mentioned. Semiconducting behavior in carbon nanotubes is demonstrated in a FET configuration. Typically with semiconducting SWNTs it is observed that the conducting state is attained with negative gate voltages, implying that the carbon nanotube forms a normally-off *p*-type conduction channel. Thus a semiconducting carbon nanotube is unintentionally *p*-doped, with oxygen as the likely dopant.

Figure 14 shows a schematic figure of such a device and its transistor characteristics [182]. The IBM group has shown that a higher transconductance can be achieved with SWNT-based FETs than with state-of-the-art silicon MOSFETs, which is encouraging, especially considering that the fabrication technique of nanotube-FETs is far from optimized. The resistance in the metallic state (ON state) is typically in the range 20 kΩ–1 MΩ. With the fabrication of gate electrodes that are strongly coupled to the nanotube, it is possible to reach ambipolar transistor action, achieving both *n*- and *p*-type behavior. Logic gates made from nanotube FETs have recently been demonstrated [183]. The nature of the Schottky barriers between bulk metal electrodes and the SWNT, a 1D object, is still being investigated [184].

6. ELECTRONIC APPLICATIONS

6.1. Introduction

Carbon nanotubes have attracted the label "building-blocks of nanotechnology" due to the range of realized and potential applications. Successful technology involving the nanoelectronic applications promises to be extremely lucrative, but the absence of reliable preparation methods for metallic or semiconducting nanotubes, either by selective synthesis or post-synthesis separation, is a major obstacle. This impediment has not been a factor in the development of nanotube-based electron sources for vacuum microelectronics. The recent establishment of pilot plants with gram

quantities per day capacity has spurred those applications that require bulk quantities of carbon nanotubes. Mass production should drive the cost down from the present $500 per gram. Production of thousands of kilograms per week from a single plant by 2004 is predicted [185]. In the immediate term, controlled growth of aligned carbon nanotube patterns will be a significant factor in several emerging applications [186].

6.2. Prospects for Nanoelectronic Applications

6.2.1. Highly Integrated Circuits

Since discovery, exploitation of the electronic properties of carbon nanotubes outlined in the previous chapters has been the driving force behind much of the research efforts directed at applications. The prospect of device densities 10^4 times greater than present day microelectronics places semiconductor carbon nanotube electronics among a number of competing technologies poised to complement or replace CMOS in the <100 nm feature-size domain [187]. As outlined in Section 5, nanotube-based electronic devices have much to offer: conductivity, electromigration, and current carrying capacity of metallic nanotubes are as good as or better than the best metal nanowires, and semiconducting nanotubes exhibit carrier mobilities and transconductancies that meet or exceed those of the best conventional semiconductors. However, there are several major barriers to the development of highly integrated circuits: (i) Current synthesis techniques produce mixtures of metallic or semiconductor nanotubes, and these tend to form in ropes or bundles; (ii) the precise nature of nanotube-metal contacts is poorly understood, but the exact atomic arrangement at the interface and the gaseous environment appear to be significant [188]; and (iii) those nanotube SPM manipulation techniques used to demonstrate single devices are totally inappropriate for manufacture of highly integrated circuits. To date, no reliable method of producing contacted carbon nanotubes of predetermined electronic structure has been demonstrated. Complex arrays of nanotube-based devices are perhaps a distant prospect, but there appear to be no fundamental barriers to the development of the technology.

Nevertheless, the potential reward for successful technology is enormous and is likely to continue to be a motor of nanotube research.

6.2.2. Interconnect

The use of carbon nanotubes as wiring for interconnection of nanoscale circuit elements is being explored primarily because SWNTs can carry a current density of up to 10^9 Acm^{-2}, compared to 10^5 Acm^{-2} for normal metals [189]. Ballistic transport on the micrometer scale suggests that nanotubes are good candidates for high-bandwidth, dissipationless interconnect. Wet processing of nanotubes tends to degrade the electrical properties, so methods of guiding nanotubes to span the desired circuit elements during growth or deposition processes are being explored. Guiding through via holes [190], by electric field [191], or surface modification [192], as well as uncontrolled self-assembly methods have been demonstrated [193], with some degree of success [194]. However, a high-growth temperature (>900 °C) incompatible with standard silicon processing is required if CVD-grown carbon nanotubes are to exhibit truly ballistic transport, thus severely limiting the possibility of integration with CMOS circuits. The usefulness of nanotube ballistic interconnect is also limited by the fact that large contact resistances are necessarily involved. A circuit involving electrical contacts to a SWNT will have a resistance of at least $h/4e^2$, or 6.5 kΩ [195]. Moreover, although nanotube interconnect promises high frequency response, any conventionally wired external circuits will determine the response of a complete system.

6.3. Vacuum Microelectronics

Carbon nanotubes are ideal field emission electron sources for various vacuum microelectronic applications due to the high aspect ratio, current carrying capacity, and chemically passive tip. The essential physics of the field emission process is contained in the expression for the current density emitted from an ideal metal surface, the Fowler–Nordheim equation: $J = aF^2 \exp(-b\phi^{3/2}/\beta F)$ where J, F, ϕ, and β are the current density, applied macroscopic field, work function, and field enhancement factor (the ratio of the microscopic local field at a protrusion to the macroscopic applied field), respectively. The β factor calculated from the geometry of a single carbon nanotube is approximately equal to the aspect ratio, or ~1000. The average work function for an ensemble of nanotubes is ~5 eV, comparable to that of graphite and 0.4 eV greater than that of the most widely used field emission metal, molybdenum. Soon after discovery, it was assumed that nanotubes would be superior field emitters due to the high field enhancement at the tip; this was finally demonstrated in 1995 [196], and has since been the subject if intense investigation. Single SWNT [196], single MWNT [197], thin films of aligned nanotubes [198], and composite materials with nanotube inclusions [199] have all proved to be excellent field emission electron sources. The exact performance is highly dependent on the synthesis conditions, electronic screening effects, open- or closed-tip structure [200], and the role of surface absorbates [201]. Unlike ordinary metal surfaces, emission occurs from discrete energy states rather than continuous bands [202]. A low threshold field of typically 1–5 V/μm for a stable long-lifetime emitted current density of 10 mA/cm^2 is common, and current densities as high as 4 A/cm^2 have been obtained [203]. Nanotube-based field emission materials can be relatively easily manufactured by screen printing nanotube-loaded pastes [204] and require a moderate vacuum of 10^{-8} torr for acceptable performance. This has considerable advantage over microfabricated arrays of tungsten or molybdenum operating in 10^{-8} torr that are the bases of conventional vacuum microelectronics.

6.3.1. Field Emission Display

Field emission displays (FEDs) are the nanotube applications with the largest potential market and industrial interest. Conceptually the FED is simple; electrons are emitted from a cathode in vacuum, accelerated toward a parallel-plate anode by a directed electric field, where the kinetic energy is imparted to a phosphor producing emitted light. FEDs offer power consumption, brightness, response time, and operating temperature advantages over liquid crystal display (LCD) technology that currently dominates the flat panel display market. However, FEDs are technically complex, requiring not just a low threshold-voltage emission material, but also significant advances in phosphor technology, spacer elements capable of sustaining high vacuum and electric field, and pixel addressing circuitry [205]. Whether nanotube-based FEDs will overcome these obstacles to compete with low-cost flat panel LCD or emerging organic light emitting diode technologies is uncertain. Nevertheless, Samsung has produced several generations of prototype FED ranging from 4.5 inch (Fig. 15) with red-green-blue phosphor columns [206] to 9-inch moving-image display [207].

Figure 16. SEM image of the apex of a conventional micromachined Si AFM tip with protruding CVD-grown MWNT.

Lighting elements with nanotube-based field emission surfaces that work on essentially the same triode principles as the FED and suitable as pixels for very large area displays have been fabricated by Ise Electronics in Japan [208].

6.3.2. E-Beam Lithography

The present minimum feature size in the semiconductor industry is 130 nm, which is achieved using extreme ultraviolet optical lithography. This technology is currently limited by the wavelength of the light and the available UV optics used to project the pattern onto a silicon wafer. Alternative technologies are being explored for production of future <100 nm devices. Conventional electron beam lithography can already deliver 5 nm minimum feature size but is limited by the writing time as a single beam is used for writing the entire pattern. Thus arrays of microelectron guns operating in parallel are being considered as a route to drastically reduce the writing time while maintaining the high resolution of electron beam lithography. Carbon nanotubes are currently the most promising candidates for use as the emission source [209].

6.3.3. Microwave Devices

Electrons transported in vacuum have a higher mobility than in materials; consequently vacuum microelectronic devices find application when higher power and higher current levels than can be achieved in solid-state devices are required. One such application with a carbon nanotube field emitter is the microwave power amplifier tube. The outstanding technical challenge is to improve the lifetime of the emitter for operation >0.5 A/cm^2 [210].

6.3.4. X-Ray Source

The design of X-ray tubes has remained unchanged for a century, comprising thermionically generated electrons accelerated toward a metal target. Continuous and pulsed X-ray sources based on a carbon nanotube field emitter with a metal anode capable of producing medical diagnostic X-rays have been recently demonstrated [211, 212]. For biological samples, the quality of image produced by these sources is an improvement on those from conventional sources, probably because the energy distribution of emitted electrons is narrower than that of electrons thermionically emitted from metal wires. The compact geometry of these devices suggests that they may be further developed as portable sources and as probes for medical exploration.

6.4. Electrochemical Devices

The high electrochemically accessible surface area, high electrical conductivity, and desirable mechanical properties make porous nanotube arrays attractive materials for devices that use electrochemical double-layer charge injection.

6.4.1. Electrodes

High-power electrochemical capacitors (also called supercapacitors) based on carbon nanotube array electrodes are under development [213]. The capacitance of an electrochemical capacitor depends on the separation between the electrode charge and the counter charge in the surrounding electrolyte. With nanoscale separation and high surface area available in nanotube arrays, capacitances of typically 10–100 F/g can be achieved. This value is much greater than for conventional dielectric capacitors. A high degree of charge injection can be achieved with just a few applied volts and thus very efficient energy storage. Further developments are likely, with debate focussing on the suitability of MWNTs, SWNTs, and composite materials [214, 215].

6.4.2. Actuators

Electromechanical actuators based on SWNT sheets have been shown to generate higher stresses than natural muscle when operating in physiological conditions and higher strains than high-modulus ferroelectrics [216]. The actuation mechanism is a geometrical expansion of the carbon–carbon covalent bond caused by electrochemical double-layer charging; it requires low operating voltages to generate large strains. Work densities per cycle substantially higher than any previously known technology are predicted for SWNT sheets with mechanical properties close to those of individual SWNTs. This can be achieved by intertube binding and alignment optimization [217]. These promising results suggest that actuators based on a single (or a few hundred) nanotubes will lead to applications on the micro- or nanoscale in the biomedical and electronic fields.

6.5. Nanoprobes

The high stiffness, aspect ratio, and nanoscale tip make nanotubes excellent probes for sensing, testing, manipulation, and fabrication on the nanoscale.

6.5.1. Scanning Probe Microscopy

Both SWNTS and MWNTs have been extensively used as tips for scanning probe microscopy (SPM) in the life and physical sciences. The report by Dai et al. [218] on the use of MWNTs attached directly to silicon cantilevers signaled a major advance for SPM techniques. The demonstrated and potential advantages are such that nanotube probes are likely to replace conventional Si and Si_3N_4 probes in the near future. The dimensions and electronic and mechanical properties of nanotubes are ideal for SPM tips. The low tip-to-surface capacitance and contact area that is independent of clamping force give carbon nanotubes great advantages over micromachined SPM probes for electronic probing and contacting. Carbon nanotube tips have been applied to atomic force microscopy (AFM) in contact [218] and noncontact mode [219], spin-resolved scanning tunneling microscopy, chemical force microscopy, and scanning electrochemical microscopy [220]. This range of SPM techniques will be undoubtedly extended in the near future to those probes commonly used to give quantitative electronic information such as conducting AFM, scanning tunneling spectroscopy, electrostatic force microscopy, Kelvin probe microscopy, and scanned gate microscopy.

6.5.2. Sensors

The possibility of chemical sensor applications of nonmetallic nanotubes became apparent when thermoelectric power measurements revealed very high sensitivity to gaseous ambients that affect the amount of injected charge [221, 222]. MWNTs exhibit ultrahigh sensitivity at room temperature to O_2, N_2O, NH_3, CO, CO_2, and humidity [223]. Electronic tuning from *p*- to *n*-type by liquid electrolyte was demonstrated with a MWNT in a FET configuration [220]. The appeal of nanoscale sensing elements is the correspondingly low quantity of species required to stimulate a response. Nanotube sensors certainly have prospects for challenging conventional gas sensors for certain uses and becoming lab-on-a-chip sensing elements for biomedical applications. However major obstacles remain, the forward and reverse response of nanotube gas sensors is not symmetrical because the species that induce a response are often strongly physisorbed; also a response that can differentiate species in complex gas species is often required.

6.5.3. Manipulators

Nanoscale electromechanical manipulators, nanotweezers, based on carbon nanotubes have been developed for manipulation and electrical interrogation of nanostructures [224]. The tweezer action is driven by electrostatic attraction between two contacted nanotubes mounted on a tapered glass probe. Manipulators such as these are likely to be integrated with scanning probe microscopy and other measurement systems to provide the tools for the characterization and manipulation on the nanoscale [225].

6.5.4. Fabricators

Carbon nanotube AFM tips for fabricating oxide nanostructures in Si and Ti by anodization is a rapidly expanding field aimed at Tbit/cm^2 data storage [226]. The technique utilizes ambient moisture in the oxidation process with the tip biased negatively relative to the surface. Line widths of 5–10 nm suitable for antidots and tunnel junctions can be achieved.

6.6. Nanoelectromechanical Systems

Nanoeletromechanical systems (NEMS) is a term that embraces the actuator, manipulator, and sensor applications outlined above. The impact of NEMS is likely to be as significant as microelectromechanical systems [227]. Carbon nanotubes are promising for the design and development of NEMS, not only because of the excellent mechanical and electrical properties, but also because the significant progress in the fabrication of carbon nanostructures of the last few years points to possible implementation of recently proposed carbon nanotube-based NEMS devices such as a nonvolatile random access memory for molecular computing [228]. The predicted behavior of carbon nanotube nanoelectromechanical switches—the basis of many NEMS devices—is favorable [229], and electronic properties have been shown to be reversible with mechanical deformation by a local probe [230].

GLOSSARY

Density of states (DOS) The density of electronic states as a function of the energy.

Electron beam lithography A method for micro- and nanoscale fabrication where a pattern on a polymeric layer (resist) is exposed to electron irradiation. In research laboratories the electron exposure is performed with a modified scanning electron microscope (SEM).

Field effect transistor (FET) A transistor where the current between two electrodes (drain and source) is modulated by the electric field from a third electrode (gate).

Field emission The emission of electrons from a metal or semiconductor into vacuum or dielectric under the influence of a strong electric field.

Fullerene (C_{60}) A soccer-ball shaped spherical and hollow molecule consisting of 60 carbon atoms.

Magnetoresistance The electrical resistance of a sample or device as a function of the magnetic field.

Mesoscopic physics A new branch of condensed matter physics where physical phenomena are studied at length scales larger than the atomic level but smaller than macroscopic scales.

Molecular electronics A term for such devices that have single molecules as the active component.

Raman spectroscopy An optical characterization tool of matter that utilizes the Raman effect.

Scanning probe microscopy The generic term given to microscopy techniques that use a scanned micro- or nanoscale tip in immediate proximity to a surface to image its topology or other physical features with almost atomic resolution. The main types are scanning tunneling microscopy (STM) and atomic force microscopy (AFM).

Tunneling conduction A process for charge conduction where the charge carriers pass through an energy barrier by quantum mechanical tunneling.

Young's modulus A quantity that describes the stiffness of a material.

Electronic Properties
of Carbon Nanotubes

J. González

Consejo Superior de Investigaciones Científicas, Madrid, Spain

CONTENTS

1. INTRODUCTION

Carbon nanotubes are tubular structures that can be thought of as the result of wrapping up the carbon honeycomb lattice of a graphene sheet. They were discovered in 1991 with the use of high-resolution transmission-electron microscopy, by observing the soot produced from an arc discharge between carbon rods [1]. Since then they have been a fascinating subject of research due to their remarkable mechanical, chemical, and electronic properties [2]. Carbon nanotubes have become very promising in the field of molecular electronics, in which atoms and molecules are envisaged as the building blocks in the fabrication of electronic devices. In this respect, the great expectations placed on the nanotubes are also shared by the fullerenes [3]. These also can be thought of as being assembled from the hexagonal carbon rings of a graphene sheet, by making a close cage by insertion of twelve pentagonal rings. The multiple forms and shapes in which the carbon-based materials may appear, with varying physical and chemical properties, are what make them so interesting for the purpose of designing and fabricating nanoscale devices.

The nanotubes as well as the fullerenes have a molecular structure that makes them particularly suitable to develop an alternative, at the nanometer scale, to the silicon-based integrated electronics. It is known, for instance, that nanotubes have a remarkable stiffness along the tubular direction, reinforcing the structure of the components based on them. On the other hand, the design of electronic devices at the molecular scale requires taking into account novel effects which stem from the reduced dimensionality of the systems under consideration. In the case of individual single-walled nanotubes at low temperatures, it has been shown that the electron waves may remain extended along the nanotubes over lengths of several microns [4, 5]. This means that the motion of the electrons cannot be understood in terms of classical diffusion, and that instead they show a genuine quantum-mechanical behavior, up to the point that interference patterns between the electron waves can be observed [6].

The behavior of the nanotubes as true quantum wires leads to remarkable predictions, like the ballistic transport along the longitudinal direction. This effect seems to have been observed in multiwalled nanotubes [7], which have an onion-like structure of concentric single-walled nanotubes. The very large current densities observed there (above 10^7 A cm^{-2}) seem to be only compatible with transport without dissipation in the nanotube structure. On the other hand, single-walled nanotubes are also commonly found forming close-packed ropes. Their behavior may give rise to interesting features, because the strong Coulomb repulsion between electrons existing in the isolated nanotubes is screened due to the intertube interactions between a large number of metallic nanotubes. A superconducting transition at temperatures below 1 K has been observed in ropes made of about three hundred nanotubes [8]. Superconductivity seems to be also a plausible phenomenon in small-diameter nanotubes, where the coupling of the electrons to lattice vibrations is largely enhanced [9].

The main goal in designing nanotechnology devices is to tailor the molecular structures to achieve a given functionality. In that respect, the various geometries that the nanotubes may adopt and the possibility of assembling them with other carbon structures open the way to the construction of common electronic devices such as diodes [10],

transistors [11–14], memory elements [15], and logic circuits [16, 17]. As explained in Section 2, the nanotubes may have metallic or semiconducting properties depending on the way the graphene sheet is wrapped [18–20]. The nanotube structure can change along the tubule from one class to the other by the presence of topological defects, that is, heptagonal and pentagonal rings in the hexagonal carbon lattice [21–23]. This kind of intramolecular junctions has shown diode-like rectifying properties [10]. Furthermore, transistors working with a single nanotube element have been produced, either by the field effect on semiconducting nanotubes [11–13] or by constraining single electrons to short islands between two buckles in a metallic nanotube [14]. An alternative to these structures can be the use of Y-junctions in which two single-walled nanotubes merge into one at a given angle [24, 25]. The response characteristics of such devices have shown interesting properties, including nonlinear transport behavior and current rectification [26–29].

One of the challenges of the carbon nanotube-based molecular electronics is the controlled high-yield production of the relevant structures in the design of the electronic devices. The progress in the development of new techniques and the synthesis of new structures is constant. Very promising is the formation of supramolecular assemblies in which fullerene cages are inserted in the hollow structure of the nanotube [30–32]. It has been shown that the presence of the fullerenes leads to a modulation of the gap in the case of the semiconducting nanotubes [33]. When the fullerenes are disposed forming an array inside the nanotube, the hybridization of the fullerene molecular orbitals with the states in the nanotube conduction band gives rise to a band with mixed fullerene-nanotube character [34]. Surely the interplay between the properties of the carbon nanotubes and the electronic features of the fullerenes has to give rise to new physical effects, opening the way to different routes in the design of components in molecular electronics.

2. METALLIC VERSUS SEMICONDUCTING NANOTUBES

2.1. Band Structure of Carbon Nanotubes

A remarkable feature of the single-walled carbon nanotubes is that their conduction properties depend on the helical arrangement of the hexagonal carbon rings on the tubular structure. Thus, carbon nanotubes can be metallic or semiconducting as a consequence of their particular geometry and, when a gap develops in the low-energy spectrum, it also depends on the diameter of the nanotube. These properties follow from the band structure of the tubular arrangements, which is composed of a certain number of one-dimensional subbands depending on the thickness of the nanotube. The conducting properties can be formally ascertained by addressing the question of whether the Fermi level crosses or not some of the subbands. The prediction of the metallic and semiconducting properties of the nanotubes depending on their geometry was actually made on theoretical grounds in 1992 [18–20]. Although the electronic properties of the nanotubes had been studied for some time, it was not until 1998 that their structure was atomically resolved by using scanning tunneling microscopy [35, 36].

In this way, it has been possible to establish experimentally the correspondence between the conducting properties and the geometric structure of the individual single-walled nanotubes.

Except in cases where the nanotube diameter is very small [37–39], the band structure of the individual nanotubes can be understood from the band dispersion of a graphene sheet, after applying the periodic boundary conditions arising from the winding of the hexagonal rings around the axis of the nanotube. The conduction properties can be obtained qualitatively from the hybridization of the carbon π orbitals, which gives rise to respective bonding and antibonding bands in the graphite sheet. The two-dimensional Brillouin zone is a hexagon and the electron energy-momentum dispersion $E(\mathbf{k})$ takes the following form in the tight-binding approximation [40]:

$$E(\mathbf{k}) = \pm t \sqrt{1 + 4\cos^2(\sqrt{3}k_x a/2) + 4\cos(\sqrt{3}k_x a/2)\cos(3k_y a/2)} \tag{1}$$

where a is the nearest-neighbor carbon–carbon distance (≈ 0.14 nm) and t is the energy scale (≈ 2.5 eV) given by the matrix element between neighboring π orbitals. The bonding π band of the dispersion relation (corresponding to the $-$ sign in front of the right-hand side of Eq. (1)) has the shape depicted in Figure 1. The cusps are attained at the corners of the hexagonal Brillouin zone, which correspond to the momenta

$$k_x = \pm \frac{4}{3\sqrt{3}}\frac{\pi}{a}, \qquad k_y = 0 \tag{2}$$

$$k_x = \pm \frac{2}{3\sqrt{3}}\frac{\pi}{a}, \qquad k_y = \pm \frac{2}{3}\frac{\pi}{a} \tag{3}$$

It has been shown that, for typical nanotubes with diameter above 1 nm, the carbon σ orbitals have a weak influence on the bonding π band, and that the bonding σ bands appear in the spectrum at energies below ~ -2 eV [18].

When the graphene sheet is not doped by impurities or other means, each carbon atom contributes with one electron to the above band structure which, taking into account the spin degeneracy, turns out to be half-filled. The Fermi level is found then at the cusps connecting the lower and upper branches of the band dispersion given by Eq. (1), so that the graphene sheet is a remarkable two-dimensional
Figure 1. Representation of the first Brillouin zone and band structure of graphene and carbon nanotubes. (a) Dispersion of the bonding π band in graphene. (b) Plot of the allowed wavevectors (vertical lines) in the first Brillouin zone for a zigzag nanotube with $N = 11$. (c) Same plot as in (b) for a zigzag nanotube with $N = 12$.

system which has a set of isolated Fermi points (only two of them being inequivalent) when the carbon lattice is half-filled.

The passage from the electronic states in the graphene sheet to those allowed in the carbon nanotubes can be made by enforcing the conditions satisfied by the electron wavefunctions when winding around the waist of the tubule. This is the point where the geometry of the nanotube plays a crucial role, since many different possibilities exist characterized by the helicity of the carbon lattice on the tubular structure. A simple instance is given by the so-called *zigzag* nanotubes, in which the graphene lattice is wrapped in the direction depicted in Figure 2, and that receive their name from the /\/\/\/\ shape perpendicular to the tube axis. Another significant case corresponds to the *armchair* nanotubes, so called because of the pattern /‾_/‾_/‾\ that they display after forming the tubular arrangement with the axis as depicted in Figure 3.

The analysis of the zigzag and the armchair nanotubes gives insight about the general argument by which a single-walled nanotube can be catalogued as metallic or semiconducting. The different subbands of a nanotube can be obtained from the band dispersion in Eq. (1) by taking into account that the electron wavefunction $\Psi(\mathbf{r})$ has to be single-valued after taking a close path around the tubule. Its dependence on the position $\mathbf{r}$ (measured with the coordinates of the graphene sheet) is of the form

$$\Psi(\mathbf{r}) \sim \exp(i\mathbf{k} \cdot \mathbf{r}) \qquad (4)$$

This means that the argument of the exponential has to increase by a multiple of 2π times i after going once around the waist of the nanotube.

In the case of a zigzag nanotube with lattice vector $\mathbf{T}_1$ in the direction perpendicular to the axis, as shown in Figure 2, we must have

$$N\,\mathbf{T}_1 \cdot \mathbf{k} = 2\pi n \qquad (5)$$

where N is the number of hexagons found when going around the nanotube and n is an integer number. The preceding constraint translates into the quantization condition

$$k_x = \frac{2\pi}{\sqrt{3}a}\frac{n}{N} \qquad (6)$$
Figure 2. Left: Schematic representation of the wrapping action leading to a zigzag nanotube. Right: Band structure of a zigzag nanotube with $N = 11$. (The energy is measured in units of the overlap integral and the momentum in units of the inverse lattice spacing.)
Figure 3. Left: Schematic representation of the wrapping that leads to an armchair nanotube. Right: Band structure of an armchair nanotube with $M = 10$ (in the same units as in Fig. 2).

which gives the allowed wavevectors in a zigzag nanotube. These correspond to a certain number of straight lines in the Brillouin zone, that have been shown for the particular cases of $N = 11$ and $N = 12$ in Figure 1. Each line corresponds to a one-dimensional subband for the tubular structure. In general, an undoped carbon nanotube can have metallic properties only when there is some subband passing by the points where the bonding and antibonding bands meet. According to Eqs. (2) and (3) and the quantization condition (6), that only happens in the case of a zigzag nanotube when the number N of hexagons around the circumference is a multiple of 3 [18, 19]. A narrow gap may open, however, due to the different strength of the electron transfer in the direction perpendicular to the tube axis, which leads to a shift of the Fermi points (in the k_x direction) from the corners of the Brillouin zone. If the number N is not a multiple of 3, a moderate gap Δ opens in the spectrum [18, 19], with a dependence on the diameter d of the form [2, 3]

$$\Delta = 2ta/d \qquad (7)$$

This sensitive dependence of the conducting properties of the nanotubes is illustrated by the band structure of the zigzag nanotube with $N = 11$ shown in Figure 2.

Moving now to the case of the armchair nanotubes, the periodic boundary conditions imply a similar quantization condition on the component k_y of the momentum, which is now in the direction transverse to the tubule axis. Calling M the number of lattice periods along the circumference of the nanotube, the requirement of having single-valued wavefunctions leads to the condition

$$k_y = \frac{2\pi}{3a}\frac{n}{M} \qquad (8)$$

n being again an integer number. The set of allowed wavevectors corresponds to a certain number of straight lines in the Brillouin zone, perpendicular to those found in the case of zigzag nanotubes. Now there is always a subband at the point where the bonding and antibonding π bands meet, irrespective of the value that M may take. This is shown in the band structure for $M = 10$ represented in Figure 3. It turns out, therefore, that all the armchair nanotubes have subbands crossing the Fermi level, and that they remain metallic even taking into account the effects due to the curvature of the tubule [18–20].

over a wider range of energies, larger than 1.5 eV. The manifest nonvanishing value of the conductance, together with its smooth behavior, is the signature of the metallic character in the nanotubes. When this happens, the geometric structure of the nanotubes has been shown to correspond either to armchair nanotubes or to chiral nanotubes with the helicity suitable for metallic behavior. It has already been mentioned that, in the latter case, a small gap, of the order of $\sim$0.01 eV, should open at the Fermi level by effect of the curvature of the nanotube. Such a gap, however, has been only observed through high-resolution measurements of the conductance in zigzag nanotubes of $(3n, 0)$ type [43]. It is believed that, in the case of the chiral nanotubes of $(3n + m, m)$ type, the small-gap feature tends to be even tinier [44] and its observation may be then precluded by the instrumental noise.

The use of tunneling spectroscopy has given then important information about the band structure of the carbon nanotubes. It has shown that they can be considered as molecular wires. The proportion of the semiconducting nanotubes in the whole set considered in the experiments seems to agree with the ratio of two thirds predicted from pure theoretical arguments. Another important point is that the measures taken on metallic nanotubes in a rope are similar to those on isolated metallic nanotubes, as reported in [36], which seems to imply a weak intertube coupling of the nanotubes within a rope.

The fact that a slight variation in the geometric structure of a carbon nanotube may produce important changes in the conducting properties opens the possibility to build metal–semiconductor or semiconductor–semiconductor junctions in a single molecule. This requires changing the helicity within the same carbon nanotube, which can be achieved by introducing topological defects like combinations of heptagon and pentagon carbon rings in the nanotube lattice [21–23]. A pentagonal ring induces some local curvature in the hexagonal lattice, which can be superposed on a plane and has therefore no intrinsic curvature. The curvature of the pentagonal ring has to be counterbalanced with the opposite induced by an heptagonal ring in order to recover the tubular structure.

The combination of adjacent pentagonal and heptagonal rings has been proposed in [21] to produce changes in the chirality of a nanotube from an (n, m) structure to another of $(n \pm 1, m \mp 1)$ type. The particular case of a junction between $(8, 0)$ and $(7, 1)$ nanotubes has been analyzed, studying in detail the change in the band structure across the interface. This would be a typical instance of a semiconductor–metal junction, and the evolution of the gap along the nanotube has been established theoretically by computing the local density of states. The example of a semiconductor–semiconductor junction formed by $(8, 0)$ and $(5, 3)$ nanotubes has been also studied, stressing the appearance of interface states in the gap from the presence of three pentagon-heptagon defects [21].

Experimental observations of the carbon nanotube intramolecular junctions have been already carried out [10, 45]. In the experiments reported in [45], the atomic structure of the nanotube segments at each side of the junction has been resolved by using scanning tunneling microscopy. This has made it also possible to study the evolution through the junction of the different features in the local density of states. On the other hand, the experiments presented in [10] have investigated the peculiar transport properties of the intramolecular junctions.

In atomic force microscope images, the intramolecular junctions appear as kinks in individual carbon nanotubes, as illustrated in Figure 5 taken from [10]. The large angle formed by the two segments at each side of the junction requires that the heptagon and pentagon rings are located at opposite sides of the nanotube section. By employing the electrodes shown in the figure, it has been characterized that the nanotubes in Figure 5a give rise to a metal–semiconductor junction, while those in Figure 5b provide an example of a metal–metal junction [10].

The conductance through the kink is very different for the two samples shown in Figure 5. In the sample shown to the left, the resistance at zero bias voltage is extremely large, higher than 250 GΩ [10]. The current I measured as a function of the bias voltage V (I–V characteristics) displays a highly nonlinear behavior. With no voltage applied to the gate, the current shows a small increase when a negative bias voltage is applied to the electrodes, while it shows a sharp increase for a positive voltage above 2 V (applied to the upper electrode) [10]. The kink induces therefore a rectifying behavior in the current, which has led to the proposal that it could be used as a molecular device resembling a diode. It has been stressed in [10] that the I–V characteristics become more asymmetric as a gate voltage is applied to the substrate. This has been presented as evidence that the lower segment of the nanotube in Figure 5a is semiconducting. The upper segment is metallic in any event, since its resistance of 110 kΩ (measured at room temperature) does not show dependence on the gate voltage [10].

It has been established that the kink in Figure 5b produces a metal–metal intramolecular junction [10]. The behavior of its conductance, however, cannot be understood in the framework of the single-electron picture described previously, which does not take into account the effects of the Coulomb interaction. This leads to a strong correlation

Figure 5. (a), (b) Atomic force microscope images of intramolecular junctions of carbon nanotubes. The pads seen in the figures correspond to titanium-gold electrodes embedded in the SiO$_2$ substrate, with the nanotubes placed on top of them. (c) Model of a kink created by the combination of the pentagonal and the heptagonal ring marked in the figure, and which gives rise to a junction between armchair and zigzag nanotube geometries. between the electrons in materials with reduced dimensionality. The features introduced by the electron-electron interaction in the behavior of the carbon nanotubes are reviewed in the following sections. See Table 1 for a summary of the physical constants reflecting the electronic properties of carbon nanotubes.

3. TRANSPORT PROPERTIES OF CARBON NANOTUBES

3.1. Luttinger Liquid Behavior

The metallic carbon nanotubes show transport properties that deviate remarkably from those of the conventional two- and three-dimensional metals. This is actually a consequence of their behavior as genuine one-dimensional conductors. Their transport properties cannot be understood from the standard Fermi liquid picture for interacting electrons, in which it is assumed that the elementary excitations are quasiparticles which behave similarly to free electrons, with just some characteristic parameters (like the effective mass) renormalized by the interaction. The failure to apply that Fermi liquid picture already anticipates the kind of exotic effects that may be found in molecular electronics, as well as it was anticipated on theoretical grounds many years ago that a new paradigm—the Luttinger liquid—should be used to describe the interacting electrons in one-dimensional systems [46, 47].

The observation of unconventional transport properties has been reported in [10], for instance, regarding the sample shown in Figure 5b. The two-terminal conductance G as a function of the temperature is represented in Figure 6, from

Table 1. Physical constants of carbon nanotubes.

| Physical property	Constant [Ref.]
Minimum intrinsic resistance (individual metallic single-walled nanotubes)	≈ 6.5 kΩ
Bandgap (semiconducting nanotubes)	~ 0.5 eV [35, 36]
Energy gap ("metallic" zigzag nanotubes)	~ 0.05 eV [43]
Dielectric constant (single-walled nanotubes on Si/SiO$_2$ substrate)	≈ 1.4 [5, 55]
Charging energy (~ 3-μm-long single-walled nanotube)	~ 2.5 meV [5]
Charging energy (~ 2-μm-long multiwalled nanotube)	~ 0.5 meV [68]
Intertube resistance (nanotube ropes)	$\gtrsim 1$ MΩ [54]
Superconducting transition temperature (nanotube ropes)	~ 0.5 K [8]
Critical supercurrent (nanotube rope between Au/Re contacts)	~ 1 μA [76]
Current density (multiwalled nanotubes)	$> 10^9$ A/cm^2 [116]
Mobility (semiconducting nanotubes at room temperature)	$> 20,000$ cm^2/Vs [117]
Figure 6. Log-log plot of the temperature dependence of the conductance, measured in the two nanotube segments and through the kink shown in Figure 5b. The straight lines correspond to the best fit to a power law for each set of data. Reprinted with permission from [10], Z. Yao et al., *Nature* 402, 273 (1999). © 1999, Macmillan Magazines Ltd.

the mentioned reference, where the behavior in the two different segments and through the metal–metal junction can be appreciated. The strong suppression of the conductance as the temperature decreases in the latter case is remarkable. In all the instances, the behavior can be fitted very well by a power-law dependence $G(T) \propto T^\alpha$ in a fairly large range of temperatures. The exponents corresponding to the upper and the lower segment of the sample are $\alpha = 0.34$ and 0.35, respectively, and the value obtained through the kink is $\alpha = 2.2$.

As remarked by the authors of [10], the fact of producing contacts between the electrodes and the nanotube with sufficiently low resistance (about or smaller than 100 kΩ in their experiment) seems crucial to observe a definite behavior of the conductance. The suppression for decreasing temperature could be attributed, in principle, to activated transport over the tunnel barrier created by each contact. This would lead, however, to a dependence $G(T) \propto \exp(-\Delta/k_B T)$, in terms of the barrier height Δ, which cannot fit well the experimental data. The measurements of the conductance refer, therefore, to a property intrinsic to the carbon nanotube. This has to do with the effects of the electronic interaction, since the large suppression of the conductance through the junction cannot be accounted for by a model of noninteracting electrons with topological defects [48].

The behavior of the tunneling conductance is actually related to that of the density of states $\rho(E)$ at energies close to the Fermi level. It will be shown that the density of states has a power-law dependence $\rho(E) \propto E^\alpha$ in the framework of the Luttinger liquid theory, with the exponent α being a function of the interaction strength [46, 47]. The fact that $\rho(E)$ goes to zero at the Fermi level is a consequence of the absence of low-energy excitations with the properties of noninteracting electrons. The observation of the power-law dependence of the tunneling conductance can be considered then as another manifestation of the carbon nanotubes as genuine one-dimensional conductors.

The data in Figure 6 show that the Luttinger liquid behavior may extend over a wide range of temperatures, up to 300 K. At sufficiently low temperatures, the power-law behavior of the tunneling conductance is modified by

the effect of the Coulomb blockade [49], which is described later in detail. That effect is observable in the experiments when the thermal energy (i.e., the temperature times the Boltzmann constant k_B) becomes low enough to be comparable to the discrete energy needed to put one more electron on the finite dimensions of the system. This quantity is the so-called charging energy E_c, which is given in terms of the electron charge e and the total capacitance C of the nanotube by the expression $E_c = e^2/2C$. The charging energy can be estimated as a few meV in the typical single-walled nanotubes (with lengths of the order of 1 μm) used in the experiments.

Evidence of power-law behavior has been also obtained from the measurements of the differential conductance dI/dV, in individual single-walled nanotubes [10] as well as in ropes of nanotubes [50]. Figure 7 illustrates the results of the experiments in ropes reported in [50]. For values of the bias voltage applied to the rope such that $eV \ll k_B T$, the effect of the temperature prevails and the differential conductance recovers the voltage-independent value given by $G(T)$. At higher bias voltage, the experimental values of dI/dV show a well-defined linear behavior in log-log scale as a function of the bias voltage at different temperatures. The exponent giving the best fit for the power-law dependence $dI/dV \propto V^\alpha$ is $\alpha = 0.36$ [50]. It is also remarkable that, upon scaling of the differential conductance by the values of T^α as dictated by the behavior of a tunnel junction [51, 52], the experimental data for the different temperatures fall into a unique universal curve when represented as a function of the scaled variable $eV/k_B T$ [50].

The exponents obtained for the transport through the tunnel junctions created by the contacts in the ropes and in the individual nanotubes are in very good agreement. From this fact, one can obtain significant information about the physical properties of the ropes. The agreement is consistent, for instance, with the results establishing the large suppression of the tunneling amplitude between the different nanotubes of a rope [53, 54]. This means that the only relevant intertube coupling arises from the Coulomb interaction.

Figure 7. Log-log plot of the differential conductance in a rope, measured at different temperatures and scaled by T^α in each case. The inset shows the curves of differential conductance as a function of the bias voltage, for decreasing values of the temperature (from top to bottom). Reprinted with permission from [50], M. Bockrath et al., *Nature* 397, 598 (1999). © 1999, Macmillan Magazines Ltd.

Consequently, it can be concluded that the transport properties measured in individual nanotubes as well as in ropes are dominated by the two tunnel junctions in the circuit, which give rise to the observed power-law behavior. In the measurements through the kink reported in [10], the reason for the enhanced decrease of the conductance has to be found in the additional suppression of the tunneling of electrons between the two ends of the nanotube segments, according to the Luttinger liquid picture.

From a theoretical point of view, the clarification of the Luttinger liquid behavior of the metallic carbon nanotubes has been accomplished in [55] and [56]. The analyses carried out there assume that the repulsive Coulomb interaction between electrons is dominant in the single-walled carbon nanotubes. The discussion focuses on the low-energy regime in which only the four linear branches near the Fermi level (as observed in the band structure of Fig. 3, for instance) contribute to the electronic properties. When two electrons interact in the nanotube, there are a large number of possible processes, which can be classified depending on whether the electrons scatter near the same Fermi point or not, or whether the electrons shift from one Fermi point to the other. One of the main conclusions drawn in [55] and [56] is that the processes in which the electrons remain in their respective linear branches after scattering are largely dominant. The interaction strength of the rest of the processes (the so-called backscattering and Umklapp interactions) is suppressed in general by a factor inversely proportional to the number of subbands in the nanotube [55, 56].

The Hamiltonian H governing the low-energy electron dynamics can be approximated then by writing the interactions of the form density times density which arise from the Coulomb repulsion,

$$H = \frac{1}{2}\hbar v_F \int dk \sum_{r\sigma} \rho_{r\sigma}(k)\rho_{r\sigma}(-k)$$
$$+ \frac{1}{2} \int dk \sum_{r,s,\sigma,\sigma'} \rho_{r\sigma}(k)V(k)\rho_{s\sigma'}(-k) \qquad (9)$$

$\rho_{r\sigma}(k)$ being the electronic density in the linear branch r for spin σ, and $V(k)$ being the Fourier transform of the Coulomb potential. The kinetic term in Eq. (9) gets the appropriate dimensions from the Fermi velocity v_F of the electrons and the Planck constant $\hbar(=h/2\pi)$.

In one spatial dimension, the density operators can be rescaled to satisfy canonical commutation relations characteristic of boson operators [46, 47]. The Hamiltonian (9) can be diagonalized in terms of these bosonic objects. For this reason, the states with well-defined energy do not correspond to the original electrons, but to collective excitations that represent physically wavelike modulations of charge or spin.

The transformation diagonalizing the Hamiltonian (9) is a pseudorotation determined by the parameter $\mu = 1/\sqrt{1 + 8V/\hbar v_F}$ [46, 47], where a suitable average value of the interaction strength V is assumed. All the properties of the Luttinger liquid are completely characterized by the parameter μ. Thus, the density of states $\rho(E)$ follows at low energies the power-law behavior

$$\rho(E) \propto E^\alpha \qquad (10)$$

with an exponent $\alpha_{bulk} = (\mu + \mu^{-1} - 2)/8$ for the density of states measured in the bulk of the liquid [55, 56]. In the case of an open one-dimensional system, the density of states is substantially smaller at the ends of the liquid, having then a power-law behavior with an exponent $\alpha_{end} = (\mu^{-1} - 1)/4$ [56].

From the measurements of the conductance when tunneling into the bulk of the nanotube, it turns out that the best fit of the experimental data corresponds to a Luttinger liquid parameter μ around 0.22 [10]. This is the signature of a significant electron–electron repulsive interaction in the single-walled nanotubes, and indeed that value for μ agrees well with the theoretical estimate obtained by assuming that the Coulomb interaction is dominant in the individual nanotubes [55, 56]. An important consistency check is that the exponent that can be predicted for the tunneling into the end of the nanotube accounts for the large suppression of the conductance through the kink observed in [10]. Taking $\mu \approx 0.22$, the exponent α_{end} becomes ≈ 0.9. For the tunneling through the metal–metal junction, the conductance has to be proportional to the product of the tunneling density of states at each end of the nanotube segments. Thus, the corresponding exponent has to be twice the value of α_{end}, which is close to the estimate (≈ 2.1) from the fit of the experimental data [10]. Overall, there is therefore strong evidence that the Luttinger liquid picture applies to the tunneling processes in the single-walled nanotubes.

3.2. Ballistic Transport Properties

The experimental signatures of Luttinger liquid behavior are consistent with another remarkable observation in the carbon nanotubes, as it is the ballistic transport. This means that the charge can move along the nanotube in such a way that it is not disturbed by inelastic collisions. This behavior as a quantum conductor is opposite to the classical behavior in which the conduction takes place by diffusion of the electrons with a certain mean free path. One of the consequences of ballistic transport is that there cannot be dissipation of energy inside the ballistic conductor, and that the heat produced has to appear at the leads of the ballistic element. Moreover, another important property is that the conductance has to be quantized in units of $G_0 = 2e^2/h$, with each mode in the waveguide contributing with one of these quanta to the conductance [57–59].

The quantization of the conductance has been observed at room temperature in fibers of multiwalled nanotubes. The peculiarity of the experiment reported in [7] is that the fibers have been used in place of the tip of a scanning probe microscope. This has allowed the raising and lowering of the fiber inside a liquid metal, used as a second contact to close the circuit. By dipping the fiber into the metal, the current has been recorded as a function of the length of the fiber within the liquid. This has shown that the conductance increases by steps whose magnitude is very close to the quantum of conductance $G_0 = 2e^2/h$. The appearance of each step corresponds to the point at which one more multiwalled nanotube becomes in contact with the liquid metal [7].

The measurements reported in [7] provide a strong indication of ballistic transport in the multiwalled samples, since they have shown that the conductance does not decay over

a variation of about 200 nm of the nanotube length submerged in the liquid. Supporting the same conclusion, there is also evidence that the heat produced by the current cannot be dissipated in the nanotubes. It has been estimated in [7] that the current densities produced in the experiment can be higher than 10^7 A cm^{-2}. These values are so large that, if the corresponding dissipation of energy had to take place within the fiber, it would give rise to a temperature well above that needed to burn the nanotubes [7].

The quantization of the conductance in the multiwalled nanotubes also sheds light on their internal structure. Each individual metallic nanotube has two modes contributing to the conduction properties, irrespective of the diameter of the tubule. This means that each metallic shell of a multiwalled nanotube could in principle contribute with two quantum units to the conductance, which is not observed in the experiment of [7]. This can be explained by the fact that only the outer shell participates in the conduction, which is plausible since, even in the event that the next layer were metallic, the resistivity in the direction perpendicular to the tubules has to be very large [3]. It still remains to be understood why the step observed in the conductance is given by G_0, instead of $2G_0$. This value accounts for the contribution of the two spin projections and the two propagating modes of the nanotubes, which suggests that the contribution of some of these degrees of freedom may be missing in the multiwalled samples [60].

The observation of ballistic propagation seems to require very pure nanotube samples and, indeed, there is evidence of the structural perfection of the multiwalled nanotubes used in the experiments of [7]. When the degree of purity is not so high, the ballistic propagation may be altered by the interactions with the impurities or defects in the samples. In the experiments presented in [61], for instance, the transport properties of several single-walled nanotubes with large intrinsic resistance have been measured, showing a highly nonlinear behavior upon variation of the length along the nanotube. For a separation between the contacts of the order of a few hundred nanometers, the resistance displays a very smooth dependence on the length of the nanotube segment. This has been interpreted as the signature of ballistic transport in the single-walled nanotubes [61]. Over larger distances, the resistance shows a steep increase, which is incompatible with Ohm's law in any event since this would imply a linear dependence of the resistance on the length of the wire. It has been argued that the overall behavior can be only consistent with a situation in which the transport is dominated by the elastic scattering with an increasing number of defects, which would give rise to the observed decrease of the probability amplitude over the length of the nanotube [61].

3.3. Low-Temperature Properties

In a different kind of experiments, it has been established that the electron wavefunctions can be extended over lengths of several microns in the single-walled nanotubes, when the conditions are such that the thermal energy is smaller than the single-particle level spacing in the tubes [4, 5]. These low-temperature experiments are measuring, therefore, a regime different from that probed by the experiments

reporting the Luttinger liquid behavior, where the interaction between a manifold of single-particle levels is manifest.

The separation ΔE between the single-particle energy levels is dictated by the length L of the nanotube according to the expression

$$\Delta E = h v_F / 2L \tag{11}$$

where v_F is the Fermi velocity ($\approx 8 \times 10^5$ ms^{-1}). For typical lengths of a few microns, the separation between the discrete energy levels is below 1 meV. When the thermal energy is below that value, single electrons can be added to the nanotube by resonant tunneling, that is, by adjusting the bias voltage applied to the leads so that the current increases by one step each time that a new molecular orbital becomes available [5]. Similarly, a series of sequential peaks can be observed in the conductance when the number of electrons is varied with the voltage applied to the gate [4]. The fact that the single-particle level splitting can be resolved by looking at the current steps working at suitably low temperatures is the signature that the electrons occupy molecular orbitals that correspond to delocalized electronic states.

Moreover, direct evidence of the extended character of the electron states has been obtained by imaging the electron wavefunctions in short nanotubes (with length $L \approx 30$ nm) by scanning tunneling microscopy [62]. By measuring the tunneling conductance along the nanotube, the spatial modulation corresponding to the electron probability amplitude has been observed, finding agreement with the expected wavevectors of the quantized states in the nanotube. The electron wavefunctions of several discrete molecular levels have been discerned with this technique [62].

Another remarkable observation, related to the existence of extended electron wavefunctions, refers to the oscillatory behavior of the magnetoresistance of multiwalled nanotubes [63]. When these are aligned with the direction of the magnetic field, it has been shown that the resistance has modulations as a function of the enclosed flux. This is a consequence of the fact that the phase of the electron wavefunction is modified by the presence of the magnetic field (the so-called Aharonov–Bohm effect). When the electrons encircle the nanotubes in opposite directions, a phenomenon of quantum interference takes place, which reflects in the behavior of the resistance [63].

The absence of localization of the electronic states in the single-walled nanotubes may be surprising at first sight. On the one hand, there is the well-known fact that a single impurity has the ability to disrupt the conduction in a one-dimensional system [64, 65]. It has been shown, however, that the case of the nanotubes is special as the electrons feel the effect of impurities averaged over the circumference of the tube [66]. Thus, the metallic nanotubes may have very good conduction properties, with delocalized states over lengths of 10 μm or more for the nanotubes produced in the experiments. Furthermore, that localization length has to be an increasing function of the diameter of the nanotube [66].

The picture that emerges from the low-temperature experiments on transport is that the quality of the contacts used for the nanotubes determines the type of experimental observation. In some metallic nanotube devices, the resistance measured at room temperature is close to the theoretical lower limit of ≈ 6.5 kΩ, given by the inverse of the conductance $2G_0$ that would correspond to two modes propagating ballistically along a single-walled nanotube. In these cases, most part of the resistance has to be attributed to the nanotube, while the contacts between the metallic electrodes and the nanotube are nearly perfect. At low enough temperatures such that the thermal energy is below the single-particle level spacing within the nanotube, the electrons pass through the interface with little reflection and the experimental observations account for the propagation intrinsic to the nanotubes.

In the experiments reported in [6], a number of nanotube devices were measured with room-temperature resistances below 15 kΩ. In these samples the average value of the conductance has been found always between G_0 and $2G_0$, the departure from the latter value being attributed to the scattering of the electrons at the nanotube–electrode interface. Moreover, the two-dimensional plot of the differential conductance dI/dV as a function of the bias voltage V and the gate voltage V_g displays a quasiperiodic pattern of dips and peaks. It has been shown that the oscillation period scales appropriately with the inverse of the nanotube length, which supports that the observed pattern is due to the quantum interference of the electron waves after being scattered at the interfaces [6]. This shows the significance of taking into account the quantum coherence, represented by the extended character of the electron wavefunction, when designing low-temperature electronic devices at the molecular level.

Opposite to the cases of devices with almost transparent contacts, there are instances where the transmission between the nanotube and the metallic leads is dominated by much more suppressed tunneling processes. In these cases, the experimental observations give a measure of the difficulty that the current finds to go through the tunnel junction. In certain circumstances, it is possible to control the tunneling of single electrons into the nanotube, entering a regime with new physical properties which is described in the next section.

4. COULOMB BLOCKADE AND QUANTUM DOT BEHAVIOR

4.1. Carbon Nanotubes as Single-Electron Transistors

One of the main interests in the technological application of the carbon nanotubes arises from the possibility of developing electronic devices made of a single molecule. Semiconducting nanotubes have been proposed to act as field-effect transistors in [11] and [12]. In these devices, source and drain electrodes are attached to the semiconducting nanotube, while this is separated from the substrate (the gate electrode) by an oxide layer which acts as a dielectric. The capacitive coupling between the nanotube and the substrate is what makes it possible to change the density of charge carriers and the conduction properties in the nanotube by varying the voltage of the gate.

Unlike field-effect transistors, however, single-electron devices are based on the intrinsic quantum-mechanical character of the tunnel effect. In the case of metallic nanotubes, the development reported in [14] is that the electrons can be confined in short islands between two buckles of the tubule, so they can be added one by one by suitable variations of the voltage applied to the external gate.

The technique applied in [14] consists of using the tip of an atomic force microscope to press the nanotube against the substrate. The tip is then moved until the nanotube is strongly bent. In this way a buckle is created in the tubular structure, leading to a tunnel barrier for electron transport in a metallic nanotube. Two of these buckles can be arranged in series in an individual metallic nanotube, in order to study the transport properties through the two tunnel barriers [14]. One of the structures which have been produced with this technique can be observed in Figure 8. The short nanotube segment that appears there between the buckles has a length of the order of 25 nm.

When the tunneling of the electrons takes place into a short nanotube island, it costs a relatively large energy to add a single electron between the tunnel barriers. This is the well-known effect of Coulomb blockade [49]. On the one hand, there is the energy needed to overcome the electro-static repulsion between the electrons which are confined in such a reduced dimension, the so-called charging energy E_c. As pointed out earlier, this is given by the expression $E_c = e^2/2C$, in terms of the total electrostatic capacitance C [49]. On the other hand, each new electron added is placed in the first unoccupied level, which requires spending an energy corresponding to the separation ΔE between quantized levels. That energy difference is inversely proportional to the length L of the island, according to the already quoted

$$135 \times 135 \, nm^2$$

Figure 8. Atomic force microscope image of a short nanotube island between two buckles, formed by manipulation with the atomic force microscope tip. Image courtesy of Cees Dekker, Delft University of Technology.

expression $\Delta E = h v_F/2L$ (or $\Delta E = h v_F/4L$ if the degeneracy between the two different low-energy modes in the metallic nanotubes has been lifted). Altogether, the energy needed to add an electron to the island is the sum of the two contributions, the so-called addition energy [67]

$$E_{add} = e^2/C + \Delta E \qquad (12)$$

For the short nanotube segments created with the technique reported in [14], the charging energy and the level spacing ΔE have comparable magnitudes, and they give rise to an addition energy E_{add} of the order of 0.1 eV, which is considerably larger than the thermal energy $k_B T$ at room temperature. For that reason, the transport properties resulting from the addition of single electrons to the island can be observed without resorting to the use of low temperatures. The number of electrons transferred between the two buckles is controlled by varying the gate voltage applied to one of the substrates, capacitively coupled to the nanotube, which allows the lowering of the successive empty energy levels of the nanotube island down to the Fermi level in the outer nanotube segments [14].

The single-electron transport properties are distinctively observed in the measurements of the differential conductance dI/dV through the tunnel barriers reported in [14]. The effect of Coulomb blockade gives rise to typical patterns in the intensity plot of the differential conductance as a function of the bias voltage V applied to the electrodes and the voltage V_g applied to the external gate. At fixed gate voltage, a gap can be generally observed in the measures of dI/dV as a function of the bias voltage, corresponding to the region where that is not large enough to reach the first unoccupied level within the island. At some values of V_g the gap closes, which marks the point at which the first empty level in the region between the tunnel barriers is aligned with the Fermi level outside the island. This produces a typical pattern of consecutive diamond-like regions with suppressed conductance in the intensity plot of the differential conductance in the (V_g, V) plane [14].

An illustration of the diamond-shaped regions (although corresponding to a different experiment reported in [68]) is given in Figure 9. The dark diamonds correspond to the regions where the differential conductance is suppressed. In each diamond the number of electrons in the nanotube segment is fixed, while it increases by one unit when shifting from a diamond to the next one. On the other hand, the addition energy E_{add} can be obtained from the height in bias voltage of the largest diamond, since that is the voltage required to establish the conduction through the nanotube segment. In the case of the short island of [14], the addition energy is $E_{add} \approx 120$ meV. The separation of the energy levels has been estimated as $\Delta E \approx 38$ meV, from which a value $E_c \approx 41$ meV has been obtained for the charging energy of the short island [14].

It turns out that, for the nanotube device described in [14], the level separation ΔE and the charging energy E_c have comparable magnitudes, and both of them are well above the thermal energy $k_B T$ corresponding to room temperature. The behavior of the conductance at lower temperatures has been also studied in [14], reaching another
Figure 9. Intensity plot of the differential conductance of a multiwalled nanotube as a function of the bias voltage V_{sd} and the gate voltage V_g. The average conductance is of the order of $\sim 2e^2/h$. According to [68], ΔE_{add}, U_c, and δE denote the addition energy, the charging energy, and the single-electron level spacing, respectively. Reprinted with permission from [68], M. R. Buitelaar et al., *Phys. Rev. Lett.* 88, 156801 (2002). © 2002, American Physical Society.

important conclusion. The conductance of the nanotube follows a clear power-law dependence with decreasing temperature, pointing at a Luttinger liquid behavior of the kind already observed in [10] and [50]. It has been remarked that the exponents measured for that dependence do not correspond to a picture in which the transport proceeds with the sequential, independent tunneling through the two barriers that form the nanotube device. Instead, it has been shown that the data can be fitted with the exponent appropriate for correlated tunneling, in which the electrons propagate coherently through the nanotube island [14]. The corresponding value found for the parameter measuring the interaction strength, $\mu = 0.23$, is in very good agreement with the earlier estimates from Luttinger liquid behavior in carbon nanotubes [10, 50].

4.2. Quantum Dot Behavior

Effects related to the confinement of the electrons in a reduced dimension have been also observed in multiwalled nanotubes. In this case, the experiments reported in [68] have been realized at temperatures reaching values down to 280 mK. Such small temperatures are needed to discern charging energies and single-particle level spacings which range below 1 meV for multiwalled nanotubes with typical lengths of a few microns.

The experimental measurements of the differential conductance carried out in [68] are represented by the intensity plot of Figure 9. The dark regions correspond to lower values of the differential conductance, and it can be clearly seen that they form a sequence of diamonds as the gate voltage increases. There seems to be periodicity in the pattern formed by a large diamond and three consecutive smaller ones. Recalling that the number of electrons in the nanotube is increased by one unit from one diamond to the next and that the height of the diamond gives the energy required to add one electron, the observed pattern points at a fourfold degeneracy of the electronic levels in the multiwalled nanotube [68]. The height of the large diamond should correspond to the addition energy $E_{add} = e^2/C + \Delta E$, as in the measurement of the short island reported in [14]. The size

of the smaller diamonds should give a measure of the charging energy alone, with the electrons being placed there in the same single-particle level [68].

The fourfold degeneracy is in agreement with the expected band structure of a metallic nanotube, in which two subbands cross at the two Fermi points of the one-dimensional structure. It may be surprising, however, to find that only two gapless modes contribute to the conduction properties in the multiwalled nanotubes. In general, these are significantly hole doped by the environment, and the Fermi level in the outermost tubule crosses several different subbands [69]. It may well happen to have an outer shell which is semiconducting, so that for appropriate choices of the gate voltage it may not contribute to the conductance of the multiwalled nanotube. As explained in [68], this seems to be the case of the experimental sample exhibiting the sequence of diamonds in the differential conductance. It has been observed that such a sequence appears for suitably large values of the gate voltage. According to the arguments given in [68], the features observed in the conductance should reflect the metallic properties of the tubule next to the outermost shell, as that nanotube would not be affected by the external doping.

As remarked earlier in this section, the height of the smaller diamonds in the intensity plot of the differential conductance gives a measure of the charging energy E_c. For the multiwalled nanotube sample considered in [68], the estimate is $E_c \approx 0.4$ meV. From the value of the addition energy, it turns out that $\Delta E \approx 0.8$ meV [68]. As explained in the preceding section, the level spacing arises from the quantization of the electron states in the finite length of the nanotube. It has been observed in [68] that the estimated value of ΔE corresponds to the propagation along the whole length of the nanotube (≈ 2.3 μm), rather than to the distance between the electrodes (≈ 300 nm). It has been argued that this further supports the idea that the outermost shell does not participate in the conduction of the multiwalled nanotube [68]. The quantization properties over the nanotube length show, as well as in the individual single-walled nanotubes, that the electron wavefunctions can be extended over large distances (above ~ 1 μm) due to the weak influence of disorder with increasing diameter size [66].

Another physical effect reported in [68] refers to the behavior of the spin of the states with different electron number. By studying the behavior of the conductance under a magnetic field perpendicular to the tubules, it has been found that the spin follows the sequence $1/2, 0, 1/2, 0 \ldots$, upon adding one more electron each time to the nanotube. This can be explained if pairs of electrons have antiparallel spins, leading to the change from spin $1/2$ for an odd number of electrons to a vanishing value for an even number [68]. In general, the Coulomb repulsion between two electrons is minimized if they can be placed in degenerated orbitals, allowing them to have parallel spins [70]. This rule is not followed in the multiwalled nanotube considered in [68], which has been interpreted there as a signal that the perfect degeneracy between the modes of the two low-energy subbands in a metallic nanotube is spoiled in the experimental sample.

Moreover, it has been found in [68] that the differential conductance increases in the regions with an odd number

of electrons as the temperature decreases below 1 K. This has been regarded as a manifestation of the Kondo effect, which deals in general with the properties of a static spin surrounded by delocalized electrons [71, 72]. In the Kondo system there is an energy scale, given by the so-called Kondo temperature, below which the itinerant electrons are able to screen the static spin, with a concomitant increase of the conductance. The Kondo temperature gives therefore a measure of the binding energy of the singlet state formed by the screening effect. According to the authors of [68], the coupling between the spin of the nanotube and the electrons in the leads is what gives rise to the formation of the singlet state and the increase of the conductance through the nanotube.

The carbon nanotubes appear then as ideal systems to study the properties of electrons confined in a very reduced spatial dimension. This confinement into so-called quantum dots can be caused by the presence of the own electrodes acting as tunnel barriers. It has been also proposed that the arrangement of two consecutive kinks made from topological defects (i.e., from the combination of pentagon and heptagon rings) can be used to lock the electrons in short nanotube segments [73]. It has been already shown experimentally that the resonant electron scattering between simple (nontopological) defects gives rise to the formation of intratube quantum dots, with conductance patterns similar to that shown in Figure 9 [74]. The charge states in the quantum dots can be actually imaged with scanned gate microscopy and electrostatic force microscopy, which may give interesting spatial information about the physical effects involved [75].

5. SUPERCONDUCTING CORRELATIONS IN CARBON NANOTUBES

5.1. Proximity-Induced Superconductivity

There have been several experiments revealing the existence of superconducting correlations in the carbon nanotubes. These observations have taken the form of a drastic drop in the resistance of the nanotube samples below certain temperature. In one of the most remarkable experiments, reported in [76], it has been shown that a rope of carbon nanotubes is able to carry an electric current with zero voltage drop, when embedded between superconducting contacts. The measurement of that so-called supercurrent implies therefore a vanishing resistance of the conductor. The experiment provides a realization of the proximity effect, by which the electronic properties of a normal metal change drastically when placed in contact with a superconductor [77, 78]. In the latter, there is no sign of electron-like particles at low energies and, instead, a condensate formed by pairs of bound electrons is found [79]. These so-called Cooper pairs may extend their propagation to the nearby normal metal, giving rise to the electric current without dissipation of energy.

The influence of the superconducting electrodes in the electronic properties of single-walled nanotubes has been investigated in the experiments reported in [76] and [80]. One of the main differences between these experiments is

that, in the latter, the transport properties have been measured in a set of individual single-walled nanotubes. In the former experiment, the supercurrents have been observed in a massive rope made of about 200 nanotubes, and in a thin rope leading to a single nanotube at one of its ends. On the other hand, a common feature in both experiments is the low resistance attained for the samples that have shown the proximity effect. Typically the values measured at room temperature have been consistent with a resistance of the individual metallic nanotubes of the order or below the inverse of the conductance quantum, $h/e^2 \approx 25.8$ kΩ [76, 80]. Such values are comparable to the resistance $(2G_0)^{-1} = h/4e^2$ corresponding to the ballistic transport in individual nanotubes, which gives a measure of the high transparency of the contacts produced in the experiments.

In the experiments reported in [76], the ability to produce highly transparent junctions has been the result of using a remarkable technique allowing to suspend the nanotube ropes between the contacts. In the transport measurements, a drop to a vanishing resistance has been observed in the two nanotube samples mentioned earlier, below the temperature T_c of the transition of the electrodes to the superconducting state. The contacts were made of bilayer electrodes with respective temperatures $T_c \approx 1.1$ K for the Re/Au bilayer in the case of the thick rope, and $T_c \approx 0.4$ K for the Ta/Au bilayer in the case of the thin rope. By applying a magnetic field perpendicular to the nanotube axes, it has been possible to reduce the value of T_c as measured in the ropes, up to a point in which the transition disappears for a suitably large field [76]. This effect of the magnetic field is one of the genuine features of superconductivity, and it serves to corroborate the nature of the phenomenon observed in the experiment.

When increasing the current that flows along the rope, it can be supported without developing any resistance up to a maximum value, that is called the critical current. The behavior of the critical currents for the ropes studied in [76] has shown unconventional features, regarding their magnitude as well as their dependence with the temperature. The critical current should vanish, for instance, at the transition temperature of the contacts, but in the thick rope of [76] the behavior is very smooth instead near T_c. In the conventional picture of the proximity effect, the magnitude of the critical current should correspond to the expression $I_c = (\pi/2)\Delta/eR_N$, R_N being the normal state resistance and Δ the binding energy of the Cooper pairs in the superconducting condensate. As it has been pointed out in [76], the value of I_c estimated in that way is, however, 40 times smaller than what is actually measured in the thick rope. The thin rope shows a better agreement in the magnitude of the critical current, but this also displays a very unusual temperature dependence, with a flat behavior until the neighborhood of T_c is reached [76].

An explanation of the unconventional behavior of the critical currents in ropes has been presented in [81]. That work has shown the relevance of taking into account appropriately the interaction among the large number of metallic nanotubes that may be present in a rope. The Coulomb potential is not screened in an individual nanotube, but the interaction between the charges in different metallic nanotubes leads to a significant reduction of the effective

interaction strength [81]. This can be understood by thinking that, instead of Eq. (9), the Hamiltonian appropriate for a rope with n metallic nanotubes is

$$H = \frac{1}{2}\hbar v_F \int dk \sum_{ar\sigma} \rho_{r\sigma}^{(a)}(k)\rho_{r\sigma}^{(a)}(-k)$$
$$+ \frac{1}{2}\int dk \sum_{a,b,r,s,\sigma,\sigma'} \rho_{r\sigma}^{(a)}(k)V_{(a,b)}(k)\rho_{s\sigma'}^{(b)}(-k) \quad (13)$$

the indices a, b labelling the electronic densities in the different metallic nanotubes. The Coulomb interaction is long-ranged and takes place therefore between all of them, so that it contributes equally to all the $V_{(a,b)}(k)$ terms. The Hamiltonian (13) can be diagonalized by passing to the total densities $\rho_{r\sigma}(k) = \sum_a \rho_{r\sigma}^{(a)}(k)$. It becomes clear that the Coulomb interaction is only felt in the channel of the total charge, while there are still $4n - 1$ noninteracting partial channels [81].

The preceding argument explains that the repulsive electron–electron interaction becomes less relevant as the number n of metallic nanotubes increases in the rope. The proximity effect for a Luttinger liquid in contact with a macroscopic superconductor has been studied in [82] and [83], showing that the Cooper pairs propagate along the one-dimensional metal but giving rise to a supercurrent I_c that decays with the length L as

$$I_c \propto 1/L^{1/\mu} \quad (14)$$

where μ is the Luttinger liquid parameter quoted above Eq. (10). Recalling that $\mu < 1$ in the case of a repulsive interaction, that kind of behavior can only account for the large critical current measured in the rope of [76] after the appropriate reduction in the strength of the Coulomb interaction is considered. It has been also shown in [81] that the temperature dependence of the critical currents can be reproduced by considering the one-dimensional propagation of the Cooper pairs, which gives further support to the picture of the single-walled nanotubes as genuine one-dimensional conductors.

In the experiment presented in [80], the resistance of individual single-walled nanotubes placed between Nb electrodes has been measured. The nanotubes have been capacitively coupled to the Si substrate, and changing the gate voltage V_g has allowed to increase the already high transparency of the contacts. Below the transition temperature of the Nb electrodes ($T_c \approx 9.2$ K) and for some interval of V_g, a dip has been observed in the broad peak of the resistance centered at zero bias voltage. That structure has disappeared by increasing the temperature above T_c, which shows its relation to the superconducting character of the electrodes [80]. Although the room-temperature resistances of the samples were comparable to those in the experiment of [76], no supercurrents have been found in this case. This can be attributed to the large strength of the repulsive electron–electron interaction in the individual nanotubes, supporting the point of view that the superconducting correlations are more likely to develop in ropes of nanotubes.

5.2. Superconductivity Inherent to Carbon Nanotubes

Superconducting properties have been also measured in nanotubes placed between metallic, nonsuperconducting contacts [8, 9]. These experimental observations open the way to use the carbon nanotubes as a testing ground to study superconductivity in molecular wires with a discrete number of conduction channels. It has been already shown that several interesting features arise, as a consequence of the finite number of metallic nanotubes involved and their small length as compared to the size of macroscopic conductors.

One of the main factors in the experiments reported in [8] is the good quality of the contacts produced for the ropes. This is essential to measure the transport properties intrinsic to the nanotubes since, under conditions of low transparency of the junctions, it is the effect of tunneling and Coulomb blockade which is measured at low temperatures, as described earlier. In the experiments of [8], the nanotube ropes have been suspended between Pt/Au bilayers by the same technique already used in the proximity-effect experiments [76]. This has allowed production of devices with a room-temperature resistance ranging from a few kiloohms down to a few hundred ohms. It has been checked that the bilayers used in the experiment do not become superconducting themselves at low temperatures. The fact that they are not the source of some kind of proximity-induced superconductivity in the nanotubes is supported by the absence of the effect in some of the shortest ropes [8].

The most clear observation of superconducting transition has been made in a rope with about 350 nanotubes and length $L \approx 1$ μm [8]. When measuring the resistance of the sample as a function of the temperature, a drop by two orders of magnitude has been observed below ≈ 0.5 K, as shown in Figure 10. The resistance does not completely vanish below the transition, but reaches a minimum value $R \approx 74$ Ω. As remarked in [8], this is a consequence of the fact that the resistance of a metallic nanotube has a minimum value, given in terms of the quantum of conductance by $(2G_0)^{-1} \approx 6.5$ kΩ. The value $R \approx 74$ Ω of the residual resistance is consistent then with the approximate number of metallic nanotubes in the rope contributing to the conduction in the superconducting state. The superconducting character of the observed transition is reinforced by the behavior under a magnetic field, which tends to decrease the transition temperature as shown in Figure 10 [8].

The finite length of the ropes can be also determinant in the development of the superconducting transition. In the experiments of [8], a rope with a room-temperature resistance of about one order of magnitude below that of the superconducting rope described in previous paragraphs has shown no sign of superconductivity at low temperatures (as it can be seen in Fig. 10). The absence of transition has been attributed to the comparatively small length of the rope ($L \approx 0.3$ μm) [8]. It has been argued that the superconducting coherence length has to be smaller than the rope length for the superconductivity to develop, that condition not being satisfied in the case of the smaller rope. Another sample with a resistance of approximately 1 kΩ and length $L \approx 1.6$ μm has shown a clear sign of transition in the drop of the resistance (although at a comparatively low temperature, below 0.15 K, as observed in Fig. 10 [8]).
Figure 10. Behavior of the resistance at low temperatures for three different ropes. The length L, the estimated number of nanotubes N, and the room-temperature resistance R are indicated in each case. The inset of (b) shows the behavior of sample Pt1 in a magnetic field ranging from 0 up to 1 T. The plot in (c) displays also the dependence of the resistance of sample Pt2 in a magnetic field ranging from 0 up to 2 T (from bottom to top). The inset at the bottom shows a transmission electron microscope image of sample Pt2, with the dark spot corresponding to a Ni/Y catalyst particle. Reprinted with permission from [8], M. Kociak et al., *Phys. Rev. Lett.* 86, 2416 (2001). © 2001, American Physical Society.

A consistent explanation of the observed superconducting transitions requires taking into account the mechanism by which the repulsive Coulomb interaction can be overcome in the ropes of nanotubes. The superconducting transition signals the point at which bound electron pairs condense in the rope. This may happen if there is an effective attractive interaction in the electron liquid [79]. In the first place, it has to be considered that the strength of the Coulomb interaction is strongly reduced in a rope with a large number of metallic nanotubes, for the reasons already presented in the discussion of the proximity-induced superconductivity [81]. Furthermore, a source of attraction between the electrons is needed for the development of the superconductivity intrinsic to the ropes. That attraction arises in the scattering of two electrons by exchange of phonons (i.e., lattice vibrations), in similar manner as it happens in the case of macroscopic superconductors [79].

The effective attraction coming from the coupling of the electrons to the lattice vibrations can naturally overcome the repulsive Coulomb interaction [84, 85]. This is because the former takes place *within* each metallic nanotube of the rope while, as emphasized below Eq. (13), the Coulomb interaction operates in fact in a single interaction channel—that corresponding to the total charge density.

Thus, although the strength of the bare Coulomb interaction is larger, the attraction between the electrons through phonon exchange prevails for sufficiently large number of metallic nanotubes in the rope [84, 85]. This argument makes clear that the relevant electron–phonon interactions come from the coupling to *intratube* lattice vibrations. The maximum energies that the optical phonons may reach in the nanotubes, of the order of ∼0.2 eV [86–88], are also appropriate to give rise to the superconducting transitions observed experimentally.

Another important factor in the onset of the superconductivity is the small but finite electron tunneling amplitude that exists between different nanotubes in the rope. These have what has been called *compositional disorder*, meaning that they are made of a mixture of nanotubes with different helicities and diameters [53]. In these circumstances, neighboring nanotubes cannot have their lattices aligned, and this constitutes a great obstacle for conserving the longitudinal momentum when an electron hops from one nanotube to the other. Thus, in a compositionally disordered rope the intertube electron coherence is largely suppressed and the single-particle electron states have to be localized on individual nanotubes [53].

The coupling resistance between tubes in a rope has shown actually wide variations when measured in different experimental samples, with values ranging from 2 MΩ to 140 MΩ [54]. It has been argued that this can be only explained by assuming that transport in the transverse directions of the rope takes place by tunneling between metallic nanotubes of the same helicity. All this is in contrast to the case of an ideal crystalline rope, with perfect alignment of the nanotube lattices, where it has been estimated that the coupling between the nanotubes should give rise to a pseudogap in the density of states of about 0.1 eV [89–91].

It has been shown, however, that when the superconducting correlations develop in the individual nanotubes, the tunneling of Cooper pairs is the mechanism that reestablishes the intertube coherence in the rope [84]. The bound electron pairs are formed at zero total momentum, and they are not affected in the tunneling processes by the misalignment of neighboring nanotube lattices. The intertube coupling established by the tunneling of the electron pairs is a small quantity but, though small it may be, it is essential to account for the superconducting transition in the rope, since in a purely one-dimensional system the electron pairs cannot condense to form the superconducting state [92]. This becomes possible when there is a coherent propagation along the transverse directions of the rope [84]. The close packing of the bundle of nanotubes (forming a triangular lattice as viewed in a cross section of the rope) helps in this respect, since each nanotube may have on the average two metallic nearest neighbors, thus making possible the percolation of the Cooper pairs in the transverse directions of the rope.

The coupling of the electrons to the vibrations of the nanotube lattice and the intertube tunneling of the Cooper pairs are the two essential factors in the superconductivity of the ropes. The former can be actually enhanced by dealing with nanotubes of small diameter, since the electron–phonon coupling increases with the curvature of the nanotube [93]. In the experiment reported in [9], large superconducting

correlations have been measured in nanotubes with a diameter of ≈ 4 Å inserted in a zeolite matrix. Such a transversal size is considerably smaller than that of typical nanotubes in a rope, which have a diameter of ≈ 1.4 nm. The measurements of the magnetic susceptibility presented in [9] show actually the tendency of the zeolite matrix with the nanotubes to expel the magnetic fields below a temperature of ≈ 10 K. This property corresponds to the usual Meissner effect in a macroscopic superconductor. The measurements of the conductance show also an unconventional behavior for a one-dimensional metallic system, in which that observable diverges as the temperature goes to zero [9]. A microscopic description of the large superconducting correlations observed in the nanotubes of short radius must take into account the enhanced electron–phonon coupling [93] as well as their particular band structure, in which more than two subbands cross the Fermi level of the nanotubes [37–39].

6. PERSPECTIVES

Carbon nanotubes have a great potential in the development of electronic devices with diverse functionality since their electronic properties are themselves diverse, depending on the geometry of the nanotube lattice, the contacts used in the devices, and the temperature. At room temperature the transport may be ballistic in samples with high structural perfection. In the cases where the contacts create tunnel junctions, one can expect nonlinear I–V characteristics which are the signature of the Luttinger liquid behavior. At much lower temperatures, quantum interference effects in the propagation of the electrons can be observed in samples with highly transparent contacts while, in the case of very thick ropes, the reduction in the strength of the Coulomb interaction may give rise to the superconductivity of the nanotubes.

The first step toward the use of the carbon nanotubes in molecular electronics requires the integration of several nanotube devices in order to produce the desired functionality. Important progress is already being made in this direction. In [15], the architecture of two perpendicularly crossed arrays of nanotubes has been proposed as a model for a nonvolatile random access memory. Each crossing point for two perpendicular nanotubes constitutes an addressable device element. The junctions have two stable positions, with a different separation between the crossed nanotubes that can be controlled electromechanically. This allows the definition of ON and OFF states at each crossing point, characterized by respective resistances which may differ in general by orders of magnitude. The feasibility of the proposal has been supported by the realization and investigation of junctions made of crossed ropes of nanotubes [15]. The measurement of the I–V characteristics of crossed nanotube junctions has been also accomplished in [94], with different combinations of individual single-walled nanotubes with metallic and semiconducting character.

Another experimental accomplishment which has opened the way for a nanotube-based electronics can be found in [16]. That work has reported the construction of the first circuit based on a single nanotube capable of performing a logic operation. The circuit represents what is called a voltage inverter, by which a logical 1 can be transformed into

a logical 0 and vice versa. This is the realization of the NOT logic function, that is combined with the AND and OR logic operations to build the complex structure of modern microprocessors. A new experimental development has been needed in the construction of the logic circuit, since this requires to place in series two field-effect transistors being respectively of n-type (with excess of conduction electrons) and p-type (with conduction achieved by electron holes). While nanotubes are usually found with the latter character, the transformation to n-type has to be accomplished by doping the nanotubes with alkali metals or, in a simpler way, by heating the nanotubes in a vacuum as shown in [95]. An important feature of the circuit is the gain, which relates the strength of the output to that of the input signal and which, in this case, reaches the value of 1.6. This opens the possibility of assembling gates of the kind proposed into more complex circuits.

The operation of several small circuits built from the combination of nanotube field-effect transistors has been also shown in [17]. What is special in the integration of these devices is that each nanotube transistor has its own local gate, so that the effect of doping by varying the corresponding gate voltage can be controlled independently in each nanotube. A very large capacitive coupling has been achieved between the semiconducting nanotube and the nearby gate, making it possible to shift the Fermi level in the nanotube from the valence band (p-doped regime) to the conduction band (n-doped regime) under variations in the gate voltage. In this way, the integration of the nanotube transistors has allowed to realize several logic circuits, like an inverter, a NOR logic element, or a static random access memory element.

An interesting finding has been that the field-effect transistors made of single nanotubes can have better performance than the leading silicon transistor prototypes [96]. This has been realized in the process of building nanotube-based transistors with larger capacitive coupling between the nanotube and the gate electrode, that controls the density of charge carriers in the molecule. The advances in the design of the transistors have come from placing the gate electrode on top of the nanotube and using a thinner dielectric between them [96]. Thus, smaller variations in the voltage of the gate electrode can lead to significant changes in the resistance of the nanotube. This new kind of transistors has led to a high transconductance (the measure of the capability to carry electric current) at low voltages, outperforming in this respect the best silicon transistor prototypes [96].

The route toward the large-scale integration of nanotube devices presents great complexities, but carbon nanotubes have already shown the potential for more straightforward applications. One of them arises from the strong coupling between the electronic properties and mechanical deformations, that may include the twisting [97], bending [98], or stretching [99–102] of the carbon nanotubes. It has been shown that, in the case of semiconducting nanotubes, a semiconductor–metal transition can take place upon application of sufficient uniaxial strain [102]. The reverse trend has been also measured, by pushing a metallic carbon nanotube with the tip of an atomic force microscope to produce

a decrease of nearly two orders of magnitude in the conductance [103–105]. These observations open the way to use carbon nanotubes as nanoscale mechanical sensors.

The carbon nanotubes have also shown the potential for piezoelectric applications. The injection of charge into the nanotubes can alter their structure, due to the fact that the carbon–carbon bonds modify their lengths according to the electrons or holes added [106]. These effects have been investigated in nanotube sheets, which are made of highly entangled mats of nanotube bundles. In the experiments reported in [107], the changes in the length of strips of such kind of nanotube paper have been measured as a function of the applied voltage, carrying the operation within a NaCl electrolyte. Thus, the expansion or contraction of the strips has been the result of the injection of electronic charge from the electrodes to the surface of the nanotube bundles, with the electrolyte ions forming layers of respective opposite charges to balance those in the nanotubes [107]. The electromechanical actuators thus designed have shown good performance, being able to generate higher stresses than those of natural muscles. An important advantage over conventional ferroelectric actuators is that the nanotube sheets can provide large strains with applied voltages of just a few volts. The mechanical performance should be enhanced in the case of nonbundled nanotubes, and it has been estimated that, for the sheets made of separate nanotubes, the actuator strain could be of the order of ~1% [107]. A number of possible uses of the nanotube actuators have been proposed, from biomedical applications to flow control at high temperatures.

The application of carbon nanotubes as chemical sensors has been also suggested. The nanotubes have the tendency to adsorb gas molecules in their surface. In the case of semiconducting nanotubes, this has been shown to lead to significant changes in the conduction properties [108, 109]. The gas molecules give rise to a transfer of charge that makes the nanotubes become p-doped semiconductors. The change in their conductivity can give then a measure of very small concentrations of particles in the chemical environment at room temperature, in a much more sensitive way than existing chemical sensors.

Carbon nanotubes can be used as tips in scanning probe microscopes, which provides several advantages over usual silicon tips [110, 111]. The ability that the nanotube tips have to buckle elastically reduces the damage that can be produced when crashing into the sample. They lead to an improvement of the resolution, as a consequence of their small diameter. Moreover, they can be modified at the ends to enable the manipulation of structures at the molecular scale [112]. The construction of nanoscale tweezers has been also possible by attaching a pair of carbon nanotubes to respective electrodes, and controlling the nanotube arms by the voltage applied between them [113]. Such a device has made possible the manipulation of different structures at the nanometer scale.

Finally, the technological applications of carbon nanotubes can also have a more direct impact in everyday life. They have been proposed for the construction of supercapacitors, which may take advantage of the large surface area accessible in nanotube arrays. These can give rise to capacitors with high power and storage capabilities. Anyhow, the carbon nanotubes may find the most interesting commercial application as electron sources in field-emission devices [114, 115]. These can be used in flat panel displays, as well as in lamps and X-ray sources. The emission is produced by applying a voltage between a surface with nanotube fibers, acting as a cathode, and a substrate with phosphor arrays. The high local fields created in the nanotube geometry make the electrons jump toward the anode, where the contact with the phosphor produces the spots of light in the display. The flat panel nanotube displays turn out to save more energy and to have higher brightness than liquid crystal displays. A similar field-emission effect can be applied to the generation of X-rays, when the anode is replaced by a metal surface, which can lead to interesting applications for medical purposes. All these developments stress once more the significance that the phenomena taking place in minute devices can have for the construction of useful engines, tailored for the needs of our time.

GLOSSARY

Ballistic transport Conduction property of a quantum wire by which the charge is carried without dissipation of energy from inelastic scattering with other quanta.

Electronic coherence Property of the electronic propagation in which the quantum state remains well-defined and continuous over a given spatial extension.

Luttinger liquid State of an electron system in which all the elementary excitations are given by wavelike modulations of either the charge or the spin texture.

Multiwalled nanotube Concentric arrangement of a large number of single-walled nanotubes in which these are disposed like shells in an onion-like structure.

Proximity effect Phenomenon by which the electronic properties of a normal metal change when it is placed in contact with a superconductor, and that is characterized by the development of superconducting correlations over a certain extension of the metal.

Quantum wire Structure in which the electrons are confined to move essentially in one dimension, in such a way that the electronic state keeps its coherence along the wire.

Single-walled carbon nanotube Macromolecule built from carbon bonds forming a hexagonal lattice that appears rolled up in a single tubular structure, with a diameter typically of nanometer size.

Electronic Structure of Semiconductor Nanoparticles

Sameer Sapra, J. Nanda, D. D. Sarma

Indian Institute of Science, Bangalore, India

CONTENTS

1. INTRODUCTION

The last two decades have witnessed a tremendous amount of research activity in the field of semiconductor nanoparticles [1–7]. Also known as nanocrystals, nanocrystallites, or quantum dots, these materials are viewed as promising candidates for technological applications in the near future for devices based on electronics and optoelectronics [8–10]. The electronic structure of these materials, which lie in the transition region between the molecular limit and the bulk limit, drastically changes as the size of the particle is varied. For example, the bandgap of a semiconductor such as CdS can be varied from 2.5 eV for bulk to about 4.5 eV for 20 Å nanoparticles [11, 12]. Optical properties, such as photoluminescence, can be tuned nearly continuously by merely changing the size of the nanomaterial and one can get emissions throughout the visible region of the electromagnetic spectrum from the same material, as in the case of CdSe, by choosing the particle size suitably [13, 14].

An understanding of these nanomaterials demands an accurate theoretical description. The first attempt to understand the bandgap variation with size in these low-dimensional systems was the use of the effective mass approximation (EMA) [15–26]. Though simple in approach, the infinite potential EMA led to overestimation of the gaps and to quantitatively wrong conclusions. Other approaches used were the effective bond orbital method (EBOM) [27, 28], the empirical pseudopotential method (EPM) [29–36], and the tight-binding approach (TB) [37–46].

Here we will discuss the EMA and the TB methods in detail as these two have been extensively used to correlate the size-gap variation, in conjunction with direct experimental investigation of the electronic structure of various nanoparticles.

We review the theoretical approaches in the first part of this chapter; we follow this up with a critical comparison of the theoretical results with experimental data in the latter part of this review.

2. BANDGAP VARIATION WITH NANOPARTICLE SIZE

2.1. Effective Mass Approximation

In crystalline materials, the energy-momentum relationship is defined by a complex set of equations. This relationship is known as the band dispersion of the crystal [47]. Semiconductors or insulators differ from metals in exhibiting an energy gap between the valence band and the conduction band. If the charge carrier has a small amount of kinetic energy, then the simplified description in Figure 1 is often applicable for a single-particle picture.

At low energies, near the band edges, delocalized electron (or hole) waves follow a quadratic equation describing the wave vector, k dependence of energy, E

$$E = \frac{\hbar^2 k^2}{2m^*}$$

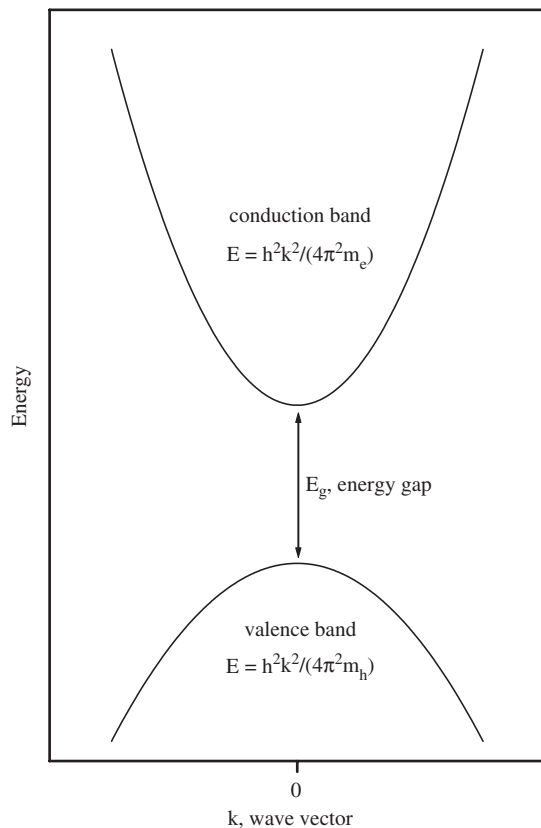
where m^* is the effective mass of the charge carrier (electron or hole). The motion of single-charge carriers under the influence of external fields is described by this relation. Within the effective mass approximation, one can also describe the motion of a coupled electron-hole pair, the exciton. To use the effective mass approximation for describing the bandgap variation with size for nanoparticles, one


Figure 1. Schematic band dispersion: energy-momentum relation for a direct bandgap semiconductor.

needs to solve the Schrödinger equation for the envelope function ψ:

$$\left[-\frac{\hbar^2 \nabla_e^2}{2m_e} - \frac{\hbar^2 \nabla_h^2}{2m_h} - \frac{e^2}{4\pi\epsilon_0 \epsilon r_{eh}} + V_0 \right] \psi(r_e, r_h) = E\psi(r_e, r_h) \tag{1}$$

where the subscripts e and h refer to the electron and the hole with m and r being the mass and position vector, respectively, and $r_{eh} = |r_e - r_h|$. ϵ_0 and ϵ are the permittivity in vacuum and the relative dielectric constant of the material. The potential V_0 inside the nanoparticle is assumed to be zero and infinite outside for the EMA calculation corresponding to an infinite barrier height. Using a trial wave function, the above equation can be solved by approximate methods.

Brus [16–18] has considered a model for the particles that incorporates (a) the effective mass approximation for the kinetic energy of the electron and the hole, (b) an electrostatic potential term from classical continuum polarizability theory, and (c) tunneling of electrons and holes out of the crystallite at the surface in the case of a finite barrier height. For an infinite barrier height the model yields the following expression for the bandgap, E_R, of the quantum dot,

$$E_R = E_g + \frac{\hbar^2 \pi^2}{2R^2}\left[\frac{1}{m_e} + \frac{1}{m_h} \right] - \frac{1.8e^2}{\epsilon R} - 0.248 E_{Ry}^* \tag{2}$$

where E_g is the bulk bandgap, and R is the radius of the quantum dot. The effective Rydberg (in meV) is defined as

$$E_{Ry}^* = 13605.8 \frac{1}{\epsilon^2}\left(\frac{m_0}{m_e} + \frac{m_0}{m_h} \right)^{-1} \tag{3}$$

The second term arises due to the Coulomb attraction, and the third term due to the spatial correlation between the electron and the hole. Brus used the EMA to calculate the bandgap variation with size for InSb, GaAs, CdS, and ZnO [17]. These results are shown in Figure 2.

Kayanuma [22] has identified two limiting cases depending upon the ratio of the radius of the quantum dot to the Bohr exciton radius, a_B of the bulk solid. For $R/a_B \gg 1$ the exciton can be pictured as a particle moving inside the quantum dot with only little increment in energy due to the confinement. This is the weak confinement regime. In the strong confinement regime where $R/a_B \ll 1$, confinement effects obviously dominate. It was pointed out that in this regime, the electron and hole should be viewed as individual particles in their respective single-particle ground states with little spatial correlation between them. Kayanuma further found that the strong confinement regime is not only limited to $R/a_B \ll 1$ but the effects are seen up to $R = 2a_B$. This is the regime where the effective mass approximation as given by Brus can be applied; however, we point out later that Eq. (2) overestimates the bandgap for all sizes, with the mismatch between the experiments and the calculated results increasing progressively for decreasing particle size.

Some improvement over the EMA with an infinite barrier was made when Shmidt and Weller [20] used a configuration interaction approach for the electron and the hole, treating

Figure 2. Calculated energy of the lowest excited electronic state of the cluster in relation to the bulk bandgap. Reprinted with permission from [18], L. E. Brus, *J. Phys. Chem.* 90, 2555 (1986). © 1986, American Chemical Society.

it like a two-electron atom. They also used the Hylleras functions and a perturbation expansion in R to obtain bandgap energies slightly better than those described by the single-particle EMA.

The effect of using infinite barrier potential is to neglect the presence of the surrounding medium which can be either a glassy matrix or a passivating agent to inhibit the growth of particle size and the ability of the electron and the hole to tunnel significantly beyond the confines of the nanoparticles. These shortcomings lead to an overestimation of bandgaps for very small crystallites. Finite barrier heights have therefore often been considered to account for the experimental data from small crystallites. Kayanuma and Momiji [23] have demonstrated an excellent agreement of the bandgap variation with size for CdS nanocrystals embedded in silicate glasses [48] by using a finite barrier potential at the interface. The confining potential $\overline{V}_e$, for the electron, and $\overline{V}_h$, for the hole, satisfies the relation $E_g + \overline{V}_e + \overline{V}_h = E_g^1$, where E_g^1 is the bandgap energy of the surrounding material. The resulting problem was solved variationally in the Hylleras coordinate system. The results obtained within this approach are shown in Figure 3 for the CdS system.

Further improvements to the EMA led to the emergence of the multiband EMA (MBEM) theory. In most of the semiconductors the conduction band is nondegenerate and the electron effective mass can be well described by the single-band theory. On the other hand, the top of the

Figure 3. Calculated ground-state energy of the electron-hole system in CdS nanocrystals embedded in silicate glass. The bold line is the total energy. The expectation values of the kinetic energy $\langle K \rangle$, the Coulomb energy $\langle C \rangle$, and the potential energy $\langle P \rangle$ are also shown. The corresponding quantities calculated in the infinite barrier model are shown by the dashed lines. The origin of the energy is chosen at the bandgap energy of CdS. The experimental peak positions from [48] are plotted by small circles. Reprinted with permission from [23], Y. Kayanuma and H. Momiji, *Phys. Rev. B* 41, 10261 (1990). © 1990, American Physical Society.

valence band is often degenerate. Hence, to describe the hole, one needs to consider various bands that contribute to the valence band edge. In CdSe nanocrystals, the size dependence of up to 10 excited states [24, 25] in the absorption spectra is successfully described by the uncoupled MBEM. This includes the valence band degeneracy but does not couple the valence and conduction bands. Banin et al. [26] have used the MBEM including the valence and conduction band coupling. They use an eight-band Luttinger Kohn Hamiltonian to calculate the quantum size levels in InAs [26].

2.2. Empirical Pseudopotential Method

The empirical pseudopotential method (EPM) has been used to investigate the electronic and optical properties of bulk semiconductor materials [49, 50]. The Schrödinger equation

$$H\Psi_{n,k}(r) = E_n(k)\Psi_{n,k}(r) \tag{4}$$

is solved at a set of k points in the Brillouin zone. The Hamiltonian H is given by

$$H = -\frac{\hbar^2}{2m}\nabla^2 + V_p(r) \tag{5}$$

where

$$V_p(r) = \sum_G [V_s(G)S_s(G) + iV_A(G)S_A(G)] \exp(iG \cdot r) \tag{6}$$

is an empirically determined pseudopotential. V_s and V_A are the symmetric and antisymmetric form factors, respectively. They are determined from the optical absorption data. S_s and S_A are the symmetric and antisymmetric structure factors, respectively, determined from the crystal structure of the semiconductor.

The wave functions $\Psi_{n,k}$ can be regarded as linear combinations of the plane waves

$$\psi_{n,k}(r) = \frac{1}{\sqrt{V}} \sum_G C_{G+k} \exp[i(G+k) \cdot r] \tag{7}$$

The Hamiltonian matrix consists of the elements

$$H(G'+k, G+k)$$
$$= \frac{1}{V}\int dr \exp[-i(G'+k) \cdot r] H \exp[i(G+k) \cdot r] \tag{8}$$
$$= \frac{\hbar^2}{2m}(G+k)^2\delta_{G'G} + V(G'-G) \tag{9}$$

which is diagonalized at a grid of k-points in the Brillouin zone to obtain the band structure of the semiconductor.

For nanocrystals, the allowed wave vectors k are discrete. For a nanocrystal of radius R, a reasonable assumption is to use the bulk pseudopotential $V_p(r)$ inside the crystallite and terminate this potential at the edge of the cluster by an infinite potential. The wave vectors k_n of the allowed states are then given by $j_l(k_nR) = 0$. The HOMO and LUMO states at the band edges correspond to $l = 0$. The solution of $j_0(k_nR) = 0$ gives the allowed wave vectors k_n. Since k_n

is along the radial direction, it is projected onto each of the cartesian axes with equal magnitude to obtain the cartesian components of k,

$$k = \frac{\pi}{\sqrt{3}R}[n_x, n_y, n_z] \qquad (10)$$

The energy levels at these k-states constitute the $l = 0$ band structure of the crystallites.

Figure 4a shows the bulk band structure of zinc-blende CdS. Ramakrishna and Friesner [29] calculated the band structure of CdS nanocrystals of $R = 15$ Å as shown in Figure 4b. In this figure, the energies of all the orbitals are specified relative to the energy of the HOMO orbital. As the cluster size is increased, all the orbitals corresponding to each band come closer in energy and the band structure of the clusters smoothly approaches that of the bulk.

From the calculated band structures of the clusters, Ramakrishna and Friesner calculated the variation of the bandgap with size for different sized CdS clusters. The bandgaps of the clusters were corrected for the electron-hole Coulomb attraction and the correlation energies by subtracting the last two terms given in Eq. (2) from the calculated bandgaps. The theoretical results for spherical and cubic shaped clusters crystallizing in the zinc-blende phase
along with the experimental data [69] and the EMA calculations [18, 22] are shown in Figure 5a. Figure 5b shows the same results except that these results are for the wurtzite phase. In the case of GaAs, GaP, and Si nanocrystals of very small sizes, Ramakrishna and Friesner [29] also observed a red-shift in the bandgap. These red-shifts have not been predicted by any other theoretical technique.

Recently, Zunger and co-workers [30–36] employed the semiempirical pseudopotential method to calculate the electronic structure of Si, CdSe [33], and InP [32] quantum dots. Unlike EMA approaches, this method based on screened pseudopotentials allows the treatment of the atomistic character of the nanostructure as well as the surface effects, while permitting the multiband and intervalley coupling. The atomic pseudopotentials are extracted from first-principles LDA calculations on bulk solids. The single-particle LDA equation,

$$\left[-\frac{1}{2}\nabla^2 + V_{\text{nonlocal}}^{ps}(r) + V_{\text{LDA}}(r) \right]\Psi_i = \epsilon_i \Psi_i \qquad (11)$$

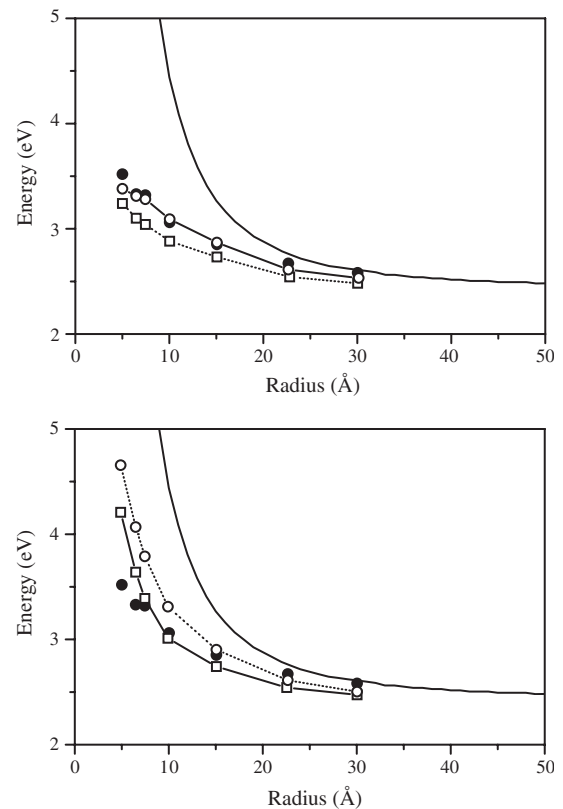

Figure 5. (a) Experimental and calculated exciton energies of CdS clusters. The solid circles are the experimental data [69] and the solid line is the result due to Bruss effective-mass model with $m_e = 0.19$, $m_h = 0.80$, $\epsilon = 5.5$, and $E_g = 2.5$ eV [18, 22]. (a) The open circles and squares are from our calculations of the zinc-blende CdS clusters with spherical and cubic shapes, respectively. is solved to obtain the electronic structure of a solid. The ionic pseudopotential consists of the nonlocal part $V_{\mathrm{nonlocal}}^{ps}(r)$ and V_{LDA} is composed of the local ionic pseudopotential, $V_{\mathrm{local}}^{ps}(r)$, and the screening potential V_{HXC} made up of the interelectron Coulomb (Hartree) and the exchange and correlation (XC) parts. For a given crystal structure, the knowledge of the atomic pseudopotentials allows one to solve Eq. (11). The wave functions are LDA-like while the band structures, effective masses, and deformation potentials match experiments. These improvements over the empirical pseudopotential method provide a better description of the electronic structure of the quantum dots. However, large size of the Hamiltonian does not allow one to calculate the properties of large sized nanocrystals.

2.3. Tight-Binding Method

The tight-binding (TB) method or the LCAO approach was first described as an interpolation scheme to elucidate the electronic structure of solids by Slater and Koster [51]. Since then it has been used widely to study the electronic structure of various metals, semiconductors, and clusters. It has the advantage over the plane wave methods that it is computationally less expensive. Thus, it is possible to study very complex systems using the TB method and it has been used for complex alloys and doped compounds. In the late 1980s, Lippens and Lannoo [37] first used the tight-binding approach for quantum dots. Since then many groups have demonstrated the effectiveness and ease of use of this method.

For calculating the electronic properties of nanoparticles using the TB method, the first step is to calculate the band structure of the bulk material with the same lattice structure as observed in the nanoparticles. This bulk band structure can be calculated using any of the standard effectively single-particle, first-principles methods such as the LAPW, LMTO, or the pseudopotential methods. Then a TB model is selected to fit the bulk band structure. The specific choice of the TB model, including the basis set and the range of interactions, depends on the specific problem to be investigated. For describing the bandgap variation with the size in nanoparticles, one is obviously most interested in the energy region around the bandgap of the bulk material. The fitting of the band dispersions of the bulk material obtained within a first-principles approach by a suitable TB model yields the optimized set of parameters suitable to describe the material within that TB model. Assuming that these parameter strengths are transferable from the bulk to the nanoparticle case, one can use the same TB model to calculate the eigenspectrum, and consequently the electronic structure of any given size and shape. However, one important difference between the approach for the bulk and the nanoparticle arises from the finite size of nanoparticles and the resulting absence of periodicity in them. The Hamiltonian matrix for the nanoparticles needs to be set up in real space, with the dimension of the matrix being equal to the total number of orbitals in the cluster. This often makes it difficult to calculate the electronic structure of the nanoparticles with very large sizes. Direct diagonalization works well for small nanoparticles, but for larger particles, one needs to revert to other methods of diagonalization, such as the Lanczos

technique [52]. In typical applications, by generating nanoparticles of different sizes, a curve for the bandgap variation with size is obtained. However, it is also possible to calculate the electron density of states as a function of size and correlate it to experimental photoemission and X-ray absorption spectra, as shall be discussed in the last section.

3. TIGHT-BINDING METHOD

Lippens and Lannoo [37] first used the TB method to describe the bandgap variation with size for CdS and ZnS nanocrystallites. They used the TB model with a sp^3s^* basis and the specific set of parameter values obtained earlier by Vogl et al. [53] for describing the bulk band structure. The calculations for CdS and ZnS crystallites were carried out for crystallites with different sizes, ranging between the smallest sized clusters with 17 atoms in 3 shells and the largest with 2563 atoms in 15 shells. The surface states or the dangling bonds were removed from the Hamiltonian, as they give rise to partially bonded electronic states in the nanoparticles and appear in the bandgap region, making the unambiguous determination of the bandgap difficult. These authors used direct diagonalization of the Hamiltonian for small crystallites with less than 83 atoms and the recursion technique for larger crystallites and obtained the variation of the valence and the conduction band edges as a function of size. An interesting feature in the variation of the band edges with size is the odd-even shell effect. Oscillations in the valence band (VB) or conduction band (CB) edge positions are observed for both CdS and ZnS. This is attributed to the manner in which the crystallites have been generated. The surface shell of the crystallites is either purely cationic or purely anionic in nature depending on whether the nanoparticle cluster considered has even or odd number of shells. The oscillations are a consequence of removing the dangling cationic or anionic orbitals. In order to compare the calculated results with experimental ones, it is necessary to take into account the changing contribution from the electron-hole interaction energy as a function of the size, besides the change in the bare bandgap energy calculated within the TB model. This is most conveniently achieved by assuming this energetic being given by the corresponding term in the EMA equation (Eq. (2)) also for the TB results. Thus, Lippens and Lannoo compared their results after the correction for the excitonic binding energy as discussed here with the existing experimental data [54, 55] as a function of particle size (Fig. 6). It is evident from the figure that this model agrees better with the experimental results compared to the single-band, infinite potential, effective mass approximation, especially for small crystallite sizes. However, the nearest-neighbor sp^3s^* tight-binding model is found to consistently underestimate the bandgap. Using the same sp^3s^* model, Lippens and Lannoo calculated the electronic structure and the bandgap variation as a function of size for various $A^{\mathrm{II}}B^{\mathrm{VI}}$ semiconductor nanocrystallites, where A = Zn, Cd and B = S, Se, Te [39]. These results are discussed later in this section, in comparison to results from other TB models.

Hill and Whaley employed a time-dependent tight-binding approach to determine the electronic structure of CdS and CdSe nanocrystals [40, 42]. This method has two
Figure 6. Comparison with experimental data for CdS. The tight-binding results are given by the solid curve and those of the effective-mass approximation (Eq. (2)) by the dashed curve. The experimental data are the exciton peak given in [54] (squares) and [55] (triangles). Reprinted with permission from [37], P. E. Lippens and M. Lannoo, *Phys. Rev. B* 39, 10935 (1989). © 1989, American Physical Society.

advantages. First, the size of the cluster is less restricted by computer memory limitations than in methods based on diagonalization of the tight-binding Hamiltonian directly. Second, the method can be extended to study excitonic states by propagating a two-particle (electron-hole) wave function and including the Coulomb interaction in the Hamiltonian, instead of introducing an *ad hoc* correction for the excitonic binding energy on the calculated single-particle bandgap. Furthermore, Hill and Whaley determined the surface atom contribution to the density of states of the nanocrystals. This is performed by calculating the density of states of the surface atoms and identifying the corresponding features in the total density of states. These results were further confirmed by two different approaches, namely (i) passivating the surface atoms with oxygen atoms and (ii) removing the dangling orbitals altogether to obtain the density of states of the unpassivated, but dangling orbital free, surfaces. Comparing these results with the density of states obtained from the usual unpassivated clusters, it is easy to identify the surface states. These authors have also studied the effect of terminating the surface with a cationic or an anionic atomic layer on the density of states. For both CdS and CdSe, a cationic surface gives rise to surface states near the conduction band edge, while the anionic surface shows states near the top of the valence band within the bandgap region. There are contributions to other parts of the density of states from the surface atoms too. These results are shown in Figure 1a and 1b in [42] for unpassivated Cd and Se. Figure 1c and 1d in [42] show the effect of passivating the Cd and Se surfaces, respectively, with oxygen. It is seen that oxygen passivation works well for the cationic surface, but fails to quench the surface states when there is an anionic surface. Removing the dangling bonds gets rid of the surface states completely, independent of the nature of the surface layer, as shown in Figure 1e and 1f in [42].

In Figure 9 in [40], a comparison between the theroretical results and the experimental photoemission data for CdS [56] for the variation of valence band maximum with size is shown. In the absence of any knowledge about the Fermi energy of the system, the experimental valence band maxima for the 38 Å crystallites were rigidly shifted in energy, such that this coincides with the calculated results. This gives a fair agreement between the experiment and the calculation for the 24 Å nanoparticles taking into account the large error bar. However, they could not compare the calculated density of states with the photoemission spectra of these samples, as Cd d levels that are a part of the bottom of the valence band and have a considerable contribution near the valence band edge, are absent in the sp^3s^* model. Thus, it suggests that the sp^3s^* model may be inadequate to account for all aspects of the experimental observations and further improvements are required in the calculational schemes.

Pérez Conde et al. [45] extended the standard sp^3s^* model by incorporating the spin-orbit coupling for CdSe and CdTe nanocrystals. The resulting bandgap variation with size for CdTe is shown in Figure 7 along with the experimental data from various groups [57–61]. Their result (open triangles) scales as a function of the nanoparticle diameter (D) as $1/D^{1.42}$ compared to the EMA (dotted line) which varies as $1/D^2$.

More recently, Allan et al. worked out the quantum confinement energies in zinc-blende III–V and group IV semiconductors [44]. They also used the tight-binding approximation including spin-orbit coupling, but expanded the basis to include the d orbitals ($sp^3d^5s^*$). Such a model gives conduction and valence bands for the bulk system in

Figure 7. Absorption bandgap vs QD diameter. The experimental data from [57] (open diamonds) and [58] (closed squares) were measured at room temperature. The data from [59] (stars) were measured at 2 K. The values from [60] were taken at temperatures higher than room temperature (open circles). The sample studied in [61] (closed circles) was measured at 77 K (higher value) and room temperature (lower value). The theoretical TB values scale (open triangles) as a function of diameter as $1/D^{1.42}$, while the EMA gap (dotted line) varies as $1/D^2$. Reprinted with permission from [45], J. Pérez Conde et al., *Phys. Rev. B* 64, 113303 (2001). © 2001, American Physical Society.

good agreement with first-principles results. The calculated effective masses are also comparable to the experimental values. Using this basis, the variations of the HOMO and LUMO energies of nanoparticles of different diameters were obtained and related to the effective cluster diameter D using the following expressions:

$$E_{\text{HOMO}} = E_{BV} - \frac{1}{a_v D^2 + b_v D + c_v} \tag{12}$$

$$E_{\text{LUMO}} = E_{BC} + \frac{1}{a_c D^2 + b_c D + c_c} \tag{13}$$

where E_{BV} and E_{BC} are the bulk band edges and the a_v, b_v, c_v, a_c, b_c, and c_c are the fitting parameters for various III–V and IV semiconductors. Figure 3 in [44] shows a comparison of these calculated results with the $sp^3d^5s^*$ basis with those obtained from pseudopotential calculations [30] as well as with experimental results obtained from photoluminescence studies of InP [62–64]. It is clear from this figure that both the pseudopotential and $sp^3d^5s^*$ tight-binding results overestimate the experimental gap energy. While the same reference [44] also shows the comparison for InAs, the experimental results in this case from various groups are not in good agreement; hence, it is difficult to comment on the extent of agreement between the calculation and the experiment in the case of InAs.

Recently, our group has proposed [65] the sp^3d^5 tight-binding model with cation-anion nearest-neighbor and anion-anion next-nearest-neighbor interactions for the $A^{\text{II}}B^{\text{VI}}$ semiconductor compounds with A = Zn, Cd, Hg and B = S, Se, Te. After a careful analysis of the band structure of $A^{\text{II}}B^{\text{VI}}$ semiconductors, it has been shown that the tight-binding model with the sp^3d^5 orbital basis on both the cation and the anion with cation-anion and anion-anion interactions describes the *ab initio* band structure extremely well. These interactions are included after a careful analysis of the crystal orbital Hamiltonian overlap populations (COHP) which give the bonding and anti-bonding contributions to the total bonding for various types of interacting pairs. It was found that the *d* orbitals are very important for a correct description of the top of the valence band and the bottom of the conduction band. It was found that most of the features of the *ab initio* band dispersions are describable reasonably well by the nearest-neighbor model; however, certain subtle features that cannot be explained by the nearest-neighbor model are described by including the anion-anion interactions. The next-nearest-neighbor sp^3d^5 tight-binding model gives the correct bandgap and the band curvatures near the band extremal points. The accurate description achieved for the *ab initio* band structure within this sp^3d^5 next-nearest-neighbor TB model, suggests that this may be an appropriate starting point to describe the electronic structure of $A^{\text{II}}B^{\text{VI}}$ nanocrystallites. A comprehensive calculation has indeed been carried out for $A^{\text{II}}B^{\text{VI}}$ nanocrystallites (A = Zn, Cd and B = S, Se, Te) within this sp^3d^5 parametrization. Since such calculations not only provide an estimate of the bandgap as a function of the particle size, but also yield a reliable description of the density of states due to the use of a realistic basis set and interactions, photoemission spectra can be meaningfully compared with the calculated density of states for these clusters.

The nanocrystallites contain atoms on the surface which are comparable in number to those in the bulk of the crystal. Therefore, the dangling bonds at the surface give rise to substantial number of midgap states. There are several important consequences of this, such as a strong suppression of the bandgap emission and a red-shift of the photoluminescence spectra. At the level of calculations, these midgap states complicate the identification of the band edges and, consequently, the determination of the bandgap. Thus, it is often necessary to obtain reliable routes to quenching and removing these midgap states both experimentally and theoretically. One such route is to overcoat a nanoparticle with a thin layer of another material with a larger bandgap such as coating CdS with ZnS. This experimental approach was theoretically explored in [66] for CdS with a monolayer of ZnS coating. In Figure 8 we show the density of states of unpassivated and thus passivated CdS nanocrystallites of 46 Å diameter. The midgap states observed in the unpassivated calculation (see inset in the upper panel) are removed upon passivation of the cluster (inset, lower panel). This allows a correct determination of the bandgap.

In Figure 9 we show the bandgap variation with size for the various $A^{\text{II}}B^{\text{VI}}$ semiconductors calculated within the sp^3d^5 model [67], along with the results based on EMA results and those from the sp^3s^* model [39]. The Coloumb term (the third term in Eq. (2)) has been subtracted from the calculated bandgaps in order to facilitate comparison with the experimental data [11, 12, 55, 57–59, 68–80] that are also plotted in the same figure. The infinite potential

single-band EMA clearly overestimates the experimental bandgaps in every case. The results of [67] are found to describe the experimental data points considerably better than the nearest-neighbor sp^3s^* model.

4. VALENCE BAND SPECTROSCOPY

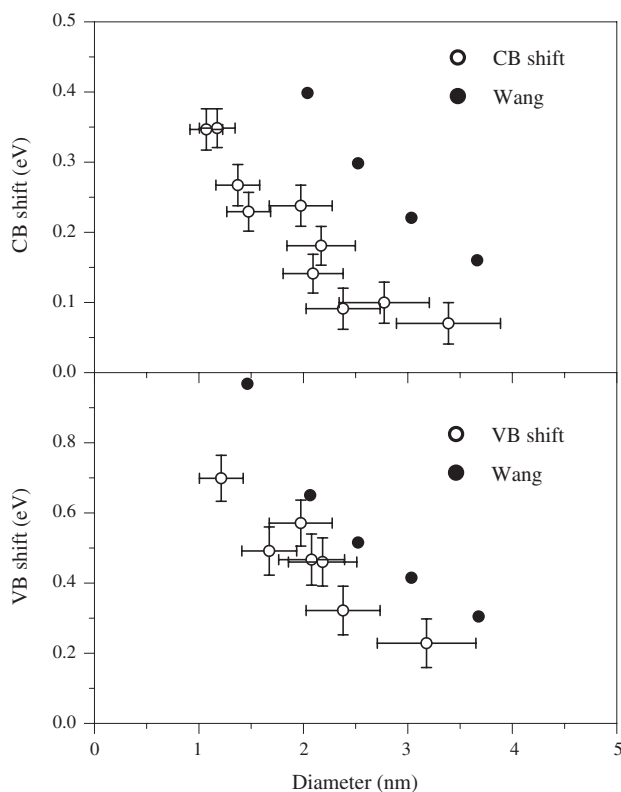
The first valence band photoemission study on nano-crystallites was reported by Colvin et al. [56] The system studied was a series of different sized CdS quantum dots on a metal surface such as gold (for 38 Å diameter cluster) or aluminum (for 24 Å and 70 Å diameter clusters) in order to avoid charging of the nanocrystallites due to electron removal from the sample. The nanoparticles were anchored to the metal surfaces using bifunctional organic groups as shown in Figure 10. The metal substrate did not contribute any observable spectral intensity possibly due to the short escape depth (10–30 Å) of the photoelectrons in the operational photon energy range. The experiments were carried

Figure 10. Photoemission spectra from CdS quantum dots bound to gold metal surface and schematic illustration of the sample. Reprinted with permission from [56], V. L. Colvin et al., *Phys. Rev. Lett.* 66, 2786 (1991). © 1991, American Physical Society.

out on a synchrotron source with variable photon energies in the range of 20–70 eV. Figure 10 shows a representative photoemission spectrum for the 38 Å CdS nanocrystallites. The data do not differ qualitatively from those of bulk CdS [81]. The valence band edges of the three differently sized nanoparticles were calculated from various spectra recorded with 50, 55, 60, and 70 eV photon energies. Extrapolation of the rising edge in each spectrum near the Fermi energy to the baseline gives the position of the valence band maximum. The experimentally determined valence band edges are plotted in Figure 11 as a function of the particle size. The solid line shows the infinite potential effective mass approximation with the effect of the dielectric material included. Due to the problem of fixing the reference of energy in absence of the corresponding bulk CdS spectrum, all the energies were rigidly shifted such that the data point for the 70 Å cluster coincides with the theoretical line. In this

Figure 11. Energy shift of the valence band maximum vs cluster size. The shift for the largest size was fixed at 0.217 eV to match with the theoretical curve. The theory includes a dielectric polarization term as well as quantum confinement. Reprinted with permission from [56], V. L. Colvin et al., *Phys. Rev. Lett.* 66, 2786 (1991). © 1991, American Physical Society.

procedure, energy shifts for the smaller nanoparticles are essentially calculated with reference to the 70 Å cluster. Colvin et al. [56] did not observe any photoemission signal from the metal surfaces to which the nanoparticles were attached. Using this method, the chain length of the organic linker can be varied to study the changes in the photoemission spectra with the nanoparticle size.

Recently van Burren et al. carried out electronic structure measurements on nanocrystalline silicon [82]. The Si nanocrystallites were grown *in-situ* at 1700 °C in an argon buffer gas of 112 mTorr followed by hydrogen exposure to passivate the surface. The size of the crystallites was controlled by varying the temperature and Ar pressure. Photoemission measurements at a resolution of 0.25 eV and X-ray absorption studies with 0.05 eV resolution were carried out using synchrotron radiation in order to determine the valence band maximum and the bottom of the conduction band, respectively. The variations of valence band and conduction band edges are plotted in Figure 12. For Si, it is seen that the ratio of the shift of the valence band edge to the conduction band edge is always 2:1. This is in agreement with various electronic structure calculations reported earlier [83]. van Burren et al. [82] compared their experimental results with the calculated results based on pseudopotential method [84]. For all sizes of the nanoparticles, the theory was found to overestimate both the band edges and the bandgap.


Lüning et al. [85] studied four different sizes of CdS nanocrystallites, namely, cadmium thiolate $Cd_8(SR)_{16}$, $Cd_{17}S_4(SR)_{26}$ (13.5 Å), $Cd_{32}S_{14}(SR)_{36}$ (17.5 Å), and CdS nanoparticle of 40 Å diameter, using a combination of soft X-ray emission (SXE) spectroscopy for the valence band edge and soft X-ray absorption (SXA) spectroscopy for the conduction band edge. Figure 13 shows the SXE and SXA spectra for the various nanocrystallites along with those of bulk CdS. For small sized nanocrystallites one can easily observe a sharp feature in SXA spectra at about 163 eV; this has been attributed to a core excitonic peak near the conduction band edge. The exciton peaks are fitted with a Gaussian with a 700 meV width and subtracted from the SXA spectra to determine the conduction band edge. Apart from the bandgap variation, they also observed a systematic

Figure 12. (a) The conduction band edge shift and (b) the valence band edge shift as a function of nanocrystal diameter. Figure 13. Right part: S $L_{2,3}$ SXA spectra (solid) of CdS bulk, a thiol-stabilized NC of 40 Å (CdS_{40}), the $Cd_{32}S_{14}(SR)_{36}$ (Cd_{32}), and the $Cd_{17}S_4(SR)_{26}$ (Cd_{17}) NC, and the Cd thiolate $Cd_8(SR)_{16}$ (Cd_8). The dotted lines show the separation into excitonic and LPDOS excitation. Left part: top part of the smoothed S L_3 SXE spectra (crosses show the non-smoothed data) mapping the local $S(s + d)$ symmetric DOS of the upper VB. The width of the upper VB is quantified by the arrows indicating the full width at half maximum of the upper VB. Gray bars indicate the linear extrapolation of the emission cutoffs and the LPDOS absorption onsets, respectively. Reprinted with permission from [85], J. Lüning et al., *Solid State Commun.* 112, 5 (1999). © 1999, Elsevier Science.

decrease in the band width of the upper part of the valence band (shown in Fig. 13), which is mainly composed of S $3p$ states; the width decreases from 4.8 eV for CdS bulk to 3.5 eV for Cd thiolate. However, the lower part of the valence band (not shown in the figure), which is derived from the more localized S $3s$ and Cd $4d$ states, is hardly affected by size quantization.

In order to separately determine the shifts in the valence band maximum (VBM) and conduction band minimum (CBM) for individual nanocrystallites, the S $2p$ core level photoemission spectra were aligned for all the spectra, serving as an internal energy reference, and the experimentally obtained shifts in the VBM and CBM are plotted in Figure 14. Also shown are the results of theoretical calculations using the tight-binding sp^3s^* model as well as using the infinite potential [15] (IP) and the finite potential [86] (FP) effective mass approximations (EMA). The FP-EMA agrees well with the experimental data whereas the TB model does not describe the data accurately. Figure 14 shows that the IP-EMA suggests a dominance of the conduction band shift in determining the variation in the total bandgap with size, with considerably lower contributions from the shifts in the
valence band edge in contrast to the experimental results. It is interesting to note that EMA with a finite potential barrier changes the results more pronouncedly for the conduction band edge compared to those of IP-EMA, yielding a better agreement with the experimental results.

The efficacy of the realistic sp^3d^5 model [65, 67] has been established recently by comparing the valence band density of states of various sizes of ZnS nanocrystallites obtained from photoemission experiments with model calculations. Figure 15 shows the comparisons of experimental valence band spectra with calculated density of states for 1.8, 2.5, 3.5 nm ZnS nanoparticles and bulk ZnS. This figure shows an excellent agreement between the experimental density of states and that calculated using the sp^3d^5 model with next-nearest-neighbor interactions. It turns out that valence bands of the $A^{II}B^{VI}$ semiconductors have substantial admixtures from the cation d states. Therefore, it is essential to consider a model containing the d orbitals in order to compare the density of states to calculated results. Shifts in the valence band edges in the nanocrystallites compared to the bulk ZnS could be easily estimated from these valence band photoemission spectra and compared with the shifts calculated within the same model (Fig. 16). The shifts

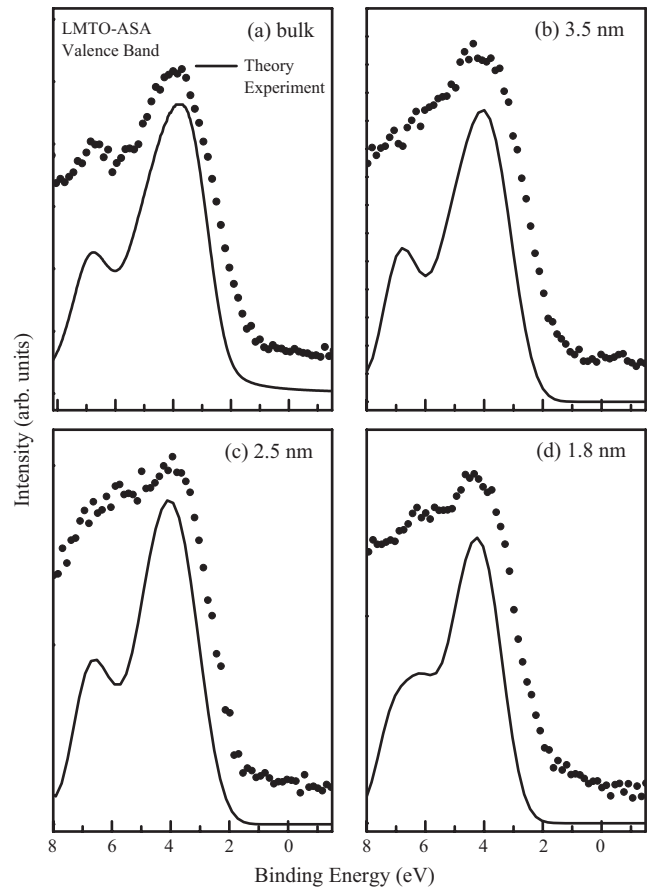

Figure 14. Experimentally determined contributions of the occupied and unoccupied states (black dots) to the total bandgap opening are compared to the EMA using infinitely high potential walls (solid lines, IP-EMA) [15], the EMA taking the finite height of the potential walls into account (dashed lines, FP-EMA) [86], and the tight-binding calculation of Lippens and Lannoo (gray diamonds, TB) [37]. The calculated spectra for bulk ZnS is obtained using the LMTO-ASA method and those for the nanocrystals are from the sp^3d^5 model with nearest-neighbor and anion-anion interactions.
Figure 16. Variation of the top of the valence band (TVB) and bottom of the conduction band (BCB) with size as obtained using the sp^3d^5 model with nearest-neighbor and anion-anion interactions. The open-up-triangles on the TVB variation curve are experimental data points obtained from the photoemission experiments. The points on the BCB curve are obtained after subtraction of the TVB data points from the bandgap values obtained from the UV-Vis absorption.

in the conduction band edge could be extracted from the total shifts in bandgaps measured by optical absorption spectra and the shifts in the valence band edges from the photoemission spectra. Thus estimated shifts in the conduction band edges are also compared to the calculated ones as a function of size in Figure 16, indicating a good agreement.

5. CONCLUSIONS

We have reviewed here several effective and widely used techniques to describe the bandgap variation with size in semiconductor nanoparticles. The infinite potential EMA is a simple method to correlate the size of a nanoparticle with its bandgap; however, this approach overestimates the size. The finite potential EMA and the multiband EMA are improvements over the IP-EMA. The FP-EMA allows for the tunneling of charged electrons or holes outside the nanoparticles, while the MBEM approximation considers the degeneracy in the band structure at the top of the valence band. However, the EMA methods are incapable of providing a detailed electronic structure of the material.

The tight-binding method is a simple description that treats nanoparticle electronic states as a linear combination of the corresponding atomic orbitals. The initially used sp^3s^* orbital basis underestimates the bandgap and also lacks the d orbitals which are necessary to describe the density of states of the nanoparticles. The $sp^3d^5s^*$ orbital includes the d orbital in the basis and is an improvement over the sp^3s^* TB model. Inclusion of spin-orbit coupling further improves the description of the bandgap and the band edges of the nanoparticles. A good comparison with the experiment is provided by the sp^3d^5 model that includes the anion-anion interactions in addition to the usual cation-anion interactions.

In the last section, the work of various groups on valence band of the semiconductor nanoparticles has been reviewed. These experiments mainly describe the variation of the band edges and the evolution of the density of states as a function of size. Comparisons are made to the existing theoretical calculations both for the total bandgap variations as well as to shifts in the top of valence band and the bottom of the conduction band.

GLOSSARY

$A^{II}B^{VI}$ semiconductors Semiconductors with cation, A from Group IIb and the anion, B from Group VIa of the periodic table.

Band edge The top of the valence band or the bottom of the conduction band.

Bandgap The difference between the bottom of the conduction band and top of the valence band in case of semiconductors and insulators.

Band structure The relationship between the energy and the momentum vector.

Effective mass approximation (EMA) A theoretical method used to estimate the bandgap shift for nanocrystals. The conduction and the valence bands are assumed parabolic and are represented by the effective masses of the electron and the hole.

Mid gap states Electronic energy levels lying between the valence and the conduction band due to the presence of unsatisfied valencies at the surface of the nanocrystals.

Photoemission The emission of electrons from a material upon irradiation with X-rays or ultra-violet radiation.

Semiconductor nanocrystals Semiconductor nanoparticles with well defined crystalline arrangement of the atoms.

Semiconductor nanoparticles Semiconductor material particles with size in the regime 1–15 nm.

Tight binding (TB) method A calculation scheme for the electronic structure of materials based on the linear combination of atomic orbitals.

CONTENTS

1. INTRODUCTION

During the last few years key subjects and, consequently, terms in materials research have been continuously changing, indicating a tendency towards smaller and smaller scales. The physics of "low-dimensional structures" was replaced by the discipline of "submicron physics," emphasizing the effects due to a reduction of size. Then the term "mesoscopic systems" was introduced referring to typical length-scales ranging from a few nanometers up to a few micrometers. Mesoscopic systems are so small, that a complete quantum-mechanical treatment of electrons is required if one wants to describe their transport properties. On the other hand, they are so large, that an exact microscopic description, starting from precise location of impurities and sample boundaries, is not useful, since only the slightest change of the mesoscopic details will completely change the result. More recently still, the terms "nanophase" and "nanostructured materials" have become popular, indicating that scientists had learned to manipulate, synthesize, analyze, and observe objects approaching the molecular and atomic scales.

Often one distinguishes between "physical" and "chemical nanostructures." Under the term "physical nanostructures" are classified all artificially built up structures, as obtained, for example, by evaporation and subsequent deposition of materials. On the other hand, the term "chemical nanostructures" comprises all those nanophase materials that can be obtained by methods of chemical synthesis, such as the chemical compounds with chainlike or layer-type structures, as well as the cluster compounds. A review of the electronic properties of nanophase materials obtained from chemical synthesis was given by de Jongh [1]. A survey of chemically synthesized metal clusters was edited by Schmid [2]. The prospect of the applications of metal and semiconductor clusters in inorganic host structures was presented by Simon and Schön [3].

The time spent by a particle in a given region of space is not a new problem, although recently it has attracted a great deal of interest [4–16]. The problem has been approached from many different points of view, and there exists a huge literature on the tunnelling problem of electrons through a barrier, although tunnelling times have continued to be controversial even until now. As pointed out by Landauer and Martin [11], there is no clear consensus about simple expressions for the time in quantum mechanics (QM), where there is not a Hermitian operator associated with it. The problem of the tunnelling time of single electrons (SE) in nanostructures or in mesoscopic systems smaller than 10 nm becomes even more complicated, due to the Coulomb blockade effects [17] on small amounts of electrons and discreteness of electric charge.

In the present review we present the theoretical approaches to tunnelling times to illustrate the problems involved in nanostructures. But this plan proved to be more difficult than expected: although there exists an extended literature on tunnelling times (see [11] and [4] and references therein),

quantum-mechanical treatments mostly deal with propagating wavepackets in a more or less general way and they do not concentrate on tunnelling times in nanostructures. As far as we know, there is not yet a proper treatment about tunnelling times in very small nanostructures with single, localized electrons, where the radius of "localization" is in the same order of magnitude as the length of the barrier L. Thus it proved to be necessary not simply to present the existing models and theories on tunnelling time but to review them with respect to these necessities together with possible alternatives and to estimate future developments. In this context some original works will be analyzed from this point of view. We will be particularly concerned with the closed analytical treatment based on Green's function formalism.

In the main part of the chapter we study the Larmor clock approach to tunnelling time, based on measuring the spin rotation of an electron under a weak magnetic field acting on the region of interest. We also develop a Green's function formalism for the traversal, reflection, and dwell times based on the previous approach. The latter corresponds to the amount of time that a particle spends in a region independently of whether it later is transmitted or reflected. We review the rest of the existing major approaches to the time problem in Section 3. In Section 4, we present numerical results about the traversal time in rectangular barriers including finite size effects. We finally extract some conclusions and present open questions.

1.1. Tunnelling Time

Tunnelling refers to the classically impossible process of a particle to penetrate an energy barrier when its energy is smaller than the maximum of the potential of the barrier. The main magnitudes involved in the problem are the height V_0 and the length L of the potential barrier. If they are large, the probability to penetrate the barrier is very small and we say that it is an opaque barrier. Examples of tunnelling processes are α-decay, transmission of electromagnetic waves (EMW) in undersized waveguides, and tunnelling of electrons. A quantum particle usually is said to have an intrinsic "wave nature," often paraphrased by "wave functions" or "wavepackets." The probability to penetrate a barrier, which is quantified through the transmission coefficient (probability) T, strongly depends on the nature of the exponential decay of the wave function under the barrier.

Tunnelling of electrons has been of utmost importance for all fast effects in ME. The first device used as a fast switch was the semiconductor tunnel-diode which was commercially introduced in the late 1950s [18]. But again, only its total relaxation time was of interest and not the pure tunnelling time through the bounding barrier. Until relatively recently, little attention was paid to Hartman's theoretical work on tunnelling time of wavepackets in the 1960s [19]. His main striking result was that under certain circumstances (opaque barrier) the tunnelling time is independent of L and the traversal time can be less than the time that would be required to travel a distance equal to L in vacuum. Similar results were found by Rybachenko [20] for electrons in a rectangular barrier. Although these were excellent pioneer works, 30 years ago time was not ripe for a further evaluation with respect to practical consequences in ME or even to

philosophical ones. Additionally, many physicists hesitated to deal with Hartman's results since a very fast tunnelling, or a zero tunnelling time, holds a serious consequence: the tunnelling velocity or the average velocity may become higher than the light velocity c. Thus superluminal speed can be expected [21, 22] or measured in some cases like in experiments where electromagnetic waves pass through a barrier [23–27] or through an optical gap [9, 10, 16].

Since SE tunnelling processes could be evaluated in many nanostructures [28–31], it provided a strong motive for advancing nanofabrication technologies and research on tunnelling, which become important even at room temperature, since the operating temperature of single electron devices is directly related to the geometrical size of the electron localization. In SE the discreteness of the electric charge becomes essential and a quantum-mechanical tunnelling of electrons in a system of rather opaque junctions can be much affected by Coulomb interactions. For ME purposes the electron interactions, the barrier height and shape, and thus the tunnelling probability can be varied at will by externally applied voltages or by injected charges.

Usually in QM we can only measure quantities for which we have introduced a Hermitian operator, for example, energy E, momentum p, coordinate y, and so on. For these quantities, expectation values can be calculated and checked experimentally. However, time appears in the standard quantum-mechanical approach only as a parameter and therefore its expectation value is not defined. Since the beginning of QM, people have been aware of the conceptual problem of how to introduce a time operator with an appropriate classical analog, and there have been different theoretical approaches to find a consistent description of this problem [4, 11, 32].

Moreover, according to QM a particle under a barrier, with energy E smaller than V_0, can only be observed with a strong inelastic inuence. If we fix its coordinate with an accuracy of Δy smaller than the length of the barrier L, it necessarily results in a variation of momentum, caused by the measurement, and correspondingly in a change of the kinetic energy of the particle. This change in energy must be greater than the energy difference between the barrier height V_0 and the energy of the particle E [33]. If such a measurement would be carried out by light quanta, then we would have $\hbar\omega \geq V_0 - E$. The latter result demonstrates impressively that it is practically impossible to measure the propagation time from one coordinate (position) to the next under a barrier. This means that in practice one must try to observe the particle outside the barrier, say left or right of the region of interest. For short wavepackets, where the length of the wavepacket approaches the barrier length L, this means "far" left and "far" right.

One can associate the traversal time with the time during which a transmitted particle interacts with the region of interest, as measured by some physical clock which can detect the particle's presence after leaving the region. For electrons, this approach can utilize the Larmor precession frequency of the spin produced by a weak magnetic field hypothetically acting within the barrier region [20, 34–36]. Similar procedures have been developed for electromagnetic waves in [37], where was proposed a clock based on the Faraday effect to measure their interaction time in a slab.

Another approach is to calculate the traversal time of a particle through a barrier by following the behavior of a wavepacket and determining the delay due to the structure of the region. In this approach one has to be careful with the interpretation of the results, since, for example, an emerging peak is not necessarily related to the incident peak in a causative way [38]. For more discussions on this problem see, for example, [11] and references therein. Martin and Landauer [39] studied the problem of the traversal time of classical evanescent electromagnetic waves by following the behavior of a wavepacket in a waveguide, and Ruiz and co-workers [15, 40] analyzed their behavior in the optical gap of a periodic structure. Japha and Kurizki [41] used the Faraday effect as a quantum clock for evanescent waves and studied its implications on two-photon correlations.

The problem of defining velocities is equally complicated as that of determining the time. One cannot use just one definition for the velocity both inside and outside the barrier at the same time. Usually, for a quantum particle when going from sub-barrier region to above-barrier region, one can do analytical continuation of the wave function. But in the first case there is an exponential decay of the wave function and in the second case we deal with a free propagation of the electron and so a wave function with oscillations. This analytical continuation is not correct for the velocity under the barrier, because one gets an imaginary velocity. So there is no definition of velocity for sub-barrier regions and as a consequence, in the limit of an opaque barrier or in the forbidden gap of a periodic system, there may be observed a "superluminal" speed.

1.2. Wavepacket Approach and Limits

The simplest model which illustrates the tunnelling problem for a quantum particle is a plane wave incident on a one-dimensional (1D) barrier. Part of the plane wave is reflected and part is transmitted. The above plane wave, which represents the electron in our model, is by nature infinitely large in space. The discussion of whether wavepackets with an infinite extension model the wave function of single photons or electrons and of whether they might be interpreted as signals is complicated [4, 11] and important for ME with nanostructures. Therefore it is better to consider a finite wavepacket and to look at its peak evolution in time (see Fig. 1). Thus the phase time is the time which elapses between the peak of the wavepacket entering the barrier and leaving it and can be defined as the energy derivative of the phase:

$$\tau_\varphi = \hbar \frac{d\varphi}{dE} \qquad (1)$$

In some cases this time can be easily calculated, but as was mentioned before, it will lead us to Hartman's effect. We will see (Section 2) that, in general, more than one tunnelling time are involved in the problem: τ_y, τ_z, and the so-called Büttiker-Landauer $\tau^{BL} = \sqrt{(\tau_y)^2 + (\tau_z)^2}$. Unfortunately this time is not additive in the sense, that when dividing the length of the barrier $L(y)$ arbitrarily into different parts, the total τ^{BL} tunnelling time is not the sum of the individual tunnelling times.

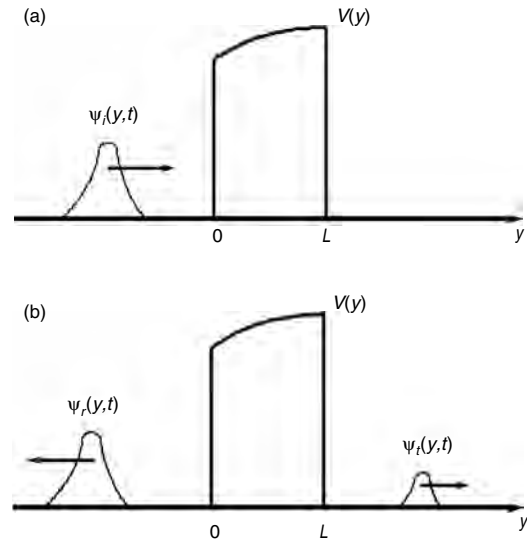

Figure 1. (a) The initial wavepacket enters from the left onto the barrier. (b) Transmitted and reflected wavepackets are moving away from the barrier in opposite directions.

To illustrate consequences from the above wavepacket model, let us consider a sharply peaked Gaussian wavepacket in space which starts to enter very far from the barrier to exclude any interaction. A wavepacket is an overlap of many plane waves with different wave numbers k. Hence, one may imagine the wavepacket as something like a group of electrons with different energies and velocities. The propagation will be dispersive and as a consequence the high-energy components of the packet will reach the barrier first. Due to the fact that higher energies can be transmitted more effectively than the low-energy components, the peak of the transmitted packet can leave the barrier long before the peak of the incident packet has arrived [11].

But what is really surprising is that even for the sub-barrier tunnelling, that is, when the wavepacket contains no energy components with energies above the rectangular barrier of height V_0, the transmitted packet will have a higher mean velocity than the free space propagation velocity. Numerical simulations show that one obtains very short tunnelling times when the spread of the Gaussian wavepacket is larger than the barrier width L. Within these restrictions even the simple rectangular barrier is an "electron accelerator." This is a manifestation of the aforementioned Hartman effect (see Section 2) which was treated by Rybachenko [20] for spin particles with analogous results. As we will show (Section 2), the tunnelling time component τ_y is independent of L and can be less than the time that would be required for a free particle to travel a distance equal to the barrier thickness L.

As a matter of principle, in ME for high information data rate, the spread of the Gaussian wavepacket must be small. Tunnelling time(s) then will depend to a higher degree on the size of the incident wavepacket and the shape of the barrier: tunnelling will become more sensitive to boundary effects at the barrier.

For the future SE logics in nanostructures, "pure" quantum-mechanical properties of monochromatic single electrons with an energy less than 1 eV will be predominant. For such particles the de Broglie wavelength $\lambda_B = \hbar/p$ will be in the same order of magnitude as the length of the barrier. At the same time, this wavelength will be comparable to the radius of localization (e.g., for electrons confined in the core of ligand-stabilized microclusters) in switches or mass memories (stores). Physically speaking, this means that the picture of a dispersive wavepacket is now failing. As far as we know, fast tunnelling for this case has not been treated theoretically until now.

1.3. Phase Time and Superluminal Velocity in Periodic Nanostructures

In ME the simultaneous transmission of electrons and of microwavepackets of selected optical signals between integrated microchips on wafers is of great importance and today much attention is paid to optoelectronics, since on the way to future ultimate miniaturization, the present generation of devices hopefully will be replaced by nanostructured systems.

While at the end of the preceding section we sketched the problems with localized electrons for the future SE logics in nanostructures, in the present section we first pay attention to microwaves in undersized waveguide barrier-systems and then to photons propagating in 1D periodic and quasi-periodic Fibonacci and Thue-Morse systems. We briefly report about the former first "superluminal" experiment, but we are mainly interested in the latter as there exists a considerable analogy between these periodic systems and, for example, chains of the above chemical nanostructures. So there also must exist forbidden bandgaps where electrons may propagate with "superluminal" speed. It must be noted that periodic structures can be easily built up in crystals of ligand-stabilized microclusters or likewise in chains or layers of supported cluster arrangements on structured wafers or other substrates or even in channels or layer spaces of porous chemical nanostructures (see [3]).

In order to avoid the problems involved with the dispersive nature of the electron's wavepacket and the invasive measuring process in QM, it was easier to look at a gaussian wavepacket of classical electromagnetic waves and to try to measure the delay time at a barrier. Indeed, in most of the past tunnelling experiments, instead of electrons, electromagnetic waves were used [8, 23], to exclude any electronic interaction with the tunnelling barrier. The analogy between the time-independent forms of the Schrödinger and the Maxwell equations confronts us again with Hartman's case: the possibility of achieving extremely high tunnelling velocities, even superluminal velocities.

Thus looking back, it was not so surprising that the actual discussion on "superluminal" speed started almost at the same time with the series of microwaves experiments by transmission through systems consisting of undersized waveguides [7, 8, 23–27]. Steinberg et al. [9] found "superluminal" velocities for electromagnetic waves in the photonic bandgap of multilayer dielectric mirrors. Spielman et al. [10] observed that the barrier traversal time of electromagnetic wavepackets tends to become independent of the barrier

thickness for opaque barriers. This phenomenon is closely related to Hartman's theoretical prediction for electron tunnelling [19]. The theoretical explanation of this phenomenon can be found in the framework of classical Maxwell equations by following the time evolution of the wavepacket in time, as it was mentioned above (see, e.g., [22, 36, 40]). It was clear that parts of the microwavepacket were able to propagate with "superluminal" speed, proving the practical use of Hartman's effect.

The propagation of electromagnetic waves in 1D quasi-periodic Fibonacci and Thue-Morse systems was studied in [14]. It was shown that, under certain conditions, again the phase time becomes independent of the system size and so "superluminal" group velocities can be obtained for very narrow-frequency-band wavepackets.

2. LARMOR CLOCK APPROACH

Baz' [34, 35] proposed the use of the Larmor precession to measure the time spent by a spin-1/2 particle inside a sphere of radius $r = a$. He considered the effect of a weak homogeneous magnetic field **B** inside the sphere on an incident beam of particles of mass m and kinetic energy $E = \hbar^2 k^2/2m$. Let us assume that the magnetic field is directed along the z axis and the incoming particles move along the y axis with their spin polarized along the x axis. As soon as a particle enters the sphere, its magnetic moment will start precessing about the field vector with the well-known Larmor frequency $\omega_L = 2\mu B/\hbar$. The precession will go on as long as the particle remains inside the sphere. The polarization of the transmitted (and reflected) particles is compared with the polarization of the incident particles. The angle $\theta_\perp$ in the plane xy, perpendicular to the magnetic field, between the initial and final polarizations is assumed to be given, in the lowest order in the field, by the Larmor frequency ω_L multiplied by the time τ_y spent by the particle in the sphere

$$\theta_\perp = \varphi_L \tau_y \qquad (2)$$

The change in polarization thus constitutes a Larmor clock to measure the interaction time of the particles with the region of interest.

Rybachenko [20] considered the simpler problem of the interaction time of particles with a one-dimensional rectangular barrier of height V_0 and width L, for which everything can be calculated analytically. Rybachenko thought that the spin, in first order in the field, remains in the xy plane. For an opaque barrier, where there is a strong exponential decay of the wave function, he found a characteristic interaction time τ_y given by

$$\tau_y = \frac{\hbar k}{V_0 \xi} \qquad (3)$$

where ξ is the inverse decay length in the rectangular barrier

$$\xi = (k_0^2 - k^2)^{1/2} \qquad (4)$$

with $k_0 = (2mV_0)^{1/2}/\hbar$. This characteristic time τ_y is independent of the barrier thickness L. Instead of being proportional to the length, L is proportional to the decay length.

For an opaque barrier this decay length can become very short and so τ_y can be very small, in fact, smaller than the time that would be required for the incident particle to travel a distance L in the absence of the barrier. A similar result was found by Hartman [19] analyzing the tunnelling of a wavepacket through a rectangular potential barrier, which is known as Hartman's effect.

2.1. Büttiker Approach

Büttiker [36] argued that the main effect of the magnetic field is to tend to align the spin parallel to it in order to minimize the energy. It means that a particle tunnelling through a barrier in a magnetic field does not only perform a Larmor precession, but also a spin rotation produced by the Zeeman effect, which necessarily has to be included in the formalism. The idea behind this Zeeman rotation is the following. A beam of particles polarized in the x direction can be represented as a mixture with equal probabilities of particles with their z component equal to $\hbar/2$ and to $-\hbar/2$. In the barrier the kinetic energy differs by the Zeeman contribution $\pm\hbar\omega_L/2$, giving rise to a different exponential decay of the wave function depending on its spin component along the direction of the magnetic field. In the limit of small fields we have

$$\xi_\pm = \left(k_0^2 - k^2 \mp \frac{m\omega_L}{\hbar}\right)^{1/2} \cong \xi \mp \frac{m\omega_L}{2\hbar\xi} \tag{5}$$

where the sign indicates whether the z component of the spin is parallel $(+)$ or antiparallel $(-)$ to the field. The particles with spin $\hbar/2$ will penetrate the barrier more easily than the particles with spin $-\hbar/2$, and so the transmitted particles will have a net z component of the spin. This net component of the spin along the direction of the field defines a second characteristic time τ_z of the particle in the barrier.

For each of the spin components, one can define a characteristic time describing the interaction of the tunnelling particle with the barrier:

$$\lim_{\omega_L \to 0} \langle S_x \rangle = \frac{\hbar}{2}\left[1 - \frac{\omega_L^2 (\tau_x^{BL})^2}{2}\right] \tag{6}$$

$$\lim_{\omega_L \to 0} \langle S_y \rangle = -\frac{\hbar}{2}\omega_L \tau_y^{BL} \tag{7}$$

$$\lim_{\omega_L \to 0} \langle S_z \rangle = \frac{\hbar}{2}\omega_L \tau_z^{BL} \tag{8}$$

Only two of these characteristic times are independent. The spin expectation values $\langle S_x \rangle$, $\langle S_y \rangle$, and $\langle S_z \rangle$ can be obtained in terms of the transmission amplitude for particles with $S_z = \pm\hbar/2$

$$t_\pm \equiv \sqrt{T_\pm}\, e^{i\varphi_\pm} \tag{9}$$

where $T_\pm$ and $\varphi_\pm$ are the corresponding transmission coefficient and phase, respectively.

For the special case of a 1D rectangular barrier, it is possible to find exact analytical expressions for the time. For energies smaller than the height of the barrier, $E < V_0$, Büttiker [36] obtained the following expression for the characteristic time associated with the direction parallel to

the field τ_z^{BL}:

$$\tau_z^{BL} = -\frac{m}{\hbar\xi}\frac{\partial \ln T^{1/2}}{\partial \xi} \tag{10}$$

For the time τ_y^{BL} associated with the direction of propagation, perpendicular to the field, he found

$$\tau_y^{BL} = -\frac{m}{\hbar\xi}\frac{\partial \varphi}{\partial \xi} \tag{11}$$

Here T and φ are, respectively, the transmission coefficient (probability) and the phase accumulated by transmitted particles due to the rectangular barrier in the absence of the magnetic field. In Figure 2 we represent τ_y^{BL} and τ_z^{BL} for a rectangular barrier.

Büttiker assumed that the relevant interaction time depends on the times associated to both the Larmor precession and the Zeeman splitting, and is given by

$$\tau^{BL} = \left\{(\tau_y^{BL})^2 + (\tau_z^{BL})^2\right\}^{1/2} \tag{12}$$

Figure 2. Components τ_y^{BL} and τ_z^{BL} of the Büttiker-Landauer time for a rectangular barrier. For energies higher than the barrier potential, both components oscillate with energy.

This traversal time is the so-called Büttiker-Landauer (BL) time for transmitted particles. Although it was obtained in the context of tunnelling, it is a general definition which applies for the traversal time of a particle or an electromagnetic wave through any given region of space. For a rectangular barrier, it is then given by

$$\tau^{BL} = \frac{m}{\hbar\xi}\left\{\left(\frac{\partial \ln T^{1/2}}{\partial \xi}\right)^2 + \left(\frac{\partial\varphi}{\partial\xi}\right)^2\right\}^{1/2} \tag{13}$$

When the energy E of an incident particle is well below the barrier height V_0 of an opaque rectangular barrier, Büttiker's result (13) is approximately equal to

$$\tau^{BL} \simeq \frac{mL}{\hbar\xi} \tag{14}$$

which is very different from the result of Rybachenko, Eq. (3). It is, however, in agreement with the traversal time obtained by Büttiker and Landauer [42] based on the transition from adiabatic to sudden limits for a time-modulated rectangular opaque barrier.

2.2. Green's Functions Method

We now derive a general expression for the traversal time using the Green's Function (GF) method [43, 44]. We will consider a 1D system with an arbitrary potential $V(y)$ confined to a finite segment $0 < y < L$, which we will call "the barrier." As for a rectangular barrier, we apply a weak magnetic field **B** in the z direction and confined to the barrier (see Fig. 3).

Our electron is incident on the barrier from the left with an energy E and with its spin polarized along the x direction. In the presence of the magnetic field, the Schrödinger equation takes the form

$$\left(-\frac{\hbar^2}{2m}\frac{d^2}{dy^2} + V(y) - E\right)\widehat{\Psi}(y) = -\mu B\begin{pmatrix}1 & 0\\0 & -1\end{pmatrix}\widehat{\Psi}(y) \tag{15}$$

Figure 3. General potential barrier restricted to the interval $0 < y < L$ with a magnetic field applied.

where the column wavevector $\widehat{\Psi}(y)$ represents compactly both spin states.

The problem is solved by perturbation theory. In the lowest order in B, the spinor $\widehat{\Psi}(L)$ of the electron on the right end of the barrier is given by [43]

$$\widehat{\Psi}(L) = \begin{pmatrix}1\\1\end{pmatrix}\psi(L) + \frac{e\hbar B}{2mc}\begin{pmatrix}1\\-1\end{pmatrix}\int_0^L \psi(y)G(y,L)\,dy \tag{16}$$

Here $\psi(y)$ is the solution of the spatial part of the Schrödinger equation in the absence of the magnetic field, which can be written in terms of the GF of the system as

$$\psi(y) = \exp(iky) - \int_0^L G(y,y')V(y')\exp(iky')\,dy' \tag{17}$$

where $G(y,y')$ is the retarded GF, whose energy dependence is not written explicitly. It should satisfy Dyson's equation:

$$G(y,y') = G_0(y,y') + \int_0^L G_0(y,y'')V(y'')G(y'',y')\,dy'' \tag{18}$$

where $G_0(y,y') = i(m/k\hbar^2)\exp(ik|y-y'|)$ is the free-electron GF. We can obtain all the relevant properties of the problem in terms of the GF, solution of the previous equation.

We first concentrate on the calculation of the traversal time. The expectation value of the component of the spin along the direction of the magnetic field of the transmitted electron is, up to second order in B:

$$\langle S_z \rangle = \frac{\hbar}{2}\langle \widehat{\Psi}(L)|\sigma_z|\widehat{\Psi}(L)\rangle$$
$$= -\frac{e\hbar^2 B}{mc}\,\text{Re}\left[\psi^*(L)\int_0^L \psi(y)G(L,y)\,dy\right] \tag{19}$$

We want to express the wave function $\psi(y)$ appearing inside the integral in the previous equation in terms of the GF. In order to do so, we take into account the following relationship between the wave function and the GF of a 1D system:

$$\psi(y) = -\frac{i\hbar^2 k}{m}G(0,y) \tag{20}$$

For one-dimensional systems also, we can further simplify the problem by writing the general expression of the GF, $G(y,y')$, in terms of its own expression at coinciding coordinates $y = y'$ [45]. One finds that the spin component along the direction of the magnetic field is given by

$$\langle S_z \rangle = \frac{e\hbar^2 B}{mc}|\psi(L)|^2\,\text{Re}\int_0^L G(y,y)\,dy \tag{21}$$

Similarly, the spin component along the y direction is equal to

$$\langle S_y \rangle = -\frac{e\hbar^2 B}{mc}|\psi(L)|^2\,\text{Im}\int_0^L G(y,y)\,dy \tag{22}$$

Büttiker-Landauer characteristic traversal times for the z and y directions are proportional to the corresponding spin components, Eqs. (8) and (7), and we finally arrive at

$$\tau^{\mathrm{BL}} = \hbar \left| \int_0^L G(y, y)\, dy \right| \qquad (23)$$

Instead of defining the modulus of τ_z^{BL} and τ_z^{BL} as the central magnitude of the problem, we prefer to define a complex traversal time τ as

$$\tau = \tau_z^{\mathrm{BL}} + i\tau_y^{\mathrm{BL}} = \hbar \int_0^L G(y, y)\, dy \qquad (24)$$

As we will see, other approaches also get a complex time. The two characteristic times of the problem can be written in a compact form as the real and imaginary parts of a single well-defined magnitude. Besides, these two time components may be separately relevant to different experimental results, and do not have to necessarily enter into the problem through the modulus, Eq. (23). We will come back to this question.

The final result, Eq. (24), only depends on the integral of the GF at coinciding coordinates. For practical purposes and in order to compare this result with those of other approaches, it is interesting to rewrite it in terms of the transmission t and reflection from the left r and from the right r' amplitudes [44, 45]. The spatial integral, over the length of the barrier, of the GF at coinciding coordinates can be expressed in terms of partial derivatives with respect to energy E:

$$\tau = \hbar \int_0^L G(y, y)\, dy = \hbar \left\{ \frac{\partial \ln t}{\partial E} + \frac{1}{4E}(r + r') \right\} \qquad (25)$$

This is a general expression, independent of the model considered.

The first term in the RHS of Eq. (25) mainly contains information about the region of the barrier. Most of the information about the boundary is provided by the term including the reflection amplitudes r and r'. This term is on the order of the wavelength λ over the length of the system L, and it becomes important for low energies and/or short systems. It can be neglected in the semiclassical WKB case and when r is negligible, for example, in the resonant case, when the influence of the boundaries is negligible. Certain approaches only obtain the contribution to the time proportional to an energy derivative, missing the terms proportional to the reflection amplitudes. The same type of problem arises when calculating densities of states or partial densities of states [46].

The components of the traversal time can be related to the density of states and the resistance. The imaginary part of $G(y, y)$ is proportional to the local density of states at the corresponding energy. So, τ_y^{BL} can also be written as $\tau_y^{\mathrm{BL}} = \pi\hbar L\nu_L(E)$, where $\nu_L(E)$ is the average density of states per unit energy and per unit length.

Thouless has shown [47] the existence of a dispersion relation between the localization length and the density of states. This relationship can be expressed [48] in the form of a linear dispersion relation between the real part, $\mathrm{Re}\,\ln t$,

and the imaginary part, $\mathrm{Im}\,\ln t$, of the transmission amplitude. The self-averaging property of τ_z^{BL} and of τ_y^{BL} is therefore an immediate consequence of self-averaging of the localization length and of the density of states [48]. While τ_z and τ_y are additive, the total tunnelling time τ^{BL}, given by Eq. (23), is not the sum of the individual transmission times. This property has also been pointed out by Leavens and Aers [49]. It is a consequence of the fact that, for an infinitesimal B, the interference between the effects of the magnetic field in the separate regions $[0; y]$ and $[y; L]$ is of higher order than linear and does not contribute to the local times [49]. Mathematically speaking, we say that the BL time, Eq. (23), adds as the absolute value of complex additive numbers, and so it is not additive.

2.3. Reflection Time

For reflected particles we can proceed in the same way as we did for transmitted particles. We will use the subindex R to indicate that the magnitude corresponds to reflection, and we understand that similar magnitudes related to transmission will have no subindex. Proceeding as above, we find for the expectation values of the spin components of the reflected wave: and

$$\langle S_z \rangle_{\mathrm{R}} = \frac{\hbar}{2} \langle (\widehat{\Psi}(0) - 1) \, |\sigma_z| \, (\widehat{\Psi}(0) - 1) \rangle$$
$$= \frac{e\hbar^2 B}{mc} |\psi^*(0) - 1|^2 \, \mathrm{Re} \int_0^L \psi(y)G(0, y)\, dy \qquad (26)$$

and

$$\langle S_y \rangle_{\mathrm{R}} = -\frac{e\hbar^2 B}{mc} |\psi^*(0) - 1|^2 \, \mathrm{Im} \int_0^L \psi(y)G(0, y)\, dy \qquad (27)$$

We can again define three new characteristic times, $\tau_{z,\,\mathrm{R}}^{\mathrm{BL}}$, $\tau_{y,\,\mathrm{R}}^{\mathrm{BL}}$, and $\tau_{x,\,\mathrm{R}}^{\mathrm{BL}}$, each of them associated with a component of the spin. Only two of these times are independent. Invoking Eqs. (26) and (27) and the relationship (20) between the wave function and the GF of a one-dimensional system, we arrive at

$$\tau_{y,\,\mathrm{R}}^{\mathrm{BL}} = \hbar \, \mathrm{Im} \, \frac{1 + r}{r} e^{-i2\theta(0)} \int_0^L G(y, y) e^{i2\theta(y)}\, dy \qquad (28)$$

$$\tau_{z,\,\mathrm{R}}^{\mathrm{BL}} = \hbar \, \mathrm{Re} \, \frac{1 + r}{r} e^{-i2\theta(0)} \int_0^L G(y, y) e^{i2\theta(y)}\, dy \qquad (29)$$

where $\theta(y)$ is a phase function given by

$$\theta(y) = \int_0^y \frac{im}{\hbar^2} \frac{dy'}{G(y', y')} \qquad (30)$$

The characteristic times $\tau_{y,\,\mathrm{R}}^{\mathrm{BL}}$ and $\tau_{z,\,\mathrm{R}}^{\mathrm{BL}}$ are the real and imaginary components, respectively, of a complex quantity. This quantity is proportional to a new integral of the GF at coinciding coordinates, which in this case involves the phase function also. The previous integral can be written in terms of the transmission and reflection amplitudes. We arrive at the following expression for the complex reflection time [50]:

$$\tau_{\mathrm{R}} = \tau_{z,\,\mathrm{R}}^{\mathrm{BL}} + i\tau_{y,\,\mathrm{R}}^{\mathrm{BL}} \equiv \hbar \left\{ \frac{\partial \ln r}{\partial E} - \frac{1}{4Er}(1 - r^2 - t^2) \right\} \qquad (31)$$

This is again a general equation, independent of the model used.

For an arbitrary symmetric potential, $V((L/2) + y) = V((L/2) - y)$, the total phases accumulated in a transmission and in a reflection event are the same, as can be deduced from the form of the scattering matrix elements, and so the characteristic times for transmission and reflection corresponding to the direction of propagation are equal:

$$\tau_y^{\text{BL}} = \tau_{y,\,\text{R}}^{\text{BL}} \tag{32}$$

as it immediately follows from Eqs. (25) and (31) (see also the review article by Hauge and Støvneng [4]). For the special case of a rectangular barrier, Eq. (32) was first found by Büttiker [36]. For an asymmetric barrier, Eq. (32) breaks down as discussed by Leavens and Aers [51].

2.4. Dwell Time

There is also another important characteristic time called the dwell time, about which there exists a vast literature (see, e.g., [4, 11] and references therein). This time was first introduced by Büttiker [36] region divided by the average number entering (or leaving) the barrier per unit time. It corresponds to the average time spent by a particle within the barrier irrespective of whether it is finally reflected or transmitted.

The dwell time in a neighborhood of y is defined as the ratio between the particle number in the interval $[y, y + dy]$ and the incoming current [36]:

$$d\tau^{(\text{D})}(y) = \frac{|\psi(y)|^2}{J} \, dy \tag{33}$$

where $\psi(y)$ is the steady-state scattering solution of the time-independent Schrödinger equation. Obviously, Eq. (33) describes a balance equation: in the stationary case the injected current equals the decay rate of the probability in $[y, y + dy]$. The dwell time $\tau^{(\text{D})}$ of a finite region within the context of a stationary-state scattering problem is obtained via a spatial integration of Eq. (33). So the dwell time $\tau^{(\text{D})}$ is given by [36]

$$\tau^{(\text{D})} \equiv \frac{m}{\hbar k} \int_0^L |\psi(y)|^2 \, dy \tag{34}$$

Here the integral extends over the barrier, and $\hbar k/m$ is the incident flux. Again we want to calculate this time in terms of the transmission and reflection amplitudes.

Let us consider again a particle moving along the y direction in the presence of an arbitrary potential barrier $V(y)$ in the interval $[0, L]$. Taking explicitly into account that the wave function appearing in Eq. (34) is a solution of the Schrödinger equation, we arrive at [52]

$$\tau^{(\text{D})} = -\frac{\hbar}{4k} \left[\psi^{*2}(y) \frac{\partial}{\partial E} \left(\frac{\psi'(y)\psi(y)}{|\psi(y)|^2} \right) \right.$$
$$\left. + \psi^2(y) \frac{\partial}{\partial E} \left(\frac{\psi^{*\prime}(y)\psi^*(y)}{|\psi(y)|^2} \right) \right]_0^L \tag{35}$$

This expression is formally the same for particles incident from the left or from the right, but we have to remember that the corresponding wave functions will not be the same. García-Calderón and Rubio [53] arrived at the same result by a completely different method.

We can now rewrite Eq. (35) in terms of the retarded GF $G(y, y')$ of the system, as we have been doing for the other times. The dwell time is given by

$$\tau^{(\text{D})} = \left[i \frac{\partial}{\partial E} \theta(y) - G(y, y) \frac{\partial}{\partial E} \left(\frac{G'(y, y)}{G(y, y)} \right) \right]_0^L \tag{36}$$

As it occurs for the wave function, the GF $G(y, y')$ depends on whether the particle arrives to the barrier from the left or from the right. After some cumbersome algebra, we can express the dwell time in terms of the transmission and reflection amplitudes:

$$\tau_-^{(\text{D})} = \hbar \, \text{Im} \left\{ \left[\frac{\partial \ln t}{\partial E} + \frac{1}{4E}(r + r') \right] \right.$$
$$\left. + \frac{1}{2} \left[\sqrt{R} \frac{\partial}{\partial E} \ln \frac{r}{r'} + \frac{1}{2E}(r - r') \right] \right\} \tag{37}$$

The subindex-indicates that the particle is coming from the left. R is the modulus square of the reflection amplitudes $R = |r|^2 = |r'|^2$. When the particle is coming from the right, the dwell time is given by an expression similar to Eq. (37), but interchanging r and r'. We will refer to this case with the subindex $+$.

Gasparian et al. [44] showed that the first term on the RHS of Eq. (37) is proportional to the density of states. Then, we finally arrive at the following expression for the dwell time:

$$\tau_\pm^{(\text{D})} = \pi\hbar L\nu(E) \pm \frac{\hbar}{2} \, \text{Im} \left[\sqrt{R} \frac{\partial}{\partial E} \ln \frac{r}{r'} + \frac{1}{2E}(r - r') \right] \tag{38}$$

For a symmetric potential we have that the reflection coefficients from the right and from the left are equal, $r = r'$, and we obtain $\tau_-^{(\text{D})} = \tau_+^{(\text{D})} = \pi\hbar L\nu(E)$, in agreement with the result of Gasparian and Pollak [43].

For an asymmetric barrier, it is easy to check that the contribution from the asymmetry is the opposite for particles coming from the left and from the right. Then we find that

$$\nu(E) = \frac{1}{2\pi\hbar L} \left(\tau_-^{(\text{D})} + \tau_+^{(\text{D})} \right) \tag{39}$$

This result was obtained in a much wider context by Iannaccone [54], which considered the relation between the dwell time and the density of states for a three-dimensional region Ω of arbitrary shape with an arbitrary number of incoming channels. He arrived at

$$\nu_\Omega(E) = \frac{1}{2\pi\hbar} \sum_{n=1}^N \tau_n^{(\text{D})} \tag{40}$$

where $\nu_\Omega(E)$ is the density of states per unit volume, and $\tau_n^{(\text{D})}$ is the dwell time for particles coming from the n-channel. This result shows that the density of states in Ω is proportional to the sum of the dwell times in Ω for all the incoming channels.

A controversial question concerning the dwell time is whether it satisfies or not the relation (see [49, 55, 56])

$$\tau^{(D)} = R\tau_{y,R}^{BL} + T\tau_y^{BL} \tag{41}$$

This result is trivial for classical particles, for which the traversal time coincides with the y component of our complex traversal time and for which there is no interference between the reflected and the transmitted particles. For the quantum coherent case, this result is not so clear. We can prove this relation, which we believe must hold because a particle incident on the barrier is either transmitted or reflected. Reflection and transmission of a particle are mutually exclusive events in the sense of Feynman and Hibbs [57]; that is, a measurement can determine, without interfering with the scattering event, whether a particle has been transmitted or reflected. Our results for the y component of the transmission and reflection times, Eqs. (25) and (31), respectively, and for the dwell time, Eq. (37), allow us to prove exactly the previous relation between these times. On the other hand, our results also prove that a similar relation involving the full BL times does not hold. This relation has been claimed very often in the literature, and has been strongly criticized by other authors [11].

3. OTHER APPROACHES

In this section, we review other approaches to the problem of the traversal and reflection times. We would like to show that most results, obtained from very different points of view, are almost compatible and coincide with Eq. (25) for the traversal time and with Eq. (31) for the reflection time. Often, these approaches only obtain the contributions to the time proportional to the energy derivative of the logarithm of the transmission amplitude.

We start with the oscillatory incident amplitude and with the time-modulated barrier approaches. Then we review the Feynman path-integral approach, where the idea of a complex time arises more naturally. We finish with the kinetic approach, which is very convenient to study finite size effects and so the standard errors inherent to the problem.

3.1. Oscillatory Incident Amplitude

We assume an incident wave of oscillatory amplitude interacting with a time-independent potential, and study the shape distortion of the transmitted wave by the barrier. This method was proposed by Büttiker and Landauer [58, 59] and analyzed by Leavens and Aers [51] and Martin and Landauer [60]. The incident wave consists of two interfering plane waves:

$$\Psi(y, t) = \exp\left\{ i\left[ky - \frac{Et}{\hbar} \right] \right\}$$

$$+ \exp\left\{ i\left[(k + \Delta k)y - \frac{(E + \Delta E)t}{\hbar} \right] \right\}$$

$$= 2\exp\left\{ i\left[(k + \Delta k/2)y - \frac{(E + \Delta E/2)t}{\hbar} \right] \right\}$$

$$\times \cos\left(\frac{\Delta ky}{2} - \frac{\Delta Et}{2\hbar} \right) \tag{42}$$

The energy difference between the two plane waves characterizes the oscillations in amplitude of the incident wave. In the region to the right of the barrier, we have the sum of two transmitted plane waves which can be written in the form

$$\Psi(y, t) = t(E)\left\{ i\left[ky - \frac{Et}{\hbar} \right] \right\} + t(E + \Delta E)$$

$$\times \exp\left\{ i\left[(k + \Delta k)y - \frac{(E + \Delta E)t}{\hbar} \right] \right\} \tag{43}$$

The shape distortion produced by the barrier on the transmitted wave will strongly depend on ΔE. If ΔE is small, the incident wave is modulated very slowly and in that case the transmitted wave (43) will reproduce the incident wave (42), in the sense that the destructive and constructive interferences will occur at the same time for both of them. As we increase ΔE, $t(E)$ and $t(E + \Delta E)$ will increasingly differ and the transmitted wave (43) will no longer reproduce the incident wave. We can assume that appreciable shape distortion will take place when a characteristic time delay, or dispersion in transit time, becomes comparable to or larger than the modulation period [58, 59]. Thus we define a new traversal time τ as $\hbar/\Delta E$, where ΔE is the energy difference which establishes the onset of significant distortion of the transmitted wave, that is, the energy such that $\Delta E|d\alpha(E)/dE| \approx 1$.

The analysis of this approach based on the WKB approximation led Büttiker and Landauer [58] to the following results. For $E < V(y)$, the phase of the transmission amplitude is of secondary importance as compared with the exponential decay of the modulus of $t(E)$. We can write the transmission amplitude in the form

$$t_{WKB}(E) = \exp\left[-\int_{y_1}^{y_2} \xi(y)\, dy \right] \tag{44}$$

where ξ is the inverse decay length, given by Eq. (4), and y_1 and y_2 are the classical turning points. From this expression of the transmission amplitude, Büttiker and Landauer obtained for the traversal time for tunnelling

$$\tau_{WKB}(E) = \frac{m}{\hbar}\left[-\int_{y_1}^{y_2} \frac{dy}{\xi(y)} \right] \tag{45}$$

When $E > V(y)$, the energy dependence of $t(E)$ comes primarily from the dependence of the phase ($|t(E)| = 1$), and then we can assume that $t(E)$ is of the form

$$t_{WKB}(E) = \exp\left[-i\int_0^L K(y)\, dy \right] \tag{46}$$

with $K(y) = i\xi(y)$. For this case, in which the phase dominates, we have

$$\tau_{WKB}(E) = \frac{m}{\hbar}\left[\int_0^L \frac{dy}{K(y)} \right] \tag{47}$$

It is easy to check that, for a rectangular barrier, the traversal time τ_{WKB} is equal to $mL/\hbar\xi$ for energies below the barrier height and equal to $mL/\hbar K$ for energies above the barrier. As it was shown by Martin and Landauer [60], the general analysis of this two-interfering-incident-waves

approach yields characteristic times that depend on energy derivatives of the transmission coefficient

$$\tau = \hbar |t_E^{-1}| \left| \frac{dt_E}{dE} \right| = \hbar \left\{ \left(\frac{d\varphi}{dE} \right)^2 + \left(\frac{d\ln T}{dE} \right)^2 \right\}^{1/2} \quad (48)$$

As in the Büttiker and Landauer approach to the Larmor clock, the time is equal to the square root of the sum of the squares of two characteristic times, one involving energy derivatives of the phase and the other energy derivatives of the logarithm of the modulus of the transmission amplitude. The same result for the traversal time is also obtained in the modulated barrier approach [60].

It is interesting to note that this oscillatory amplitude approach without resort to the WKB approximation led Leavens and Aers [51] to complex times. Let us write the transmission amplitude as

$$t(E) = \exp[i\beta(E)] \quad (49)$$

where $\beta(E)$ is in general complex. For sufficiently small ΔE, we may expand $t(E + \Delta E)$ to lowest order in ΔE:

$$t(E + \Delta E) \cong \exp\left[i \left(\beta(E) + \Delta E \frac{d\beta(E)}{dE} \right) \right]$$

$$= t(E) \exp\left[i\Delta E \frac{d\beta(E)}{dE} \right] \quad (50)$$

This expression should be substituted in Eq. (43) for the transmitted packet. For sufficiently small ΔE, the difference in exponents of the two components of the transmitted wave at $y = L$ and $t = \Delta t$ is greater than that of the two components of the incident wave at $y = 0$ and $t = 0$ by an amount

$$i\left[\Delta k L - \frac{\Delta E}{\hbar \Delta k} \left(\Delta t - \hbar \frac{d\beta(E)}{dE} \right) \right]$$

$$\cong i\Delta k \left[L - v(k) \left(\Delta t - \hbar \frac{d\beta(E)}{dE} \right) \right] \quad (51)$$

with $v(k) \equiv \hbar^{-1} dE/dk = \hbar k/m$ being the group velocity. In the absence of the potential barrier, the traversal time associated with the propagation of the wavepacket from $y = 0$ to $y = L$ is the value of Δt for which $L - v(k)\Delta t = 0$, that is, $\tau = L/v(k)$. Formally, in the presence of the potential, Leavens and Aers [51] obtained from Eq. (51) the complex barrier interaction "time"

$$\tau^E = \frac{L}{v(k)} + \hbar \frac{d\beta(E)}{dE} \equiv -i\hbar \frac{\partial \ln t}{\partial E} \quad (52)$$

This final answer for the time is just proportional to $\partial \ln t/\partial E$, and so is correct for infinitely large systems only $(L \gg \lambda)$. The difference between this expression for the traversal time and our general expression (25) is the term proportional to the reflection amplitude, which cannot be obtained with this type of approach.

We can deduce explicit expressions for all these times, and so see clearly the difference between Eq. (52) and Eq. (25), obtained with the GF formalism, for the special case of a rectangular barrier. Let us associate the real and imaginary components of this complex time, Eq. (52), with the previous

characteristic times for the y and z components, and let us denote them as τ_y^E and τ_z^E. The explicit expressions for the two components of the traversal time τ_y^E and τ_z^E for this special case of a constant potential can be written in the form [51]

$$\tau_z^E = -\hbar \frac{\partial \ln T^{1/2}}{\partial E}$$
$$= \frac{mk_0^4}{2\hbar\xi^2 k^2} \frac{2(\xi^2 - k^2)\sinh^2(\xi L) + k^2\xi L \sinh(2\xi L)}{4k^2\xi^2 + k_0^4 \sinh^2(\xi L)} \quad (53)$$

$$\tau_y^E = \hbar \frac{\partial \varphi}{\partial E} = \frac{m}{\hbar k\xi} \frac{2\xi L k^2(\xi^2 - k^2) + k_0^4 \sinh(2\xi L)}{4k^2\xi^2 + k_0^4 \sinh^2(\xi L)} \quad (54)$$

After an obvious change of notation, it is easy to check that the times τ_y^E and τ_z^E are related to the exact results τ_y^{BL} and τ_z^{BL} through

$$\tau_y^E = \tau_y^{BL} + \frac{1}{2E} \operatorname{Im} r$$
$$-\tau_z^E = \tau_z^{BL} + \frac{1}{2E} \operatorname{Re} r \quad (55)$$

where τ_z^{BL} and τ_y^{BL} are given by Eqs. (10) and (11). Figure 4 compares τ_y^E with τ_y^{BL} for a rectangular barrier. It can be

Figure 4. Components of the traversal time for a rectangular barrier according to Eqs. (25) and (54).

seen that, even for an opaque barrier ($\xi L \gg 1$), the differences between these times can be very significant. This is particularly so at very small energy E where τ_y^{BL} goes to zero as $E^{1/2}$, while τ_y^E diverges as $E^{-1/2}$, and, at the same time, τ_z^{BL} is approximately equal to 0, while τ_z^E diverges as E^{-1}. The oscillatory amplitude approach in general does not give the same answer as the GF formalism, based on the Larmor clock approach. As the difference between the corresponding tunnelling times is proportional to the amplitude of reflection, we concluded that it arises from boundary effects [44].

3.2. Time-Modulated Barrier

The time-modulated barrier approach to the traversal time was introduced by Büttiker and Landauer [42] (see also [58, 61]). Its basic idea is simple and can be explained as follows. Let us add to the static barrier potential which we discussed before a time-dependent potential which is zero everywhere except in the region of interest. So the 1D potential can now be written in the form

$$V(y, t) = V(y) + V_1 \cos(\omega t) \tag{56}$$

where V_1 is the amplitude of the small modulation added, and ω is its corresponding frequency. For the sake of simplicity, it is more convenient in this approach to consider the barrier restricted to the region $-L/2 < y < L/2$.

Suppose that there is a characteristic time τ during which the particle interacts with the barrier. If the period of the modulation $T = 2\pi/\omega$ is long compared to the time τ, then the particle sees an effectively static barrier during its traversal. In the opposite extreme, that is, for slowly tunnelling electrons, for which $\omega\tau > 1$, the barrier oscillates many times during the period of traversal of the electron. There is thus a crossover from a low-frequency behavior to a high-frequency behavior, and we expect to occur two distinct types of electron-barrier interactions, depending on the value of $\omega\tau$ as compared with unity.

We will use a rectangular barrier extensively, for illustrative purposes, but in principle all the results can be generalized to an arbitrary potential barrier by considering the adiabatic limit, $\omega \to 0$, of this inelastic scattering process [62]. The Hamiltonian for the time-modulated rectangular barrier in the scattering region is

$$H = -\frac{\hbar}{2m}\frac{d^2}{dy^2} + V_0 + V_1 \cos(\omega t) \equiv H_0 + V_1 \cos(\omega t) \tag{57}$$

As it is well known from the time-dependent perturbation theory [63], incident particles with energy E, interacting with the perturbation $V_1 \cos(\omega t)$, will emit or absorb modulation quanta $\hbar\omega$. In first-order corrections to the time-independent case, this means that inside the barrier, for $|y| > L/2$, the reflected and transmitted waves, used to represent the tunnelling electrons, we will now have a main feature at the initial energy E and also sidebands at the energies $E + \hbar\omega$ and $E - \hbar\omega$, as it is schematically represented in Figure 5. Taking V_1 as a perturbation, the two independent eigensolutions of the corresponding

Figure 5. For an oscillating barrier, besides a main transmission and reflection component at the initial energy E, there are two lateral components at energies $E \pm \hbar\omega$. Reprinted with permission from [86], V. Gasparian et al., "Handbook of Nanostructured Materials and Nanotechnology" (H. S. Nalwa, Ed.), Vol. 2, Chapter 11, 1999. © 1999, Elsevier Science.

time-dependent Schrödinger equation, within the rectangular barrier, can be written as [63]

$$\Psi_{bar}(y, t; E) = \varphi_E(y) \exp\left\{-\frac{iEt}{h}\right\} \exp\left\{-\frac{iV_1}{\hbar\omega}\sin\omega t\right\} \tag{58}$$

Here $\varphi_E = e^{\pm\xi y}$ is a wave function solution of the time-independent problem $H_0\varphi_E = E\varphi_E$, with the simpler Hamiltonian H_0.

As it was shown by Büttiker and Landauer [42], the next stage to find the solution for the oscillating rectangular barrier is to match Eq. (58) with the corresponding solutions at the same energy outside the scattering region. For an electron of energy E impinging on the scattering region, there will be reflected and transmitted waves at the three energies E, $E + \hbar\omega$, and $E - \hbar\omega$. So, if the electron is coming from the left, its wave function in the region to the left of the barrier, $y < -L/2$, will be of the form

$$\Psi_{inc+ref} = (e^{ik(y+L/2)} + re^{-ik(y+L/2)})e^{-iEt/\hbar} + r_+ e^{-ik_+(y+L/2)}$$
$$\times e^{-i(E+\hbar\omega)t/\hbar} + r_- e^{-ik_-(y+L/2)}$$
$$\times e^{-i(E-\hbar\omega)t/\hbar} \tag{59}$$

where $k_\pm$ are the wavevectors corresponding to the side energy bands, defined as $k_\pm = (2m/\hbar^2)^{1/2}(E \pm \hbar\omega)^{1/2}$. Equation (59) represents an incident plane wave of unit amplitude and three reflected waves, one of amplitude r at the incident energy and two of amplitudes $r_\pm$ at energies $E \pm \hbar\omega$. To the right of the barrier ($y > L/2$), we have for the transmitted wave

$$\Psi_{tra} = te^{ik(y-L/2)}e^{-iEt/\hbar} + t_+ e^{ik_+(y-L/2)}e^{-i(E+\hbar\omega)t/\hbar}$$
$$+ t_- e^{ik_-(y-L/2)}e^{-i(E-\hbar\omega)t/\hbar} \tag{60}$$

where t is the transmission amplitude at the energy of the incident wave and $t_\pm$ are the transmission amplitudes of the sidebands.

In the barrier, for an infinitesimal amplitude of the time-dependent potential, $V_1 \ll \hbar\omega$, we can expand Eq. (58) to

lowest order in V_1 and represent the wave function in the form

$$\Psi_{\text{bar}} = [Be^{\xi y} + Ce^{-\xi y}]e^{-iEt/\hbar}\left[1 + \frac{V_1}{2\hbar\omega}e^{-i\omega t} - \frac{V_1}{2\hbar\omega}e^{i\omega t}\right]$$
$$+ [B_+e^{\xi_+ y} + C_+e^{-\xi_+ y}]e^{-i(E+\hbar\omega)t/\hbar}$$
$$+ [B_-e^{\xi_- y} + C_-e^{-\xi_- y}]e^{-i(E-\hbar\omega)t/\hbar} \tag{61}$$

$\xi_\pm$ are the inverse decay lengths for the sidebands, defined as $\xi_\pm = (2m/\hbar^2)^{1/2}(V_0 - E \mp \hbar\omega)^{1/2}$. The coefficients r, $r_\pm$, B, $B_\pm$, C, $C_\pm$, t, and $t_\pm$ are determined by matching the wave functions and their derivatives at $y = -L/2$ and at $y = L/2$ in the usual manner. Note that the matching conditions must hold for all times; therefore, we have to match each time Fourier component separately. r and t play the role of the static reflection and transmission amplitudes, respectively. Using the standard matching relations, it is straightforward to show that for an almost completely reflecting barrier in the opaque limit, $\xi L \gg 1$, the coefficient t of the static barrier is given by the standard expression [63]

$$t = \frac{4k\xi}{k_0^2}e^{-\xi L}\exp\left\{-i\arctan\left[\frac{\xi^2 - k^2}{2k\xi}\right]\right\}$$
$$\times \exp\left\{i\left[y - kL - \frac{Et}{\hbar}\right]\right\} \tag{62}$$

For the transmitted waves at the frequencies $(E/\hbar) \pm \omega$, Büttiker and Landauer found that their transmission coefficients are

$$t_\pm = \mp t\frac{V_1}{2\hbar\omega}(e^{\pm\omega\tau} - 1)$$
$$\times \exp\left\{i\left[k_\pm \mp \frac{m\omega L}{2\hbar} - \frac{(E \pm \hbar\omega)t}{\hbar}\right]\right\} \tag{63}$$

$\tau = mL/\hbar\xi$ is the time it would take a particle with the velocity $v = \hbar\xi/m$ to traverse the opaque rectangular barrier. To obtain Eq. (63) it was additionally assumed that $\hbar\omega \ll E$, so that the wavevectors of the sidebands are approximately equal to $k_\pm \cong k \pm m\omega/\hbar k$, and also that $\hbar\omega \ll V_0 - E$, so that the decay lengths satisfy $\xi_\pm = \xi \mp m\omega/\hbar\xi$.

Note that for opaque barriers the traversal time τ^{BL} obtained in the Larmor clock approach, Eq. (14), coincides with the expression considered in the previous equation, $\tau = mL/\hbar\xi$. The classical time that one would obtain in the WKB limit at energies below the peak of the barrier is given by the integral

$$\tau = \int_{y_1}^{y_2}\frac{m}{\hbar\xi(y)}\,dy = \int_{y_1}^{y_2}\left\{\frac{m}{2(V_0(y) - E)}\right\}^{1/2}dy \tag{64}$$

where y_1 and y_2 are the classical turning points. This result also reduces to the value appearing in Eq. (63) for the case of a rectangular barrier, when $V_0(y)$ is constant.

The probability of transmission at the sideband energies, determined from Eq. (63), is

$$T_\pm = |t_\pm|^2 = \left(\frac{V_1}{2\hbar\omega}\right)^2(e^{\pm\omega\tau} - 1)^2 T \tag{65}$$

where T is the transmission coefficient for the static barrier. For small frequencies, so that $\omega\tau \ll 1$, the probabilities of transmission for the upper and lower sidebands obtained from Eq. (65) are the same and equal to

$$T_\pm = \left(\frac{V_1\tau}{2\hbar}\right)^2 T \tag{66}$$

Remember that τ is the approximate expression for the Büttiker–Landauer time for an opaque barrier, given by Eq. (14).

At high frequencies, the upper sideband is exponentially enhanced, while the lower sideband is exponentially suppressed. So for an opaque barrier we do indeed have a rather well-defined crossover between tunnelling at high frequencies and tunnelling at low frequencies, with the characteristic time corresponding to the value given by Eq. (14). This characteristic crossover time is the same one appearing in the expression of the transmission coefficients of the sidebands in the adiabatic limit.

3.2.1. General Barrier

Let us briefly discuss the results of the general oscillating barrier problem following the papers of Hauge and Støvneng [4] and [62]. It was shown that in the adiabatic limit, $\omega \to 0$, the expression for the transmission coefficients for the sidebands, Eq. (65), can be generalized in the form

$$T\pm = |t_\pm|^2 \to \left(\frac{V_1|\tau^{\overline{V}}|}{2\hbar}\right)^2|t(E, \overline{V})|^2 \tag{67}$$

where $|t|^2 = T$ and we have written explicitly the E and $\overline{V}$ dependence of the transmission amplitude t. $\overline{V}$ is the average value of the barrier potential in the scattering region, that is,

$$\overline{V} \equiv \frac{1}{L}\int_{-L/2}^{L/2} V(y)\,dy. \tag{68}$$

$\tau^{\overline{V}}$ is a complex quantity, with the dimensions of time, defined as

$$\tau^{\overline{V}} = i\hbar\frac{\partial \ln t(E, \overline{V})}{\partial \overline{V}} \tag{69}$$

This quantity characterizes the crossover from the adiabatic to the high-frequency limits, and we define it as the traversal time in the time-modulated barrier approach.

The corresponding definition of the reflection time appeals to the adiabatic limit of the reflected sidebands. Their reflection coefficients $R_\pm = |r_\pm|^2$ tend in the adiabatic limit to an expression that can be written as

$$|r_\pm|^2 \to \left(\frac{V_1|\tau_{\text{R}}^{\overline{V}}|}{2\hbar}\right)^2|r(E, \overline{V})|^2 \tag{70}$$

where $|r|^2 = R$ is the static reflection coefficient. Again, we have explicitly written the E and $\overline{V}$ dependence of the

reflection amplitude r. $\tau_{\mathrm{R}}^{\overline{V}}$ is a new complex quantity, playing the role of a reflection time, defined as

$$\tau_{\mathrm{R}}^{\overline{V}} = i\hbar \frac{\partial \ln r(E, \overline{V})}{\partial \overline{V}} \qquad (71)$$

The complex times $\tau^{\overline{V}}$ and $\tau_{\mathrm{R}}^{\overline{V}}$ are related to the real quantities τ_z^{BL}, τ_y^{BL}, $\tau_{y,\mathrm{R}}^{\mathrm{BL}}$ and $\tau_{z,\mathrm{R}}^{\mathrm{BL}}$ and therefore the BL traversal time can be formally written in the form

$$\tau^{\mathrm{BL}} \equiv \hbar \left| \frac{\partial \ln t(E, \overline{V})}{\partial \overline{V}} \right| \qquad (72)$$

It is still not so clear how this time, which was obtained from an analysis of the time-modulated barrier and which is valid for an arbitrary shaped potential $V(y)$, whose average is $\overline{V}$, can be justified as a traversal time for a general barrier [64]. In any case, note that Eq. (72) for an opaque barrier leads us to Eq. (14), which was obtained by Büttiker's analysis of the Larmor clock [36]. The BL reflection time can be defined as in Eq. (72), but replacing $t(E, \overline{V})$ by $r(E, \overline{V})$.

3.3. Complex Time

Although common sense dictates that the tunnelling time must be a real time and that there are no clocks that measure a complex time, nevertheless the concept of complex time in the theory of the traversal time problem of electrons appeared in many approaches (see [65], and references therein). The optical analog of the Larmor clock for classical electromagnetic waves based on Faraday effect lead us also to a complex time [37].

We saw, with the help of the GF formalism, that the two characteristic times appearing in the Larmor clock approach correspond to the real and imaginary components of a single quantity, which we define as a complex traversal (or reflection) time. In the subsection on the oscillatory incident amplitude, we also discussed that Leavens and Aers [51] arrived at a complex barrier interaction time, Eq. (52), by studying the shape distortion of the transmitted wave by the barrier.

It is in the Feynman path-integral approach where the concept of a complex time arises more naturally. Sokolovski and Baskin [55], using this kinematic approach to quantum mechanics, showed that a formal generalization of the classical time concept to the traversal time led to a complex quantity. The starting point for the Feynman path-integral approach [57] to the traversal time problem is the classical expression for the time that the particle spends in an arbitrary region $[0, L]$, which can be calculated through the expression

$$\tau_{0L}^{\mathrm{cl}} = \int_0^{\tau} \theta(y(t')) \, \theta(L - y(t')) \, dt' \qquad (73)$$

where θ is here the step function, equal to 1 when its argument is positive and zero otherwise. The two θ functions ensure that we only count the time while the particle is in the barrier region. To use Eq. (73) in the quantum regime one has to generalize the expression for the classical time by replacing the classical trajectory $y(t)$ in the previous expression by a Feynman path and average Eq. (73) over all possible paths that start at position 0 on the left side of the barrier

and end at position L at time t. Each path is weighted by the quantity $\exp(iS\{y\})$, where

$$S\{y(t)\} = \int_0^t \left(\frac{m}{2} \left(\frac{dy}{dt'} \right)^2 - V(y(t')) \right) dt' \qquad (74)$$

is the action associated with the path $y(t)$. As we are weighting each trajectory with a complex factor, it is natural to obtain a complex result for the average value. This weighting assumption has generated some controversies [4, 11, 66, 67]. Sokolovski and Baskin [55] arrived at the following complex time:

$$\tau_{0L} = i\hbar \int_0^L \frac{\delta \ln t}{\delta V(y)} \, dy \qquad (75)$$

where $\delta/\delta V(y)$ represents the functional derivative with respect to the barrier potential.

This result, Eq. (75), is strictly equivalent to our expression of the traversal time. We would like to emphasize that this coincidence is quite natural, because in the tunnelling time problem we always deal with an *open* and *finite* system. The functional derivative with respect to the potential appearing in Eq. (75) is equivalent to a derivative with respect to energy plus a correction term proportional to the reflection coefficient (see Eq. (25)).

The modulus of this expression, Eq. (75), is the time that Büttiker [36] obtained for the tunnelling time in a square potential barrier and related to the Larmor clock times via

$$\mathrm{Re}\,\tau_{0L} = \tau_y \qquad (76)$$

$$-\mathrm{Im}\,\tau_{0L} = \tau_z \qquad (77)$$

Sokolovski and Connor [68] extended the Feynman path-integral approach to include the treatment of wavepackets. In their method the complex tunnelling formally appears as a transition element $\tau_{0L} = \langle \Psi_{\mathrm{F}} | \tau^{\mathrm{cl}} | \Psi_{\mathrm{I}} \rangle$ between the initial wavepacket Ψ_{I} and the final one Ψ_{F}. Nevertheless, we have to note that Feynman and Hibbs [57] themselves do not associate any physical significance to transition elements.

Fertig [69, 70] avoided the problem of having to use wavepackets by considering restricted operators, for a fixed energy or for a fixed time. In this way, he was able to evaluate exactly the amplitude distribution for the traversal time for a rectangular barrier. He assumed that the weight of each path is proportional to $\exp(iS\{y\})$, where the action S is given by Eq. (74). He obtained the following amplitude distribution for the traversal time [70]:

$$F(\tau) = \frac{1}{2\pi t(E, V_0)} \int_{-\infty}^{\infty} e^{-i\omega t} t(E, V_0 - \omega) \, d\omega \qquad (78)$$

where $t(E, V_0)$ is the transmission amplitude at energy E through a barrier of height V_0. With this probability amplitude distribution for the average traversal time for the square potential barrier, he arrives at

$$\langle \tau \rangle = -\frac{d\varphi}{dV_0} + \frac{i}{2} \frac{d \ln T}{dV_0}$$

which is the result of Sokolovski and Baskin [55].

The Wigner path distribution provides another approach to compute the traversal time. Jensen and Buot [71] used it

to calculate the time for stationary waves, and Muga et al. [72] for wavepackets.

Yamada [73] claimed that the probability distribution of the tunnelling time cannot be properly defined. He arrived at this conclusion from the fact that Gell-Mann and Hartle's weak decoherence condition [74] does not hold for the tunnelling time due to the absence of a classical, dominant Feynman path. Yamada defined a range of values of the time and concluded that it is the only "speakable" magnitude.

Sokolovski [75] criticized the previous results on the grounds that the weak decoherence criterion is too restrictive. He showed that the probabilities for the outcomes of tunnelling time measurements can be described in terms of positive-operator-valued measurements, related to the interaction between the system and its environment.

3.3.1. Complex Time and Kramers-Kronig Relations

As it has just been shown, the concept of a complex time in the theory of the traversal time problem of electrons and electromagnetic waves (EMWs) has arisen in many approaches [4, 11, 37, 65]. In [37] was obtained, with the Faraday rotation scheme, a very similar result to Eq. (25) for the characteristic interaction time τ of an EMW. The Faraday rotation in the finite system, which is our magnetic clock, plays for light the same role as the Larmor precession for electrons [34, 36]. The emerging EMW is elliptically polarized and the major axis of the ellipse is rotated with respect to the original direction of polarization. All relevant information about both the angle of rotation and the degree of ellipticity is contained in a complex angle whose real part corresponds to the Faraday rotation, and whose imaginary part corresponds to the degree of ellipticity. This motivated us to associate a complex interaction time of the light in the region with magnetic field which can be written in terms of derivatives with respect to frequency as [37]

$$\tau(\omega) = -i\left[\frac{\partial \ln t}{\partial \omega} - \frac{r + r'}{4\omega}\right] = \tau_1(\omega) - i\tau_2(\omega) \qquad (79)$$

As was shown by Ruiz et al. [15], this is a general expression for the interaction time of an EMW with a one-dimensional region with an arbitrary index of refraction distribution, independent of the model considered. It can be rewritten in terms of the GF for photons analogously to Eq. (25), because all the general properties of the GF formalism for electrons which lead us to Eq. (25) are valid for any wave (sound or electromagnetic), whenever its propagation through a medium is described by a differential equation of second order [45].

Thus, most approaches indicate that the characteristic time associated with any wave (classical or quantum-mechanical) is a complex magnitude; which of the two components of this complex time is the most relevant depends on the experiment. It was shown in [15] that the real component $\tau_1(\omega)$ corresponds to the traversal time, and the main effect of the imaginary component $\tau_2(\omega)$ is to change the size of the wavepacket. Balcou and Dutriaux [16] experimentally investigated the tunnelling times associated with frustrated total internal reflection of light. They have shown that the real and imaginary parts of the complex tunnelling time

correspond, respectively, to the spatial and angular shifts of the beam. Note that in most tunnelling experiments, instead of electrons, electromagnetic waves were used to exclude interaction effects (see, e.g., [10–23]).

It is known that the frequency dependence of the real and imaginary parts of certain complex physical quantities are interrelated by the Kramers-Kronig relations, for example, the real (dispersive) part of the complex dielectric function $\epsilon(\omega)$ to its imaginary (dissipative) part, the frequency-dependent real and imaginary parts of an electrical impedance, etc. [76]. The derivation of these relations is based on the fulfillment of four general conditions of the system: causality, linearity, stability, and that the value of the physical quantity considered is assumed to be finite at all frequencies, including $\omega \to 0$ and $\omega \to \infty$. If these four conditions are satisfied, the derivation of Kramers-Kronig relations is purely a mathematical operation which does not reflect any other physical properties or conditions of the system. These integral relations are very general and have been used in the theory of classical electrodynamics, particle physics, and solid-state physics as well as in the analysis of electrical circuits and electrochemical systems.

It is straightforward to show that the complex interaction time, $\tau(\omega)$, Eq. (79), is an analytical function of frequency in the upper half of the complex ω-plane (see, e.g., [76]). In other words, the four conditions mentioned above are fulfilled for the complex time (79) and the following relationship between the $\tau(\omega)$ and its complex conjugate $\tau^*(\omega)$ holds on the real axis (see Eq. (79)):

$$\tau(\omega) = \tau^*(-\omega) \qquad (80)$$

which means that the complex interaction time $\tau(\omega)$ has the following properties:

$$\tau_1(\omega) = \tau_1(-\omega), \quad \tau_2(\omega) = -\tau_2(-\omega) \qquad (81)$$

Therefore, the real part $\tau_1(\omega)$ is an even function of frequency and can have a finite value at zero frequency (for the slab we have $\tau_1^{sl}(0) = L/vA$). As for the imaginary part $\tau_2(\omega)$, it is an odd function and must vanish in the limit of zero frequency: $\tau_2(0) = 0$. These conditions imply that the real and imaginary components of the time likewise obey Kramers–Kronig integral relations, and so we may write

$$\tau_1(\omega) - \tau_0 = \frac{2}{\pi}\mathbf{P}\int_0^\infty \frac{y\tau_2(y)}{y^2 - \omega^2}\, dy \qquad (82)$$

$$\tau_2(\omega) = -\frac{2\omega}{\pi}\mathbf{P}\int_0^\infty \frac{\tau_1(y) - \tau_0}{y^2 - \omega^2}\, dy \qquad (83)$$

where $\mathbf{P}$ means principal part and $\tau_0 = Ln/c$, that is, the crossing time in the dielectric system, without any boundary. In particular, if we make $\omega = 0$ in Eq. (83), we arrive at the so-called "macroscopic sum rule" for the complex interaction time

$$\tau_1(0) - \tau_0 = \frac{2}{\pi}\int_0^\infty \frac{\tau_2(y)}{y}\, dy \qquad (84)$$

Thus we see from Eq. (84) that in general if no imaginary component $\tau_2(\omega)$ exists at any frequency, then $\tau_1 = \tau_0$ always holds. In the case of the interaction time in the dielectric

slab, the integral relations (82)–(84) can be verified, using the explicit expressions for the components of time (see Eqs. (85) and (86)).

The validity of the Kramers-Kronig relations for the complex interaction time has a rather deep significance because it may be demonstrated that these conditions are a direct result of the causal nature of physical systems by which the response to a stimulus never precedes the stimulus. It can serve also as a starting point to understand the origin of the complex time, and state that the interaction time for any classical or quantum-mechanical wave will always have two components: the real part $\tau_1(\omega)$ and the imaginary part $\tau_2(\omega)$. At this point it is worth mentioning that the experiments with, for example, undersized waveguides [23, 24] or periodic dielectric heterostructures [9, 10], where the so-called "superluminal velocities" have been observed for the barrier tunnelling time, need to be interpreted carefully.

For the dielectric slab, Eq. (79) leads us to the following expressions for the two time components [37]:

$$\tau_1^{\text{sl}}(\omega) = \frac{T\tau_0^{\text{sl}}}{2A}\left\{(1+A^2)+(1-A^2)\frac{\sin 2\Delta}{2\Delta}\right\} \quad (85)$$

and

$$\tau_2^{\text{sl}}(\omega) = \frac{T\tau_0^{\text{sl}}}{2A}\frac{1-A^2}{2A}\left\{(1-A^2)\frac{\sin 2\Delta}{2}+(1+A^2)\frac{\sin^2\Delta}{\Delta}\right\} \quad (86)$$

where $\tau_0^{\text{sl}} = L/v$ is the time that light with velocity $v = c/n_0$ would take to cross the slab, when reflection in the boundaries is not important, $\Delta = \omega\tau_0^{\text{sl}}$, $A = n_1/n_0$, n_0 is the refraction index of the slab, and n_1 is the refraction index of the two semi-infinite media outside the slab. T is the transmission amplitude for the slab in the absence of a magnetic field and is given by [63]

$$T = \left\{1+\left(\frac{1-A^2}{2A}\sin\Delta\right)^2\right\}^{-1} \quad (87)$$

The complex time components $\tau_1^{\text{sl}}(\omega)$, Eq. (85), and $\tau_2^{\text{sl}}(\omega)$, Eq. (86), are plotted against one another in the complex plane (see Fig. 6). We see that for small frequencies we have a skewed arc. With increasing frequency, the influence of the second terms in Eqs. (85) and (86), due to boundary effects, becomes less important and the curve, in the limit $\omega \to \infty$, approximates to an ideal circle.

Note that in the case of the Debye dispersion relations for the complex dielectric function $\epsilon(\omega)$, an ideal semicircle in the complex plane means that we deal with a single relaxation time. In our case it means that for high frequency or short wavelength, we deal with the classical crossing time, taking into account multiple reflection in the slab [15].

It is not difficult to show that in the limit $\omega \to \infty$ we have

$$\left(\tau_2^{\text{sl}}\right)^2 + \left\{\tau_1^{\text{sl}} - \left[\frac{\tau_0^{\text{sl}}}{2A}(1+A^2) - r\right]\right\}^2 = r^2 \quad (88)$$

which is the equation of a circle in the complex plane of $-\tau_2^{\text{sl}}$ and τ_1^{sl} with the center $\{\tau_0^{\text{sl}}/2A(1+A^2) - r, 0\}$ and with a radius given by

$$r = \frac{\tau_0^{\text{sl}}}{4A}\frac{(1-A^2)^2}{1+A^2}$$

Figure 6. Complex plane interaction time diagram for a dielectric slab. The arrow indicates the direction of increasing frequency. Reprinted with permission from [86], V. Gasparian et al., "Handbook of Nanostructured Materials and Nanotechnology" (H. S. Nalwa, Ed.), Vol. 2, Chapter 11, 1999. © 1999, Elsevier Science.

Thus the two components, the real part $\tau_1(\omega)$ and the imaginary part $\tau_2(\omega)$, of the complex barrier interaction time for EMW are not entirely independent quantities, but connected by Kramers-Kronig relations. This means that the response to a stimulus never precedes the stimulus and thus the experiments [9, 10, 23, 24], where the so-called "superluminal velocities" have been observed need to be interpreted with respect to the fact that any classical or quantum-mechanical wave will always have two components; which of the two components is the most relevant depends on the experiment.

The validity of the Kramers-Kronig relations was only checked analytically for EMW, but in general this implies that they are also valid for all quantum particles represented by a differential equation of second order as indicated by the numerical calculations for the complex tunnelling time for electrons.

3.4. Escape Time of Electrons from Localized States

As we have seen in most approaches of the tunnelling time problem, only the scattering configuration in which the free electron (or wavepacket) is coming from the left (right) on a 1D arbitrary potential barrier has been considered. More than one tunnelling time is involved in this time problem, no matter whether we deal with the Büttiker-Landauer τ^{BL} or complex $\tau = \tau_1 - i\tau_2$ characteristic times (see Eqs. (12) and (24)). Furthermore, this seems not to be a peculiarity of a quantum-mechanical wave, but a general result, as the characteristic time associated with a classical wave is also a complex magnitude [37]. Which of the two components of this complex time is the most relevant depends on the experiment. For photons [37], the real part is proportional to the Faraday rotation or the density of optical modes, while the

imaginary part gives the degree of ellipticity. In [16] the tunnelling times associated with frustrated total internal reflection of light were experimentally investigated, and the real and imaginary parts of the complex tunnelling time were shown to correspond to the spatial and angular shifts of the beam, respectively.

On the other hand, it is clear that there are other similar situations of practical interest which should be discussed in the same context of two time components as was done in the scattering problem. One of these situations is the escape of an electron from localized states in a quantum well with one or several surrounding barriers. The escape of an electron from a localized state in the quantum well connected to a continuum by a small barrier only by one side (Fig. 7) can be found, for instance, in miniaturized metal-oxide-semiconductor transistors, in which electrons arrive to the quantized accumulation or inversion layers after scattering and subsequently they can tunnel to the metal gate through a very narrow oxide layer which acts as the barrier [77]. Physically, this implies that the particles entering the quantum well region remain there for some time before being allowed to escape outside. Tunnelling escaping time has also been studied by transient-capacitance spectroscopy [78], where electrically injected electrons undergo an escaping process out of the quantum well, for example, in a three-barrier, two-well heterostructure [79, 80].

Let us consider a potential shape that includes a well and one surrounding barrier (see Fig. 7). A hard wall condition at $x = -w$ reduces the problem to escape to only one open channel, that is, transmission to the right.

To calculate the escape time $\tau^{\text{esc}}(k)$ of an electron from a quantum well when boundary effects can be neglected, we closely followed [81] and introduced the following complex quantity ($k = \sqrt{E}$):

$$\tau^{\text{esc}}(k) = -i\frac{d \ln t}{2k \, dk} \tag{89}$$

where $t = T^{1/2}e^{i\phi}$ is the complex amplitude of transmission of the electron through only the right barrier taking into account the hard wall condition at $x = -w$.

Using standard methods of quantum mechanics, it is easy to show that the Re and Im parts of the complex escape time
$\tau^{\text{esc}}(k) = \tau_1^{\text{esc}}(k) - i\tau_2^{\text{esc}}(k)$ of an electron from a quantum well when boundary effects can be neglected and near the resonance energy E_1 and in the limit of an opaque barrier ($\gamma d \gg 1$) are given by [81]

$$\tau_1^{\text{esc}}(k_1) = \frac{\xi(1 + \gamma w)(1 + \beta^2)}{2k^2(1 + \xi^2)} \exp(2\gamma d) \tag{90}$$

$$\tau_2^{\text{esc}}(k_1) = \frac{(1 + \gamma w)(1 + \beta^2)(1 - \xi^2)}{4k^2(1 + \xi^2)} \exp(2\gamma d) \tag{91}$$

where $\xi = \gamma/k_3$, $\gamma = \sqrt{E_1 - U_2}$, $\beta = k_1/\gamma$, and w, d, U_1, U_2 are defined in Figure 7.

Let us examine the relationship between the two components we have defined above and the lifetime expression

$$\tau_{\text{LT}}(k_1) = \frac{(1 + \gamma w)(1 + \beta^2)(1 + \xi^2)}{16 \cdot k_1^2 \cdot \xi} \exp(2\gamma d) \tag{92}$$

which follows from an approximate perturbative approach based on Bardeen's perturbation Hamiltonian [82].

Despite the similarity between Eqs. (90), (91), and (92), they only allow a qualitative comparison at the bound level E_1. Since components τ_1^{esc} and τ_2^{esc} show a sharp variation around this energy, a comparison with Eq. (92) as a function of energy is interesting in order to study their behavior at the quasi-bound level, which is shifted with respect to E_1. Such comparison is shown in Figure 8 for the following parameter values: $U_1 = 1$, $U_2 = -1$, $w = 3$, for two d values ($d = 5$ in Fig. 8a, and $d = 2$ in Fig. 8b). An opaque barrier has been

Figure 7. Schematic representation of the simplified potential profile, with a hard wall condition at $-w$.

Figure 8. The time components as a function of energy for the potential profile depicted in Figure 7, with $U_1 = 1$, $U_2 = -1$, and $w = 3$, for two different d values: (a) $d = 5$, and (b) $d = 2$. The vertical line corresponds to the ground energy level when the barrier width is infinite. Reprinted with permission from [81], J. A. Lopez Villanueva and V. Gasparian, *Phys. Lett. A* 260, 286 (1999). © 1999, Elsevier Science.

chosen in Figure 8a to ensure the accuracy of the lifetime expression, but in Fig. 8b the estimated relative error for the lifetime expression is about 16%. The vertical line corresponds to the ground energy level when the barrier width is infinite. It is seen that the maximum of component τ_2^{esc} coincides with the τ_{LT} lifetime expression (92) at an energy very close to the bound level in the opaque barrier case (Fig. 8a). With the narrow barrier (Fig. 8b) both results deviate, but in this case the lifetime expression overestimates the lifetime by about 16% while the maximum of component τ_2^{esc} still provides an accurate value. Furthermore, this maximum is produced at an energy lower than the bound level, as predicted by the first-order perturbation theory.

Let us represent the complex time components $\tau_1^{\text{esc}}(k)$ and $\tau_2^{\text{esc}}(k)$ in the complex E plane. They are plotted against one another in Figure 9 and as it is seen, provide ellipse. This is what we expected, as the maxima of $\tau_1^{\text{esc}}(k)$ and $\tau_2^{\text{esc}}(k)$ are not the same. Nevertheless, there is a property of an ellipse that could be interesting: it is symmetric with respect to its main axis. Therefore, the maximum (and the minimum) of $\tau_2^{\text{esc}}(k)$ are found at the points where $\tau_1^{\text{esc}}(k)$ has a value of half its maximum. As this value is used to compute lifetime (width of the $\tau_1^{\text{esc}}(k)$ peak at half height), this width must be exactly the difference in energies between the maximum and minimum of $\tau_2^{\text{esc}}(k)$. It is easy to check that we have the following condition:

$$(E_{\min} - E_{\max})\tau_2^{\text{esc}} = 1$$

which confirms our previous conclusion concerning the fact that τ_2^{esc} at an energy close to the bound level in the well, coincides with the lifetime expression.

3.5. Wavepacket Approach

The delay time of a particle through a region can be directly calculated by following the behavior of its wavepacket. This approach has been criticized from different points of view, mainly due to the lack of causal relationship between the peaks or the centroids of the incident and transmitted wavepackets, and also because of the difficulties of an experimental setup to measure delay times. The dispersive character of electron propagation has been claimed as responsible for the acceleration of wavepackets under appropriate circumstances. High-energy components of the

Figure 9. Complex plane escape time diagram for the quantum well used in this chapter.

packet travel faster and are transmitted more effectively than the other components, and so the transmitted packet comes almost entirely from the front of the incident packet. However, similar results were also obtained for dispersiveness electromagnetic waves [15]. The fact that the transmitted wavepacket comes from the beginning of the incident wavepacket is mainly a consequence of interference effects. The results obtained from the wavepacket approach are similar to the results obtained with other approaches, and can be easily generalized to include finite size effects. In this section we review how to obtain delay times from the transmission coefficients.

Let us assume a region of interest, which in principle can be of any dimensionality, coupled to the outside by two 1D leads with a constant potential that we will assume equal to zero. We choose a coordinate system such that the incident lead extends from $-\infty$ to 0, and the other lead from L to $+\infty$. A gaussian wavepacket of spatial width σ_1 is incident from the incoming lead on the region of interest. This packet is characterized by a wave function of the form

$$\Psi(y, t) = \int_{-\infty}^{\infty} C \exp[-(k - k_0)^2/2(\Delta k)^2]$$
$$\times \exp[iky - i\omega t]\, dk \qquad (93)$$

where C is a normalization constant, k_0 is the central wavenumber, $\omega = E/\hbar$, and $\Delta k = 1/\sqrt{2}\sigma_1$ is the spread of the packet in the wavenumber domain. The time evolution of this wavepacket is governed by the Schrödinger equation, although the results are directly applicable to any other type of wave, including classical electromagnetic waves. Part of the packet is transmitted and continues travelling outward along the second lead. Its wave function is given by

$$\Psi_t(y, t) = \int_{-\infty}^{\infty} C|t(k)|e^{i\varphi(k)} \exp[-(k - k_0)^2/2(\Delta k)^2]$$
$$\times \exp[iky - i\omega t]\, dk \qquad (94)$$

$t(k)$ is the amplitude of transmission and $\varphi(k)$ is its phase, which here we prefer to write as functions of the wavenumber k. The functions $t(k)$ and $\varphi(k)$ contain all the relevant information to calculate the delay time of the electronic wave function due to the region of interest.

The general solution for finite size wavepackets has to be obtained numerically, but we can get close expressions for the delay time in the limit of very long wavepackets from a series expansion along the central wavenumber k_0. Let us assume that the wavepacket is so long (and so Δk so small) that $t(k)$, $\varphi(k)$, and $\omega(k)$ only change smoothly on the scale of Δk. Then, in evaluating $|\Psi_t(y, t)|^2$, where $\Psi_t(y, t)$ is given by Eq. (94), we can expand $t(k)$, $\varphi(k)$, and $\omega(k)$ to second order in $k - k_0$. We write the phase of the transmission amplitude as

$$\varphi(k) = \varphi(k_0) + \tau_1(\omega - \omega_0) + \frac{1}{2}\tilde{\tau}_1(\omega - \omega_0)^2 \qquad (95)$$

where ω_0 is the frequency corresponding to the central wavenumber, τ_1 is the first derivative of the phase $\tau_1 = d\varphi(\omega)/d\omega$, which roughly corresponds to the component τ_y of the Büttiker-Landauer time, and $\tilde{\tau}_1$ is its second

derivative $\tilde{\tau} = d^2\varphi(\omega)/d\omega^2$. Analogously, we write the modulus of the transmission amplitude as

$$|\log t(k)| = |\log t(k_0)| + \tau_2(\omega - \omega_0) + \frac{1}{2}\tilde{\tau}_2(\omega - \omega_0)^2 \quad (96)$$

where $\tau_2 = d|\log t(\omega)|/d\omega$, and $\tilde{\tau}_2 = d^2|\log t(\omega)|/d\omega^2$. We can also expand the frequency ω in terms of k:

$$\omega = \omega_0 + v_{\mathrm{g}}(k - k_0) + \frac{1}{2}a_{\mathrm{g}}(k - k_0)^2 \quad (97)$$

v_{g} is the group velocity $v_{\mathrm{g}} = d\omega/dk$, and a_{g} is its derivative with respect to k, $a_{\mathrm{g}} = d^2\omega/dk^2$. For electrons, the group velocity is equal to $v_{\mathrm{g}} = \hbar k/m$, while the group acceleration is $a_{\mathrm{g}} = \hbar/m$.

If we keep terms up to second order in $k - k_0$, we can do analytically all the integrals appearing in the expression of the average value and the variance of y. After some trivial calculations we obtain that the average position $\langle y \rangle$ of the transmitted wavepacket as a function of time is given by

$$\langle y \rangle = (t - \tau_1)v_{\mathrm{g}}\left[1 + \frac{\tau_2 a_{\mathrm{g}}}{b}\right] - \frac{\tau_2\tilde{\tau}_1 v_{\mathrm{g}}^3}{b} \quad (98)$$

where b is equal to

$$b = \frac{1}{(\Delta k)^2} - \tau_2 a_{\mathrm{g}} - \tilde{\tau}_2 v_{\mathrm{g}}^2 \quad (99)$$

We have chosen the phase of the incident wavepacket so that its peak is at the origin of coordinates in $t = 0$, in the absence of perturbations due to the presence of the barrier, that is, $\langle y_i \rangle(t = 0) = 0$. The peak of the transmitted wavepacket would be at the same position at a time τ implicitly defined by

$$\tau = t(\langle y_t \rangle = 0) \quad (100)$$

The barrier delays the gaussian wavepacket by an amount of time τ, which according to Eqs. (100) and (98) is equal to

$$\tau = \tau_1 + \tau_2\tilde{\tau}_1 v_{\mathrm{g}}^2(\Delta k)^2 \quad (101)$$

This equation constitutes a useful tool for calculating the tunnelling time of an electron that has transversed a (rectangular) barrier as a function of the width of the incident wavepacket, Δk.

We can express Eq. (101) in terms of Büttiker–Landauer's times and their first derivatives. If we neglect the terms proportional to the reflection amplitudes in the expressions for Büttiker–Landauer's times, we have $\tau_1 = \tau_y$ and $\tau_2 = \tau_z$. Taking into account the dispersion relation for electrons, we also have

$$\tilde{\tau}_1 = \frac{1}{v_{\mathrm{g}}}\tilde{\tau}_y \quad (102)$$

and a similar expression for τ_2 and τ_z. Thus Eq. (101) can be rewritten in the form

$$\tau = \tau_y + \tau_z\tilde{\tau}_y v_{\mathrm{g}}(\Delta k)^2 \quad (103)$$

This is the main result of the long wavepacket approximation up to second order in Δk. We will check the limit of validity of this expression in the section on numerical results.

3.6. Time-of-Arrival Operator Approach

A direct attempt to obtain an observable for the time runs into the problem pointed out by Pauli [83] that the existence of such an operator would imply an unbounded energy spectrum, given the uncertainty relation between time and energy. The time-of-arrival is the natural candidate to become a property of the system, rather than an external parameter, and it plays a role similar to our traversal time.

Leon et al. [84, 85] have recently developed an interesting time-of arrival formalism, which we briefly describe. Classically, the time-of-arrival of a particle with coordinate q and momentum p at a point x is given by the expression

$$t_x(q, p) = \mathrm{sgn}(p)\sqrt{\frac{m}{2}}\int_q^x \frac{dq'}{\sqrt{H(q', p) - V(q')}} \quad (104)$$

where $H(q, p)$ is the classical hamiltonian. Leon et al. (1996) showed that $t_x(q, p)$ is canonically conjugate to the hamiltonian $\{t_x(q, p), H(q, p)\} = -1$, where $\{\}$ are the Poisson brackets, but were unable to quantize this magnitude directly. Instead they considered first the time-of arrival for a free particle $t_{x0}(q, p) = m(x - q)/p$, which after symmetrization is quantized as

$$t_{x0}(q, p) = -e^{-ipx}\sqrt{\frac{m}{p}}q\sqrt{\frac{m}{p}}e^{ipx} \quad (105)$$

This operator is not self-adjoint, a difficulty related to the Pauli theorem. The measurement problem associated to the time-of-flight operator can be solved by means of a positive-operator-valued measure.

As a second step, Leon et al. [84] considered the canonical transformation that connects the free particle system with the general system including a potential $V(q)$. The Möller operators perform this canonical transformation. They are normally used to connect the free particle wavefunctions with the scattering and bound states of a given potential. In their formalism, Leon et al. applied these unitary operators to the time-of-arrival operator of the free particle in order to produce the corresponding operator in the presence of an arbitrary potential. Given this operator, one can then obtain the full distribution for the time-of-arrival of a particle at a position.

We believe that an especially interesting result of their approach is the average value of the time-of-arrival for a particle originally in state $\psi(k)$ which traverses a barrier with amplitude $\hat{t}(k)$. The expected average value is equal to

$$\tau = \frac{\int_{-\infty}^{\infty} dk |\hat{t}(k)\tilde{\psi}(k)|^2 \tau_y(k)}{\int_{-\infty}^{\infty} dk |\hat{t}(k)\tilde{\psi}(k)|^2} \quad (106)$$

where $\tilde{\psi}(k)$ is the Fourier transform of $\psi(k)$. This expression has a very intuitive interpretation. The time corresponds to an average of the characteristic time τ_y over the transmitted components of the wavepacket. It is very easy to calculate this expression and can be applied to packets of any size. In the section on numerical results we will estimate the validity of this expression.

4. NUMERICAL RESULTS

The long wavepacket limit, when the spread of the wave function is longer than the size of the system, is well understood [86]. In all cases studied, the traversal and the reflection times correspond to the real component of time, τ_y. In this limit, the numerical problem reduces to the evaluation of the transmission and reflection amplitudes and their energy derivatives, which can be conveniently achieved through the use of the characteristic determinant method, introduced by Aronov et al. [45] and explained in Appendix A. Different similar mathematical methods, allowing us to take into account multiple interfaces consistently and exactly without the use of perturbation theory, have been proposed [87–91].

Numerical simulations are needed to clarify finite size effects. In this case we have to consider a specific wavepacket and evaluate its probability amplitude at different values of the time in order to calculate the amount of time taken to cross the system. In this section, we first review the results for periodic structures which, due to their complexity, are treated as nondispersive media, and so the conclusions are directly applicable to electromagnetic waves. Second, we consider the case of resonant tunnelling and we finish by presenting the results for finite size effects in electron tunnelling.

4.1. Periodic Structure

Let us consider a periodic arrangement of layers with potential V_1 and thickness d_1 alternating with layers with potential V_2 and thickness d_2. We assume that the energy is higher than max $\{V_1, V_2\}$, and so the wavenumber in the layers of the first and second type is $k_i = [2m(E - V_i)]^{1/2}/\hbar (i = 1, 2)$. In this case, the results for long wavepackets apply equally well to electromagnetic waves considering $k_i = \omega n_i/c$, where n_i is the index of refraction of the two types of layers. We concentrate on the simplest periodic case, which corresponds to the choice $k_1 d_1 = k_2 d_2$. This case contains most of the physics of the problem and is also used in most experimental setups [9]. Let us call a the spatial period, so $a = d_1 + d_2$. The periodicity of the system allows us to obtain analytically the transmission amplitude using the characteristic determinant method [40]:

$$
t = e^{-ik_1 d_1} \left\{ \cos(N\beta a/2) - i \frac{\sin(N\beta a/2)}{\sin \beta a} \right.
$$

$$
\left. \times \sqrt{\sin^2 \beta a + \left[\frac{k_1^2 - k_2^2}{2k_1 k_2} \sin k_2 d_2 \right]^2} \right\}^{-1} \quad (107)
$$

where β plays the role of quasi-momentum of the system, and is defined by

$$
\cos \beta a = \cos k_1 d_1 \cos k_2 d_2 - \frac{k_1^2 + k_2^2}{2k_1 k_2} \sin k_1 d_1 \sin k_2 d_2
$$

$$
(108)
$$

When the modulus of the RHS of Eq. (108) is greater than 1, β has to be taken as imaginary. This situation corresponds to a forbidden energy band. The term within brackets in Eq. (107) only depends on the properties of one barrier, while the quotient of the sine functions contains the information about the interference between different barriers. The transmission coefficient is equal to 1 when $\sin(N\beta a/2) = 0$ and β is different from 0. This condition occurs for

$$
\beta a = \frac{2\pi n}{N} \qquad (n = 1, \ldots, N/2 - 1) \quad (109)
$$

and we say that it corresponds to a resonant frequency.

For the reflection amplitude we have

$$
r = te^{-ik_1 d_1} \frac{k_1^2 - k_2^2}{2k_1 k_2} \sin k_2 d_2 \frac{\sin(N\beta a/2)}{\sin \beta a} \quad (110)
$$

With these expressions for the transmission amplitude, Eq. (107), and for the reflection amplitude, Eq. (110), we can calculate the traversal time through Eq. (25) and the reflection time via Eq. (31). From Eqs. (107) and (110), Ruiz et al. [15] calculated numerically the traversal time for electromagnetic waves considering a system of 19 layers ($N = 20$) with alternating indices of refraction of 2 and 1, and widths of 0.6 and 1.2, respectively. Their main conclusions are also applicable to the problem of an electron in a periodic potential. In Figure 10 we represent τ_1 and τ_2 for electromagnetic waves in a periodic system as a function of k_1. In the energy gaps, the traversal times are significantly smaller than the crossing time at the vacuum speed of light (horizontal line). The average of τ_1 with respect to wavenumber is equal to 22.8, and coincides with the classical crossing time, that is, for very short wavepackets, without including multiple reflections. It corresponds to the horizontal straight line in Figure 10.

The kinetic approach is suitable to study numerically the evolution of wavepackets with sizes of the order of the width of the region of interest. We will describe the numerical simulations of the time evolution of finite size wavepackets that cross the region of interest and measure the delay of the peak of the transmitted wave as a function of the size of the
Figure 10. Traversal times versus the size of the wavepacket for a periodic system. The solid line corresponds to τ_1, and the dashed line to τ_2. The values of the parameters are $N = 20$, $n_1 = 2$, $n_2 = 1$, $d_1 = 0.6$, and $d_2 = 1.2$.

original packet. The simulations also calculate the change in size of the packets. First we consider the results for periodic structures without including dispersion effects, so we will use a nomenclature most appropriate for electromagnetic waves, although the results are equally valid for electrons, in the absence of dispersion, provided that we translate indices of refraction into their corresponding potentials. Later we will also present results about finite size effects in electron tunnelling.

Let us consider a three-dimensional layered system with translational symmetry in the Y-Z plane, consisting of N layers labelled $i = 1, \ldots, N$ between two equal semi-infinite media with a uniform dielectric constant n_0. The boundaries of the ith layer are given by y_i and y_{i+1}, with $y_1 = 0$ and $y_{N+1} = L$, so that the region of interest corresponds to the interval $0 \le y \le L$. Each layer is characterized by an index of refraction n_i. In the case of electrons, we assume that the energy E of the electron is higher than the potentials of the different layers and that the wavenumbers are inversely proportional to the indices of refraction; so the potential V_i in layer y is equal to $V_i = E(1 - (n_0/n_i)^2)$.

One calculates the position of the packet at different times and from this information one extracts the time taken by the packet to cross the region of interest. In particular, neglecting dispersion, one can measure the average positions $\bar{y}_1$ and $\bar{y}_2$ of the square of the modulus of the wavepacket at two values of t, t_1 and t_2, such that the packet is very far to the right of the structure at t_1 and very far to the left at t_2. These average positions are defined as

$$\bar{y}(t) = \int_{-\infty}^{\infty} y |\Psi(y, t)|^2 \, dy \qquad (111)$$

The traversal time of the wavepacket through the region of interest is given by

$$\tau = t_2 - t_1 - \frac{(\bar{y}_2 - \bar{y}_1 - L) n_0}{c} \qquad (112)$$

Although we refer to this time as a traversal time, it is learned that, strictly speaking, it is a delay time. Part of the interest of this type of simulations is to study how delay times relate to the previously obtained expressions for the traversal time.

Figure 11 represents the delay time versus the size of the wavepacket for two values of the central wavenumber, $k_0 = 3.927$ and $k_0 = 4.306$, which correspond to the center of the gap and to a resonance, respectively. There is again a strong similarity in the behavior of the traversal time and of the transmission coefficient [15]. The long wavepacket limit of the traversal time coincides with the characteristic time τ_1, while the short wavepacket limit is independent of wavenumber and equal to 29. The speed of the wave is greater than in vacuum for a wide range of sizes. The minimum size of the packets that travel faster than in vacuum is about 9, so that the corresponding width $2\sigma_I$ is very much the same as the size of the system. Velocities larger than in vacuum occur when the transmission coefficient is very small. In regions with a very small density of states, the traversal time is very short and, at the same time, transmission is very difficult due to the lack of states at the corresponding energies.

Figure 11. Traversal time versus the size of the wavepacket for a periodic system. The solid line corresponds to a central wavenumber $k = 3.927$, and the dashed line to $k = 4.3$.

The width of the transmitted packet σ_T is slightly smaller than the width of the incident packet σ_I. According to the results in the subsection on the wavepacket approach, we obtain that, in the absence of dispersion and up to second order in perturbation theory, this change in width depends on the derivatives with respect to frequency of τ_1 and τ_2. As the first of these derivatives is equal to zero in the center of the gap, one arrives at

$$\sigma_T^2 = \sigma_I^2 - \frac{v_g^2}{2} \frac{d\tau_2}{d\omega} \qquad (113)$$

In order to check up to which sizes second-order perturbation theory is valid, Ruiz et al. [15] plotted $\sigma_I^2 - \sigma_T^2$ as a function of the size of the packet and compared it with the value of $(1/2)(d\tau_2/d\omega)$ obtained from the characteristic determinant. Second-order perturbation theory works adequately for a wide range of sizes and, in particular, for the sizes for which one obtains velocities larger than in vacuum. The error in the measurement of the traversal time of a single wavepacket is its width divided by its velocity. All the packets that travel faster than in vacuum are so wide that their uncertainty in the traversal time is larger than the traversal time itself and even larger than the time it would take a wave to cross the structure travelling at the same speed as in the vacuum.

4.2. Resonant Tunnelling

A double-barrier structure is a special case of a periodic system consisting of $N = 4$ interfaces with two evanescent regions separated by a propagating one. In the evanescent layers, the potential energy V_2 is larger than the energy of the electron E. The results of the previous part also applied to this case where one type of layers are evanescent. We merely have to replace k_2 by $-i\kappa$ where $\kappa = [2m(V_2 - E)]^{1/2}/\hbar$. (Correspondingly, $\sin k_2 d_2$ becomes $\sinh \kappa d_2$.) Double-barrier potential structures present resonant tunnelling, which has been studied for electrons since the early days of quantum mechanics [56]. Resonant tunnelling for electromagnetic waves is easier to carry out than corresponding experiments on electrons [24].

The traversal time τ for electromagnetic waves through a double-barrier structure was calculated by Cuevas et al. [40]

using the previous equations for the transmission and reflection amplitudes, Eqs. (107) and (110) with $N = 4$. They considered the finite resolution of the experimental devices by convoluting these expressions with a gaussian distribution function with a standard deviation of 6 MHz, which reproduces the same average height of the peak of the transmission coefficient as the corresponding experiments [24]. They found that at each resonance the Büttiker-Landauer traversal time is basically double the lifetime.

The dependence of the traversal time with frequency at a resonance is fairly universal. The phase of the transmission amplitude changes by an angle of π at each resonance, as predicted by Friedel's sum rule. Its frequency dependence can be fitted quite accurately by an arc tangent function. The time, proportional to the derivative of this phase, is a Lorentzian with the same central frequency and width as the Lorentzian corresponding to the transmission coefficient. As the lifetime τ_l of the resonant state is the inverse of the width of the transmission coefficient at half maximum, we conclude that it must be equal to half the traversal time at the maximum of the resonant peak:

$$\tau_l = \frac{1}{2}\tau_{\text{res}} \qquad (114)$$

This result was obtained by Gasparian and Pollak [43] by considering the traversal time for an electron tunnelling through a barrier with loses, that is, with a decay time.

4.3. Finite Size Effects in Tunnelling

We have simulated the evolution of a finite wavepacket tunnelling across a rectangular barrier of height V_0 and length L and we have measured the delay of the peak of the transmitted wave as a function of the size of the original packet. The results are used to establish the limit of validity of the long wavepacket approach up to second order and of the time-of-arrival operator approach, previously analyzed.

As we have explained at the beginning of this section, one calculates the position of the packet at different times and from this information one extracts the time taken by the packet to cross the region of interest. Part of the interest of this type of simulations is to study how this time relates to the previously obtained expressions for the traversal time. In Figure 12 we represent the tunnelling time, τ, versus the width of the wavepacket in k-space, Δk, for an incident electron with a momentum $p_0 = 2.6$. The units are set by the choice $\hbar = m_e = 1$. The barrier parameters are $V_0 = 6$ and $L = 15$ (squares), 30 (circles). The numerical results are represented by geometrical figures, each one corresponding to a different barrier length L. The continuous curves represent the results obtained in the large wavepacket approach up to second order, Eq. (103). In the limit $\Delta k \to 0$ the tunnelling time tends to τ_y and is independent of L, in agreement with the so-called Hartman effect [19]. The continuous curves fit the numerical results relatively well up to values of Δk of the order of $3/L$. This limit of validity is quite general and has been checked for many different values of p_0, V_0, and L.

The width of the transmitted packet σ_T is slightly smaller than the width of the incident packet σ_I. According to the results in the subsection on the wavepacket approach,

Figure 12. Tunnelling time τ versus the size of the wavepacket Δk for an incident electron with momentum $p = 2.6$ and barrier parameters $V_0 = 6$ and $L = 15$ (squares), 30 (circles). The curves represent the results for the long wavepacket approach up to second order.

we obtain that, up to second order in perturbation theory, this change in width depends on the derivatives with respect to frequency of τ_2. Second-order perturbation theory works adequately for a wide range of sizes.

We now want to analyze the applicability of the time-of-arrival operator approach previously studied. The average traversal time in this method is given by Eq. (106). Up to second order of approximation, this method coincides with the long wavepacket approach except for a term which depends on the second derivative of the Büttiker time τ_y with respect to the wavenumber k:

$$\tilde{\tilde{\tau}}_y \equiv \frac{\partial^2 \tau_y}{\partial k^2} \qquad (115)$$

This term is negligibly small in most practical situations. Then it is feasible that the time calculated via Eq. (106) (to all orders in Δk) constitutes a very good approximation to the exact results.

In Figure 13 we show the tunnelling time τ versus Δk for an incident electron with momentum $p_0 = 2.5$ and rectangular barrier parameters $V_0 = 5$ and $L = 85$. The numerical results are represented by circles and the continuous

Figure 13. Tunnelling time τ versus Δk for an incident electron with momentum $p = 2.5$ and barrier parameters $V_0 = 5$ and $L = 85$. The numerical simulations (circles) and the results of the time-of-arrival approach (continuous curve) are similar up to sizes $\Delta k = 3.5/L$.

curve corresponds to Eq. (106), while the dashed curve corresponds to the wavepacket approach up to second order. We note that the weighting method fits the numerical results for a larger range of sizes. We estimate that it can be considered an excellent approximation for values of Δk smaller than $3.5/L$. The weighting method is also very practical since it only requires the evaluation of an integral in k and it can be applied to all kind of wavepackets.

5. CONCLUSIONS

In this review we have discussed the topic of tunnelling time in mesoscopic systems including nanostructures, particularly in 1D systems with arbitrary shaped potential. But the treatment of tunnelling time in "nanostructured materials" approaching the molecular and atomic scales is still open. In the field of tunnelling time, there are problems in any of the existing approaches, and we do not have a clear answer for the general question "How much time does tunnelling take?". Unfortunately no one of these approaches is completely adequate for the definition of the time in QM. Nevertheless, we note that all these different approaches can be consistently formulated in terms of Green's function, and their main differences can be fairly well understood.

For 1D systems we obtained closed expressions for the traversal and reflection times, Eqs. (25) and (31), in terms of partial derivatives of the transmission and reflection amplitudes with respect to energy. Results of other approaches can be related to these expressions and the main differences can be grouped into two categories: the complex nature of time and finite size effects.

Our conclusion about the complex nature of time is the following. It is clear that there are two characteristic times to describe the tunnelling of particles through an arbitrarily shaped barrier. (Similar conclusions can be reached for reflecting particles.) These two times correspond to the real and imaginary components of an entity, which we can choose as the central object of the theory. They are not entirely independent quantities, but are connected by Kramers-Kronig relations. Different experiments or simulations will correspond to one of their components or to a mixture of both. Büttiker and Landauer argue that these two times always enter into any physically meaningful experiment through the square root of the sum of their squares, and so claim that the relevant quantity is the modulus of the complex time.

As regards finite size effects, we believe that Eqs. (25) and (31) are exact, and adequately incorporate finite size effects. These effects correspond to the terms which are not proportional to derivatives with respect to energy. They are important at low energies and whenever reflection is important (as compared to changes in the transmission amplitude). Several approaches do not include finite size terms, since they implicitly consider very large wave functions. The WKB approximation, the oscillatory incident amplitude approach, and the wavepacket analysis, for example, do not properly obtain finite size effects. On the other hand, our GF treatment, based on the Larmor clock, the generalization of the time-modulated barrier approach, and the

Feynman path-integral treatments arrived at exact expressions. In order to see that these expressions are all equivalent, one has to transform the derivative with respect to the average barrier potential, appearing in the time-modulated barrier approach, into an energy derivative plus finite size terms. The same has to be done with the functional derivative with respect to the potential appearing in the Feynman path-integral techniques.

Finite size effects can be very important in mesoscopic systems with real leads with several transmitting modes per current path. The energy appearing in the denominator of the finite size terms, Eqs. (25) and (31), corresponds in this case to the "longitudinal" energy of each mode, and so there is a divergence whenever a new channel is open. In the exact expressions there are no divergences; the problematic contributions of the finite size terms is cancelled out by the terms with energy derivatives.

GLOSSARY

WKB approximation   This approximation takes advantage of the fact that the wavelength is changing slowly, by assuming that the wave function is not changed much from it would take if the height of the potential barrier were constant.

Embedded Metal and Alloy Nanoparticles

K. Chattopadhyay, V. Bhattacharya

Indian Institute of Science, Bangalore, India

CONTENTS

1. BASIC CONCEPTS

1.1. Introduction

Nanostructured materials can be defined as those materials which exhibit microstructure having the characteristic length scale of the order of a few nanometers in any dimensions. Based on dimensions, the nanostructured materials may be classified into many categories [1]. These may be of zero dimension (e.g., clusters), one dimension (e.g., single crystalline multilayers), two dimension (e.g., filamentary rods), and three dimension (e.g., embedded nanoparticles). In this article, only the embedded nanoparticles will be discussed.

Gleiter [2, 3] had first drawn attention to the fact that a higher volume percentage of the atoms (about 30% for very fine sizes) at the interfaces in nanocrystalline materials makes these materials different from the coarse-grained crystalline materials or glasses. This is because nanocrystalline materials have a significant contribution from the atoms configured at the grain boundaries. This is in addition to the effects arising from the fine-sized crystalline grains. Fine-grained materials share the following features: spatial confinement of atomic domain to less than 100 nm; a significant fraction of atoms associated with the interface and a higher probability of interactions between the constituent domains [4]. With such reduced length-scale, the physical and chemical behavior exhibited by these materials is different from free atoms or a bulk solid of same chemical composition [5].

Some of the examples of the size-related effects manifested in these nanostructured materials are "quantum-size effects" because of the spatial confinement of the delocalized valence electrons, alteration in the "many-body" atomic phenomena like melting (by lattice vibrations), suppression of the lattice-defect mechanisms like dislocation generation, and migration and alloying in immiscible systems. Exciting properties like giant magnetoresistance, superplasticity, optical transparency, etc. appear in materials below a critical (nanometric) length scale. This set of unique and improved properties has enhanced the drive for the study of these materials from both technological and fundamental viewpoints in the recent past. Advances in the high performance materials depend on the control of size, distribution, morphology of the constituent grains, and phases present at the nanoscale, nature of the interface between the constituent phases, and the interaction across the interface. Consequently, a significant amount of research is devoted to the controlled synthesis and property evaluation. The materials with embedded nanostructures are a special class of nanomaterials which are very promising because of the opportunities for materials development. This comes from the observations that the behavior of embedded nanoparticles is often different from both the free nanoparticles and the bulk. The combination of nanometric dimension and the type of constraining matrices can produce materials with new behavior. The properties of the embedded nanoparticles are intimately associated with the morphology and crystallography of these particles. However, several issues like the morphology of these small particles and their transformation behavior, are still not fully understood and are the subject of vigorous activities. The research on embedded nanomaterials covers all kinds of materials. However, in this article, we shall primarily focus on embedded metals and alloy particles, which have attracted significant attention in recent times.

1.2. Effects Controlling the Properties of Nanoembedded Materials

The properties of nanoscaled materials are different from that of bulk materials due to the changes in size, atomic configuration, and chemical structure. We will briefly discuss the different factors that lead to these changes.

1.2.1. Size Effect

The most obvious effect of reducing the particle size is the increase in surface and interface areas. The atoms lying at the surfaces or interfaces have a different environment both in terms of coordination and chemistry, since the structure of the grain boundaries is significantly different from that of the bulk crystal. The structure depends on orientation of the neighboring grains and interaction of the atomic potentials across the boundaries. The end result is a more open structure with local variation. Such a structure is also subjected to a relaxation process as the atoms try to arrive at a lower energy configuration. This difference in structure and chemistry of the boundary phase becomes important at nanoscale, since the boundary volume increases significantly with the reduction in the size of the particles. The above reasoning is equally applicable to free particles as well as for nanoembedded particles. One can estimate the volume fraction of the embedded particle interface regions by initially assuming a spherical shape and a reasonable thickness of the boundary where the effect of interactions of the potentials of different grains is significant. For the embedded case, the amount of this boundary phase will also depend on the volume fraction of these materials. Figure 1 gives a typical plot of the volume fraction of the boundaries as a function of size for three different volume fractions. The material, therefore, behaves like a two-phase composite and depending on the property of the boundary phase, can yield novel properties. Besides the effect of surface energy, one can anticipate additional effects. The presence of lattice defects near the interface represents a constrained state, which is structurally different from the constrained state of crystals or glasses. When the volume fraction of the defects becomes comparable to the volume fraction of the crystalline regions, this has a tremendous effect on the change in properties.
Figure 1. Typical plot of the volume fraction of the boundaries as a function of size for three different volume fractions.

In case the size of the particles is reduced such that the critical length scale of physical phenomena becomes comparable (viz. mean-free path of electrons, coherence length) with the characteristic microstructural length scale, size seems to play a key role in dictating the properties of such materials. For example, the band spacing is expected to expand with small confinement, and magnetocrystalline anisotropy can get evened out leading to a more isotropic behavior. With small size, one can observe significant changes in the alloying behavior. This leads not only to a change in the chemistry of the phases present but also to their structures. We will present in brief some of the recent results highlighting this scenario in the subsequent sections.

2. NANOEMBEDDED METALLIC PARTICLES

2.1. Synthesis

There exist several synthesis routes by which nanoembedded particles of metals and alloys can be manufactured. In the following sections, we briefly summarize some of the more popular techniques used in recent times.

2.1.1. Rapid Solidification

One of the popular techniques to synthesize nanoembedded metallic particles is by rapid solidification. This processing technique involves the achievement of a high cooling rate in the range 10^4–10^7 K/s, and significant undercooling of the melt that leads to a large departure from equilibrium conditions. This process involves the ejection of a stream of molten metal/alloy into a thin layer or fine droplets, which is brought in intimate contact with a cooling medium (solid substrate). The heat transfer is primarily by conduction through a solid substrate. The primary requirement for the synthesis of nanomaterials from liquid involves a high nucleation rate and a low growth rate of the solid phases involved in the liquid-solid phase change. The high nucleation rate can be achieved by increasing the undercooling and kinetically avoiding the heterogeneous nucleation sites. The principle of rapid solidification processing of embedded nanomaterials incorporates two major steps. In the first step, the dispersed phase should nucleate in the melt with a high nucleation rate and a low growth rate. In the second step, the matrix phase should nucleate and grow at a very high growth velocity, enabling trapping of the dispersed solid phase coexisting in the melt [6–7]. With a judicial choice of systems and processing conditions, we can observe that both the above processes are achievable in the rapid solidification process. Johns [8] and Cahn [9] have reviewed the rapid solidification process technology. There are several processes that can be classified under rapid solidification processing. A brief description of some of these is given below.

Atomization   The process of gas atomization involves formation of fine droplets from a molten metal when it is impacted with an inert gas. The transfer of kinetic energy from the atomizing fluid to the molten metal results in the process of atomization. The cooling rates of the particles are controlled by several different parameters. These

include thermal properties of the gas, and the parameters controlling the heat and fluid flow like viscosity and conductivity of the cooling media and the size of the droplets. Generally, with all the other parameters remaining constant, the cooling rate increases with a decreasing size of the droplets. Thus, finer sizes experience larger cooling rates and the melt experiences larger deviation from the equilibrium conditions.

Chill Block Melt Spinning In chill block melt spinning [10], which emerged as the most popular technique of rapid solidification, the molten material is forced through a nozzle onto a rotating wheel. The wheel is generally made of a good thermal conductor. A schematic of the melt spinning set up is shown in Figure 2. The heat transfer from the melt is primarily by conduction. The process parameters are optimized to obtain a mass flow through the nozzle in such a way that a dynamically stable pool of molten metal or alloy forms on the wheel surface from which the tape is spun out due to the rapid solidification at the pool/wheel interface. Thus, the rate of solidification is directly related to the surface velocity of the wheel. All the process parameters involved in melt spinning viz. nozzle diameter, nozzle to substrate distance, melt ejection pressure, velocity of the

wheel, are critical and they control the length of puddle of the molten metal. The thickness of the ribbon is generally of the order of 10–100 μm and width of the sample varies from 1–3 mm. The thickness of the ribbon "t" is given by the expression [11]

$$t = (\alpha_T \cdot \Delta T / V_R \cdot \Delta T) \qquad (1)$$

where α_T is the empirical heat transfer coefficient, V_R is the linear velocity of the substrate (that is, the speed of the rotating wheel), ΔT is the temperature difference between the opposite sides of the ribbon, ΔH is the latent heat per unit volume of the liquid metal, and l is the contact zone between the liquid metal and substrate.

2.1.2. Mechanical Alloying

Mechanical alloying is a solid-state powder processing technique where mechanical energy is used to drive the system away from the equilibrium. This results in the development of highly nonequilibrium structures and microstructures. One of the ways the mechanical energy that is imparted on the sample can be stored is by creating a very large number of interfaces. This results in the reduction of the scale of the microstructures. The physical mechanisms responsible in case of ductile materials are repeated fracture, welding and rewelding of powder particles. For brittle materials, the process of fracture dominates the process although the actual mechanism is less clearly understood. Benjamin and his colleagues at Paul D. Merica Research Laboratory of the International Nickel Company (INCO) developed the process around 1976 [12]. Originally developed to produce oxide dispersion strengthened (ODS) nickel and iron-based superalloys for aerospace industry, mechanical alloying has been used to synthesize a variety of equilibrium and nonequilibrium alloy phases. The nonequilibrium phases synthesized include supersaturated solid solutions, amorphous alloys, metastable crystalline, and quasi-crystalline phases and nanostructured materials [13–15]. The amorphization of alloys by this technique was first obtained by grinding a Y-Co intermetallic compound in 1981 [16] and the Ni and Nb powders in the Ni-Nb system in 1983 [17]. Furthermore, it was realized that powder mixtures can be mechanically activated to induce chemical reactions. Known as mechanochemical reactions, this can produce at room temperature nanocomposites and a variety of commercially important materials having ultrafine microstructure [18]. Efforts are also underway since the early 1990's to understand the process fundamentals of mechanical alloying through modelling studies [19]. Maurice and Courtney [19] have developed a simple model for collision events involving ductile elements. Murty and Ranganathan [15] have prepared milling maps, taking into account the various parameters involved during milling like milling intensity, ball-to-powder weight ratio and the number of balls. Murty and Ranganathan [15] converted these factors into two energy parameters, that is, (i) energy of the balls, and (ii) total energy. The milling maps give the milling conditions required for amorphization. Recently, mechanical alloying has been used extensively to synthesize nanocrystals of pure metals and alloys [20, 21]. The process is also promising to synthesize embedded nanoparticles.

Figure 2. (a) A schematic of the melt spinning set-up is shown here. (b) A schematic showing the ion implantation set-up.

2.1.3. Physical Vapor Deposition

The physical vapor deposition (PVD) process involves the creation of a vapor phase species via evaporation, sputtering, or ablation of a target material. During transportation, the vapor phase species may undergo collision and ionization. Subsequently, it condenses onto a substrate where nucleation and growth occurs leading to the formation of films or droplets. The physical vapor evaporation process takes place in a vacuum, and therefore vacuum plays an important role on the deposition and growth of films. It is possible to introduce a reactive species in the chamber to initiate a chemical reaction with the vapor species prior to deposition. Known as reactive sputtering/ablation, this opens up the new possibility to synthesize nanoscaled materials including embedded nanoparticles. A detailed description of the PVD process is available in literature [22–24].

2.1.4. Sol–Gel

The evolution of colloidal solutions with rigidity (gel) from a liquid-like mixture of alkoxides and inorganic salts in a common solvent, which does not have the ability to resist shear stress (sol), is the essence of the sol–gel route [25]. The technique gradually became known as the sol–gel process because of the sudden characteristic change of viscosity at the onset of gel transition [25–27]. Sol–gel processing of nanocomposite materials has attracted much attention, because the process is simple and the conversions can occur readily with a variety of precursors available and reactions take place at room temperature. The gel generally contains a dispersed component in a dispersion medium and the dispersed component has three-dimensional networks [28]. The conversion of sol to gel and vice versa is brought about by a change in temperature, agitation, and peptization. Diphasic xerogels (gels dried conventionally in air) can be prepared by controlling the homogeneity of the sol. Two phases develop when the material is heterogeneous (*i.e.*, when the liquid has a considerable fraction of metal ions) or by the later addition of the metal phase precursor [29]. The derived gel is then a mixture of ceramic oxide and metal oxide. Under a suitable reduction environment, an extreme finely dispersed metallic phase in ceramic matrices can be obtained. Bhattacharya et al. [30, 31] has synthesized dispersion of lead in silica and alumina matrix. In the case of silica, the matrix is glassy while in the case of alumina, they report that the matrix is composed of ultrafine γ alumina. In both cases, the dispersoids of lead is of 10 to 20 nm in size. A typical micrograph of lead in alumina is shown in Figure 3. Iron nanoparticles are produced in a alumina matrix using Al $(Osec-Bu)_3$ as a sol–gel precursor [32]. The Fe/alumina nanocomposite exhibits weak saturation magnetization. Recently, Co nanocomposites have been synthesized using zirconia-modified silica aerogels [33]. Thus, sol–gel [34] has formed an excellent technique in recent times for synthesis of nanocomposites and embedded nanomaterials.

2.1.5. Ion Implantation

Ion implantation is a high technology approach used to modify surface properties of materials. The process is similar to a coating process, but it does not involve the addition of a

Figure 3. (Top) Typical bright field transmission electron micrograph showing Pb dispersed in γAl_2O_3 matrix, (Bottom) corresponding electron diffraction pattern. Reprinted with permission from [60], P. Bhattacharya, 2000.

layer on the surface. Originally developed for use in semiconductor applications, and, in fact, still used extensively in that capacity today, ion implantation utilizes highly energetic beams of ions (positively charged atoms) to modify surface structure and chemistry of materials at low temperature. The ion implantation process is conducted in a vacuum chamber at very low pressure (10^{-4}–10^{-5} torr). Large numbers of ions (typically 10^{16}–10^{17} ions/cm^2) bombard and penetrate a surface, interacting with the substrate atoms immediately beneath the surface. The typical depth of ion penetration is a fraction of a micron (or a few millionths of an inch). The interactions of the energetic ions with the material modify the surface, providing it with significantly different properties than the remainder of the material. Specific property changes depend on the selected ion beam treatment parameters—for instance, the particular ion species, energy, and the total number of ions that impact the surface. Ions are produced via a multistep process in a system. Ions are initially formed by stripping electrons from the source atoms in plasma. The ions are then extracted and passed through a mass-analyzing magnet, which selects only those ions of

a desired species, isotope, and charge state. The beam of ions is then accelerated using a potential gradient column. Typical ion energies are 10–200 keV. A series of electrostatic and magnetic lens elements shape the resulting ion beam, and scans it over an area in an end station containing the parts to be treated. Ion implantation offers numerous advantages for treating component surfaces. A primary benefit is the ability to selectively modify the surface without detrimentally affecting the bulk properties, largely because the process is carried out at low substrate temperatures. The process is also extremely controllable and reproducible and can be tailored to modify different surfaces in desired ways. In recent times, a significant amount of work on nano-embedded materials has been carried out on samples prepared by ion implantation [35–37]. A schematic of the ion implantation set-up is shown in Figure 2b. The implantation of ions by high-energy ion beam onto a substrate yield embedded particles with fairly uniform distribution and ultrafine sizes. The sizes of the particles are generally less than 20 nm and their density can be controlled by irradiation time. Johnson et al. at Lawrence Berkeley National Laboratory (LBNL) [38] have shown in recent times that it is possible to follow the deposition process by real-time electron microscopy/Rutherford backscattering.

2.2. Embedded Nanoparticles of Metals and Alloys in Inorganic Matrix

The most popular techniques for the synthesis of nano-embedded metallic particles in metallic matrix are via rapid solidification and ion implantation. Nanoembedded metallic particles can be synthesized by physical vapor deposition of alloys. Such films are often termed granular thin films and are the subject of great interest due to the advent of giant magnetoresistance and spintronics. Recently, dispersions of low melting metallic particles like lead, indium, tin, and bismuth in high melting metallic matrices have attracted major interests in the scientific community. In the following sections, we shall summarize some of the current work.

2.2.1. Synthesis of "Soft Nanoembedded" Particles by Rapid Solidification in Systems Exhibiting Miscibility Gap

Soft metallic phases of elements like Pb, Bi, In, and Sn can be dispersed in a higher melting point matrices of metals and alloys provided they form an immiscible alloy system. These soft, dispersed nanoembedded particles can be produced by rapid solidification processing (RSP) from the liquid phase in monotectic systems. The discussion below is restricted to those in the low-volume fraction regime of the dispersed phase because of the interest in developing a microstructure with fine dispersions of low-melting metals and alloys in a high-melting matrix. Figure 4 shows schematic of a typical binary monotectic phase diagram exhibiting a miscibility gap. The figure shows the possible metastable extensions mentioned above [39]. In order to evaluate the possible pathways of the microstructural evolution, one needs to determine, using thermodynamic calculations, the metastable phase diagram of the system. These

Figure 4. A typical monotectic phase diagram showing all the metastable extensions.

include the metastable extrapolation of the binodal and spinodal lines for liquid and a determination of equal, free-energy curve (T_o) between solid and liquid. In addition, one needs to determine the limit set by homogenous nucleation in case we are evaluating the stability of the liquid during quenching.

During solidification, the process of the development of the microstructure will be different, depending on the composition of alloy melt, that is, hypomonotectic or hyper-monotectic. When an alloy melt is cooled through the immiscible domain (hypermonotectic composition), the liquid (L) phase separates into two liquids ($L_1 + L_2$). Depending on the melt composition, two possibilities exist that govern the kinetics of this phase separation. Spontaneous decomposition of liquid ($L \rightarrow L_1 + L_2$) occurs if the melt is cooled through the spinodal domain. However, if the melt is in binodal domain, the phenomena is one of nucleation and growth of L_2 from the melt. As the temperature decreases continuously, the primary solid phase (S_1) nucleates below the monotectic temperature (T_m) and the S/L interface moves at a very high velocity thereby trapping liquid L_2 within it. The size of the phase-separated liquid (L_2) droplets in the melt is dictated by the growth and coarsening rate and the time available before the L_2 droplets are trapped by the growing solid (S_1). In addition to the purely diffusional growth, the collisions of the different particles also play a major role in the coarsening process. As pointed out by Ulhmann et al. [40], the critical velocity required for the growing solid to trap the droplets is inversely proportional to the size of the droplet. As the growth velocity of the solid depends on the amount of the undercooling achieved during rapid solidification, a higher cooling rate is required to synthesize finer dispersions. The particles that are not trapped ultimately get engulfed at the grain boundaries creating a network of particles decorating the grain boundaries. This is more prominent at a lower cooling rate.

With a very high cooling rate, it is also possible to suppress the decomposition of liquid within the immiscible liquid domain, if the liquid does not enter the limit given by the spinodal regime. The liquid in such a case can kinetically avoid the process of nucleation and may enter the domain below the equal, free-energy curve T_o between the melt and the solid. In this domain, it is kinetically possible to achieve solidification without partitioning, leading to the formation of transient metastable solid solution. This solid is metastable and often decomposes spontaneously to yield a nanodispersed microstructure or may follow a typical precipitation process depending upon the composition in the G versus x curve. The size distribution in the latter case is narrower (region 5) compared to the liquid-phase separation route due to the large driving force for nucleation from the highly metastable solid solution and relatively slower diffusion in the solid state. In many cases, both liquid trapping and decomposition of the metastable solid solution can occur simultaneously. The microstructure under such a processing condition is characterized by a bimodal distribution of very fine dispersoids due to the solid-state decomposition and a coarser distribution of particles through the trapping of the phase-separating second liquid (L_2) by the moving interface.

The shapes of the particles depend on the evolutionary route it followed during the processing. Since the size is in nanodimension, the time the particles require to equilibrate with the surrounding matrix is very small and the equilibrium can easily be reached during solidification. The equilibrium shape of the particles in such a situation is dictated by the point group symmetries of the matrix and the particles. The symmetry of the entrapped liquid particles is (∞, ∞, ∞). The intersection group of the liquid particles in solid matrix will, therefore, be the same as the point group of the matrix. Upon solidification, the solid may conform to the same symmetry, if it does not have enough time in solid state to equilibrate. In case when the liquid transforms to solid in a massive manner without any solid partition and yield-dispersed microstructure through a subsequent solid-state decomposition, the symmetry of the particle will be dictated by the intersection symmetry of the point group of the solid particle and the matrix. Thus, a crystallographic shape analysis is a powerful tool to determine the evolutionary pathways of the embedded nanoparticles. This is further discussed in subsequent sections.

2.2.2. Nanoembedded Metallic and Intermetallic Particles by Nucleation and Devitrification

Even in the system where there is no miscibility gap, it is possible to synthesize nanoembedded particles via rapid solidification. This can be achieved in two ways. Nanoembedded particles can be obtained by controlling nucleation and growth. The basic principle is to promote a high nucleation rate of the embedding phase in the melt and restrict the growth rate. This is essentially followed by the rapid growth of the matrix phase, such that the matrix can entrap the fine particles formed earlier in the melt resulting in the formation of a desired nanocomposite [7]. This can be achieved by carefully selecting the alloy composition and controlling

the undercooling of the melt, by selectively altering specific parameters during the process of rapid solidification. The addition of trace glass-forming elements can help achieve the above goals by controlling the viscosity of the melt and thereby promoting undercooling and altering the nucleation and growth processes. The synthesis of intermetallic Ti_2Ni nanoparticles embedded in a TiNi matrix via rapid solidification is an example of such an approach [6]. Another powerful way of synthesizing nanoembedded particles is to synthesis glassy alloy by choosing the correct chemistry and utilizing rapid solidification processing. This is followed by controlled devitrification. During the process of devitrification, many of these glasses yield nanocrystalline phases thus resulting in a composite of glassy matrix in which these particles are embedded [41]. The magnetic alloy "FINEMET" is the best-known example of this class of materials where the Fe_3Si particles are embedded in the glassy iron-rich matrix.

2.2.3. Structure of the Particle-Matrix Interface and Orientation Relationship

As discussed in the previous section, the embedded nanoparticles often exhibit well-defined morphology. The shape depends on the crystallography of the particles as well as the matrix. As pointed out in the previous section, the symmetries of the liquid particles are dictated by the matrix symmetry [42]. For example, the liquid will have a cuboctahedral shape (a regular octahedron bounded by eight {111} and truncated on six {100} facets) if the matrix is cubic, while it will adopt the shape of hexagonal prism or bipyramid if the matrix belongs to a hexagonal system [43]. Alternately, in the case of a glassy matrix, the liquid or glassy nanoparticles will possess spherical symmetry. In case the symmetry of the matrix and the particles are the same, the situation is relatively simpler. A large number of systems on which extensive investigations have been carried out falls into this category. The experimental results available for the dispersion of lead in different fcc matrices provide important insight. Both in aluminium and copper matrices, the lead particles show well-developed cuboctahedral shape [44]. The orientation observed was cube-on-cube, despite the fact that the lattice parameter differences are large between Pb and the two matrices. The high-resolution imaging of the interface indicate that the interface is semicoherent with very little strain.

The shape in this case is clearly dictated by the intersection symmetry. In the case of Ni as matrix, the situation is different. The orientation of the solid Pb particles with Ni does not follow a cube-on-cube orientation relationship. The observed relationship is $(100)_{Ni} \parallel (100)_{Pb}$ and $[011]_{Ni} \parallel [001]_{Pb}$. The embedded particles in this case exhibit a distorted cuboctahedral shape. Obviously, the liquid lead particle has a perfect cuboctahedral shape dictated by the symmetry of the matrix. During solidification, the solid lead nucleates with a distinct orientation. The problem then is to fill up a cuboctahedral cavity with solid lead growing with an orientation, which does not conform to this symmetry. This is achieved by nucleating other variants such that the shape is closer to the preexisting cavity. This results in a distorted shape and a multigrained nanoembedded particle. The same principle seems to dictate the shapes and the nature of the interfaces of the nanoembedded particles

having structure different from the matrix. The shapes of Pb, In, Bi, Cd, and Sn viewed along the [011] zone axis of the Al matrix are shown in Figure 5. The corresponding diffraction pattern is also shown in the same figure. From the projected images along prominent zone axes, one can reconstruct the actual three-dimensional (3d) shapes of the dispersoids. It has been experimentally observed that like Pb, the In particles conform to a cuboctahedral symmetry. A careful diffraction analysis shows that these In particles exhibit a cubic structure. However, in the case of Bi and Sn [45–47], one observes particles with a spectrum of shapes. These particles do not exhibit a strict orientation relationship with the matrix. In contrast, the Pb particles embedded in zinc matrices obtained by rapid solidification possess an epitaxial relationship with the matrix given by $(0001) Zn \| (111) Pb$ and $[11\bar{2}0]Zn \| [1\bar{1}0]Pb$ [43]. The shape of the Pb particles can be obtained by systematic tilting to many different zone axes and from the series of images we conclude that the shape is truncated hexagonal bipyramid consistent with the symmetry of the matrix. Larger Bi particles embedded in Zn matrix obtained by rapid solidification also corresponds to a truncated hexagonal bipyramid. However, fine Bi particles obtained from the decomposition of the solid solution matrix formed by diffusionless solidification show only hexagonal plates with rounded edges and corners [48]. Table 1 summarizes the crystallography of lead particles embedded in different matrices, the intersection group, and the expected shape based on the detailed study carried out by Chattopadhyay et al. [49]. Even if the intersection point group symmetry is the same, the actual shape in different matrices are different, since the anisotropy of surface energies in the solid state may be very different.

In case of ion-implanted samples, the shape of Pb on Al varies with size and shape, occasionally showing truncations on {100} planes and to a smaller extent on {111} facets. Thus, the equilibrium shapes of smaller inclusions include polyhedra mainly bounded by eight {111} facets and to a lesser extent by {100} facets [36, 37].

2.2.4. Shapes of Alloy Particles

Studies on alloy particles are limited, and only in recent times attempts have been made to synthesize such particles. Pb-In alloy particles embedded in aluminium have been

200 nm
Figure 5. Electron micrograph and corresponding selected area diffraction pattern showing the orientation between the nanoscaled inclusion and aluminium is shown for (a) Pb, (b) In, (c) Bi, and (d) Sn.

Table 1. Crystallography of lead and equilibrium shape in different matrices [49].

System	Orientation relation	Matrix point group	Intersection group	Shape
Zn-Pb hcp-fcc	$(0001)_{Zn} \| (111)_{Pb}$ $[11\bar{2}0]_{Zn} \| [1\bar{1}0]_{Pb}$	6/mmm	$\bar{3}m$	Truncated hexagonal biprism
Cu-Pb fcc-fcc	$(111)_{Cu} \| (111)_{Pb}$ $[110]_{Cu} \| [110]_{Pb}$	m3m	m3m	Truncated cubeoctahedron
Al-Pb fcc-fcc	$(111)_{Al} \| (111)_{Pb}$ $[110]_{Al} \| [110]_{Pb}$	m3m	m3m	Truncated cubeoctahedron
Ni-Pb fcc-fcc	$(100)Ni \| (100)Pb$ $[011]Ni \| [001]Pb$	m3m	4/mmm	Truncated cubeoctahedron

investigated by Bhattacharya et al. [50]. Lead and indium form a complete solid solution. These particles are cuboctahedral in shape and bounded by {111} and {100} facets and exhibits a cube-on-cube orientation relationship with aluminium matrix. In these particles, there is a preference for the formation of the 111 interfaces leading to the occasional occurrence of the octahedral shape.

Bi-crystalline Pb-Cd inclusions in an aluminium matrix consist mostly of an fcc Pb part forming the segment of a cuboctahedron and a hcp Cd slab attached to one of {111} Pb facets [51]. The close-packed planes and directions in the three structures are parallel to each other yielding a simple orientation relationship. Pb-Sn alloy particles embedded in aluminium have been recently studied by Johnson et al. [52] and Bhattacharya et al. [53]. Pb in most cases possess a cube-on-cube orientation relationship with the aluminium matrix. Sn shows different orientation relations. For ion-implanted samples, Johnson et al. [52] have reported two orientation relations for Sn particles with the matrix:

$$(111)Al \| (100)Sn \text{ and } [1\bar{1}0]Al \| [001]Sn$$

$$(111)Al \| (100)Sn \text{ and } [1\bar{1}0]Al \| [0\bar{1}1]Sn$$

Bhattacharya et al. [53] have reported an alternate orientation relationship of $(2\bar{2}0)Al \| (101)Sn$ and $[220]Al \| [020]Sn$ between Al and Sn. In this case, the particles were synthesized by rapid solidification. In most of the cases, the overall shape of these embedded nanoparticles are near cuboctahedral (Fig. 6) and the relationship among Pb, Sn, and Al can be written as

$$(2\bar{2}0)Al \| (2\bar{2}0)Pb \| (101)Sn \text{ and}$$

$$[220]Al \| [220]Pb \| [020]Sn.$$

In-Sn nanoalloy inclusions in Al have been recently investigated [54] and they show the presence of two phases, $\beta(In_3Sn)$ and $\gamma(InSn_4)$, at nanoscale. It has been shown that while β possesses an orientation relationship with Al, the γ phase only possesses a planar relationship. The indium-tin alloy particles exhibit a distorted cuboctahedral symmetry as shown in Figure 7. The research in alloy particles is still at a very early stage. However, already they show promise of extending our understandings.
Figure 6. Micrograph shows Pb-Sn alloy particles. Majority of the particles correspond to a cuboctahedral symmetry. Reprinted with permission from [53], P. Bhattacharya et al., *J. Mater. Res.* 17, 2875 (2002). © 2002, Materials Research Society.

2.2.5. Defects in the Embedded Particles and the Matrix

There exist a limited number of studies to unravel defects at the interfaces and inside the nanoembedded particles. The possible defects that can arise from the geometrical effect of a constraining cavity have been discussed by Pond and Vlachavas [55]. In case the particles have the same intersection symmetry as that of the matrix, one does not expect any geometrical defect to occur. However, if they are different, defects can exist either at the interface as steps or in the interior as additional interfaces among variants. In

the latter case, the particle does not remain a single crystal anymore. The twin boundaries observed in germanium crystal embedded in an aluminium matrix by Gouthama are a classical example of such a defect [56]. This is shown in Figure 8. In case of Pb particles embedded in an alloyed matrix of Cu and Zn with lower zinc concentration, the particles are cuboctahedron in shape bounded by 111 and 100 facets as shown in Figure 9. High-resolution electron microscopy reveals that the particle-matrix interface in the as-spun sample contains steps of height 0.42–1.9 nm on the {111} planes [57]. Repeated thermal recycling from room temperature to a temperature above the melting point leads to a complete removal of these steps indicating that these stepped structures are of kinetic origin and not geometrical. Recently, a model for the origin of these stepped interfaces has been proposed [58]. At small sizes, the embedded particles sometime exhibit twin or faults particularly if the matrix is rigid. As an example, stacking fault-like defects could be observed in lead embedded in an amorphous silica matrix [30].

In case of Pb-Cd eutectic inclusions in aluminium reported by Dahmen et al. [51, 58, 59], the hcp Cd parts of the inclusions are oriented with the close-packed planes and directions parallel to close-packed planes and directions of both Pb inclusion and an aluminium matrix. The different moire patterns from the Pb and Cd parts of the particles help identify the Pb/Cd interface containing close-packed planes of Pb(111) and Cd(0001) parallel to each other which is shown in Figure 10. The Pb/Cd interfaces are not always planar and slight curves and internal kinks are occasionally seen. The melt-quenched aluminium samples containing embedded lead, indium, bismuth, tin, and cadmium nanoparticles contain quenched in vacancies. In case of Pb-In alloy particles embedded in aluminium, the presence of dislocation loops in the particles [50] has been reported. In the case of Al-1.8 at%($Pb_{56}In_{44}$), the particles retain faceted shape even at 723 K, while some of the particles show slow atomic step activity. This is shown

Figure 7. Micrograph shown In-Sn alloy particle corresponding to eutectic composition. The particle shows near-cuboctahedral symmetry and shows the presence of both β and Sn phases. Reprinted with permission from [62], V. Bhattacharya and K. Chattopadhyay.

Johnson et al. [52, 59] have studied bi-phase alloy inclusions in aluminium matrix synthesized by ion implantation and observed the presence of voids. The presence of voids was also observed in many cases in particles in the rapidly solidified melt-spun samples containing lead-tin and lead bismuth alloy inclusions [61]. The presence of voids are also observed in case of alloy particles viz. Pb-Sn [53] and In-Sn [54, 62] in rapidly solidified samples.

2.3. Transformations in Embedded Particles

2.3.1. Shape Changes in Embedded Particles

The embedded nanoparticles bounded by sharp interfaces often exhibit superheating during melting [57]. Careful analysis of the ratio of the distance between 111 and 100 plane for nanoparticles of Pb embedded in Al matrix indicates that the values are widespread in the melt-spun state with the peak at around 1.18 [63]. This increases steadily with recycling and the ratio shifts to 1.3–1.5 indicating the dominance of 111 planes. This is so because along with the annihilation of surface defects, which act as heterogeneous nucleating site for phase change, the facets sharpen and surface energy ratio of the planes are altered. There is a tendency of increasing the surface energy for 111 facets with lower energy and decreasing defects leading to the emergence of superheating. Kjeldgaard and Johnson et al. [64, 65] have experimentally studied the morphological changes of liquid Pb inclusions embedded in an aluminium matrix. Their reports show a hysteresis in the morphology of liquid Pb inclusions. Immediately after melting, the {100} planes bulge outwards and become rounded, whereas the {111} planes remain flat until the temperature reaches around 500 °C when the inclusion rapidly becomes spherical. In a significant contribution, Gabrisch et al. [65] have focused on the characteristics of the equilibrium shape for small Pb inclusions in Al matrix. They observed a relation between the size and the location in an Al matrix. Using high-resolution electron microscopy, they established that unlike

the equilibrium shape of free particles, the shape of inclusion changes with size and certain "magic sizes" are preferred [66]. This behavior can be ascribed to the oscillatory nature of strain energy that dominates at small sizes.

Bhattacharya et al. [50, 60] have conducted *in-situ* heating experiments on Pb-In nanoparticles embedded in an aluminium matrix in order to confirm the kinetic origin of shape of the particles. The results indicate that the behavior can be different from particle to particle [50]. Melting reports show that while some particles roughened to give spherical shape, there are other particles that do not exhibit roughening of both the 100 and 111 planes as shown in Figure 11. In a few cases, they report that while few adjacent sets of planes still remain faceted, the planes opposite to them have undergone roughening transition. It suggests that a major role is being played by interfacial segregation during roughening transitions. Since segregation can be different for different particles, the roughening behavior can also be different.

2.3.2. Liquid to Solid Transformation

Considerable interest in studying phase transformation in embedded nanoparticles exists with particular emphasis in liquid to solid transformation [67–69]. The primary issue is the nucleation behavior of the solid in the entrapped liquid. It has been shown that if the melt is divided into small metal clusters with no connectivity among them, large supercooling is achievable [70]. From the classical nucleation theory [71], energy due to the creation of interface is associated with the nucleation of solidification from the melt. The cause of the barrier is the energy expended for the creation of interface associated with the new phase that appears during solidification. Therefore, solidification always occurs below the thermodynamic freezing temperature. Classical nucleation theory predicts that the transformation of super-cooled liquid to solid phase can occur homogeneously. However, even in samples quoted to be very pure, certain amounts of impurities are present, and they act as a catalyst for heterogeneous nucleation [72] at temperatures above the homogeneous nucleation temperature. Turnbull [67–70, 73–75] have systematically studied undercooling of liquid metals and obtained a maximum undercooling of $\sim 0.18\,T_m$. It was then inferred that by entraining the droplets in emulsifying liquids, homogeneous nucleation could be achieved. But the later experiments by Southin and Chadwick [76] and Perepezko [77] succeeded in obtaining a much higher undercooling. Thus, it became clear that most of the Turnbull's results probably correspond to the heterogeneous solidification.

Heterogeneous Nucleation of Solidification Nucleation of solidification of individual droplets has been studied in the presence of clean substrates [73, 75, 78–80] and in the absence of substrate [81–83]. Irreproducible results in supercooling measurements led to the development of entrained droplet technique [84] and its adoption by Southin and Chadwick [76] to the study of solidification of low-melting metal in a higher melting matrix. Alloys from a eutectic or monotectic system are thermally treated to produce micron-sized dispersions in a matrix.

More recently, rapid solidification of monotectic alloys and other systems has been employed to produce a finely dispersed, nanoscaled embedded particle of a low-melting element in a high-melting matrix [43–47]. This provide an excellent opportunity to study the kinetics of heterogeneous nucleation of a solid in the entrapped liquid particles in contact with the matrix. Calorimetry, dilatometry, and microscopy can be employed to monitor the solidification behavior of these particles. Solidification of such fine droplets generally occurs by a single nucleation event with insignificant growth. In case the calculated critical nuclei size exceeds the size of these embedded liquid droplets, solidification might be bypassed. Droplet solidification is catalyzed by epitaxial nucleation by the surrounding matrix, and hence is controlled by the matrix and the crystallographic shape of the cavity inside the matrix. Doping of the matrix with trace alloying elements [85, 86] has enabled investigations of the influence of chemistry of droplet-matrix interface on heterogeneous nucleation.

The thermodynamic limit to which a liquid can be undercooled (0.5–$0.75\,T_m$) was predicted by Kauzmann [87] from the entropic instability [88]. Experimentally, it is found that if the liquid can be cooled by avoiding crystallization, it forms glass between 0.3–$0.75\,T_m$. Singh and Holz [89] gave the estimate of the limit of maximum supercooling that can be obtained from classical nucleation theory for homogeneous nucleation. The reasonable value that comes up from their results is $\sim 0.56\,T_m$. However, this does not take into account the variation of surface energy with temperature. In certain embedded nanoparticles [30, 46], a wide temperature range for solidification could be observed. Undercooling achievable during nucleation of solidification is not directly related to size. However, since the smaller sized particles are expected to contain less impurity, they will have a lesser concentration of heterogeneous nucleation sites. Therefore, the smaller particles would solidify later, closer to the homogeneous nucleation temperature [90]. A wide range of particle size distribution—an outcome of the processing route (like melt spinning)—is expected to yield a broad range of solidification event. However, broad solidification event is not true for all samples produced by melt spinning. The contact angle during heterogeneous nucleation of solidification is a very important parameter that plays a crucial role. There are two important variables that influence the heterogeneous nucleation. These are potency and concentration of nucleation sites. The wetting angle is a measure of the potency of the nucleation site in the framework of classical heterogeneous nucleation theory. A related question is correctness of the assumption of classical heterogeneous nucleation event. Kim and Cantor [91], and Goswami et al. [43] have shown that the number of catalytic nucleation sites N_c and the contact angle θ can be estimated for nanodispersed particles from controlled differential scanning calorimetric (DSC) experiments. Unreasonable low N_c values are obtained for a large number of cases. These results have suggested an apparent breakdown of the classical heterogeneous nucleation theory with a hemispherical cap model. However, the later work suggests that the microscopic details of the interface plays an important role in the nucleation process and may have biased the earlier results. The interface in the presence of defects cannot be treated

as having a single contact angle. Instead, it can be modeled with a spread in the contact angle. This gives a reasonable reproduction of the DSC curve using the classical heterogeneous theory as shown by Goswami and Chattopadhyay [46]. In cases where the anisotropy of liquid-solid surface energy is very large, the nanodispersed particles bounded predominantly by low-surface energy interfaces can be used to test the classical heterogeneous nucleation theory. Such a study employing dispersion of lead in a zinc matrix strongly suggests the validity of the classical theory of heterogeneous nucleation [43].

The depression of the freezing point as a function of size has been studied extensively. Buffiat and Borel [92] have developed the thermodynamic criterion to estimate this depression. Recently, Sheng et al. [93] and Li et al. [94] have shown a size-dependent freezing behavior for Pb nanoparticles embedded in an Al matrix synthesized by mechanical milling. The freezing temperature decreased with an increase in milling time for Al-Pb and a subsequent reduction in the particle size of incoherent Pb nanoparticles. They have also investigated In, Sn, Bi, and Cd nanoparticles in ball milled samples. However, such an effect has not been established for embedded nanoparticles in an Al matrix obtained via rapid solidification. In this case, the particles have an orientation relation with a matrix and no apparent size-dependent effect can be detected.

Analysis by a classical nucleation theory gives us the free energy for homogeneous and heterogeneous nucleation. For bulk liquid freezing below equilibrium freezing point T_o, this is given by $\Delta G_v = cL_o \Delta T_f / T_o$, where $\Delta T_f = T_o - T_f$.

However, for particles with radius r, freezing starts at a different temperature T_r, and ΔG_v is modified to give the driving force for solidification as

$$\Delta G_V = \frac{\rho L_o}{T_o} \Delta T_f + \frac{3\alpha(\sigma_{lm} - \sigma_{sm})}{r} \qquad (1)$$

where $0 < \alpha < 1$ because only a fraction of the liquid/matrix interface is replaced by a solid matrix interface upon nucleation.

Maximum ΔG is given by the condition,

$$\left(\frac{\partial \Delta G}{\partial R}\right) = 0 \qquad (2)$$

$$R^* = \frac{2\sigma_{ls}}{\Delta G_v} \qquad (3)$$

$$I = N_C \frac{kT}{h} \exp\left(-\frac{\Delta G^*}{kT}\right) \exp\left(-\frac{Q}{kT}\right) \qquad (4)$$

where N_C = number of nucleation sites per unit volume and Q = activation energy for transferring atom across liquid-solid interface.

The nucleation frequency I is determined from ΔG^*. The ΔG^* contains ΔG_v and undercooling, ΔT_r for a given particle-matrix system. Both of these are size dependent for small particles system.

It can be shown that

$$\Delta T_r = \Delta T_o + \frac{T_o}{\rho L_o} \frac{3\alpha(\sigma_{sm} - \sigma_{lm})}{r} \qquad (5)$$

$\Delta T_r = \Delta T_o + \alpha \Delta T_m$ where $\Delta T_m = T_o - T_m$ reflects the melting point depression. Thus, the undercooling of nanoparticles is larger compared to the "bulk materials" or corresponding micrometer counterparts.

Nanoparticles with more pronounced melting-point depressions show larger undercooling on freezing as is clear from Eq. (5). Indeed, such an analysis is supported by interrupted DSC thermograms of In nanoparticles embedded in Al produced by mechanical milling. Smaller particles, which melt first on heating, solidify at an undercooling that is larger than the undercooling of the larger particles. Thus, undercooling increases with a decrease in particle size, and apparent large undercooling is interpreted as a combined consequence of dependence on the need for nucleation of solid and the size-induced melting-point depression.

2.3.3. Melting

Melting of small particles has received considerable attention over the last few decades [95]. Results show that the melting points of fine particles have a strong dependence on their sizes. Ubbellohde [96] has reported the importance of Lindemann's criterion of melting. Lindemann [97] proposed melting as a vibrational instability released when the root mean square amplitude of vibration reaches a critical fraction of atomic distances. According to Lindemann, the melting temperature is given by $T_m(r)/T_m(\infty) = \exp[-(\alpha - 1)(r/3h - 1)^{-1}]$, where $T_m(\infty)$ is the bulk melting temperature, $T_m(r)$ is the melting temperature of a spherical particle with radius "r" and "h" corresponds to the height of a monolayer of atoms on the bulk crystals; α can be obtained directly and is given by σ_s^2/σ_v^2. σ_s^2, and σ_v^2 represents the mean-square displacements for the surface and the interior atoms of the corresponding crystals. Sheng et al. [98] have shown that when α is less than 1, the surface (interface) atoms are constrained to smaller vibrations than the interior atoms and superheating can be observed. However, if the interface atoms thermally vibrate with higher intensities, melting point depression takes place. There have been attempts to calculate the critical temperature for different planes where the instability will appear. However, only recently, a conclusive relationship between the melting temperature of surface planes and Debye temperature has been experimentally observed by Gråback and Bohr [99]. The change in the melting temperature with particle size was reported earlier. Buffiat and Borel [92] showed that the small particles of Au, Pt, and other the metals suffer a depression in the melting point as much as 30% for particles of 20–30 Å in diameter. Hoshino and Shimamura [100] have explained the change in the melting point in terms of the theory based on Lindemann's criterion. The mean-square amplitude of a solid surface is 1.5–2 times higher than the bulk, and the Lindemann's criteria can explain the depression in the melting point. Rossouw and Donnelly [101] have injected Ar ions into aluminium at room temperature. The melting temperature of argon at atmospheric pressure was 84 K. However, from precise measurements of diffraction intensities a metastable superheating of 480 K was reported [101]. The amplitude of vibration of embedded Ar particles was smaller than that for free solid argon. The Debye temperature, which was a measure of cohesion

deduced from the intensities of the diffraction peaks of the embedded particles, was 139 K compared to 70 K for bulk Ar at atmospheric pressure. A high Debye temperature implies a higher cohesion, smaller vibration amplitudes, and generally a higher melting temperature. Since the bubbles are small, the amplitude of surface (interface) vibration is depressed due to the constraining effect of the Al matrix. Hence, superheating is possible because the surface (interface) atoms are constrained to smaller vibrations than the interior atoms. Clear evidence of superheating metallic particles due to embedding was first reported by Dages et al. [102] in an experiment where small (0.15 nm) silver nanocrystals were coated with gold. Following this, several investigations on the melting behavior of embedded nanoparticles has been carried out [99].

Allen et al. [103] first discussed the effect of embedding on the melting point. Allen et al. [103] and Malhotra and Van Arken [104] reported that micron-sized indium particles embedded in aluminium melt at a temperature higher than the bulk melting point of indium. They tried to explain superheating in terms of strain energy effect on melting. Sasaki and Saka [105] explained the elevation based on the interfacial energy difference between the liquid particle-matrix and the solid particle-matrix interfaces. Allen et al. [106] have shown that the melting temperature in most cases is inversely proportional to their particle size.

A large number of investigations on the melting of small particles of Pb, In, Bi, and Cd have been reported. Zhang and Cantor [107] observed that indium and lead particles embedded in aluminium matrix melt at a temperature 0–40 K above the bulk melting temperature. According to Zhang and Cantor [107], the elevation in the melting temperature was due to "superheating" phenomena caused by a kinetic difficulty in melt nucleation. Recent experiments on In and Pb particles embedded in Al and Cu matrices prepared by melt quenching [108] and ion implantation [35] shows that the particles superheat much above ($\geq$100 K) their bulk melting temperature.

According to Couchman and Jesser [109], the heterogeneous nucleation of melting at the crystalline surfaces played the most important role. The melting point of thin films or fine particles may be enhanced or depressed depending on the nature of the interfaces. The size-dependent change in melting point is given by the thermodynamic equation:

$$\frac{T_{ml}}{T_o} = 1 - \frac{3\left(\frac{\sigma_{sm}}{\rho_s} - \frac{\sigma_{lm}}{\rho_l}\right)}{rL_o}$$

where T_{ml} = melting point of the embedded particle; T_o = bulk melting point; σ_{sm} = solid particle-matrix interfacial energy; σ_{lm} = liquid particle-matrix interfacial energy; ρ_s = density of solid; ρ_l = density of liquid; L_o = latent heat per unit mass, and r = radius of the metal particle. Spaepen and Turnbull [110] have given an expression for the pressure difference developed due to the difference in thermal expansion of the matrix and the embedded particle

$$\Delta P = \frac{[12(\alpha_p - \alpha_m)\Delta T\mu_m k_p]}{(3k_p + 4\mu_m)}$$

where α_p = linear thermal expansion coefficient of the particle; α_m = linear thermal expansion coefficient of the matrix;

k_p = bulk modulus of the precipitate; μ_m = shear modulus of the matrix. A change in the melting point can be obtained from the Claussius–Clapeyron equation

$$\Delta T = \frac{\Delta P T_o \Delta V}{L_v}$$

The effect of changes in volume during solidification of embedded particles has been discussed by Uhlmann [111] and Malhotra and Van Aken [104]. The volume change leads to an additional strain energy, which results in a reduction in the driving force for solidification. The change in free energy due to strain is given by

$$\Delta G_{st} = \frac{(2\mu_s k_l \Delta V^2)}{(3k_l + 4\mu_s)}$$

where μ_s = shear modulus of the embedded solid; k_l = bulk modulus of entrained liquid; ΔV = relative volume change. The reduction in the driving force has to be compensated by superheating. Efforts were undertaken to rationalize the maximum, observed superheating of Pb particles embedded in Al and Cu matrices [108] in terms of all the above pressure effects. Goswami and Chattopadhyay [108] have shown that the explanation for observed superheating for Pb embedded in Al, Cu, Ni, and Zn matrices [43, 44] cannot be explained in terms of all the pressure effects (Table 2).

The explanation for an increase in superheating is controversial due to strain energy effects [103, 104], interface energy effects [109, 112, 113], and a kinetic barrier to nucleation [102, 107, 114]. Sheng et al. [98] have tried to rationalize the difference in behavior of indium nano particles in different matrices. They attempted to rationalize the observed superheating for In particles in an aluminium matrix and melting point depression in an iron matrix. It was suggested that different types of Al/In and Fe/In interfaces [115] cause the different melting behaviors of the embedded indium particles. Cahn [116] suggested that the observed superheating originates from the epitaxy between the embedded particles and the matrix, and no superheating is expected from the incoherent interfaces. The melting behavior of the small particles may be different in an isotropic matrix. Experimental evidence of the influence of crystallographic shape on the melting point exist. Allen et al. [103] have shown that the plate-shaped particles do not show any size-dependent melting point depression. However, Metois and Heyraud [117] have found that the triangularly shaped Pb particles melt 3 K above that for the surrounding irregular particles, whose melting point is assumed to be the equilibrium melting temperature. Spiller [114] has reported evidence of superheating of 2 K for entrained Pb particles, condensed on either

Table 2. Calculations showing a change in temperature obtained due to different contributions effecting the melting point of Pb in different matrices [108].

	Volume	Thermal	Size	Total ΔT (calc.)	ΔT (expt.)
Al-Pb	17	4	54 (10)	75	103
Cu-Pb	17	14	48 (25)	79	125

30(Ni-Pb)	−5	−40	−20 to −30

graphite or amorphous carbon. In general, little research has been devoted to exploring the effect of the interface structure on the entrained particles on the melting behavior. There exist results for embedded Pb and Bi [114, 118] that suggest shape-dependent superheating ability. It has been found that on heat treatment, though the bounding planes do not change, superheating is observed. For Pb in Zn [43], the lead superheats only when the sample is thermally cycled several times to room temperature from above the melting point. Goswami et al. [57] attempted to correlate the shape with melting behavior. Table 3 summarizes the melting results of Pb in different matrices as reported by different investigators and Table 4 summarizes melting results of Pb in a Zn matrix obtained by careful DSC experiments.

Electron microscopy studies indicate an increase in sharpness of facets after recycling in a fraction of particles. It has been suggested that this is responsible for the observed superheating. The most significant of all the results observed is that of Pb dispersed in Cu-10% Zn matrix. The lead particles in as-spun particles show steps or ledges [57]. Repeated thermal recycling from room temperature to a temperature above the melting point leads to the complete removal of these steps. The particles are now bounded by sharp interfaces and the sample exhibits superheating during melting [57]. Careful analysis of the ratio of the distance between 111 and 100 planes indicates that the values are widespread in the melt-spun state with the peak at around 1.18. This increases steadily in recycling and the ratio shifts to 1.3–1.5 indicating the dominance of 111 planes. In addition to faceting, the recycling leads to the annihilation of surface defects, which act as heterogeneous nucleating sites. In the absence of nucleating agents (defects) and also with shortened 100, superheating is expected.

In order to understand the changes in the interface upon heating, *in-situ* X-ray diffraction studies and *in-situ* transmission electron microscopic studies were carried out. Sheng et al. [119] have monitored the melting of embedded lead nanoparticles in aluminium matrix using a high temperature *in-situ* X-ray diffraction technique. The analysis of X-ray diffraction data shows that melting took place when the root mean-square displacement of Pb atoms reached about 10%

of their nearest neighbor atomic distances. Their investigation [119] suggests that the Lindemann's criterion [97] for melting is applicable to nanocrystals.

One of the issues that are addressed during *in-situ* experiments are how and where melting nucleates. Sasaki and Saka [105] have observed the melting processes for indium nanoparticles embedded in an aluminium matrix. Their observations suggest that melting initiates in the cavity at one of the {100} facets and then proceeds into the interior of the In particles. At the beginning of the melting process, the liquid droplets nucleated at a {100} facets and assume two different configurations alternatively before the liquid reaches the next {100} facets.

Johnson et al. [120] have reported results of *in-situ* studies for Pb in Al. Their results show that inclusions located in bulk Al are free of defects and sharply faceted along {111}, and to a lesser extent on {100} planes and assume dimensions of magic sizes. For larger inclusions, interfaces become more important and they assume a cuboctahedral shape. These shape changes affect the melting behavior of the particles. Gabrisch et al. [121] have first proposed that the difference in melting behavior of lead nanoparticles in different matrices is not only a function of inclusion size but also of their shape and interface structure.

Ohashi et al. [115] have investigated by *in-situ* microscopic studies the melting and solidification of indium nanoparticles embedded in an iron matrix. The melting temperature of small indium particles was found lower than that of the bulk material and decreases with decreasing radius "r." The difference in melting behavior of In nanoparticles embedded in an Fe matrix are in sharp contrast with that of particles embedded in an Al matrix. Saka et al. [105, 115] tried to rationalize the discrepancy in terms of interface energies between Al or Fe matrices and liquid and solid In.

Hagege and Dahmen [51] have investigated eutectic Pb-Cd inclusions in an aluminium matrix by *in-situ* microscopic studies. They have observed that the bimetallic inclusions were found to melt at the eutectic bulk melting point, irrespective of size. Melting was found to initiate at the triple interface junction of Pb, Cd, and Al [37, 51, 59].

2.4. Phase Selection in Small Particles

The questions of phase selection and phase stability of embedded pure metals are restricted to the issue of melting and solidification. These were discussed in previous sections. Multiphase isolated nanoparticles, however, provide newer challenges. Both the stability of the phases, as well as phase composition, can be altered as a function of size in these particles. The research in this direction is at a preliminary level and the salient findings are discussed in the next section.

2.4.1. Transformation in Multiphase Isolated Nanoparticles

As mentioned at the onset, the phase diagram that delineates the region of stability of different phases needs to be modified for nanosized particles. Recently, such a modification has been attempted for a Bi-Sn system [122]. As pointed

Table 4. Summary of the DSC results on the melting of nanodispersed Pb in Zn matrix [43].

Sample	Melting peaks K	ΔT K
As cast	591 ± 0.6	Eutectic melting point
Melt spun	584 ± 0.2	−7
Melt spun and heat treated 30 h at 550 K	589 ± 0.25	−2.5
	651 ± 2	62 superheating

out by Allen et al. there is a dramatic change in the phase coexistence with a significant depression of eutectic point [103]. This was verified by the observation of a molten layer on submicron Bi-Sn particles. Lee et al. observed crystalline to amorphous transition [122]. Recently, a series of experiments have been carried out by a group led by Mori [123–125] at an electron microscopy laboratory at Osaka University. They used a novel technique of *in-situ* metal deposition within the electron microscope to study the alloying behavior of nanosized particles. It was shown that when Bi is deposited on Sn nanoparticles, a spontaneous alloying takes place driving a crystalline to amorphous transition. Similar results were also observed in the case of Sn deposition on In particles. On the other hand, in systems like Au-Zn [126], spontaneous alloying leads to the formation of solid solution and intermetallic compounds viz. Au_3Zn and $AuZn$. These investigations highlight the size-dependent phase transformations that are possible in alloy nanoparticles.

2.5. Magnetic and Superconducting Transition in Small Particles

The embedded particles at small length scale provide exciting opportunities in tuning the magnetic properties. At very small sizes, they undergo superparamagnetic transitions. If the sizes of the particles are of the order of exchange interactions, the magnetic domains interact with each other. This leads to a significant decrease in magnetocrystalline anisotropy. Thus, the materials are expected to have enhanced soft magnetic properties. A classical example to such a class of material is FINEMET, where nanoscaled Fe-Si particles are embedded in an iron-based glassy matrix [127]. The exchange interaction is also employed to design cheaper, hard magnetic materials by diluting the expensive rare earth magnets with cheaper, soft ferromagnetic materials like iron. Because of the small sizes, the domains of the softer phase get coupled with the domains of the hard phase. Thus, the material behaves as a hard magnet although it contains a soft magnetic phase. The magnetic behavior of the nanoscaled materials is discussed in details elsewhere.

2.5.1. Magnetic Properties of Nanoembedded Particles

During the last two decades, amorphous and nanocrystalline materials are being investigated for applications in magnetic devices requiring either magnetically hard or soft materials. Nanomagnetic materials and nanocomposite magnetic materials are potential candidates for a variety of new applications in the fields of image sensors, catalysis, biotechnology, drug delivery systems, medical diagnostics, magnetic refrigeration, magnetically assisted chemical separation of radioactive and hazardous wastes, besides enhancing the recording density in information storage and reducing core losses for high frequency and microwave applications.

In particular, amorphous and nanocrystalline materials have been investigated for various soft magnetic applications. Due to the rapidly increasing working frequencies in several power electronics applications, such as power conversion banks, uninterruptible power supplies, magnetic filters, etc., there is a corresponding increasing interest in the use of special magnetic cores for transformers, inductive devices, switch mode power supplies, etc. In these materials, it has been shown that an averaging of the magnetocrystalline anisotropy over many grains coupled with an exchange length is the root cause of the magnetic softness of these materials. The $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$, FINEMET alloy is one among these materials [128]. The nanostructured FINEMET alloy powders and ribbons were prepared by a mechanical alloying technique and a melt spinning technique and their soft magnetic properties were studied. Because of a weak coupling between the α-Fe(Si) nanograins, due to the amorphous ferromagnetic components, the FINEMET powders are inferior to those of melt-spun ribbons. But the Al addition in FINEMET alloy improves their soft magnetic property and it gives the better frequency responsibility.

2.5.2. Superconductivity in Small Particles

In 1911, while examining the electrical resistivity of pure mercury at a low temperature, Professor Kamerling Ohnes discovered that the resistivity vanished abruptly and completely at 4.15 K instead of decreasing continuously as expected upon cooling. Ohnes continued work on this topic till 1913, confirmed this unexpected result and the phenomena of disappearance of resistivity below a certain temperature (known as transition temperature) is known as superconductivity. Gradually, it was found that most metals exhibit superconductivity. In 1933, Meißner and Ochsenfeld performed an experiment to test whether superconductors behave the same way as Maxwell's law predicts a perfect conductor to behave. Maxwell's law predicts that a perfect conductor would not allow any change in flux. However, their experiments proved that rather than resisting changes in magnetic flux, a superconductor will expel the magnetic flux and acts as a perfect diamagnet. The description of a superconductor as a perfect diamagnet is known as Meißner effect.

Arising from the theoretical and experimental investigations of superconductivity, the concepts of two characteristic lengths, that is, the "London Penetration Depth" and "Coherence Length" emerge. The depth to which the magnetic flux penetrates before it exponentially decays to zero is known as the London Penetration Depth (λ). Pippard first formulated the concept of coherence length in 1953. When a superconductor is cooled below the transition temperature, some extra form of order sets in among the conduction electrons. So, coherence length (ξ) is the minimum length over which pair correlation takes place. The ratio of the penetration depth λ and the coherence length (ξ) is represented by a parameter κ known as the Gindsburg–Landau constant. When $\kappa < 0.71$, surface energy is positive and when $\kappa > 0.71$, surface energy is negative. If the electron mean-free path is very short, and λ increases, κ increases. Since the two characteristic length scales play a vital role in determining the type of transition taking place in superconductors, it can be intuitively felt that if the length scale of the sample becomes comparable to that of these two characteristic length scales, some new phenomena could be observed. The depression of a critical point for a superconducting transition occurs when the particle size is of the order of coherence length. In recent times, this has been

quantitatively evaluated for nanoembedded lead particles in an aluminium matrix [129]. The results till date suggest that matrices do have influence over the nature of the depression in transition temperature. Inoue et al. [130, 131] have reported few results, which aimed at exploring the superconducting behavior of the composites containing a granular superconducting phase. It is well known that in some cases, the isolated particles may get coupled if the particle separation is of the order of London penetration depth. A percolation threshold exists when the entire composition behaves like a superconductor [132]. This depends upon size distribution, volume fraction, and interparticle separation of the second-phase particles. The size-dependent behavior of Type II superconductors has not been explored rigorously for the nanoembedded particles and of interest in recent times.

3. CONCLUSIONS

In this chapter, we have tried to give an overview of our current understanding of nanoembedded particles of metals and alloys with an emphasis on synthesis, structure, and stability. These types of materials have very wide applications, which include catalysis, spintronics, giant magnetoresistance, and tribological applications. There is a potential for these materials to develop additional functional properties making them prime candidates as small materials. Readers will find details of these in companion articles.

GLOSSARY

Intersection symmetry The common symmetry operations between the matrix and the particle.

Melting Solid to liquid phase transformation.

Monotectic system Binary system in which the two components are immiscible in the liquid state.

Nanoembedded Nanoembedded particles are a special class of nanomaterials, where the nanoscaled particles are constrained in a matrix.

Orientation relationship A set of planes and directions, which describe the particle and matrix orientation with respect to each other in space.

Rapid solidification The phenomena of rapid extraction of heat from the melt leading to high cooling rates.

Solidification Phase transformation from liquid to solid.

Superheating The elevation in melting temperature above the bulk equilibrium temperature.

Epitaxy of Ion-Irradiated Quartz

Klaus-Peter Lieb

Universität Göttingen, Göttingen, Germany

CONTENTS

1. INTRODUCTION

Covalent Si-based materials like silicon carbide, nitride, and oxide, in both their various crystalline phases and amorphous states, are of high technological interest since they uniquely combine important material properties: high mechanical strength, high thermal and chemical stability, low mass density, wide bandgap, and other interesting electronic and optical properties. Quartz (SiO_2) and related silicate glasses have applications in optical devices such as wave guides, optical switches, and amplifiers. Because of the high melting points of these materials, ion-beam processing and implantation are indispensable tools for electrical and optical dopings. These materials are very sensitive to ion bombardment and amorphize even at very low fluences. Therefore, damage accumulation and (radiation-induced) impurity diffusion and their relevance for materials modifications are important issues. Quartz in its challenging behavior shows fascinating similarities under high pressure and during ion implantation concerning amorphization, melting, and phase transformations but, despite numerous attempts, remains one of the most difficult materials to describe theoretically.

The long-range ordered crystalline state is usually the lowest free-energy form of elemental and compound solids. Irradiation-induced atomic rearrangements may occur along the trajectories of swift heavy ions or in collision cascades generated by low-energy ion beams, and can result in the loss of translational or orientational order ("amorphization"), at temperatures below which thermally activated diffusion processes may lead to epitaxial recrystallization. Over the past two decades, many attempts have been made to achieve epitaxial recovery of the crystalline state in Si-based compounds, disordered or amorphized by ion irradiation, and to model, on the basis of topological and bonding arguments, optimal conditions for epitaxy. Solid phase epitaxial regrowth (SPEG) of thin amorphous SiO_2 films, which the present chapter focuses on, has therefore been studied in considerable detail.

SiO_2, like Si, SiC, and Si_3N_4 in their various crystalline polymorphous and amorphous phases, can be considered as networks of corner-sharing $[SiX_4]$ tetrahedra formed by four $X = C, N, O$, or Si atoms around each Si atom. In α-quartz, each O atom is bound to two Si atoms. The Si—O bond length is 0.161 nm and the O—O tetrahedral distance 0.260 nm; the Si—O—Si intra-tetrahedral angle ranges between $\theta = 108.74°$ and $110.54°$. This tetrahedral structure unit is very robust and preserved intact upon irradiation. The slight structural changes induced by irradiations or amorphization concern the Si—Si and O—O distances (by about 5 pm) and the Si—O bond length (at most 2 pm). The angle θ shows more pronounced changes of 7.5–12° [1–4]; Figure 1 illustrates the atomic configuration and topology of α-quartz.

The topology and connectivity of such polyhedral networks can be characterized by the two numbers $\{V, C\}$, where V denotes the number of vertices in the polytope and C the average number of polytopes sharing each vertex; for SiO_2 $\{V, C\} = \{4, 2\}$. According to Gupta and Cooper [5], the *structural freedom f* of each vertex is defined as the difference between the number d of degrees of freedom and the number of constraints h, originating from the surrounding structure:

$$ f = d - h = d - C\,\delta[1 - (\delta + 1)/2V] \tag{1} $$

where δ is the dimensionality of the network-forming polytope. For SiO_2 we have $d = \delta = 3$ and therefore, like for Si, the structural freedom vanishes: $f = 0$. According to Hobbs and co-workers [6], this is important for any transformation of an ordered network into a disordered network and vice versa. SiO_2, crystalline and amorphous, represents a fully connected network and is therefore most likely to become disordered by ion implantation (and rather unlikely to be thermally recrystallized). Indeed, SiO_2 and Si become disordered at the rather low energy of 7 eV/atom and
Figure 1. Atomic configuration and topology of SiO_2.

11 eV/atom, as compared to SiC (26 eV/atom) and Si_3N_4 (>700 eV/atom) [7–11].

This chapter is organized as follows: after the present short introduction into the phases and topology of the SiO_2 network and the ion analytical methods used, in Section 2 we briefly summarize recent results on ion-beam induced damage and the kinetics of damage accumulation. Recrystallization of such amorphized or damaged nm layers, via dynamic, chemically guided, or laser processes, will be covered in Section 3. Finally, in Section 4 we touch upon luminescence properties of nanocrystalline particles in silica, and discuss possible future doping and processing techniques and applications in optoelectronics. For previous review papers on ion-induced amorphization of quartz, we refer to the work of Mazzoldi and Miotello [12], Hobbs and co-workers [6], Götz [7], Douillard and Duraud [13], Bolse [14], and Piao et al. [15]. As alkali ion diffusion in silicate is of importance in the context of this chapter, we also mention the corresponding report by Frischat [16] and briefly summarize some important results in Section 4. Optically active defect centers and nanoparticles in silica have been reviewed, for example, by Haglund [17], Polman [18], and Townsend et al. [19]. For theoretical treatments of the of SiO_2 phases and dynamic instabilities under pressure, we mention [20–23] and references given therein.

For studying the microstructure in SiO_2 layers, tens to hundreds of nm thick, various experimental techniques have been employed, such as transmission electron microscopy (TEM), X-ray diffraction (XRD), electron spin resonances (ESR), nuclear magnetic resonance (NMR), profilometry and ellipsometry, Raman and other optical spectroscopy. Ion-irradiation-induced damage and epitaxy of thin quartz films have also been studied with ion analytical methods, which offer unsurpassed advantages as will be shown. The crystallinity and/or the damage profile of the matrix can be measured by means of Rutherford backscattering channeling spectroscopy (RBS-C) for the Si-sublattice using a 1- to 2-MeV α-particle beam [24, 25]. This technique also provides the depth profiles (and in favorable cases even the lattice locations) of heavier implanted ions. For depth-profiling light elements or isotopes, either after implantation or as constituents of the SiO_2 matrix, one may use resonant nuclear reaction analysis with 100- to 500-keV proton beams (RNRA) or elastic recoil detection analysis with energetic heavy ions (ERDA) [26, 27]. The latter technique allows one to scan simultaneously the depth profiles of all light- and medium-weight elements in the near-surface region of the

samples, while RNRA offers the advantage of being sensitive to an individual isotope distribution only. By combining these methods, a full picture of important transport and microstructural properties of the matrix and the implants can be gained. There are a number of recent articles and books surveying the various ion-beam analytical methods and their combined use in thin-film analysis [24–27]. A brief description is given in Box 1.

2. ION-BEAM-INDUCED AMORPHIZATION OF QUARTZ

2.1. Damage Accumulation and Amorphization

Before describing processing techniques, which were developed to epitaxially regrow amorphous nm surface layers in α-quartz, it appears advantageous to characterize the type and degree of radiation damage in this matrix introduced by energetic ion impact. For a general discussion of radiation defect production see, for example, [40]. The effects of irradiating α-quartz or silicon dioxide have been extensively studied both experimentally and theoretically. According to Douillard and Duraud [13] and Piao et al. [15], these studies have shown that upon various particle irradiations α-quartz gradually becomes disordered and evolves towards a single amorphous state, which slightly differs from ordinary vitreous silica and which is classified by geologists as *metamict*. This amorphous end product is an "optically isotropic, glass-like material with virtually identical density, thermal expansion and elastic properties" [15]. It is

(i) almost independent of the irradiation process, that is, whether neutrons, ions, electrons, or photons are used for the irradiation;

(ii) nearly indistinguishable from the end product of an ordinary vitreous silica; but

(iii) has a slightly higher density (by 3–4%) as compared to vitreous silica.

Early irradiation experiments on quartz [28–30] by fast reactor neutrons (>1 MeV) at low neutron fluences ($\Phi_n < 10^{16}$ neutrons/cm^2) indicated that the neutrons create point defects, mainly B'-centers and oxygen hole centers. Their concentration increases as a power function with the neutron fluence. For medium fluences ($1 \times 10^{16} < \Phi_n < 1 \times 10^{20}$ neutrons/cm^2), α-quartz under-goes an $\alpha \rightarrow \beta$ phase transition, followed by full amorphization at $\Phi_n > 1 \times 10^{20}$ neutrons/cm^2. These studies suggest that amorphization proceeds by progressive disordering of a highly defective β-matrix [31, 32]. Measurements of the density and refractive index after high-fluence neutron irradiations of α-quartz showed no difference relative to vitreous silica.

There also exist extensive irradiation studies of quartz with protons and α-particles (for which electronic stopping dominates) and with heavy ions (in the regimes of both electronic and nuclear stopping) [28, 33–39]. Macaulay-Newcombe, Thompson, and collaborators [35, 36] investigated the effects of implanting heavy ions in quartz. Fischer et al. [37] studied defect production and annealing up to 1100 °C in quartz after 150-keV Ar and 35-keV

Box 1. Ion-beam analysis.

Ion-beam analytical methods are particularly suited for depth profiling the various components in ion-beam irradiated quartz (matrix, dopants) and to monitor the damage profiles and/or crystallinity of the matrix. For that reason we briefly explain the essence of these techniques. More detailed descriptions are given in [24–27].

Rutherford backscattering spectroscopy (RBS) mainly measures the depth profiles of medium-mass (or heavy) elements in a matrix composed of light (or medium-mass) elements. The primary beam (element number Z_1, mass number M_1, well-defined energy E_0) hits the target. The energy E_f and yield N_f of the backscattered particles are analyzed at the scattering angle θ in a Si surface barrier detector or a magnetic spectrometer having the solid angle $d\Omega$. The backscattering energy E_f depends on the mass M_2 of the backscattering nucleus (isotope sensitivity) and its location $\times$ relative to the surface (depth sensitivity). The beam energy E_0 is chosen so that the scattering is purely Coulombian. Hence the differential scattering cross section scales approximately as $d\sigma/d\Omega \propto (Z_1 Z_2 e^2/E)^2 \sin^{-4}(\theta/2)$, where E denotes the incident energy just before the collision and thus is corrected for the energy loss $\Delta E_1^{in}(x)$ of the beam between the surface and the target nucleus: $E = E_0 - \Delta E_1^{in}$.

In the present application of ion-beam irradiated quartz, RBS with 1- to 3-MeV α-particles is very well suited to measure the profiles of the implants such as Rb, Cs, Xe, and Ba, whose signals are well separated in energy from those of the SiO_2 matrix and enhanced in intensity due to their relatively large Z_2 values. RBS is less suited to differentiate between the oxygen isotopes ^{16}O and ^{18}O, due to their smaller charge $Z_2 = 8$ and mass $M_2 = 16$ and 18 u, relative to silicon ($Z_2 = 14$, $M_2 = 28, 29, 30$ u). The depth resolution depends on the energy definition of the beam, the straggling on its way in and out, the surface roughness, and the energy resolution of the detector. To very good approximation, RBS can be considered nondestructive.

Extensions to ion beams of higher masses, ion energies above the Coulomb barrier, and focused beams of micrometer diameter (microbeam) are known.

RBS channeling is related to RBS, but additionally uses the fact that the stopping power for the incoming beam along a crystalline channel direction is much smaller than that outside the channel (random direction). When travelling along a channel, the ions thus experience a reduced hit probability and consequently give a smaller backscattering yield (virgin curve).

RBS channeling provides the main information concerning the damage profiles and/or amorphous and recrystallized zones of the irradiated quartz samples. In most of the work a 1.0-MeV α-particle beam and a three-axis goniometer were used.

Elastic recoil detection analysis is complementary to RBS in the sense that a beam of heavy projectiles (Z_p, M_p) is directed onto a matrix composed of lighter elements/isotopes (Z_T, M_T). Again a Coulombian elastic collision takes place, which changes both the energy E_p and direction of the projectile and accordingly ejects the hit atom from its site and possibly out of the sample. Measuring the ejectile's energy E_T (in a silicon surface barrier detector) and mass M_T (by a time-of-flight equipment) allows one to measure the depth distributions of the matrix and possible light dopants.

In the epitaxy of ion-irradiated quartz, TOF-ERDA was applied to determine the concentration profiles of ^{16}O and ^{18}O in the annealed matrix and that of light implanted ions, such as ^1H, ^7Li, ^{20}Ne, and ^{23}Na. In the present work, beams of 30- to 55-MeV ^{107}Ag or ^{113}I and the TOF-ERDA equipment installed at the University of Helsinki were used. The element sensitivity is comparable to that quoted above for RBS, while the depth sensitivity is somewhat lower. Care should be taken concerning the amorphization of the samples due to the high projectile mass and energy loss. Some sputtering is inevitable. Otherwise ERDA can be considered nondestructive. It is a very versatile ion beam method, which scans a whole range of elements in a single measurement.

Nuclear reaction analysis (NRA) is a depth- and isotope-sensitive profiling method, which is mostly used for particular light isotopes in the target, such as ^1H, ^{15}N, or ^{18}O, for which nuclear resonance reactions with narrow resonances and sufficient cross sections are known. Sometimes also reactions with smoothly varying cross sections are useful. In the case of a narrow resonance, the sensitive depth $\times$ is defined by the energy loss of the beam, $\Delta E_1^{in}(x)$, which equals the difference between the initial beam energy E_0 and the resonance energy E_R. Measuring the yield of ejectiles or γ-rays for constant projectile number as function of the beam energy, scanned in small steps, provides the depth profile of the component searched for. For instance, the ^{18}O content can be determined by the $^{18}O(p,\alpha)^{15}N$ resonance reaction at $E_R = 198$ keV.

The depth resolution depends again on the energy precision of the beam from the accelerator, its straggling inside the target, and the roughness of the surface. Although NRA is in principle nondestructive, modifications of the samples by the rather intense analyzing beam cannot always be avoided (amorphization, heating, diffusion, even disintegration). NRA is most suitable for strong and narrow resonances in proton-induced reactions, but often suffers from long measuring times and the need to cover different resonance energies for different isotopes/elements.

He implantation, that is, in the regime of nuclear stopping power. These authors observed three defect annealing stages depending on the energy density deposited by nuclear stopping:

(i) simple defects at energy densities of <0.1 keV/nm^3, which can be removed by thermal annealing at 500 °C;

(ii) amorphized microregions generated between 0.1 and 0.25 keV/nm^3, which anneal out at temperatures up to 1000 °C;

(iii) amorphous layers (as seen by RBS-C) produced at energy densities larger than 0.25 keV/nm^3, which cannot be annealed below 1100 °C.

For low- and medium-mass ions (H, N, Ne, Na) in the 10–100 keV range, Harbsmeier and Bolse [38, 39] recently carried out detailed analyses, whose results we shall now describe in more detail. Typically, the 1-mm-thick single-crystalline (0001) quartz samples were irradiated at liquid nitrogen temperature with ions in the fluence range from 10^{13} to 10^{17} ions/cm^2. The 1-μA beam homogeneously covered the sample by means of a sweeping system. The crystallinity of the matrix was analyzed with RBS channeling. As an example, Figure 2 displays spectra in the (0001) channel obtained after implanting 50-keV ^{23}Na$^+$ ions at fluences of $\Phi = 2 \times 10^{13}$–6×10^{15} ions/cm^2, together with spectra taken in *random* and in-channel (*virgin*) directions from a nonirradiated sample. Below 5×10^{13} ions/cm^2, the backscattering spectra clearly indicated accumulation of radiation damage in the surface layer, giving rise to bell-shaped damage profiles (see Fig. 2). However, above a fluence of 5×10^{13} ions/cm^2, the backscattering signal reached the random yield, which we take as the *criterion of full amorphization* of this layer. Note that the thickness of the amorphous layer increased when the ion fluence was further increased. These two trends, first the rising damage profile and afterwards the increasing thickness of the amorphous layer, are a common feature in ion-irradiated Si and Si-based ceramics, for example, in SiC, Si$_3$N$_4$, SiO$_2$ [41, 42]. When-ever the mass of the implanted ions was much higher than that of Si and O, RBS channeling also allowed one to determine the depth profiles of the implanted ions. In the case of low-mass implants, TOF-ERDA or nuclear resonance reactions were used to measure their profiles.

The measured implantation profile of 50-keV Na ions was compared with the one calculated with the Monte Carlo code TRIM95 [50]. The measured projected range, $R = 7.8 \times 10^{17}$ at/cm^2, and distribution width, $\Delta R = 5.9 \times 10^{17}$ at/cm^2, agree rather well with the predictions of TRIM95, $R = 6.9 \times 10^{17}$ at/cm^2 and $\Delta R = 5.3 \times 10^{17}$ at/cm^2.

Irradiations of quartz with swift heavy ions at energies of up to 10 MeV/u were carried out by Douillard et al. [43] and by Wilson et al. [44] for 730-MeV Pb and 540-MeV Ni ions,
Figure 2. RBS channeling spectra in the (0001) channel obtained after implanting 50-keV ^{23}Na$^+$ ions at fluences of $\Phi = 2 \times 10^{13}$–6×10^{15} ions/cm^2, together with spectra taken in *random* and *virgin* directions from a nonirradiated sample [39].

by Ramos and co-workers [45, 46] for 0.5- to 10-MeV Au ions, and by Trautmann and collaborators for 90-MeV Ar ions [47] and 820-MeV Pb ions [48]. The ion-induced modifications in the near-surface regions were again analyzed by means of RBS channeling, TEM, profilometry, and AFM. These experiments provided information on amorphization, swelling or compaction, surface roughening, and sputtering as well as single-ion track formation and surface craters. Most important, these investigations demonstrated that very similar damages are produced via electronic stopping as via nuclear stopping.

2.2. Model Calculations

For modeling the damage accumulation, in relation to the ion fluence Φ and the depth distribution of the deposited energy density, $E_D(\Phi, z)$, we define the damage depth profile $\chi(z)$ and the integral damage $I_\chi(\Phi) = \int \chi(z)\,dz$, summed over the full implantation profile. Evidently, $\chi(z) \leq \chi^{max} \leq 1$, where χ^{max} denotes the maximum damage of the distribution. The limit $\chi^{max} = 1$ indicates that the backscattering yield in the channeling direction reaches the random level. The experimental functions $\chi(z)$ and $I_\chi(\Phi)$ were derived from the RBS-C spectra by means of the program DAMAGE [49] and compared with the calculated deposited energy density $E_D(\Phi,z) = \Phi F_D(z)$. The quantity $F_D(z)$ was estimated with the Monte Carlo code TRIM95 [50]:

$$F_D(z) = E_d[2n_V(z) + n_D(z)] \qquad (2)$$

Here $n_D(z)$ and $n_V(z)$ denote the number of displacement and replacement collisions, respectively, and $E_d = 25$ eV is the displacement threshold energy. In Figure 3, two of the bell-shaped damage profiles $\chi(z,\Phi)$ after 20-keV H$_2^+$ and 50-keV Na$^+$ implantations are compared with the calculated energy density $F_D(z)$. Obviously, the damage profile $\chi(z,\Phi)$ does not directly scale with $F_D(z)$, but follows the power-law function $[F_D(z)]^{n_1}$. The exponent n_1 is of the order of 3–5 (see Table 1). The experimentally deduced fluence dependences of the maximum damage $\chi^{max}(\Phi)$ and integrated damage $I_\chi(\Phi)$ can be parametrized again with the power law [39]:

$$\chi^{max}(\Phi) = (\Phi/\Phi_C)^\alpha \ \text{ and } \ I_\chi(\Phi)/I_\chi(\Phi_C) = (\Phi/\Phi_C)^\beta \qquad (3)$$

where the exponents α and ß are given in Table 1. It is at the critical ion fluence Φ_C that the backscattering yield first reaches the random level and an amorphous layer starts growing.

Various models have been developed to describe the damage accumulation and transition to full amorphization. In Figure 4, the 50-keV Na data are compared with the predictions of the direct impact model by Dennis and Hale [51], the damage overlap model by Gibbons [52], and the nucleation and growth model by Avrami [53], as discussed by Campisano et al. [54] and Harbsmeier and Bolse [38, 39]. Clearly, the latter model fits the data best. Indeed, the maximum damage follows the function

$$\chi^{max}(\Phi) = 1 - \exp[(-K\Phi)^n], \ \text{ where } K = R_a V_a^{n-1} \qquad (4)$$

Here R_a denotes the nucleation rate and V_a the growth rate of the disordered phase. It was concluded [39] that for all
Figure 3. Comparison of the measured and calculated damage profiles after 20-keV H_2^+ ($\Phi = 4 \times 10^{15}/cm^2$) and 50-keV $^{23}Na^+$ ion implantation ($\Phi = 3 \times 10^{13}/cm^2$). The measured damage profiles do not linearly scale with the deposited energy density $F_D(z)$, but with the power $n_1 = 5.7 \pm 1.0$ in the case of $^2H_2^+$ and $n_1 = 3.2 \pm 0.1$ in the case of Na [39].

the cases listed in Table 1, the exponent n lies between 3 and 6, indicating three-dimensional defect nucleation. Furthermore, the parameter K is proportional to the maximum deposited energy density F_D^{max}, and the critical fluence Φ_c scales with $1/F_D^{max}$. The authors summarize their conclusions: "Amorphization of quartz occurs by three-dimensional nucleation and growth of defect agglomerates or small spatially separated amorphous zones in a still crystalline matrix, until, after a deposition of a certain critical density $E_C = 1.92 \pm 0.07$ eV/atom ($=0.04$ displacements per atom), a continuous amorphous layer has formed."

2.3. Build-up and Relaxation of Stresses During Ion Implantation

The accumulation of defects and the excess volume created during ion im-plantation are connected to the build-up of a huge strain field in the damaged region, which, however, is relaxed in the high-fluence regime. Density changes in the
Figure 4. Comparison of the maximum damage $\chi^{max}(\Phi)$ with the predictions of the three models discussed in the text. Evidently the nucleation and growth model by Avrami–Johnson–Mehl gives the best fit to the data [39].

irradiated volume may also cause shear forces relative to the nonirradiated parts of the sample (below and beneath the irradiated volume) resulting in a bending of the whole sample. Furthermore, the possible local melting of small volumes as a consequence of ion-induced thermal spikes may exhibit similarities to the processes of pressure-melting or thermal quenching of SiO_2. It is therefore appropriate to briefly discuss similarities between ion-irradiation and pressure-induced modifications of quartz and silicon dioxide.

According to Polman and collaborators [55], three different radiation-induced deformation phenomena are known in SiO_2: densification, radiation-enhanced viscous flow, and anisotropic deformation. Densification (compaction) in amorphous SiO_2 is caused by the arrangement of the SiO_2 network in smaller, more compact rings as a consequence of atomic collisions. Densification eventually saturates with fluence and results in a tensile stress if the irradiated region is constrained by a substrate. The radiation-induced viscosity has been found to be inversely proportional to the nuclear energy loss over several orders of magnitude. Concerning the anisotropic deformation, Snoeks et al. [55] proposed a model which considers the competition between bulk and surface deformation effects. Depending on the ion energy and ratio between nuclear and electronic stopping power, these effects can give rise to either compressive stress (for >3.6-MeV Xe ions) or tensile stress (for low-energy Xe ions).

Table 1. Irradiation conditions and values of the critical fluence Φ_c, the maximum of the deposited energy density F_d^{max}, the exponents of the fitted power laws (n_1, α, β), and the parameters n and K used in the nucleation and growth model [39].

Ion	Energy (keV)	Φ_c^a ($10^{15}/cm^2$)	$F_d^{max a}$	n_1	α	β	n	K (10^{-16} cm^2)
H_2	20	530 (20)	0.04	5.7 (10)	8.6 (16)	0.32 (7)	5.7 (4)	2.08 (2)
N	50	15 (1)	1.8	2.4 (3)	2.3 (1)		3.2 (4)	81 (2)

^{a} In units of 10^{-14} eV cm^2/at ion.

The high-pressure behavior of α-quartz has been a subject of extensive experimental and theoretical studies, but is far from being understood. The stable phases of SiO_2 under pressure are α-quartz, coesite, and stishovite (in this order). At room temperature, the phase transformation to coesite (at $\approx$3 Gpa) and to stishovite (at $\approx$7 Gpa) are inhibited and quartz remains metastable up to about 15–25 Gpa [56, 57]. This seems to be a common property of systems that amorphize under pressure: the parent phase is driven far beyond its stability range before it amorphizes. The crystalline-to-amorphous transition is accompanied by an increase in the silicon coordination. Kingman et al. [57] have shown that the pressure-induced amorphization is preceded by another reversible phase transition at 21 Gpa. This new phase persists up to 30 Gpa, beyond which irreversible amorphization sets in. Hemley et al. [56] proposed that pressure-induced amorphization in SiO_2 represents the metastable extension of the melting curve. In parallel argumentation to a similar behavior of ice at room temperature, it has been argued that the melting of quartz first leads to an extremely unrelaxed, high-density amorphous state, which then relaxes towards an energetically more favorable glass-like state. At the end of this process, pressure glass and thermal glass are almost indistinguishable.

The build-up and relaxation of stress related to changes of the atomic density can be monitored via X-ray diffraction, transmission electron microscopy, Raman spectroscopy, or simply by measuring, with a profilometer, the step height and curvature between the implanted and virgin parts of the sample. In the case of 50-keV Na ion implantations at fluences of more than 10^{15} ions/cm^2, which we discussed before [39], the step size Δh was found to be proportional to the size of the amorphized layer. The ion-induced decrease of the density in quartz due to radiation damage can be as large as 20%. In the case of 50-keV Na ions mentioned above, the maximum pressure amounted to 1.6 Gpa at 10^{14} ions/cm^2. It decreased by about one order of magnitude when the fluence was increased to 10^{15} ions/cm^2. The step size rose from 5 nm to 22 nm in this fluence range, as illustrated in Figure 5.

The swelling of quartz has also been investigated with fast heavy ions using energies of several MeV/u, where the energy loss is due to electronic stopping. For 4-MeV/u Pb ions, the step height Δh was found to increase linearly up to a fluence of 6×10^{11} ions/cm^2, at a rate of $\Delta h/\Phi \approx 1\ \mu m/10^{12}$ ions/cm$^2 = 10^{-16}$ cm^3/ion. For higher fluences the step height reached saturation. It has been customary to normalize the step height Δh to the total ion range R. In quartz the ratio $\Delta h/R$ also reached a saturation value. For the case of 2.3-MeV/u Ar ions, the saturation step height of $\Delta h_{sat} = 2.9\ \mu m$, which corresponds to $\Delta h_{sat}/R = 0.16$, was reached at a fluence of 2×10^{14} ions/cm^2. Trautmann et al. [48] pointed out that this value of $\Delta h_{sat}/R$ just equals the relative difference in density between the amorphous state ($\rho_a = 2.22$ g/cm^3) and the crystalline state ($\rho_X = 2.65$ g/cm^3). Like in the case of nuclear stopping, it is important to note that no swelling occurs below a critical (electronic) energy loss of $S_e = 1.8(5)$ keV/nm. Above this threshold value, the ratio $\Delta h/R$ increases linearly with S_e, the slope being 1×10^{13} cm^2 nm/keV.
Figure 5. Amorphization of quartz after 50-keV Na implantation [39]. The fluence dependence of the change of curvature, $\Delta(1/R)$, and the step height $H \equiv \Delta h$ are shown.

Ion irradiation of amorphous solids produces plastic deformation in the form of stress-induced creep and anisotropic growth consisting of an expansion perpendicular to the ion-beam direction, together with a shrinkage parallel to it [58]. Both phenomena have been treated by Trinkaus [59] in terms of shear stress relaxation in thermal spikes, followed by the freezing-in of strain during rapid cooling. The viscosities measured over a wide range of ion masses (Ne–Au) and energies (0.15–8 MeV) [55] covering the stopping power range between 0.2 and 4 keV/nm indicate a local spike temperature between 2000 K and 4000 K.

2.4. Surface Effects on SiO$_2$ Induced by Ion Bombardment

Defect production and sputtering at the surface provide further possibilities to study the energy transfer of incident ions to silicon dioxide. Changes of the surface morphology via single-ion impact and high-fluence sputter erosion were investigated by means of energy-dispersive X-ray reflectivity and/or atomic force microscopy [60, 61]. Mayer et al. [60] reported on $\approx$1-keV proton, He$^+$, and Xe$^+$ irradiations of SiO$_2$ layers (35 nm–2 μm) on Si wafers. For the Xe$^+$ irradiations, these authors observed roughening and ripple formation at the surface and explained them in terms of the Bradley–Harper theory [62]. This approach considers stochastic sputtering (atom removal) as well as surface diffusion and viscous flow. In the case of proton and He$^+$ implantations, sputtering was found to be negligible and therefore surface smoothing occurs as a consequence of diffusion. The Bradley–Harper theory turned out to account for both phenomena. The measured relaxation rates of the rms roughness during light-ion bombardment were interpreted by a radiation-enhanced relaxation mechanism of short-lived defects. The extracted viscosity is comparable to the thermal viscosity at about 1000 °C [60].

Sputter erosion and the evolution of surface ripples ("waves") in fused silica as function of the ion fluence and angle of incidence were recently studied by Flamm et al. [61], who irradiated the samples with 0.6- to 1.5-keV Ar ions

at fluences of 200–600 μA/cm^2 and inclined incidence to the surface normal. Patterns of surface ripples with wavelengths of 30–250 nm were established. The orientation of these patterns depends on the angle of incidence: up to about 70° the ripples were oriented perpendicular to the projection of the ion beam on the surface, while at 80° the ripple orientation had changed parallel to the beam direction. This rotation of the ripple pattern as function of the angle of incidence was also observed in the case of Xe irradiation of graphite [63]. Figure 6 shows AFM pictures of the ripple patterns obtained for 0.8-keV Ar ions on SiO$_2$ as function of the tilt angle, showing the rotation of the pattern. The measured fluence dependences of the rms roughness σ and ripple wavelength λ at this energy are plotted in Figure 7. The ion flux density was 400 μA/cm^2 corresponding to about 2.5×10^{15} ions/cm^{2}s. The lines are fits with the scaling functions $\sigma(t) \propto t^\beta$ and $\lambda(t) \propto t^\gamma$, with the scaling exponents $\beta = 0.46 \pm 0.03$ and $\gamma = 0.15 \pm 0.01$. The authors pointed out that these power-law scalings do not agree with the predictions of the Bradley–Harper theory in the linear approximation and that nonlinear effects have to be included.

Gebeshuber and collaborators [68] have recently reported on nanodefects on α-quartz (0001) surfaces produced by 1-keV Ar$^+$ single-ion impact at normal incidence and scanned via AFM. The AFM images exhibit hillocks, few nm high, but no craters.

3. EPITAXIAL RECRYSTALLIZATION OF QUARTZ

3.1. Dynamic Epitaxy

The high energy density of some 1–10 keV/nm, which an energetic heavy ion beam deposits in the irradiated material along its track or in the collision cascade, may not only destroy the crystalline order, but rather induce self-organizing processes of the microstructure, such as epitaxy, texturing, grain growth, surface ripples, and even
Figure 7. Evolution of the rms roughness σ and ripple wavelength λ with the sputtering time t, in the case of 0.8-keV Ar$^+$ ions incident at an angle of 60° to the surface normal and at a flux density of 400 μA/cm^2 [61]. The two quantities scale with the exponents $\beta = 0.46 \pm 0.03$ and $\gamma = 0.25 \pm 0.01$, respectively.

magnetic textures. "Dynamic" epitaxial regrowth, which is often called ion-beam-induced epitaxial growth (IBIEG), is a process in which the radiation-induced damages in the crystalline matrix anneal out during the implantation process itself, due to vacancy and self-interstitial diffusion in the cascade or spike zone, restoring the long-range order of the matrix. Concerning future ion-beam doping of quartz for optoelectronic purposes, this process appears to be very promising to retain the crystalline structure, depending of course on the clustering and/or solving properties of the dopants. Dynamic epitaxy of quartz has been reported by Townsend and collaborators [64] after Cu, Ga, and Ag implantations at 55 keV beam energy and at a fluence of 6.4×10^{16} ions/cm^2. Above 225 °C, the implantation profiles of these metals were found to deviate from the predictions of the TRIM code [50], showing bimodal distributions and indicating (radiation-enhanced) diffusion processes during the implantation. Evidence of recrystallization of the amorphized quartz layer at 600 °C was gained for Ag ions and also for Ga ions. These authors recently reported on the formation of Cu nanoclusters in SiO$_2$ at an implantation fluence of 8×10^{16} ions/cm^2 and also studied their behavior during excimer laser annealing [65].

Dhar et al. [66] investigated 50-keV ^{20}Ne irradiations of quartz at fluences between 1×10^{13} and 4×10^{15} ions/cm^2 and substrate temperatures ranging from liquid nitrogen temperature to 973 K. The aim of this study was to determine, for each ion fluence Φ, the temperature at which no damage was left after the implantation. Figure 8 illustrates RBS channeling spectra obtained at a fixed Ne fluence of 1×10^{15} ions/cm^2, over the full temperature range up to 973 K.

The damage profiles deduced from these spectra are given in Figure 9. Fully amorphized surface layers were found
Figure 6. Surface ripples on SiO$_2$ after 0.8-keV Ar ion irradiation at various angles of incidence [61]. The direction of the ion beam is indicated by the arrow. (a) 50°; (b) 60°; (c) 70°; (d) 80°.

Figure 8. RBS channeling spectra of α-quartz samples irradiated with 50-keV Ne ions at a fluence of 1×10^{15} ions/cm^2 at the temperatures indicated. Above 415 K, the amorphous layer starts to transform into a bell-shaped damage profile, which disappears at 625 K. For this and higher sample temperatures, the ion-beam-induced damages are annealed out during the implantation process, leaving a single-crystalline matrix [66].

up to 500 °C implantation temperature. The thickness of the amorphized layer decreased from 11×10^{17} at/cm^2 for the as-implanted sample to 8.5×10^{17} at/cm^2 at 773 K. For higher temperatures, the damage profiles had the bell shape described in Section 2, their maximum damage χ^{max} decreasing with increasing temperature, until above 900 K no damage was left in the sample anymore.

Such series of irradiations and RBS-C analyses were performed over the full fluence and temperature range indicated above. In Figure 10, the deduced critical fluence Φ_c for epitaxy is plotted versus the temperature. One notes a slow increase of Φ_c with the temperature up to about 800 K, followed by a sudden increase above 800 K. The data closely follow a model proposed by Morehead and Crowder [67],

$$\Phi_c(T) \propto [1 - (L^0/R^0)\exp(-E_{ax}/2k_BT)]^{-2} \qquad (5)$$
Figure 9. Damage profiles obtained at various sample temperatures and Ne ion fluences. Also shown are the calculated damage profiles $F_D(z)$ in linear and third power [66].
Figure 10. Temperature dependence of the critical fluence Φ_c for 50-keV Ne ion irradiations in quartz. The solid line corresponds to a fit according to the model by Moorehead and Crowder with the parameters $T_c = 986 \pm 50$ K and $E_a = 0.28 \pm 0.02$ eV [66].

The fit gives the activation energy $E_{ax} = 0.26 \pm 0.02$ eV and the critical temperature $T_c = (E_{ax}/k_B)\ln(L^0/R^0) = 986 \pm 50$ K. The value of T_c indicates that temperature at which epitaxy becomes independent of the ion fluence Φ. The parameter L^0 is the diffusion length at infinite temperature and R^0 the radius of the radiation-damaged zone (for each impact ion), in which no thermal diffusion of radiation-induced defects takes place at low temperatures. The ratio L^0/R^0 does not depend on the temperature [67].

The deduced activation energy $E_{ax} = 0.26$ eV agrees well with the known activation energy $E_a = 0.28$ eV for defect diffusion in quartz and suggests that the same annealing process is active below and above Φ_c. The values of E_{ax} and T_c depend on the deposited energy density F_D and consequently on the ion species and energy. For 1.5-MeV Xe irradiations of SiO$_2$ at 15–1023 K, Wang et al. [69], from *in-situ* transmission electron microscopy, found $T_c = 1446$ K and $E_a = 0.17$ eV. For $\langle 100 \rangle$ InP crystals irradiated with 100–600 keV boron, silicon, argon, and selenium ions, Wendler et al. [70] combined RBS-channeling, TEM, and optical spectroscopy and deduced values of $T_c =$ 350–420 K and $E_{ax} = 0.35$ eV.

Recently, Dhar and collaborators [71] extended the work on dynamic epitaxy of quartz to the implantation of 170-keV Ba ions by measuring damage profiles in the range from room temperature up to 1175 K. Figure 11 illustrates RBS-channeling spectra for some of these samples. Evidently, the Ba profile shown in the upper part of the spectra is essentially stable, while the matrix partially recrystallizes around 1100–1125 K, but never reaches the virgin status in the top layer. Possibly Ba stabilizes in nanocrystals at this temperature, which disturbs the progression of the crystalline/amorphous (c/a) interface towards the surface; TEM analyses are required to check this conjecture.

3.2. Chemically Guided Epitaxy of Silicon Dioxide

3.2.1. First Attempts

While thermal recrystallization of ion-irradiated Si and Si-based compounds *in vacuo* is a common process [72–74], previous attempts at the epitaxy of ion-irradiated synthetic
Figure 11. RBS channeling spectra of Ba-irradiated quartz [71]. The Ba ion fluence was $1 \times 10^{15}/cm^2$ and the sample temperature varied from RT up to 900 °C. One notes that the SiO_2 matrix gets amorphized during implantation at room temperature and stays damaged near the surface up to and including 900 °C, while the thickness of the amorphous layer decreases for rising sample temperature. The Ba depth profile is essential immobile at all temperatures.

quartz were generally not successful up to about 1270 K and led to partial epitaxy at most [75–78]. This is particularly true concerning thermal annealing of the irradiated samples *in vacuo*, in which case the results for different ion species, energies, and fluences are somewhat conflicting, depending on the type and concentration of impurities in the matrix before ion implantation. For instance, when irradiating natural Brazilian quartz with Si and O ions at a fluence of 1×10^{16} ions/cm^2 and annealing the samples in air, Devaud et al. [77] observed SPEG of the matrix to be completed at 1120 K and concluded that impurity OH groups were responsible for recrystallization. As early as 1980, Arnold and Peercy [75] in their implantation studies of noble gas ions in $Li_2O \cdot 2SiO_2$ and of Li ions in quartz had found evidence of the special role of alkali ions for epitaxy in silicates. These authors obtained crystalline $Li_2O \cdot 2SiO_2$ when annealing the irradiated sample at 775 K, and recrystallization of Li-doped SiO_2 at 970–1070 K, respectively. After the implantation of 3-MeV Ar ions in quartz, Wang et al. found recrystallization to occur below half the melting temperature [76]. More recently, Harbsmeier et al. [78] carried out similar experiments on α-quartz after 50-keV carbon and nitrogen ion implantations at a fluence of $10^{16}/cm^2$ and annealing in air up to 1670 K. In these experiments, SPEG was found to set in at 820 K (after N-doping) and at 1470 K (after C-doping), visible as a reduced thickness of the amorphous layer and a movement of the amorphous/crystalline (a/c) interface towards the surface. However, no full recrystallization was achieved below 1670 K, the highest annealing temperature used in these experiments.

3.2.2. Epitaxy after Cs Implantation and Annealing in Oxygen

The breakthrough in solving this problem emerged from systematic outdiffusion studies of Na ions implanted into various metals [79–84], Si [74], and SiO_2 [85] as well as

into Ni/Si and Ni/SiO_2 bilayers [86, 87], which were performed at the University of Göttingen. Roccaforte et al. [88–92], when investigating Cs-ion implantations in synthetic α-quartz, achieved full epitaxy below 1170 K when annealing the samples in air or oxygen. Similar observations were subsequently made for other alkali ions, for example, by Gustafs-son et al. for Li ions [93], by Dhar et al. for Na ions [94], and by Gasiorek et al. for Rb ions [95]. Finally, Bolse et al. [96] reported on the (so far unsuccessful) attempt to recrystallize quartz after proton implantation. This so-called chemically guided epitaxy via alkali-ion irradiation turned out to be extremely efficient, since after the annealing process the implanted alkali atoms were found to have diffused to the surface, from where they evaporated. Figure 25 illustrates a typical set of RBS channeling spectra for the case of 250-keV Cs^+-ion implantations and annealing in oxygen up to 1120 K [88]. One notes that up to 970 K the a/c interface remains at the as-deposited location, then moves towards the surface, and finally disappears at 1150 K, leaving a fully recrystallized matrix. The recrystallization speed follows an Arrhenius dependence with an activation energy of $E_{ax} = 2.83 \pm 0.20$ eV.

Figure 12 also illustrates various steps of the diffusion of the implanted Cs: the Gaussian implantation profile is stable
Figure 12. Epitaxy of α-quartz after Cs implantation and annealing in air [88]. (a) RBS channeling spectra at 900 keV α-particle energy obtained after implanting 2.5×10^{16} Cs^+ ions/cm^2 at 250 keV and annealing for 1 h in air at the temperatures given. The Si signal indicates epitaxy between 850 and 875 °C. For the evolution of the Cs profile, see text. (b) Arrhenius plot of the recrystallization speed v corresponding to the activation energy $E_{ax} = 2.83 \pm 0.20$ eV and the pre-exponential factor $v_0 = 152 \pm 10$ m/s.

up to about 825 K, but starts broadening at 870 K, until at 1075 K it extends over the full amorphous layer and reaches the c/a interface. During this process more and more Cs leaves the sample. At 1150 K, that is, when epitaxy of SiO_2 has been completed, no more Cs can be identified in the sample. Chemically guided epitaxy therefore is a catalytic process. Figure 13 displays the retained Cs fraction after a 1-h annealing as function of the temperature. The loss of implanted Cs follows an Arrhenius dependence with an activation energy of $E_a^{Cs} = 0.98 \pm 0.10$ eV.

The third partner in this process is the oxygen, whose role was highlighted by using an isotopically enriched ^{18}O atmosphere during the annealing. In Figure 14, the ^{18}O and Cs depth profiles in the recrystallizing layer are compared with each other. [In these first experiments, the ^{18}O concentration profiles were monitored via the nuclear reaction $^{18}O(p,\alpha)^{15}N$ at 151 keV resonance energy [97]. In the subsequent Cs experiments [91, 98], time-of-flight elastic recoil detection analysis (TOF-ERDA [26]) was used to depth profile ^{18}O. TOF-ERDA was also most useful after Li and Na ion implantation for a simultaneous profiling of all light elements, such as ^7Li, $^{16, 18}O$, and ^{23}Na, while hydrogen profiling was done with the resonant reaction $^1H(^{15}N,\alpha\gamma)^{12}C$ (see below).] Returning to Figure 14, the ^{18}O and Cs profiles barely overlap at 775 K, but starting at 875 K ^{18}O moves into the amorphized layer and extends over its full width at 1075 K. It turned out that up to half the oxygen content in the surface layer was replaced by ^{18}O, indicating a pronounced $^{16}O \Leftrightarrow {}^{18}O$ exchange between the silica matrix and the annealing gas during the recrystallization process.

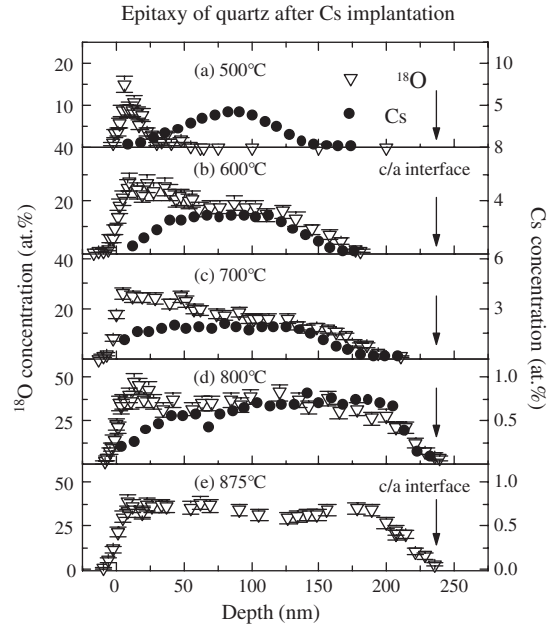
These findings were substantiated by a number of additional experiments [92, 95, 98]. First, it was verified that neither annealing *in vacuo* (after Cs implantation) nor annealing in oxygen (after Si, O, or noble gas ion implantations) led to epitaxy, which is in good agreement with previous results. Furthermore, the recrystallization temperature T_x was measured for various ion fluences and annealing times. Figure 15 shows the recrystallization speed at


Figure 14. Epitaxy of α-quartz after Cs implantation and annealing in $^{18}O_2$ [97]. For increasing annealing temperature, one first notes indiffusion of ^{18}O, then broadening of the Cs profile, and finally complete loss of Cs.

the fixed temperature of 1070 K strongly increasing with the Cs fluence, while Figure 16a–d shows the corresponding channeling spectra as a function of the implanted Cs fluence (in the range from 5×10^{15} to 1×10^{17} Cs$^+$/cm^2) and the annealing time (1–5 h at T = 1070 K). Evidently, full epitaxy was achieved at the highest ion fluence within a 2-h annealing, whereas for the lowest fluence the layer was still fully amorphous after a 5-h annealing.
Figure 13. Epitaxy of α-quartz after Cs implantation and annealing in $^{18}O_2$. The retained Cs fraction plotted as function of the annealing temperature displays Arrhenius behavior with an activation energy of 0.98 ± 0.10 eV.

3.2.3. Experiments with H, Li, Na, and Rb Ion Implantations

The studies on chemically guided epitaxy of SiO$_2$ layers after Cs implantation were extended in two directions:

(a) epitaxy after the implantation of other alkali ions or protons, such as Li, Na, and Rb, and

(b) epitaxy with Cs ions of samples amorphized by other methods.

For details concerning the proton and alkali ion implantations, see Table 2. Most irradiations were carried out at LN temperature and the annealing was done in air or in ^{18}O$_2$ atmosphere. The same ion analytical methods as described above were used to depth profile the various species. For all elements with Z < 20 (except H), the evolution of the profiles of the implanted species (Li, Na) and the ^{16}O $\Leftrightarrow$ ^{18}O exchange between the annealing gas and the matrix were monitored via TOF-ERDA. As an example, Figure 17 compares the temperature variation of the retained Na and Cs fractions (relative to their implanted doses and integrated over the full profiles in the damaged region) and that of the integrated ^{18}O content [94]. The major difference lies in the temperature shift between the two ion species. The temperature T^R, at which half of the implanted ions have left the sample, is clearly lower for Na ($\approx$830 K) than for Cs ($\approx$1065 K). On the other hand, the quality of the epitaxy of the quartz matrix is about equally good for both ions and much better than after Li implantation, where full epitaxy was never achieved [93]. Finally, in the case of proton irradiations, no epitaxy could be found and the samples stayed amorphous up to 1225 K. The hydrogen implantation profile was stable up to 725 K, but then diffused out at around 875 K [96].

We finally discuss the case of chemically guided epitaxy after Rb$^+$ implantations in quartz recently studied in detail by Gasiorek and collaborators [95, 99]. Figure 18 shows RBS spectra, damage profiles, and Rb depth distributions after 175-keV implantation at LN temperature and 1-h annealing in ^{18}O$_2$ atmosphere at the temperatures given. For increasing temperature, one notes a gradual motion of the a/c interface to the surface and a loss of Rb. The quality of epitaxy achieved is as good as for Na and Cs (and better than for Li), and the values of T^{Rb} and T$_x$ are very similar to the ones for Cs. What is different is that the epitaxy occurs in two steps, as shown in Figure 19. The recrystallization speed follows a double Arrhenius dependence with activation energies of E$_{ax}^L = 0.58 \pm 0.12$ eV below and E$_{ax}^H = 3.55 \pm 0.32$ eV above 1175 K, respectively. The origin of this behavior is not understood yet.

In this system, a systematic comparison of annealing in air and ^{18}O was performed and the influences of the gas pressure and Rb fluence were investigated as well. Besides RBS channeling and TOF-ERDA analyses, detailed atomic

Table 2. Processing parameters of chemically guided SPEG in quartz after alkali ion implantation.

	Implanted ion		Processing parameters				
Type	Energy (keV)	Fluence (10^{16}/cm^2)	Annealing gas	T^R (K)	T$_X$ (K)	E$_{ax}$ (eV)	Ref.
^{1}H	20	5.0	air	830 (50)	—^{a}	—	[96]
^{7}Li	15	2.5	^{18}O	870 (59)	925^b		[93]
^{23}Na	50	2.5	air	835 (40)	1070		[94]

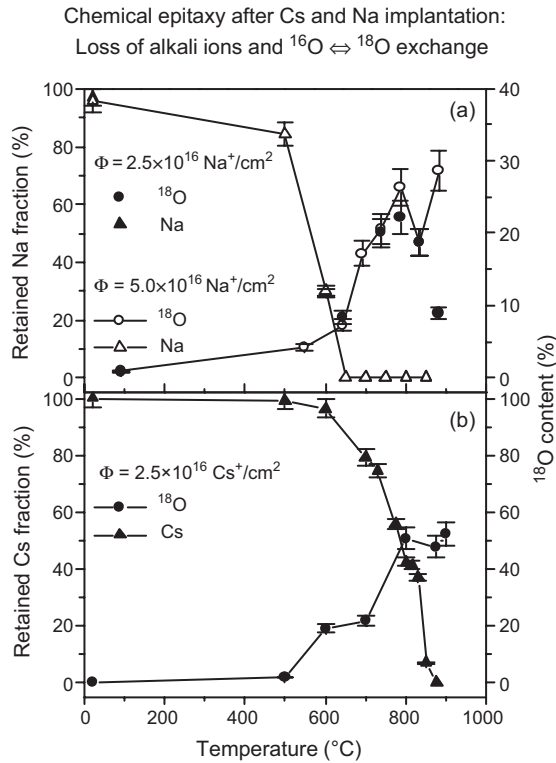
Loss of alkali ions and $^{16}O \Leftrightarrow {}^{18}O$ exchange


Figure 17. (a) Average fraction of implanted Na retained in the quartz samples (relative to the total implanted Na content at fluences of 2.5 and 5.0×10^{16} Na$^+$ ions/cm^2) and of ^{18}O having entered the samples during annealing in ^{18}O$_2$ [94]. (b) A comparison is made with the results on Cs-doped samples [94].

Figure 18. Epitaxy of quartz after 275-keV Rb implantation and annealing in ^{18}O. (a) RBS-C spectra of samples, annealed in ^{18}O$_2$ atmosphere for 1 h between 673 and 1133 K. (b) Depth distributions of the irradiation damage as function of the annealing temperature. (c) Rb concentration profiles extracted from the RBS spectra.

force microscopy was done for these samples in order to gain information on compaction or swelling during ion bombardment and epitaxy. Figure 20 displays the temperature dependence of the step height at the boundary between irradiated and virgin parts of the sample during annealing in ^{18}O$_2$, for 2.5×10^{16} Rb/cm^2 implanted at 250 keV. At 1123 K, when recrystallization has been completed, the step height has reached zero.

3.2.4. Separation of Amorphization and Epitaxy

In the studies presented so far in this section, the implanted alkali ions induced both the radiation damage and amorphization of the matrix during implantation and, under proper annealing conditions, its recrystallization. Of course, this correlation can be relaxed and attempts have been made to separate amorphization (via ion implantation or amorphous silica deposition via evaporation) and chemically guided epitaxy.

Figure 21 illustrates channeling backscattering spectra obtained for three such cases [98]. The spectra plotted in Figure 21a refer to a 90-nm-thick amorphous SiO$_2$ layer deposited via electron-gun evaporation on (0001) crystalline α-quartz. The process is sketched in Figure 22. The sample was then post-irradiated with 250-keV Cs ions at a fluence of 2.5×10^{16}/cm^2 and annealed for 1 h in air at 840 °C or 875 °C. The Cs post-implantation increased the mass

density of the amorphous layer by about 6%. Annealing in air at 1120 K led to full epitaxy and outdiffusion of Cs. This experiment confirmed that chemically guided epitaxy of silica is successful, irrespective of the amorphization process.
Figure 19. Epitaxy of α-quartz after Rb implantation and annealing in ^{18}O$_2$. Recrystallization speed v(T) deduced from the Si signal. The two straight lines correspond to the activation energies indicated.
Figure 20. Height difference between implanted and unimplanted regions for quartz irradiated with 275-keV Rb ions at $2.5 \times 10^{16}/cm^2$ and annealed in ^{18}O at the temperature given.

Figure 21. Epitaxy of a-SiO$_2$ by Cs post-implantation and annealing in air. (a) A 90-nm-thick amorphous SiO$_2$ layer evaporated onto quartz is post-irradiated with 250-keV Cs ions and annealed at 840 °C or 875 °C in $^{18}O_2$. (b), (c) Double implantation with Si (or Xe) and Cs ions and subsequent annealing in $^{18}O_2$ at 850 °C and/or 875 °C.

Figure 22. Epitaxy of a thin a-SiO$_2$ layer via Cs post-implantation.

In the other two experiments illustrated in Figure 21, the quartz samples were first surface-amorphized via ion implantation by either 70-keV Si or 100-keV Xe ions and afterwards epitaxially regrown by chemical SPEG with 250-keV Cs$^+$ ions under air [93]. Indeed, these double irradiations and subsequent annealing at 1150 K or 1125 K again led to full SPEG. The corresponding channeling spectra are displayed in Figure 21b and c. This series of experiments might be important in the context of ion doping quartz with luminescent species and subsequent epitaxy via chemical SPEG, as will be discussed later.

3.2.5. A Possible Scenario

The obvious correlation of epitaxy of the SiO$_2$ matrix, outdiffusion of the implanted alkali ions, and $^{16}O \Leftrightarrow {}^{18}O$ exchange between the matrix and the annealing gas was explained qualitatively by Roccaforte et al. [97, 98] who considered changes of the tetrahedral [SiO$_4$] network and the structural freedom parameter f introduced before. Extended X-ray absorption fine structure (EXAFS) measurements [14] indicated that the [SiO$_4$] units remain almost preserved, even during high-fluence irradiations. This means that the network connectivity parameter $C = 2$ does not change during amorphization (see Fig. 23). The elemental interhedral connection of SiO$_2$ can be represented by the basic chain unit

$$(O_3) \equiv Si - O - Si \equiv (O_3) \tag{6}$$
where $(O_3) \equiv Si$ indicates the continuation of the network. Introducing *network modifiers* like alkali-oxide breaks the continuity of the network by creating oxygen atoms, which do not bridge adjacent tetrahedra. In the case of alkali ion implantation only a marginal fraction of nonbridging oxygen atoms has formed, which arises by the "scavenging" of oxygen atoms by the implanted ions located in weakly bound
Figure 23. Left: Disturbed [SiO₄] tetrahedra network. Right: Incorporation of alkali ions in SiO₂.

interstitial positions. When oxygen diffuses into the alkali-doped matrix, alkali oxide (i.e., $Cs_2^+O^{-2}$) is dissolved in the matrix by forming an alkali-glass silicate, in which bridging oxygen atoms are replaced with nonbridging ones. The effect of Cs implantation and annealing thus may be described as

$$(O_3)\equiv Si-O-Si\equiv(O_3) + 2Cs + O^*$$
$$\rightarrow (O_3)\equiv Si-O-Cs\ Cs-O^*-Si\equiv(O_3)$$
$$\rightarrow (O_3)\equiv Si-O^*-Si\equiv(O_3) + (Cs_2^+O^{*-2})_{jump} \quad (7)$$
where O^* denotes external ^{18}O. Those oxygen atoms (O or O^*) with a strong bond to Si and a weaker one to Cs can easily migrate through the opened glassy structure. The pronounced oxygen migration is thought to arise from preferential diffusion paths, which are opened at broken tetrahedral linkages.

The correlation between diffusion of Cs and ^{18}O suggests that each oxygen isotope exchange is accompanied by a "jump" of Cs from one linkage to another, as indicated above. When at 800 °C, Cs and ^{18}O reach the c/a interface, the high flexibility of the structure caused by the formation of nonbridging oxygen atoms favors epitaxial regrowth.

On the basis of this scenario, Roccaforte et al. [97] also estimated the amount of oxygen diffusing in the amorphous layer. Considering the lattice parameter of quartz along the c-axis (0.54 nm) as the average jump distance, the number of diffusion steps N_{step} of each Cs atom can be taken from the typical distance which Cs needs to reach the surface or the c/a interface, $\Lambda = 71 \pm 5$ nm at 800 °C and for 1 h. This corresponds to $N_{step} = 131 \pm 9$ diffusion steps. The diffusion of Cs implanted into an a-SiO₂/Si bilayer has been studied by Fishbein and Plummer [100] by means of RBS. At 970–1270 K, the diffusion constant (under nitrogen and in the constraint geometry due to the presence of the SiO₂/Si interface) is given as $D = 0.50 \exp(-2.9 \text{ eV}/k_BT)$ cm²/s. The estimated diffusion length at 1075 K during 1 h, $\Lambda = 81$ nm, is in good agreement with this number.

Since according to this interpretation the isotope exchange of one oxygen atom is accompanied by the movement of two Cs ions, the total number of oxygen atoms $N(O^*)$ is given by $N(O^*) = N_{Cs} N_{step}/2$. Using the experimentally determined Cs-content, $N_{Cs} = 11.4 \times 10^{15}$ at/cm², the authors arrived at $N(O^*) = 7.5 \times 10^{17}$ at/cm², which is rather close to the experimental ^{18}O content of $(6.2 \pm 0.4) \times 10^{17}$ at/cm². This rough estimate evidently neglects the anisotropic mobility of alkali ions in "preferential pathways" or "channels

and pockets" in SiO₂ [101–106] to be discussed in the next subsection.

3.2.6. Alkali Ion Diffusion in SiO₂ and Silica

Diffusion of alkali ions in quartz, a-SiO₂, and various silicate glasses under different environments and the role of defect structures related to the impurities in the samples have been studied in much detail over several decades and have been reviewed extensively by, among others, Day [105], Frischat [16], Ingram [101], and Jund et al. [103]. Although the role of different types of defects, and in particular those associated with alkali ions, in the diffusion kinetics (and the optical and electrical properties of the SiO₂ matrix, see Section 4) is still not fully understood, we would like to briefly allude here to some concepts and results dealing with the diffusion of alkali ions in SiO₂. The main body of the experimental information derives from Na diffusion [107–116] and some from diffusion studies of Rb tracers in the context of mineral dating in geosciences. Si and O diffusion studies in quartz have recently been carried out by Bejina and Jaoul [117] and by Hamann [118]. Concerning the role of Al-associated defects in alkali ion diffusion in quartz, we refer to the work by Breton, Giradet, and collaborators [119].

The non-Debye behavior observed in the electric response has led to local ion motion based on a "forward-backward hopping mechanism" or hopping processes over random potential barriers [103]. Ingram introduced the notion of "preferential pathways" governing the dynamics on large scales. Recent molecular dynamics (MD) calculations of Na^+ diffusion in NSn silicate glasses of the structure formula $(Na_2O)n(SiO_2)$ (n = 2, 3, 4) and neutron scattering measurements [107] appear to confirm this Ingram concept and gave evidence of the following details [102–104]:

1. Na diffusion is much faster than Si or O diffusion, its diffusion constant being two orders of magnitude larger. Up to about 2500 K, the SiO₂ matrix can thus be considered as frozen.
2. At temperatures T < 3000 K, Na diffusion proceeds along "preferential pathways" or "channels with pockets" [101]. This means that even after diffusion times of several ns, large fractions of the SiO₂ matrix have not been "visited" by migrating Na ions and the diffusion trajectories do not fill the space uniformly. The sodium-free regions form a percolating structure around a channel network ("Swiss cheese" structure). The characteristic distance between these channels is of the order of 0.66 nm [104].
3. The MD calculations indicated uncorrelated Na diffusion within the channels and did not support the cooperative motion proposed by Greaves [106]. There are preferred sites for the sodium ions inside the channels associated with dangling bonds. These bonds do not disappear until the network has rearranged itself.
4. According to Horbach et al. [104], the fast Na diffusion within the channels and the rearrangement of the channel network within SiO₂—although proceeding on very different time scales—are closely related to each other.

As mentioned before, the diffusion of implanted Cs ions in a-SiO₂ at temperatures relevant for chemically guided SPEG

was of Arrhenius type with an activation energy of $E_a = 2.9$ eV [100].

3.3. Epitaxy of Quartz via Laser Annealing

Epitaxy in ion-irradiated quartz by means of dynamic or chemically guided SPEG has the advantage that both methods may provide full epitaxial regrowth of the a-SiO$_2$ layers. But these methods may have severe drawbacks in optoelectronic device fabrication. In the case of chemically guided SPEG, annealing in oxygen at elevated temperatures may influence the dopants via oxidation and/or diffusion. With regard to oxidation, dynamic SPEG is more favorable (since it proceeds in high vacuum), but it requires implantation into heated samples, and the layer structures and implantation profiles may suffer from unwanted diffusion of the dopants and the matrix and from ripening precipitates. For that reason, attempts have been made to overcome these obvious deficiencies by laser-annealing ion-doped SiO$_2$ samples.

Stepanov et al. [139] reported on laser annealing experiments of silica after Ag or Cu ion implantations, at a typical energy of 50 keV and fluences of $4–8 \times 10^{16}$ ions/cm^2. Pulsed laser treatment with a KrF excimer laser was applied (wavelength $\lambda = 248$ nm, average energy density $= 0.25$ J/cm^2, pulse length $= 25$ ns FWHM, up to 250 pulses per irradiation spot). Properties of the metal nanoparticles were studied via RBS and optical reflectivity and transmittance. The changes in cluster size and diffusion of the implants were found to depend on the energy absorption by the clusters themselves on the one hand and the repeated melting and long-term warming up of the matrix on the other hand. Dissolution of dopant clusters, long-range atomic diffusion of dopant atoms, and formation of new dopant clusters are the consequence of this complicated mechanism, which is far from being fully understood. Electroluminescence (EL) of these samples was recorded as functions of the sample temperature and pulse structure of excitation [141], giving evidence of a stabilization of the defect centers in silica.

First attempts of laser-induced epitaxy in α-quartz after Cs, Ba, and Xe ion implantation have been undertaken by Schaaf et al. [146], using a pulsed XeCl excimer laser ($\lambda = 208$ nm, pulse length $= 55$ ns, up to 150 pulses, laser energy density ≤ 4.7 J/cm^2). A typical RBS-C spectrum obtained after implantation of 250-keV Cs ions at a fluence of 2.5×10^{16}/cm^2 and laser annealing is illustrated in Figure 24. At energy densities between 3.6 and 4.7 J/cm^2, one notes the diffusion of the implanted Cs towards the surface (and some loss of Cs) and a reduction of the thickness of the amorphous layer, but both processes are incomplete and suggest that a higher laser power is required to achieve full epitaxy. Preliminary results on the laser annealing after the implantation of 3.5×10^{16} Ba ions/cm^2 at 250 keV into silica have been obtained for laser powers of up to 5.0 J/cm^2.

4. LUMINESCENCE OF IMPLANTED NANOCLUSTERS IN SiO$_2$

One of the possible future applications of (ion-beam) doped quartz layers appears to be in photonic device design and production by making use of luminescence effects. It is

Figure 24. RBS-C spectra taken after implantation of 2.5×10^{16} Cs ions/cm^2 at 250 keV into α-quartz and laser annealing with a pulsed excimer laser of the energy densities indicated.

well known that amorphous SiO$_2$ containing silicon, germanium, or metal nanocrystals shows intense photoluminescence (PL), electroluminescence (EL), and even ion-beam luminescence (IBL) in the visible range [120–143], but little is known about such luminescence phenomena in ion-beam doped, crystalline quartz. For that reason, we briefly review some information on PL and EL in a-SiO$_2$ and then describe first attempts of laser annealing to grow optically active crystalline SiO$_2$ elements.

Si and Ge nanoclusters in a-SiO$_2$ can be produced by several methods including ion implantation (see [122–134]), chemical vapor deposition [121, 144, 145], sputtering, and laser ablation/deposition. The generation of strong PL from Si nanocrystals after Si$^+$ ion implantation into a-SiO$_2$ films or a-SiO$_2$/Si bilayers is rather well understood and many attempts have been undertaken to optimize the light output in different regions of the visible spectrum [122–128, 130, 134]. The obtained PL spectra have some common features: the PL peak is quite broad, due to the size distribution of the nanocrystals, and its position shifts towards smaller wavelengths when reducing the cluster size. Both findings are a consequence of quantum confinement. An additional and less well-understood component of the PL spectrum arises from color centers in the a-SiO$_2$ matrix. The PL spectrum thus contains contributions from both the recombination of quantum defined excitons in the nanocrystals and ion-irradiation defects. By etching layer by layer of the photoactive SiO$_2$ film, Bongersma et al. [136] have been able to locally identify the various sources of PL. Defect luminescence originates from near-surface nanocrystals, while large nanocrystals luminescing at long wavelengths ($\lambda \approx 900$ nm) are mainly located in the center of the film, where the Si concentration is highest. A large density of small nanocrystals luminescing at $\lambda \approx 700$ nm, which escape detection by electron microscopy, was found near the SiO$_2$ surface and SiO$_2$/Si interface. Luterova et al. [142] recently reported on blue PL in SiO$_2$ films doped with Si nanocrystals after picosecond pulsed UV excitation. These authors found that the PL signal increases more than linearly with the exciting photon intensity and decays in time via a superposition of exponential functions. Space- and time-resolved

investigations have considerably contributed to the microscopic description and interpretation of luminescence.

Electroluminescence and EL light amplification in Si nanoclusters embedded in substoichiometric SiO_x ($x < 2$) have recently been reviewed by the Catania group [121, 144, 145]. The excitation occurred by impact of hot electrons with the Si nanoclusters and subsequent electron-hole generation and recombination. The EL signal was found to strongly depend on the amount and distribution of Si in the samples, via both the stoichiometry of the SiO_x matrix and the size of the Si nanocrystals. Efficient EL requires a compromise between the parameter x (increased injection current and excitation probability due to increased Si content) and the nanocrystal size (increasing light output in the visible spectrum for decreasing nanocrystal diameter). Pacifici et al. [144] also studied defect production and annealing of these Si nanocrystals under 2-MeV ion bombardment and the influence of these defects on the PL output.

Violet PL of implanted Ge nanocrystals in SiO_2 was first observed by Bao and co-workers [129, 130] and a Caltec–Amsterdam collaboration [135]. The Rossendorf group studied PL and EL in Ge-doped SiO_2/Si bilayers in detail [131–134] and, based on their findings, developed the first integrated Si-based optocoupler containing Ge nanocrystals and luminescing in the blue [131]. When using two subsequent Ge implantations and optimizing the ion energies and fluences, these authors achieved a nearly homogeneous distribution of 2- to 6.5-nm diameter clusters throughout the SiO_2 layer, after annealing the samples at 500–1200 °C in a dry N_2 atmosphere [132]. Electron microscopy combined with RBS indicated a cluster-free zone at the surface and the accumulation of small clusters near the SiO_2/Si interface. These optocoupling devices hold great promise for integrated optoelectronic devices, especially in the field of sensors and biotechnology.

Optical properties of metallic clusters or nanocrystals in a-SiO_2 have been reviewed, by for example, Townsend, Chandler, Zhang, and collaborators [19, 138, 140], and by Polman, Atwater, and collaborators [18, 135–137]. Rebohle et al. [132] reported on strong PL in the violet after doping a-SiO_2 with Sn ions, 2–20 times higher in intensity than after Si or Ge implantation. A further line of research for optimizing the light output in certain spectral regions is doping the nanocrystals with impurities, such as Er [137]. Furthermore, double ion irradiations of a-SiO_2 samples, first with low-energy C ions at high fluences of the order of 5×10^{16} to 1×10^{18}/cm^2 and subsequently with high-energy Ar, Kr, Xe, or U ions at low fluences of some 10^{12} ions/cm^2 have been shown to produce intense blue-violet PL [143].

The question whether one of the methods, which have been developed for epitaxial regrowth of SiO_2 after ion irradiation and discussed in Section 3, leads to PL or EL of doped quartz, is still open. First experiments in this direction by Dhar et al. [71] after 175-keV Ba ion implantation have recently been successful. Going back to Figure 11, partial dynamic epitaxy was achieved, when implanting 1×10^{15} ions/cm^2 at temperatures up to 900 °C into α-quartz: for increasing temperature, the c/a interface has moved towards the surface, leaving, however, a very thin nonrecrystallized subsurface layer. Figure 25 displays PL and EL spectra taken at 12 K and room temperature for this series of samples.

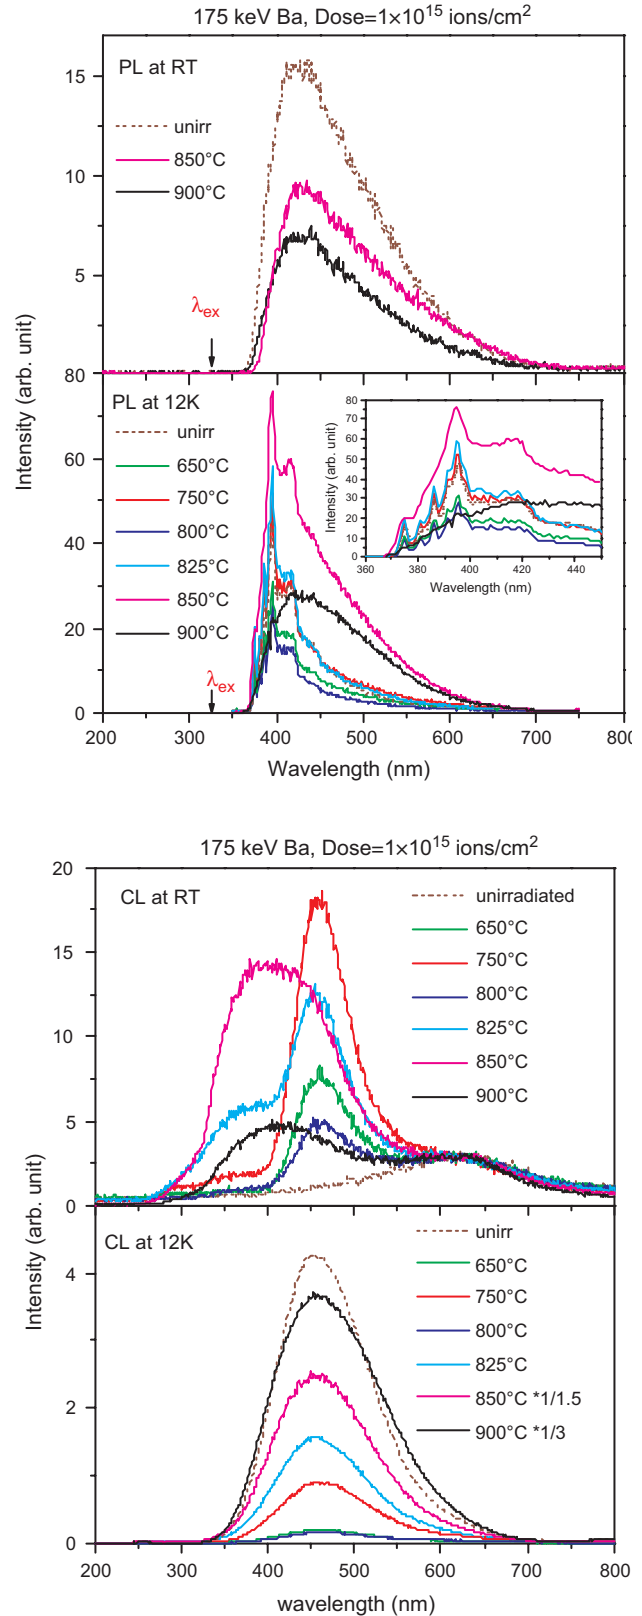

Figure 25. Photoluminescence (PL) and electroluminescence (EL = CL) spectra obtained at RT and 12 K after 175-keV Ba ion implantation in quartz at the temperatures given. The ion fluence was 1×10^{15}/cm^2 in all the cases.

Clearly luminescence can be stimulated by both 325-nm photon and 5-keV electron excitation. An interpretation of these spectra, some of which strongly depend on the sample temperature, is in progress. Now already we emphasize the strong dependence of the CL spectrum both in shape and intensity, on the implantation temperature (see Fig. 25 upper right corner). A strong blue and violet peak appears at an irradiation temperature, where the a/c interface has started moving to the surface indicating the onset of epitaxy. It is interesting to note that the violet peak survives the epitaxy and may be attributed to the implanted Ba ions.

This study has been recently extended by Sahoo and collaborators [147] to Ge ion-implantation of quartz at elevated temperatures. The CL yield was measured as function of the sample temperature during ion irradiation (300–1223 K) and CL analysis (30–300 K). In this case, only partial dynamic epitaxy was achieved at rates of 0.1 nm/s (at 920 K) to 0.3 nm/s (at 1250 K) for a fluence of 7×10^{14} Ge-ions/cm^2. Above 920 K, two intense violet bands at 381 and 418 nm appeared in the CL spectra, which were associated with properties of the incorporated Ge ions (Ge—Si bonds, Ge nanoclusters, Ge oxide) and not with the damaged SiO_2 matrix.

GLOSSARY

Chemically guided epitaxy of ion-irradiated quartz The radiation defects and ion-beam amorphized surface layer can be transformed into a quartz single crystal, if alkali ions are implanted near the amorphous/crystalline interface and the sample is annealed in air or oxygen. Amorphization may occur by the alkali ion implantation itself or by implantation of other ions.

Dynamic epitaxy Ion irradiation of a single crystal at elevated temperature leaving the long-range order of the sample intact. The unavoidable radiation defects anneal out due to the thermal mobility of the implanted ions and the matrix atoms.

Elastic recoil detection analysis Ion-beam analytical method in which a beam of heavy projectiles is directed onto a matrix composed of lighter elements/isotopes.

Laser epitaxy Quartz, which has been surface-amorphized by ion bombardment, can be recrystallized by intense laser irradiation.

Luminescence of nanoclusters in silica Photo- and/or electroluminescence in silica arises after the implantation of semiconductor (Si, Ge), rare earth, or other ions. The spectral shape and intensity of the luminescence light after UV photon or keV electron irradiation depend on the ripening conditions of the nanoparticles as well as on the implanted ion species and the defects created during ion implantation in the silica.

Nuclear reaction analysis A depth- and isotope-sensitive profiling method used mostly for particular light isotopes in the target for which nuclear resonance reactions with narrow resonances and sufficient cross sections are known.

Rutherford backscattering spectroscopy Ion-beam analytical method that mainly measures the depth profiles of medium-mass (or heavy) elements in a matrix composed of light (or medium-mass) elements.

Sputter erosion Ion beam impact produces atomic transport near the sample surface leading to removal of surface atoms and self organization (ripple formation, smoothing).

Epoxy/Clay Nanocomposites

Nandika Anne D'Souza

University of North Texas, Denton, Texas, USA

CONTENTS

1. INTRODUCTION

When two or more phases are mixed together to make a composite, a combination of properties that are not available in any of the individual components is possible. In particulate-filled plastics, the role of clay as a filler has been clearly established [1]. When clays were previously used as fillers, they were primarily utilized for increasing the modulus of the matrix resin they are dispersed in. The scale of dispersion is macroscale. Separately, clays have been used in water dispersions aimed at enhanced oil recovery. In the early 1990s, a merger of the two technologies occurred. Researchers at Toyota determined that, when montmorillonite clay was treated with amino acids, the individual layers of the clay could be separated [2–10]. The decreased van der Waals attraction was exploited to swell resins such as polyamides into the intergallery spacing and separate out the platelets. The resulting system then consists of the host resin and individual platelets whose approximate diameter would be around 2 μm, and whose thickness would be 1 nm. Thus, a new classification of composites was born: nanocomposites. The word "nanocomposite" refers to composites where the reinforcement has at least one dimension in the nanometer scale. The nanoscale filler belongs to a class of expandable smectic clays since, for nanoscale reinforcement, key requirements are that the individual layers of the clay can be separately dispersed into the host resin. Because the building blocks of a nanocomposite are nanoscale, they have an enormous surface area ($\sim$760 m^2/g), leading to a high interfacial area between the filler and the matrix. The unique properties of the nanocomposite arise from the interactions of its phases at the interfaces [11, 12]. In contrast, in a conventional composite based on micron-sized fillers such as carbon fibers and glass fibers, the interfaces between the filler and matrix constitute a much smaller volume fraction of the bulk material, and therefore influence its properties to a much smaller extent.

Nanocomposites have found widespread applications in the automobile industry (exterior and interior body parts), packaging industry (bottles, containers, plastic films, and fuel tanks), electronic industry (packaging materials and exterior parts of electronic devices), coating industry (paints, wire enamel coatings, etc), and aerospace industry (body parts of airplane and exterior surface coatings) [11–13]. A key to the burgeoning interest is that the reinforcement aspect ratio and scale require much lower volume fractions compared to micro- and macroreinforced polymers Where filled plastics have filler volume fractions of around 40–50% and fiber-reinforced materials have fractions around 60–70% to meet effectiveness based on scaling laws, nanocomposites often contain reinforcements below 7%. Since the basis of improvement is based on expansion of the smectic layers of the clay and subsequent increased particle wetting, the influence of clay treatment on dispersion has driven much of the earlier research [14–17]. Scientists have also tried to correlate and explain the behavior of nanocomposites through thermodynamic models to understand clay treatments and the formation of nanocomposites [18–24]. Improved barrier properties [25–29], higher mechanical properties [30–34], improved flame retardance [35, 11–13], and increased dimensional stability [36–40] have been determined in polymer nanocomposites. All of these benefits are obtained without significantly raising the density of the compound or reducing light transmission [18].

The multifunctional properties are dependent on the ability to disperse the inorganic material throughout the polymer and increase the interfacial area. First, at the nanometer level, if the individual smectic layers retain some range of order, an intercalated dispersion is obtained. If the layers are completely separated with an interlayer distance

greater than 100 nm, a delaminated or exfoliated dispersion results. On the macroscopic level, it is possible for the clay to self-aggregate so that clay-rich and polymer-rich domains result, giving rise to a morphology similar to that of particle-reinforced polymers, where individual self-aggregated regions can range in size from 10 to 50 μm [16, 18]. Factors limiting the successful dispersion of the layered silicates are the hydrophilic nature of the silicates and the largely hydrophobic nature of most engineering polymers. To produce an intercalated nanocomposite, the polymer has to wet the clay particles to some extent, so that the polymer chains are intercalated between the clay galleries. To make delaminated or exfoliated nanocomposites, a higher degree of wetting is required [16, 34]. To counter the problem of particle agglomeration, the clay interlayer surfaces of the silicate are chemically treated to make the silicate less hydrophilic, and therefore more wettable by the polymer. This is accomplished by a cation exchange process where hydrophilic cations such as Na^+, K^+, and Ca^{2+} are exchanged by alkyl ammonium cations. The role of alkyl ammonium cations in the organosilicates is to lower the surface energy of the inorganic host, and improve the wetting characteristics with the polymer. In general, the length of the alkyl ammonium cations determines the hydrophobicity of silicate layers.

Epoxy nanocomposites, in particular, have been actively investigated, although the number of critical parameters is far larger than for thermoplastics. Organic treatment of the clay surface, curing agent, epoxy type, temperature of curing, and method of premixing are all interactive variables that must be considered. Thus, epoxy nanocomposites pose an interesting scientific and technological challenge where the state of current investigations point as much to the understanding of the present as to where the research needs to be headed. Keeping that in mind, this review of epoxy montmorillonite is divided into separate sections. A review of montmorillonite and key factors affecting nano- as opposed to microcomposite dispersions is covered in Section 2. Efforts to develop epoxy nanocomposites and the influence of different curing agents is covered in Section 3. The role of clay concentration in dispersion is covered in Section 4. The final section, Section 5, is geared toward unique results that stimulate the curiosity for future research.

2. MONTMORILLONITE

Clay is distinguished from sand and silt on the basis of size [41]. Sand has a grain size between 2–0.050 mm, silt is between 0.050–0.002 mm, and clay is below 0.002 mm. On the basis of the SiO_4 tetrahedra, six soil silicates are generally identified: cyclosilicates, inosilicates, neosilicates, phyllosilicates, sorosilicates, and tectosilicates. Clay minerals belong to the phyllosilicates (Table 1) [42]. Phyllosilicates are two-dimensional arrays of silicon–oxygen tetrahedra and two-dimensional arrays of aluminum or magnesium–oxygen–hydroxyl octahedra. In the case of silicon–oxygen sheets, silicon atoms are coordinated with four oxygen atoms. The oxygen atoms are located on the four corners of a regular tetrahedron with the silicon atom in the center. This is

Table 1. Major phyllosilicate minerals in soils [41].

Layer type	Group name	Charge per unit formula	Common minerals
1:1	Kaolinite–serpentine	~0	Kaolinite, halloysite, chyrsotile, lizardite, antigorite
2:1	Pyrophyllite–talc	~0	Pyrophyllite, talc
	smectite or montmorillonite	~0.25–0.6	Montmorillonite (smectite) bedellite, notronite, saponite, hectorite, sauconite
	Mica	~1	Muscovite, paragonite, biotite, phlogopite
	Brittle mica	~2	Margarite, clintonite
	Illite	2	Illite
	Vermiculite	0.6–1.9	Vermiculite
2:1:1	Chlorite	Variable	Chlorite

shown in Figure 1 [43]. In the sheet, three neighboring tetrahedra share three of the four oxygen atoms of each tetrahedron, and the fourth oxygen atom of each tetrahedron is pointed downward, as shown in Figure 2 [43]. The structure of clay, however, is not a three-dimensional network of simple linkages of silicon–oxygen units. By linking three oxygens of each tetrahedron with adjacent tetrahedra, a tetrahedral sheet is formed. The silicon–oxygen sheet is called the tetrahedral sheet or the silica sheet. In this network of silica tetrahedra, one oxygen in each tetrahedron remains electrically imbalanced, and is therefore linked to Al or Mg in octahedral coordination (Figs. 3 and 4). In the tetrahedral sheet, Si^{4+} replaces Al^{3+}. In the octahedral sheet, Al^{3+} replaces Mg^{2+}. The substitution of higher valence atoms results in a deficit positive charge or an excess of negative charge. The excess of negative charge within the layers is balanced by adsorption of cations. These clays, which are hydrophilic in nature, have Na^+, K^+, or Ca^{2+} cations in the layer gallery. The imbalance leads to the possibility of cation exchange which varies between the different clay minerals. For example, kaolinite has a cation exchange capacity (CEC) of 1–10 meq/g, while montmorillonite is in the range of 70–100 meq/g.

The packing of a silicate tetrahedron and aluminum octahedron sheets results in a layered structure. While several layers can be stacked, each layer is an independent crystal unit. Within each layer, there is a repetition of structure, and therefore it is referred to as a unit cell. The distance between a certain plane in the layer and the corresponding plane in the next layer is called the basal or d spacing. The basal

Figure 1. Tetrahedral arrangement of Si and O.

**Figure 2.** Perspective sketch of tetrahedral linking.

Figure 4. Perspective sketch of octahedral linking.

spacing can be determined by XRD. The basal spacing is around 7.2 Å in kaolinite and 9.2 Å in 2:1 layer clays. The bonding between the layers is weak (van der Waals type), but a strong covalent bond exists between the atoms of the same layer. The suggested crystallographic structure for a layered silicate is shown in Figure 5 [43]. This structure is derived from pyrophyllite and talc by substitution of certain atoms for other atoms.

The bonds between the layers can be strong, as in the case of kaolinite, or weak, as in montmorillonite. On the basis of the number of tetrahedral to octahedral sheets in one layer, dimorphic (1:1), trimorphic (2:1), or tetramorphic (2:2) types are identified. Kaolinite, for instance, has a 1:1 structure where one tetrahedral sheet has one octahedral sheet. The smectite group, however, is a 2:1 since two tectahedral sheets are related to 1 octahedral sheet.

Montmorillonite-layered silicates (MLSs) are distinguished by the location and type of cations in the layer. Due to a high concentration of negative charge, the surface oxygens of tetrahedrally substituted MLS are stronger electron donors than the surface oxygens of octahedrally substituted MLS. The high CEC is responsible for interest in combining MLS with polymers as the potential for swelling and separation of the individual sheets is high. Alternative clays such as magadite and mica have been investigated, but to a smaller extent [44]. An exfoliated nanocomposite was synthesized [45], but the high cost of synthetic magadite over the low cost of natural montmorillonite has limited extensive investigation.

2.1. Surface Treatment of Clay Minerals

Clays are hydrophilic by nature, while polymers are hydrophobic and organophilic. To encourage interaction between the clay and the polymer, the surface of the clay is treated to make it hydrophobic and more organophilic. This is a cation exchange reaction where inorganic cations such as Ca^{2+}, K^+, and Na^+ are replaced by organically modified cations, such as alkyl ammonium ($R–NH_3^+$) groups. R is a long aliphatic residue. The cationic head of the aliphatic group is found close to the surface layer due to the presence of negative charge on the layer, and the tail without charge is found
away from the layer. Four types of structures are possible, depending on the packing density, temperature, and chain length of the aliphatic groups [43]. When the alkyl ammonium chains lie parallel to the host layers, a lateral monolayer or lateral bilayer is formed. If alkyl ammonium chains radiate away from the host layers, an extended paraffin-type monolayer or paraffin-type bilayer structure is formed [46, 47]. These are shown in Figures 6–9.

The hydrophilic clays are typically intercalated by alkyl ammonium ion (onium) using an ion-exchange reaction. Based on the alkyl chain length, X-ray diffraction and FTIR are typically use to determine which structure is formed in the clay prior to introduction into the polymer. When alkyl ammonium ions with 12–18 carbons are ion exchanged for the inorganic cations in smectic clays with a CEC around 100–120 meq/100 g, a lateral bilayer (18 Å results) or an inclined paraffin-like structure (20–23 Å) results. At higher concentrations of onium ions, a lipid-like bilayer is also formed. For epoxies in particular, a detailed study was conducted to understand the influence of alkyl chain length on the basal spacing of the clay. Lan et al. [32] calculated the final structure by first assuming that the gallery cations would orient vertically from their initial monolayer or bilayer orientation. Basal spacings were expected to follow the relation $d_{001} = 1.27(n-1) + d_A + r_M$, where $(n-1)$ is the number of methylene groups in the onium ion chain, d_A is the basal spacing for the NH_4^- montmorillonite (12.8 Å), r_M is the van der Waals radius of the methyl end group (3 Å), and 1.17 Å is the contribution due to the CH_2 segments when the chain adopts an all-trans configuration. Table 2 shows the results. The difference in the epoxy-solvated value and the calculated value for $x = 1$ was caused by the onium ion taking an inclined orientaion as opposed to a vertical one.

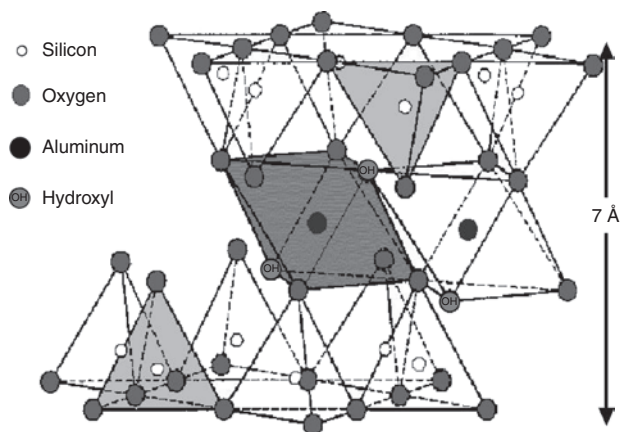

Figure 3. Octahedral arrangement of Al or Mg with O or OH.

**Figure 5.** Suggested layered structure of mica-type layered silicates.

Figure 6. Lateral monolayer.

The similar values between the measured and predicted values for $x > 8$ implied that, for higher chain lengths, a vertical orientation was obtained, and multiple epoxy monomers can be accommodated in the galleries. Vaia developed a schematic structure model for organically modified fluoro-hectorite (FH–C_n) [43]. Fourier transform infrared spectroscopy (FTIR) along with X-ray diffraction were used. By monitoring the frequency shifts of the asymmetric CH_2 stretching and bending vibrations, it was found that the alkyl ammonium chains exist in states with varying degrees of order. Depending upon the number of carbon atoms present in an alkyl ammonium chain, the model adopts a more ordered structure. For the least number of carbon atoms, that is, when the chain is short, the molecules are isolated from each other. For intermediate chain lengths, a structure with varying degrees of in-plane disorder is formed. At higher chain lengths, an increase in interlayer order was determined. Thus, as the interlayer packing density increases, the alkyl ammonium chains adopt a more disordered structure.

2.2. Dispersion of Montmorillonite

As stated before, the alkyl ammonium chains in the galleries make the clay organophilic. The surface energy of the layered silicates is reduced due to the presence of alkyl ammonium chains, thus allowing organic species with varying degrees of polarities to intercalate between the layers. In considering particulate-reinforced polymer composites, an important parameter is the dispersion of reinforcement. Uniform dispersion is key to better mechanical and thermal properties. The addition of clay in a host matrix produces three different types of dispersion:

- intercalated dispersion
- exfoliated dispersion
- immiscible dispersion.

Figure 10a shows an intercalated dispersion. As it indicates, a finite penetration of polymer chains into silicate galleries results in the finite expansion of silicate galleries. A well-ordered multilayered structure with retention of clay structure is obtained. Extensive penetration of polymer chains into silicate galleries, which results in disorder
Figure 7. Lateral bilayer.
Figure 8. Paraffin-type monolayer.

and eventual delamination with a complete disruption of clay structure, is called an exfoliated dispersion. The exfoliated dispersion is shown in Figure 10b. An immiscible or macrosystem represents complete immiscibility of clay and polymer on the molecular level. Both clay and polymer retain their individual identities without affecting their structure. This effect is shown in Figure 10c. The factors which affect the dispersion and miscibility in a polymer clay nanocomposite are as follows:

- packing density of clays
- chain length of organic cations
- charge on the layer
- processing temperature
- shear during nanocomposite formation
- type of bonding at polymer/silicate interface
- polymer–polymer, polymer–silicate, and silicate–silicate interaction.

2.3. Influence of Epoxy Resin, Surfactant Treatment, and Clay on Dispersion

Since treatment of the clay is vital to generating nanocomposites and epoxy polymerization, is a critical contributor to the generation of nanocomposites, it is important to consider if the alkyl ammonium surfactant itself contributes to the polymerization. Lan et al. [32, 33] argued that the acidity of the alkyl ammonium ions may catalyze the homopolymerization of the digycidyl either of bisphenol A molecules inside the clay galleries. Kornmann et al. [37] investigated the effect of the cation exchange capacity of the base clay on epoxy polymerization. If the CEC is

Figure 9. Paraffin-type bilayer.

Table 2. Cation chain-length influence on *d* spacing in montmorillonite.

CH$_3$(CH$_2$)$_x$NH$_3^+$	Air dried	Epoxy solvated	Calculated distance between plates	Initial cation orientation
3	13.5	16.5	19.6	Monolayer
7	13.8	27.2	24.7	Monolayer
9	13.8	30	27.2	Monolayer
11	15.6	31.9	29.8	Bilayer
15	17.6	34.1	34.9	Bilayer
17	18	36.7	37.4	Bilayer

high, more alkyl ammonium surfactant would lie next to the clay, and therefore the effect of homopolymerizaiton would be clarified. First, in treating the low CEC clay, an increase in (001) spacing from 9.7 to 17.2 Å was obtained for the organoclay, whereas the low CEC clay swelled from 12.4 to 21.4 Å. The organoclays, when swollen in DGEBA resin at 75 °C, quickly increased in *d* spacing to 30 Å. This was associated with the development of a lateral bilayer of perpendicular orientation. As the time for swelling reached 24 h, the interlamellar spacing of the higher CEC clay was constant around 34 Å, while the low CEC clay was completely exfoliated. An increase in viscosity of the low CEC clay was also apparent, which the authors explained as resulting from self-polymerization. However, they also acknowledged that the exfoliated state with increased effective clay particle size would lead to increased viscosity as well. Thus, Kornmann et al. showed that a low CEC permits higher diffusion of alkyl ammonium ions. Butzloff et al. [48] also investigated the competing homopolymerization versus epoxy + curing agent polymerization. For a given clay, they showed that the kinetics of the two-part system given by the epoxy + organoclay are substantially lower than epoxy + hardener; therefore, the homopolymerization of the epoxy and clay had little influence on the final nanocomposite. By increasing the swelling temperature to 80 °C and decreasing the

time for epoxy + clay swelling to 1 h, they found that the DSC trace showed only a single hump as opposed to the two-stage hump shown by Lan et al. [32] at 75°. They investigated the influence of changing clay concentration, and found that all of the kinetics of the three part (epoxy + clay + curing agent) system dominated the homopolymerization. However, there were definite signs that the alkyl ammonium ions were participatory in the reaction since changing the heating rate changed the area under the curve of the polymerization. One of the few attempts to study a high T_g epoxy resin was recently made by Becker et al. [49]. They investigated the tri- and tetrafunctional epoxies. They found that, while the DGEBA system had an exfoliated dispersion, the high-crosslink-density resins had intercalated dispersions. A general increase in modulus and fracture toughness was obtained. This was related to the intercalated dispersion. The comparative results of curing agent, epoxy, and clay on dispersion are shown in Table 3.

3. PROCESSING OF POLYMER CLAY NANOCOMPOSITES

Techniques for polymerization include melt intercalation, solution polymerization, and *in-situ* polymerization. Melt intercalation is primarily applicable to thermoplastics, and is adaptable to conventional processing technologies such as injection and extrusion. It is briefly reviewed in Section 3.1. The most generally followed approach in epoxy nanocomposites is the *in-situ* polymerization covered in Section 3.2. Solution polymerization is followed when the polymer is mixed with an organic solvent, the clay swells, and the polymer chains diffuse between the clay platelets. When the solvent is evaporated, often an intercalated nanocomposite results. The use of a solvent with epoxy has been successful when high clay loadings are considered. This is elaborated on in Section 3.3.

3.1. Melt Intercalation

In 1993, Vaia and his colleagues were the first to report melt intercalation to make thermoplastic nanocomposites. The method is not applicable for thermosets because the process involves the melting of a polymer. The process involves blending of a molten thermoplastic with organoclay, and then annealing at a temperature above the glass transition temperature of the polymer. The mechanism is shown in Figure 11 [43]. The observation that polymer chains can undergo center of mass diffusion in essentially two dimensions is rather surprising because the unperturbed chain diameters (10 nm) are approximately an order of magnitude greater than the interlayer distance between the silicate sheets (1 nm). The proposed driving force for this mechanism is the important enthalpic contribution of the polymer–clay interactions during the blending and annealing steps. Since the process involves the blending of polymer with clay, melt intercalation is one of the most popular methods to prepare nanocomposites in industry. Different thermoplastics have been tried so far to make nanocomposites by this technique, for example, polypropylene, polyethylene, nylon, and polystyrene.

3.2. *In-Situ* Polymerization

This was the first method used to synthesize polymer clay nanocomposites. The first polymer used was nylon (polyamide 6). However, it is the central processing technique for epoxy nanocomposites. Strategies with conventional epoxies follow two paths. In one case, the epoxy monomer swells the clay, and subsequently, the curing agent is added (two stage). In the second case, epoxy and the curing agent are mixed, and the clay is added (one stage). The two-stage method is generally followed. Figure 12(a) shows the flowchart of a single-stage reaction where epoxy + hardener + MLS are added together. Figure 12(b) is a flowchart for the two-stage polymerization route. The first

step is to achieve the swelling of organoclay in monomer. This is a time-consuming step since the swelling depends on the polarity of monomer molecules, surface treatment of clay, and swelling temperature. Then, depending upon the type of polymer, the reaction is initiated. In the case of

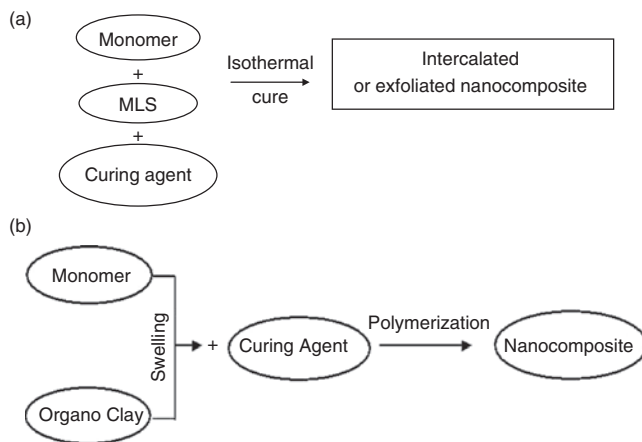
Figure 11. Flowchart of the "melt intercalation."


Figure 12. (a) One-stage epoxy *in-situ* polymerization. (b) Flowchart of the "*in-situ* polymerization" two-step process.

thermoplastics, the polymerization is achieved by the addition of free radicals or by an increase in temperature. In the case of thermosets, a curing agent is added to initiate polymerization. Figure 13 shows the interactions between the clay and the monomer at different stages of polymerization [43].

The driving force for this "*in-situ* polymerization" depends on the polarity of monomer molecules. Due to the high surface energy of the clay, monomer molecules get diffused between the clay layers. The diffusion is continued until equilibrium is reached. During polymerization, the monomer starts to react with the curing agent or free radical. This reaction lowers the overall polarity of the intercalated molecules so that more polar molecules are driven between the clay layers. The most important thing is to control the polymerization occurring between the layers (intragallery polymerization). If the cure kinetics is lower between the layers than outside the layers (extragallery polymerization), delamination of clay is possible. Therefore, greater importance is given to intragallery polymerization than to extragallery polymerization.

One of the first publications on developing epoxy nanocomposites was by Wang and Pinnavaia [26]. Prior to their paper, the only report was a filed patent [50]. The patent utilized a solvent intermediate. They introduced the organoclay into epoxy at 75°. After stirring for 30 min, they gradually increased the temperature at 20 °C/min, and obtained a powder. The reaction took place between 200–300 °C. The powder obtained was a delaminated nanocomposite. When no clay was present, the epoxy had an onset polymerization temperature of 384 °C, which went to 229 °C when 0.2% clay was present. The enthalpy of reaction was similar with and without clay. Comparing clays of different acid values, they determined that the interlayer accessibility and gallery cation acidity were important parameters guiding nanocomposite formation. Examining reaction kinetics, they determined that, while the epoxy activation energy was around 75 kJ/mol, the clay-filled epoxies had activation energies over 100 kJ/mol. The higher values were associated with the steric hindrance caused by intercalated clay layers. The first publication of epoxy nanocomposites, which was compatible with curing agents and coating-based processing
Figure 13. Chemical steps involved in the "*in-situ* polymerization."

techniques, was by Messersmith and Giannelis [35]. Nanocomposites using anhydride, BDMA and BTFA were used. TEM showed layer spacings of over 100 Å. Using a low T_g curing agent, Lan and Pinnavaia [30] established the possibility of increasing both the UTS and modulus (a generally unachievable combination in macrofilled composites.) Lan et al. [33] established the foundation for the formation of epoxy nanocomposites by setting up the need for epoxy swelling of the clay galleries prior to reaction initiation. Lee and Jang [51] investigated *in-situ* polymerization of epoxy with an emulsified epoxy. They indicated that an approximate 0.5 nm increase in d spacing over the based montmorillonite (001) peak was obtained. Kornmann et al. [37, 52] showed that the demarcation between exfoliated and intercalated dispersions is primarily associated with the nature of the curing agent. They postulated that, first, the clay's high surface energy attracts the polar monomer molecules. Once saturation is reached and the hardener is introduced, the polymerization serves to decrease the polarity of the system adjacent to the clay. To compensate for the decreased polarity, more polar species diffuse to the clay surfaces, pushing the platelets apart, and leading to an exfoliated system. This last aspect is governed by competition between intragallery polymerization and extragallery polymerization, which proceeds at two rates [33]. Kornmann et al. compared three systems of different reactivities. By comparing the slope of the curing peak in the DSC, they showed that the slower the reaction (the smaller the initial slope), the higher the likelihood for an exfoliated nanocomposite. However, decreasing the reaction rate of any curing agent did not increase the likelihood for exfoliation. It is clear that intragallery versus extragallery polymerization—is an active variable. One could decrease the temperature for curing of a highly reactive curing agent to slow the reaction rate; however, then, the migration of the curing agent between the clay galleries would be impeded. Thus, extragallery polymerization would dominate. The migration capability not due to polarity differences between the curing agents (all curing agents had similar polarities), but to the flexibility of the main chain. A supportive case for this argument is the work done by Kong and Park [64]. They associated the increased likelihood exfoliation in a slow reacting DDS agent to its low electronegativity ($pK_a = 2.15$) which provides a medium of low viscosity for the clay layers. PDA with $pK_a = 4$. and MDA with pK_a intermediate between DDS and PDA lead to intercalated and partially exfoliated nanocomposites. Slow curing delays the extragallery gelation, and provides time for intragallery polymerization. Conducting real-time SAXS, they showed that, at room temperature, no change in the diffraction peak of the organoclay is evident even after 1 h. At 50° the DGEBA molecule has sufficient thermal energy, and diffuses into the intergallery of C_{18} clay from the edge to the inner region. The change in d spacing is sudden and not gradual, indicating that the C_{18} amine attached to the edge of the clay interacts with the DGEBA, and changes the configuration from mono- or bislanting to a bilipid perpendicular to the clay surface. The sudden increase in d spacing permits more DGEBA to diffuse into the galleries.

A second increase is associated with the clay layer folding, translating, and expanding from the self-polymerization of DGEBA with the catalytic effect of a protonated C_{18} amine cation. The third increase takes place from the cross linking of epoxy resin with the amine and the amine curing agent in the intergallery region. Jiankun et al. [53] investigated the relationship between the acidic nature of the clay and the generation of intercalated or exfoliated dispersions in epoxy clay nanocomposites. They found that, in the DDM curing agent, the more acidic clay resulted in exfoliated dispersions as opposed to the less acidic clay. Thus, Lan et al.'s prediction was confirmed independently. *In a more acidic clay, the clay is catalytic to the amine curing reaction of the epoxy. The intragallery epoxy polymerization is accelerated, and becomes comparable to that of the extragallery polymerization. The clay can then be exfoliated.*

The case for catalytic activity of the clay was not a contributor to the anhydride-cured completely exfoliated nanocomposites which resulted from both the low and highly acidic organoclays. The difference in the curing chemistry of amine over anhydride curing agents and its influence on intercalation over exfoliation were related more to the viscosity of the amine-curing agents. Thus, in the less acidic clays, the amine was unable to penetrate the galleries since both chemical and physical interactions were restricted. Brown et al. [58] investigated a hydroxyl-substituted quaternary ammonium modifier, and found a high level of exfoliation. The premise is that the catalytic activity of the acidic onium ions is more pronounced when the alkyl chains of the onium ions provide an intragallery hydrophobic environment compatible with both the epoxy polymer precursors and the diamine curing agent [54]. Triantafillidis et al. [54] very recently investigated the use of a difunctional amine. Here, the onium ions act concomitantly as a clay surface modifier, intragallery polymerization catalyst, and curing agent.

Tolle and Anderson [55] investigated the migration of the curing agent into the epoxy-swelled clays using SAXS. They conducted the mixing using the two-stage method at 60°, and then monitored the cure temperature effect on exfoliation and intercalation. They showed that, for the same curing temperature, the purity of the organoclay was critical to developing an exfoliated structure.

3.3. Polymer Solution Intercalation

This method is different from the "*in-situ* polymerization" in that it makes use of a preformed polymer instead of monomer. Polymer solution intercalation is based on a solvent system in which the polymer is soluble and the silicate layers are swellable. The first step is the swelling of clay in a solvent, usually a polar solvent (Fig. 14). Then the polymer, dissolved in the solvent, is added to the solution, and intercalates between the clay layers. The last step is the removal of the solvent by evaporation, normally under vacuum. After solvent removal, the intercalated structure remains.

The driving force for polymer solution intercalation is the entropy gained by desorption of solvent molecules, which compensates for the decrease in conformational entropy

Figure 14. Intercalation of the polymer by the "solution."

of the intercalated polymer chains. Therefore, a relatively large number of solvent molecules need to be desorbed from the clay to accommodate the incoming polymer chains. The advantage of this method is that it offers the possibility of synthesizing intercalated nanocomposites based on polymers with low or no polarity.

The water-soluble polymers, which have been used to make nanocomposites by this technique, are poly(vinyl alcohol), poly(vinyl pyrrolidone), poly(ethylene oxide), poly (ethylene vinyl alcohol), and linear poly(ethylenimine) using water as the solvent. Salahuddin et al. [56] report on the use of acetone in conjunction with a dimethyl benzyl hydrogenated tallow ammonium-chloride-treated montmorillonite. To the suspension of the organoclay and acetone, epoxy and hardener were added. Based on the dispersion scaling that stacks of parallel layers with an average of ten lamellae form a primary clay particle (10 nm), the association of a few particles would lead to a few hundred nanometers, and large-scale aggregates of primary particles form microaggregates of 0.1–10 μm, they determined that the use of acetone resulted in uniform platelet distribution [57]. Even though the dispersion was intercalated, transparency equal to the unmodified epoxy was obtained. The resulting composites containing over 60% MLS had a 100% maximum increase in Vicker's hardness. Brown et al. [58] also used acetone, but their suspension was based on using acetone, organoclay, and epoxy. The concept explored by them was to extend the ability of the epoxy to enter between the platelets in order to enhance the intragallery reaction during the curing stage. Comparing a range of surfactants, they found that bis(2–hydroxy–ethyl) methyl tallow surfactant compatibilizes the diamine/epoxy mixture, resulting in a highly exfoliated nanocomposite, and it also serves to catalyze the epoxy/diamine reaction. A clay-concentration-dependent processing scheme was followed. Epoxy with acetone was mixed with the layered silicates at room temperature. Room-temperature drying and vacuum drying at 90 °C were followed to remove remnant acetone. The curing agent was added at 75 °C, and the mixture was cured. For clay concentrations greater than 10%, 100 psi of vacuum was applied during the cure.

4. CLAY CONCENTRATION EFFECTS

Butzloff et al. investigated the clay concentration effect in epoxies [48]. First, by comparing the reaction between just the montmorillonite and the epoxy to the inclusion of hardener, they determined that the migration of the epoxy between the galleries of the clay prior to introduction of the curing agent was clay concentration dependent. Without hardener, they found that

1. increased clay concentration decreased the epoxy homopolymerization peak substantially (Fig. 15)
2. the slope of the exotherm was clay concentration dependent (Fig. 16).

They also found that the epoxy + clay system showed only one peak compared to two peaks shown in the work of Lan et al. [27]. Lan et al. had attributed this to a difference in the concentration of reactive acidic onium protons inside the nanoclay gallery as compared with the chemical environment outside the gallery. Therefore, Butzloff et al. determined that the single peak observed indicated that the acid protons from inside or outside the nanoclay galleries behaved no differently in the attack of the epoxide ring. It was therefore concluded that the gallery environment in the premix was not sufficiently different to cause the peak-splitting effect observed in the work of Lan et al. This brought up an interesting premix temperature effect on intercalation versus exfoliation since the preparation used by Butzloff et al. was 80 °C with a 1 h shear, whereas the preparation reported by Lan et al was 75 °C with a 24 h shear. No significant change in the area under the curve or enthalpy as a function of composition for the resin was obtained. When hardener was introduced into the epoxy + montmorillonite mixture, there was a significant change in the concentration effect of the montmorillonite on the epoxy. Introduction of 1% montmorillonite by weight decreased the reaction enthalpy, but after that, there is little change in enthalpy, except for a peak value at 2.5% montmorillonite by weight. It was ascertained that at 2.5 wt% montmorillonite, a critical concentration is established, analogous to the critical micelle concentration in surfactant sols. Activation energy and the Arrhenius frequency factor for the nonisothermal kinetic runs both peaked at this concentration. TEM results of the epoxy nanocomposite are shown in Figure 17. The assertion of a 2.5% critical concentration related to charge

Figure 16. Exotherm peak on curing of epoxy + curing agent + clay mix as a function of clay concentration and slope of the exothermal peak.

aggregation was based on observation of the 45° edge–edge interaction seen in the TEM micrographs. Charge nonuniformity due to different layer spacings of adjacent platelet stacks, or tactoids, was indicated as a mechanism for aggregate formation. An interesting change in dispersion was evident at higher clay concentrations. The TEM of the 5% MLS nanocomposite is shown in Figure 18. This micrograph indicates a change to a much more compact parallel arrangement of the intercalated regions of nanoclay. Little or no space between these was left for individual exfoliated platelets. This structure is short range, not long range. It is clearly illustrated in this figure that some regions of parallel cards or intercalated montmorillonite plates have their grains oriented at right angles to others. No flocs or micelle-like structures were observed. All compositions were completely exfoliated. X-ray diffraction patterns for the MLS and composites are shown in Figure 19. The X-ray pattern of the treated montmorillonite clay showed a strong 001 reflection at $2\theta = 72°$, corresponding to the interlayer spacing of the regular stacked nanoclay structure, and the 002 reflection at $2\theta = 8.02°$. Another point made on epoxy nanocomposites in their work was that, since the chemical formula for the nanoclay is not that for an ideal montmorillonite, the 003 ($2\theta = 12.01°$) and 004 ($2\theta = 16.25°$)

**Figure 15.** Epoxy + clay homopolymerization.

reflections are weak for the treated nanoclay [59]. Thus, they performed slower scan speeds, and determined that the 005 ($2\theta = 20.16°$) reflection overlaps a 02;11 band at $2\theta = 19.72°$. This band at $2\theta = 19.72°$ corresponds to a turbostratic stacking disorder common in smectic minerals, and is confirmed by a 20;13 asymmetrical band at $2\theta = 34.84°$ [60]. The critical concentration determined by Butzloff et al. has also demonstrated other phenomena. For instance, the dielectric permittivity–concentration (Fig. 20) and thermal conductivity–concentration (Fig. 21) results show a minima and maxima at the same concentration. The presence of a peak in the property-concentration profile led to a hypothesis that the behavior of the clay within the epoxy resin is similar to a colloid suspension. This was investigated separately by Park et al. [61]. Using an octadodecyl amine montmorillonite, they determined that the organoclays had an effect of decreasing the pH, increasing the Boehm's acid value, or decreasing the base value. Using another analysis by Panzer et al. [62], Park et al. determined that modification of the clay results in an acid value higher than the unmodified clay due to an increase in cation groups on the clay surface or reaction of the –OH groups at the clay surface. Their experimental schedule showed complete exfoliation of the clay in epoxy. A result similar to that was shown by Butzloff and D'Souza [48]. Park et al. analyzed the FTIR spectra of the nanocomposites. Peaks at 1027 and 793 cm^{-1} of MLS

associated with the Si–O vibrations were retained. Comparing pristine and organoclay, a new peak at 3000–2900 cm^{-1} due to the CH$_2$ mode of the epoxy and the disappearance of the 918 cm^{-1} peak of the epoxy ring indicated that the clay interlayer was modified by the octadodecyl amine, and that the epoxy ring was opened by homopolymerization [63]. It has been generally presumed that the influence of the surface treatment of clay is to decrease the hydrophilic nature of clay in favor of hydrophobic. Park et al. compared the contact angle measurements of diiodomethane, ethylene glycol, and water on the treated and untreated clay. They showed that the hydrophilic nature of the clay is retained even after organo treatment. The greater response to diiodomethane indicated that the decreased pH of the untreated clay increased the acid values of the organoclay.

The curing agent effect on exfoliation has been associated with its electronegativity [64]. Kong and Park found that, when DDS was the curing agent, a completely exfoliated system was obtained. One approach to minimizing the amount of organic presence in the epoxy nanocomposite was recently investigated by Triantafillidis et al. [65]. They substituted some organic cation exchange sites with inorganic cations within the same galleries [66, 67]. Such a mixed exchange ion clay was considered "homostructured" because each gallery in the stacked tactoid would be equivalent in composition and intercalation properties. Homostructured mixed-ion clays were distinguished from "heterostructured" clays by the fact that, in the latter, the intercalation properties of each gallery would be different. Further, the state of homostructure versus heterostructure was dependent on

Figure 19. X-ray of the 001, 002, and 004 reflections in the clay and nanocomposite.

Figure 21. Thermal conductivity as a function of MLS concentration showing maxima at 2.5% montmorillonite by weight.

the nature of the inorganic and organic exchange ions, the charge density of the clay layers, and the method used to form the mixed-ion composition. While the thermodynamic driving force would direct the reaction toward segregation into different galleries, trapping of the ions kinetically would permit presence within the same gallery. The key solution presented in the mixed ion homostructure was the ability to develop uniform gallery spacing. Triantafillidis et al. synthesized low-onium-content ions using Jeffamine D2000, which is a long-chain primary diamine. The basal spacing of the clays was independent of the amount of onium ion substitution, indicating that an increased onium ion presence only served to increase chain coiling. Onium ion substitution of both montmorillonite and hectorite was carried out. It was found that only high onium substitutions (above 50% in MLS and 65% in fluorohectite) led to exfoliated nanocomposites.

5. EPOXY NANOCOMPOSITE PROPERTIES

5.1. Flammability

Thermooxidative degradation comparison of epoxy and its nanocomposite have shown that the nanocomposites are inferior to the epoxy at lower temperatures, but at high temperatures, above 400 °C, the nanocomposites fared better [68]. In a departure from the conventional nanocomposite synthesis, Kim et al. [69] investigated intercalating triphenyl phosphate (TPP) into the galleries of a mica-type silicate. A significant improvement in flame retardance in the corresponding epoxy nanocomposite was obtained.

5.2. Glass Transition and Beta Transition Effects

The influence of the clay on the glass transition was investigated substantially, especially in the context of confinement of polymers [70–73]. For controlled pore geometries, they determined two glass transitions related to the liquid plug in the core and an interacting surface layer. A hump in the specific heat plots was indicative of material not confined in the pores. The influence of solvent elution and its influence on the generation of two glass transitions were also reviewed [74]. In epoxy nanocomposites, Butzloff et al. [48] reported no significant influence of the MLS on the glass transition at concentrations below 5%. A substantial drop in glass transition was evident at higher concentrations. No change in the beta relaxation temperature was determined for the same systems. However, recently, Becker et al. [49] investigated the beta transition, and found that a decrease in both the glass transition and beta relaxation (associated with the crankshaft rotation of the hydroxy ether segments of the cross-linked network) decreased with increased clay presence. It is to be noted that their study was on high T_g epoxy resins. The decreased T_g was associated with a decreased density in the epoxy resin. Using organoclay density of 1.6748 g/cm^3 as determined by gas-displacement pycnometry, they found that the actual densities were slightly lower than that of the theoretically predicted. They inferred

that the lower density was related to poorer packing of the polymer molecules near the silicate layers.

Acetone solution polymerized epoxy nanocomposites have displayed no change in the sub-T_g relaxations and minimal changes in the glass transition. A decreased tan δ has often resulted from the introduction of MLS into epoxy [58].

5.3. Thermal Degradation

A critical limitation in using the organically treated clays is considered to be the thermal stability of the organic treatment. For montmorillonite, Xie et al. [75] conducted a detailed analysis of evolution of volatiles in organically modified montmorillonite. For temperatures between 200 and 500 °C organics, CO_2 long-chain alkyl fragments are detected. The surfactant degradation is supposed to present an upper limit to processing temperatures of the polymers they are introduced in. It is to be noted that Ranade et al. [76], investigating another thermosetting nanocomposite processed using the solution polymerization route, determined that, even when the surfactant degradation takes place, the small fraction that it represents need not do any damage to the host polymer. DSC and TGA scans of the as-processed sample showed significant exotherms in the first heating run (taken from 30 to 400 °C). The second scans, however, showed a single glass transition temperature. To determine if the PAI was affected by the surfactant degradation, FTIR was conducted on samples before and after being subjected to 1 h at 400°. There was complete overlap of the spectra, showing no degradation. Thus, they surmise that interacting polymer chains between the clay layers serve not just to shield the polymer as typically inferred, but rather are influenced by the level of intercalation. For a highly intercalated material, the increased solvation between the chains and the end-tethered alkyl ammonium group ensures protection from the alkyl ammonium degradation with the clay acting as barriers for thermooxidative stability.

5.4. Mechanical Properties

The general results for mechanical properties reported are of increased modulus, decreased or retention of ultimate tensile strength, and decreased strain to failure. The compressive strength of epoxies is a significant issue to be considered, while exfoliated and intercalated nanocomposites have demonstrated no significant change in compression [77, 78]. However, the mechanisms of yielding changes from large-scale yielding in unfilled epoxies with no void formation to yielding with shear bands and gradual expansion of these shear bands to cover the entire sample [78]. Fracture toughness increased with clay concentration up to 5%, which was correlated to decreasing distance between particle distance (particle referred to self-aggregated clumps of groups of intercalated clays in the epoxy). The crack propagation front in the unfilled epoxies was straight, but the filled nanocomposites displayed significant crack branching along the length. The creation of new surfaces rather than changes in host matrix deformation was determined to be the leading contributor to the increased fracture toughness. They attributed the intercalated morphology to be a significant

contributor to the increased toughness. Based on a prediction that effective toughening required a particle size not smaller than 0.1 μm [79], they inferred that an exfoliated structure was ineffective in toughening the matrix.

The mechanical properties of nanocomposites prepared by using hectorite, montmorillonite, and fluorohectorite were examined in early work [33]. Relative to the unmodified epoxy, the failure strength and modulus of the hectorite reinforced epoxies improved. Fluorohectorite showed a decrease in failure strength, but an improvement of tensile strength. Montmorillonite, relative to hectorite, showed a higher increase in tensile strength, but a low modulus. No values of failure strain were given.

6. SUMMARY

Epoxy nanocomposites are significantly influenced by the method of processing. Exfoliated and intercalated dispersions are obtained by changing the chemical environment of the clay + epoxy interaction. The strong dependence of the pH of the clay and the critical concentration of the clay + epoxy interaction point to a strong likelihood that the anisotropic charge distribution of the clay is operative in the epoxy. Significant improvements in modulus of the epoxy can be obtained, but the decreased strain to failure is of concern. Ongoing research is now concentrated on translating the nanocomposite technology to composite technology in the form of ternary composites.

GLOSSARY

Clay A family of 2:1 layered- or phyllosilicate materials. The layers made up of two silica tetrahedral fused to an edge-shared octahedral sheet of either aluminum or magnesium hydroxide.

Epoxy A class of thermosetting synthetic polymers containing epoxy groups. Epoxies are used in surface coatings, laminates, and adhesives.

Montmorillonite One of the most commonly used layered silicates having a chemical structure: ($M_{1/3}(Al_{5/3}Mg_{1/3})$ $Si_4O_{10}(OH)_2$). Montmorillonite is miscible with hydrophilic polymers, such as poly (ethylene oxide) and poly (vinyl alcohol).

Nan Phase mixing of atleast two dissimilar materials occurring on a nanometer scale.

CONTENTS

1. INTRODUCTION

The emergence of mesoscopic physics has led to the discovery of many striking new phenomena in solid-state physics in the last two decades [1]. This field is also intimately related to the progress in fabrication techniques: the possibility of creating objects of submicron size has allowed us to fabricate and manipulate conductors which are fully coherent.

In solid-state physics, one usually considers *macroscopic* systems. This term often refers to the notion of the thermodynamic limit: the number of particles N and the volume of the system Ω both tend to infinity, whereas the ratio $n = N/\Omega$ is kept constant [2, 3]. This idea is also closely related to the physical size of the system: the sample is considered as macroscopic as soon as its size is larger than some characteristic length, for example, the typical distance between two particles, $n^{-1/3}$. Below this size, the system is said to be *microscopic*.

It is well known from our daily experience that macroscopic objects obey classical mechanics, whereas microscopic ones are governed by quantum mechanics. This dichotomy between microscopic and macroscopic behavior is quite familiar: small particles exhibit wave-like attributes, and they must be described by quantum mechanics that allows for wave behavior like diffraction or interference. Electrons have been observed to interfere in many experiments in vacuum. However, if one considers a large number of electrons in a disordered medium, like a macroscopic piece of metal at room temperature, the conductivity is described in a classical way *via* the Boltzmann equation, which leads to the Drude formula.

The question is then: is it possible to observe the wave-like behavior of the electrons in a solid? Actually, the characteristic length which is relevant is the length over which the electronic wave keeps a well-defined phase, namely, the *phase-coherence length l_ϕ*. This phenomenon is well known in optics: incoherent light cannot give rise to interference patterns.

At room temperature, the phase-coherence length of an electron in a metal is on the order of a nanometer, roughly the $n^{-1/3}$ factor mentioned above. However, at low temperature, let us say below 1 K, this phase-coherence length increases, and may reach several micrometers in metals or

even more than 10 μm in the highest quality semiconductor heterojunctions. Combined with the progress of fabrication techniques, this allows us to observe the quantum behavior of the electrons in solids. It should be stressed that a micron size sample is, in a sense, really macroscopic when compared to microscopic scales (for example, the interatomic distances): if a mesoscopic sample behaves like a large molecule to some extent, it still contains a rather large number of atoms and electrons (more than 10^{20}). However, as the electronic wavefunction is fully coherent over the whole sample, this sample is really a *quantum conductor* [4, 5].

It is important to point out that the physics of such a system is completely different from the physics of free electrons in vacuum. First, as we said, the sample is macroscopic, and some notions, reminiscent of the standard solid-state physics, are still relevant: the Fermi wavelength, Fermi level, Fermi velocity, or chemical potential still make sense; more importantly the energy spectrum is discrete or, at least, the interlevel spacing $\Delta \approx L^{-d}$, where L is the size of the system and d is the dimensionality, may become comparable or even smaller than the temperature T. Secondly, disorder is still present in solids at the micron scale: thus, the electronic wave propagates in a random medium, and its electronic motion is still diffusive.

It is often tempting to make analogies between interference phenomena in mesoscopic physics and optics. Such a comparison may sometimes be appropriate: for example, the Young slit experiment and the Sagnac effect are very similar to some transport experiments on mesoscopic rings like the Aharonov–Bohm conductance oscillations [6, 7] or the quantization of the conductance, which may be understood in the light of the theory of waveguides [8]. There are, however, two important differences: first, electrons are fermions, and this obviously strongly affects the energy spectra of mesoscopic samples, and consequently their transport and thermodynamic properties; second, electrons are charged particles, and couple to the vector potential of the electromagnetic field. This provides a powerful tool to control interference effects simply by applying a magnetic flux.

This chapter is organized as follows: in the first part, we give the fundamental length scales which are important in mesoscopic physics. We then give an overview of the different materials commonly used in this field. In the second part, we present a comprehensive overview of the different fabrication techniques. Finally, the third part is devoted to the thermodynamics of theses mesoscopic systems.

2. MESOSCOPIC SYSTEMS

2.1. Mesoscopic Samples

2.1.1. Characteristic Lengths

Mean-free path A mesoscopic sample is a disordered sample: even at zero temperature, electrons are scattered by static defects like impurities, grain boundaries, or the edge of the sample. Such events are elastic scattering in the sense that their energy is conserved during the collision. The disorder just acts like a static, random potential which adds to the lattice potential. In such a system, Bloch states are no more eigenstates, but the system is still Hamiltonian. It

should be pointed out that the translational invariance of the crystal lattice is destroyed by such defects, but this usually does not affect the electronic properties of the system. The typical length associated with these scattering processes is l_e, often called the mean-free path. The time associated with these collisions is τ_e, and they are related via the relation $l_e = v_F \tau_e$, v_F being the Fermi velocity.

On the contrary, other collisions are inelastic in the sense that the energy of an electron is not conserved. Such processes are irreversible, and are related to the coupling of the electrons with their environment, that is, other electrons, phonons, or photons. The inelastic length is given by $l_{in} = \min\{l_{e-e}, l_{e-photon}, l_{e-phonon}\}$. At high temperature (typically above 1 K), the dominant mechanism is electron–phonon scattering. At low temperature, however, the dominant process is electron–electron scattering [2, 3].

Another important source of decoherence is electron–photon scattering. This is especially the case in micrometer size samples, where small dissipation (10^{-15} W) is sufficient to heat the conduction electrons at very low temperatures. Extreme care should therefore be taken for external radiofrequency filtering [9–11] when working in the millikelvin temperature range.

Phase-coherence time After an inelastic scattering event, the energy of the electron changes, and the phase of the wavefunction is randomly distributed between 0 and 2π; thus, the quantum coherence is lost, and the phase-coherence time is mainly limited by the inelastic time $\tau_\phi \approx \tau_{in}$. It is important to note, however, that elastic scattering also leads to dephasing: the wavevector $\vec{k}$ changes to $\vec{k'}$ after such a diffusion; elastic scattering implies only that $|\vec{k}| = |\vec{k'}|$, but there is a priori no condition on their respective directions. The point is that this dephasing is perfectly deterministic and reproducible: two successive electrons with the same wave vector $\vec{k}$ will be scattered and dephased in exactly the same way, which could be calculated if the scattering potential were known. The phase coherence is thus preserved, and interference effects are not destroyed. On the contrary, inelastic scattering depends on the state of the environment the electron interacts with at the time of the interaction. In this case, the dephasing is random, and the phase coherence is lost. This is why, at room temperature, the dominant scattering process is the electron–phonon scattering, and the phase-coherence length is very short, typically $l_\phi \approx 1$–10 nm. In the frawework of Fermi liquid theory, the available phase space at low temperature tends to zero. As a consequence, electron–electron, electron–photon, and electron–phonon couplings all tend to zero, and hence, the phase-coherence length should diverge [12]. Recent experiments, however, seem to show that this is not the case. Presently, there is still an ongoing debate concerning this point, and we will not address this issue in this chapter [13].

Finally, it is important to mention magnetic impurities. As they are static defects at low temperature, scattering by magnetic impurities is elastic as the energy of the electron is conserved. However, the electronic spin is flipped in such a collision, and the phase coherence may be lost. The exact effect of magnetic scattering on the phase coherence time, especially when entering the Kondo regime, is far from being understood [14]. In this chapter, we will not elaborate on this

point, and will consider only systems containing no magnetic impurities.

Thermal diffusion length and the Thouless energy   At distances beyond the elastic mean-free path l_e, electrons propagate in a random medium. This diffusive nature of the movement is characterized by the diffusion coefficient $D = (1/d)v_F^2\tau_e = (1/d)v_F l_e$, where d is the dimensionality of the sample. To propagate over a distance L, an electron then needs a diffusion time $\tau_d = L^2/D$. In a semiclassical picture, each diffusion path l is characterized by a probability $\Psi_l = |\Psi_l| \exp(iS_l/\hbar)$, where $S_l = \int_l \vec{k} d\vec{l} - Et_l$, with E being the energy of the electron and t_l the diffusion time along the path l. Over the whole sample of size L, this diffusion time is then simply τ_D. If one considers an energy range larger than $2\pi\hbar/\tau_D$, the phase of the electrons in this energy range will be distributed between 0 and 2π, and interference effects will not be observable anymore. This defines the Thouless energy (or correlation energy) $E_c = h/\tau_D = hD/L^2$. When the energy range involved is larger than E_c (e.g., when $k_B T \geq E_C$), interference effects do *not* disappear; they are simply no longer observable [15]. If the size of the sample is smaller than l_e, the time for an electron to travel across the sample becomes simply L/v_F, and the Thouless energy simply expresses as $E_c = hv_F/L$.

2.1.2. Disorder Configurations

In a macroscopic sample, one usually characterizes the disorder by some characteristic length, say the elastic mean-free path l_e. Such a parameter is relevant when considering the disorder from a "global" point of view. From a mesoscopic point of view, things may be quite different: the electronic wavefunctions are fully coherent over the whole sample, and the acquired phase depends on the precise path one electron follows. Thus, the interference pattern depends on the *microscopic* disorder configuration of the sample. Moving even a single impurity drastically affects the electronic properties of the sample. That is why two samples identical from a macroscopic point of view may behave in a completely different way due to their microscopic individuality (their *fingerprints*). This phenomenon is equivalent to the speckles observed when a coherent light beam diffracts in a random medium.

2.1.3. Quantum Coherence and the Effect of Aharonov–Bohm Flux

The most important parameter that physicists can use to probe a mesoscopic sample is the magnetic flux. As an electron is a charged particle, it couples to the vector potential $\vec{A}$ (the momentum changes as $\vec{p} \rightarrow \vec{p} + e\vec{A}$ in the Hamiltonian, with e the charge of the electron) *even if the magnetic field $\vec{B}$ is zero* ($\vec{B} = \vec{\nabla} \times \vec{A} = \vec{0}$). Note, however, that as the field is zero, or at least very weak in all of the experiments,[1] the effect of the magnetic field on the trajectories of the electrons is negligible. When propagating along a path i, the wavefunction Ψ acquires a phase simply given by

$S = \int_i (\vec{k}(\vec{r}) + e\vec{A}(\vec{r})) d\vec{r}$. The first term is simply the equivalent of the optical path, whereas the second one characterizes the quantum coupling of the charge with the magnetic flux. This shows how applying a small magnetic field can indeed control the interference pattern of a mesoscopic sample [16]. There is no equivalent of such a possibility in optics: this is a powerful way to play with the quantum, wave-like nature of the electrons.

2.2. Materials

2.2.1. Ballistic Versus Diffusive Versus Localized

The different length scales for a mesoscopic sample are the Fermi wavelength λ_F, the elastic mean-free path l_e, and the size of the sample L. The ratio between λ_F and l_e characterizes the strength of the disorder: for $\lambda_F \ll l_e$ (or, equivalently, $k_F l_e \gg 1$ or $h/\tau_e \ll E_F$), the disorder is said to be "weak," whereas for $k_F l_e \ll 1$, the disorder is said to be "strong."

Considering the ratio between these different length scales, one can distinguish different regimes for a mesoscopic sample.

Ballistic regime ($\lambda_F \ll l_e$ and $L \leq l_e$)   In this regime, the disorder is very weak, and the elastic mean-free path is on the order of the size of the sample. In this case, the phase coherence length is mainly limited by electron–electron collisions. The trajectories of the electrons is mainly governed by the shape of the sample, implying that the reflections at the edges of the samples are specular. In this case, transport properties as well as equilibrium properties depend on the shape of the sample. Such systems are powerful tools to probe the energy spectra of quantum billiards.

Diffusive regime ($\lambda_F \ll l_e \ll L$)   In such systems, electrons experience a large number of collisions during the traversal of the sample. Their movement is rather a Brownian motion, a random walk between impurities. The phase coherence length is then given by $l_\phi = \sqrt{D\tau_\phi}$. In this regime, the exact shape of the sample does not affect its electronic properties; only its size is relevant.

Localized regime   In the case of a strong disorder, Anderson has suggested that each electron is confined in a part of the sample, and cannot travel through it: its wavefunction is exponentially decreasing on a length scale ξ, and the electron is localized in a domain of size ξ^d, with d the dimensionality of the sample, and the sample becomes an insulator [17]. For $d = 3$, there is a critical value for the disorder below which the sample becomes insulating, and one observes a metal-to-insulator transition. For $d = 1$ and $d = 2$, on the other hand, electrons are localized for an arbitrary small disorder [18]. Recent experiments, however, show that there is indeed a metal-to-insulator in some two-dimensional electron gas. As both the experimental and theoretical situations are at least unclear, we will not address this topic in this chapter [19].

Two limits are then to be considered[2]: when $\xi \prec L$, electrons are confined in some regions of the sample, and

---

[1] Except in the case of the quantum Hall effect, which we will not address in this chapter.

[2] Note that one always has $\xi \geq l_e$.

conduction occurs by hopping from domain to domain. On the other hand, when $\xi \succ L$, localization domains are larger than the sample: electrons are indeed localized, but they can still explore the whole sample.

2.2.2. Dimensionality

One defines the dimensionality of a sample by comparing its size with the intrinsic characteristic lengths [20]. Usually, the most relevant length scale is the Fermi wavelength. Considering a rectangular sample of sizes L_x, L_y, and L_z, with $L_x \prec L_y \prec L_z$, one has

$$\lambda_F \ll L_x \prec L_y \prec L_z: \text{3D (bulk samples)}$$

$$L_x \leq \lambda_F \ll L_y \prec L_z: \text{2D (films)}$$

$$L_x \prec L_y \leq \lambda_F \ll L_z: \text{1D (quantum wires)}$$

$$L_x \prec L_y \prec L_z \leq \lambda_F: \text{0D (quantum dots)}$$

Such a definition is certainly the most relevant from a microscopic point of view. Note, however, that when considering transport properties, and due to the quantum nature of a mesoscopic conductor, one can also define the dimensionality of a sample by comparison with the phase-coherence length:

$$l_\phi \ll L_x \prec L_y \prec L_z: \text{3D}$$

$$L_x \leq l_\phi \ll L_y \prec L_z: \text{2D}$$

$$L_x \prec L_y \leq l_\phi \ll L_z: \text{1D}$$

2.2.3. Metals

Metals have a high charge carrier density of about $10^{22}\,\text{cm}^{-3}$. Because of this high carrier density, the Fermi wavelength is very short, in the range of the angström. Moreover, it is impossible to use gates to modulate this electron density (a too important voltage would be necessary in the case of metals). Another consequence is that the Coulomb interaction is very efficiently screened on the scale of the Thomas–Fermi vector $q_{TF} = 2\pi e^2 / \rho_0$, with ρ_0 the carrier density at the Fermi level. Even if metals can be very pure from a chemical point of view, the intrinsic disorder usually makes them diffusive conductors. The elastic mean-free path l_e is on the order of 1–100 nm, and the phase coherence length l_ϕ is on the order of a micrometer.[3]

At low temperature, some metals become superconductors. This provides a new degree of freedom and a wide variety of mesoscopic effects. In particular, the superconducting state is quite different on a mesoscopic scale as compared to its macroscopic equivalent.

2.2.4. Semiconductors

Bulk semiconductors   In semiconductors, the carrier densities can range practically between 10^{14} and $10^{19}\,\text{cm}^{-3}$. Moreover, this density can be controlled using metallic gates deposited at the surface of the sample or simply by varying the doping concentration.

In the case of very pure semiconductors, for example, those obtained by molecular beam epitaxy, the elastic mean-free path is basically limited by the distance between two doping impurities. This leads easily to l_e of ≈ 100 nm, whereas l_ϕ is on the order of several micrometers. Finally, another important difference between metals and semiconductors is that, in the latter, the effective mass of the electrons, which is related to the band structure, can be very small.

Heterojunctions   To reduce the dimensionality of a conductor, one may reduce the thickness of the film itself. However, it is quite difficult to obtain real two-dimensional conductors on the scale of the Fermi wavelength λ_F. An alternative way consists of playing with the band structure of two different semiconductors. Using the impressive control of growth offered by the molecular beam epitaxy, it is possible to grow two different semiconductors on top of each other, especially if their lattice parameters are matched [21]. The most common example is GaAs and GaAlAs (III–V heterostructures), but there also exist II–VI heterostructures (CdTe/HgCdTe) or even IV–IV heterostructures (SiGe).

The different band structure, mainly the energy gap and the work function,[4] causes changes in the charge transfer between the two adjacent materials in order to equalize the electrochemical potentials. Electrons are attracted to the remaining holes, and the dipole layer formed at the interface leads to the band bending at the vicinity of the interface. True two-dimensional electron (or hole) gas at the scale of λ_F can be formed using this technique [22].

The spatial separation between charge carriers and doping impurities leads to very high-mobility materials.[5] The electronic density is typically in the range of $10^{11}\,\text{cm}^{-2}$, leading to a relatively large Fermi wavelength, on the order of 300 Å. This large Fermi wavelength allows us to create easily true 1D or 0D structures. Moreover, the use of electrostatic gates on the top of the sample allows us to deplete the 2D electron gas underneath. Using this technique, one can modulate *in-situ* and in a reversible way the shape of the 2D electron gas, allowing us to create a wide variety of quantum devices, like quantum wires or quantum dots [20]. Moreover, the edges defined by electrostatic gates are by far less rough than those produced by etching techniques.

3. SAMPLE FABRICATION TECHNIQUES

3.1. The Size to Reach

Typically, one wants to be able to tailor samples with a size smaller than 1 μm. But the smallest size is not the ultimate goal since the roughness of the edge may play an important role. In metals, the Fermi wavelength λ_F is very short, and the roughness is always much larger than the Fermi wavelength. But in semiconductor samples, where λ_F can be several tens of nanometers, the roughness can be on

---

[3] In extremely clean metals, obtained by molecular beam epitaxy (MBE), the phase-coherence length can reach $\approx 20\,\mu$m at best.

[4] For example, in GaAlAs [23, 24], the gap E_g varies linearly with the concentration of aluminum as $E_g = 1.424 + 1.247x$ at 300 K, x being the concentration in aluminum. Moreover, the mismatch in the lattice parameter does not exceed 0.3%.

[5] The highest mobility achieved in GaAs-GaAlAs heterostructures [25] is $14 \cdot 10^6\,\text{cm}^2 \cdot \text{V}^{-1} \cdot \text{s}^{-1}$. Mobilities of $\approx 10^6\,\text{cm}^2 \cdot \text{V}^{-1} \cdot \text{s}^{-1}$ are currently achieved in this material.

the same order. In this case, one wants the edges to be defined with a precision much smaller than λ_F. As discussed in the previous paragraph, the dimensionality of the sample depends strongly on the physics involved. For interference effects, the phase-coherence length is the characteristic length which is on the order of 1 nm at low temperatures for a good metal and more than 10 μm for high-quality 2DEG. So typically, one wants to be able to fabricate samples with a width smaller than 100 nm for metal structures and a few hundred nanometers for semiconducting ones.

3.2. Nanofabrication Technique

First of all, let us recall a standard process flow. Figure 1 resumes the main steps one must follow. The starting material is the substrate, which can be the system one wants to pattern or just a flat and neutral surface used as a support. By spinning, the substrate is coated with a layer of resist.

The resist is a material sensitive to irradiation. After exposure, the resist is developed, and the exposed (nonexposed) area will be cleared off for the case of positive (negative) resist. A rich variety of processes can be done after the lithography. A commonly used process is the lift-off technique. In this case, one covers the whole patterned substrate with a metal, for instance. The resist is then completely removed by rinsing it with a strong solvent. Only the part which had been previously patterned will be covered by the metal, so one may say that we have replaced the design on the resist by a solid pattern made of metal. This metal can be just the structure wanted or can be used as a mask for a subsequent etching process. Other processes can also be used, such as ion implantation, electrochemical growth, and so on.

3.3. Optical Lithography

Optical lithography is the dominant lithography in industry. With this technique, UV light is shed through a mask, which contains the drawing information, on a resist. The
Figure 1. Typical flowchart for a fabrication process.

resolution is mostly limited by the diffraction, and hence depends on the wavelength of the light. This explains why short wavelengths are employed. Optical lithography, which started with UV (400–366 nm) is now in the DUV range (248–193 nm), and EUV (13 nm) is the next predicted range. DUV lithography can reach the sub-100 nm range, but with a complexity and costs which are too high for any scientific laboratory. For instance, the complexity of masks which use phase-shift techniques to overcome diffraction makes them difficult, and hence very expensive, to produce. Only mass production can afford such high costs. Refractive optics are presently not available in the EUV range. The fabrication of reflective optics at this wavelength is also very delicate, and it is hopeless that this technique will be inexpensive for laboratory use. Classical optical lithography, on the other hand, which uses a quartz plate mask directly pressed onto the resist with a standard DUV light, is not able to produce samples with a sub-100 nm resolution.

3.4. Electron-Beam Lithography

The possibility to finely focus an electron beam has been exploited in electron microscopy for a long time. Starting in the 1960s, focused electron beams have been used to expose a resist, and a 0.1 μm resolution was readily obtained. Ten years later, a 10 nm wide line was demonstrated using an inorganic resist. Unfortunately, this technique is essentially sequential: the electron beam is scanned pixel by pixel on the resist to draw the entire design; hence, the process is too slow to be included in an industrial processes. It is, on the other hand, the perfect technique for the laboratory. An advantage of this maskless technique is its versatility. The drawing can be easily changed on a computer with no additional cost.

In the following, we detail the electron-beam lithography to explain the resolution and limitations of this technique.

3.4.1. Resolution and Proximity Effect

Most of the resists employed in nanotechnology are polymers. The effect of the electron is to break the chain, hence leaving a polymer with a small chain, giving a better solubility. This resist is then sensitive to a very small energy compared to the one of the electron beam. Typically, one needs 10 eV to break a polymer chain, whereas for technical reasons, the focused electron beam is accelerated at several tens of kilovolts. It is then important to know how the electrons diffuse into the resist and lose their energy in order to understand how the resist is affected.

An analytical treatment is quite complex, especially in three dimensions. Monte Carlo simulations are widely used to follow the electron trajectory. Figure 2 shows electron trajectories obtained for electrons with energies of 10 and 20 kV in a silicon substrate covered with 400 nm of PMMA resist. The effects of electron diffusion are twofold. First, a forward diffusion which enlarges the spot in the resist is observed. Second, a backscattering diffusion, mainly from electrons diffused in the substrate back into the resist, but far from the initial impact of the electron, takes place. This latter effect, known as the proximity effect, has important consequences, as we will see later. The energy of the beam is quite important, as can be seen in Figure 2: higher energy
Figure 2. Monte Carlo simulation of electron trajectories in silicon substrate covered with PMMA at 10 and 20 keV. Adapted with permission from [28], D. F. Kyser and N. S. Viswanathan, *J. Vac. Sci. Technol.* 12, 1305 (1975). © 1975, Vacuum Society.

Figure 3. Resolution and sensitivity of various organic resists positive and negative for electron-beam lithography. Polymethylmetacrylate (PMMA) is presently the best organic resist, and is most widely used in scientific laboratories around the world. An example of sub-10 nm lines of PMMA with a 50 nm pitch is shown in Figure 4.

decreases the forward scattering angle and shrinks the effective beam spot. On the other hand, the electrons penetrate more deeply into the substrate as their energy increases, and are backscattered at larger distances from the impact. In other words, higher energy dilutes the proximity effect. This is the reason why recent electron-beam machines use a 100 kV source.

The total dose received by the resist at one point depends on the exposed dose at that point, but also on the vicinity around this point. Hence, a large square uniformly exposed, for instance, will be more dosed in the center than on the edge. It is also very difficult to expose two large patterns close to each other. The gap between these two patterns being exposed by proximity may result in an unwanted connection between them. Arrays of lines with a very small pitch are also very difficult. It is possible, however, to correct the dose at each point by calculating the proximity effect of the overall pattern. Softwares have been developed for that purpose, but cannot completely cure the effect of the diffusion since it may require a negative dose at certain points!

The problem of proximity effect arises from the sensitivity of organic resists to small energies. It is thus natural to try to use a resist which needs higher energy to be exposed. This is the case of an inorganic materials, for example, NaCl, AgF_2, or Al_2O_3. Such inorganic resists have been used to demonstrate the finest lines obtained by e-beam lithography, around 1 nm. The beam energy in that case gives rise to the partial or total sublimation of the resist. For instance, on AlF_3, the electron energy evaporates fluor, leaving a layer of aluminum. Hydrocarbon films have also been used where, under irradiation, a polymerization takes place. In most cases, the dose necessary to expose these types of resists is orders of magnitude higher than with a conventional resist. The total time to expose the pattern can reach nonreasonable values. Furthermore, this type of resist can be used only with thin layers which enable any lift-off process. Another possibility to avoid proximity effects is to use a very small energy. In this case, however, it is very difficult to focus the beam in conventional electron optics due to chromatic aberration. Another drawback is the forward scattering which rapidly enlarges the beam in the resist.

Figure 3 shows the best resolution obtained with different organic resists and the dose needed with e-beam lithography. One should keep in mind that the maximum current available in an e-beam system with a small spot size (less than 10 nm) is about 100 pA with a field effect gun source. This means that exposing an area of 100 μm × 100 μm at a nominal dose of 10^{-1} C/s takes more than 27 h!

An electron microscope with a computer-assisted deflection system is the basic tool for e-beam lithography. It is enough to make simple patterns in a single field. The available field size depends on the desired resolution. Lens aberrations induce severe distortions at the edge of the field which depend on the field size. With a conventional microscope, 50 μm × 50 μm is usually the maximum size one can afford to produce sub-100 nm structures. The nanostructure then has to stand within a single field since there is no possibility to displace the sample holder with enough accuracy to stitch with the previous writing field. The stability of the electron column is also a problem for long time exposure. Dedicated machines have been built to overcome the difficulties mentioned above with conventional electron microscopes. They include a laser-interferometry-controlled stage with an accuracy better than 1 nm to measure mechanical displacement. A feedback to the electron deflection is usually chosen for the field alignment. The overall field stitching accuracy is on the order of 20 nm. Using patterned marks on the sample, it is also possible to align several layers of lithography. The mark detection system combined with the laser interferometry also allows us to calibrate the deflection amplifier and to correct field distortion. It is simply done by moving a mark at different positions in the field. The exact position of the mark is known using the laser interferometry, and is compared to the position of the mark obtained by deflecting the beam. All of these essential features explain that there is at least one order of magnitude in the price of such a machine compared to a standard electron microscope.

3.5. Other Charged Particle Lithography

Focused ion beam lithography arose rapidly after electron-beam lithography as a good candidate for nanofabrication. Ions offer several advantages compared to electrons. First,
Figure 4. The image shows an example of sub-10 nm lines with a 50 nm pitch. Reprinted with permission from [26], C. Vieu et al., *Microwave Elect. Eng.* 35, 253 (1997). © 1997, American Institute of Physics.

they very quickly deliver their energy, and consequently, a much smaller dose is necessary. Second, the throughput is much better, and the proximity effect is much smaller. In addition, ions can directly erode the material, and is a resist-free process which can be very interesting for materials which are sensitive to pollution by organic materials.

In this etching mode, by varying the dose, it is also possible to produce three-dimensional structures: the paradigm of nanofabrication. Finally, at higher energy, one can locally implant atoms. On the other hand, ion lithography did not take an important place among the nanofabrication techniques. The major reason is the difficulty in producing fine spots with enough current and good stability. Recent progress in ion optics and ion source technology succeed in producing sub-10 nm spot sizes with a particle density sufficient for etching. Figure 5 shows an 8 nm line produced by such a high-resolution ion system [27].

3.6. Near-Field Techniques

Shortly after their discovery, near-field techniques have been used to produced nanostructures. The ultimate resolution has been obtained by the IBM group, who wrote the acronym of their company using Xenon atoms with a scanning tunneling microscope (STM). But such nanostructures are unfortunately very volatile. An STM can also be used in a more conventional way as a source of focused electrons. Indeed, the size of the electron spot of an STM is approximately on the order of the sample-to-tip distance, and a 10 nm spot size can readily be obtained.

Exposure of the resist is complicated by the fact that most of the resists are nonconducting. Another problem due to the proximity of the tip to the resist is the swelling of the resist under irradiation that can damage the tip. STM lithography is used more without resist by electrochemical process. For instance, it is possible to remove a group of atoms by applying a pulse on a gold surface [31]. Local oxidation is also an electrochemical process that is widely used with atomic force microscopy (AFM) lithography. The native water film on the surface of a sample at room temperature is the medium for this anodization process. In GaAlAs/GaAs samples, it is possible, for instance, to locally oxidize the surface, and the oxide formation destroys the two-dimensional electron gas beneath. Several mesoscopic structures have been produced with this technique [32]. Another example is the use of niobium, which can be anodized [33]. One of the advantages of this technique is that, using a small voltage on the tip, one can visualize the structures obtained at a higher voltage. Usually, one is limited to a small writing field because of the hysteresis of the piezodisplacement. In most cases, this technique is combined with other techniques like optical lithography. The possibility of visualization, with the AFM in the nonwriting mode, allows for the alignment of the two steps.

4. PERSISTENT CURRENTS: THEORETICAL ASPECTS

Usually, one considers *transport* properties of quantum conductors, measured by connecting voltage and current probes to the sample. In this case, however, two important properties of such a measurement must be pointed out.

- First, the strong coupling between these voltage and current probes certainly affects the quantum properties of the sample, and thus the measurement itself.
- Second, in a transport experiment, one only probes an energy range eV around the Fermi energy, with e being the electron charge and V the applied voltage. That is why one cannot access the entire energy spectrum

It is therefore very interesting to deal with the *equilibrium* properties of mesoscopic samples. It has to be stressed that such experiments in the field of mesoscopic physics are by far much more difficult than transport experiments. This is why there is only a very small number of experimental data available.

The existence of persistent currents was first suggested by London in 1937 [34], in his studies on the diamagnetism of aromatic rings (benzene rings). In 1938, Hund suggested

that such an effect could be present in clean, metallic samples at low temperature [35]. The amplitude of the persistent currents was first calculated by Bloch and Kulik in the case of a clean, 1D ring [36, 37], but their existence in a real, diffusive 3D metallic ring was only been predicted by Büttiker et al. [38] in 1983.

It is important to note that the persistent current we are considering here is a *nondissipative* current flowing in a *nonsuperconductor* ring. Another interesting point is that persistent currents and orbital magnetism are two phenomena completely equivalent from a physical point of view. Only the geometry of the sample makes one term or the other more "intuitive."

4.1. A Simple Picture: The 1D Ballistic Ring

The simplest model for the persistent currents is the case of a pure, 1D metallic ring, without disorder. Although somewhat "academic," this example allows us to present the main idea of the problem. Let us consider a ring of perimeter L pierced by a magnetic flux Φ. We take the ring to be smaller than the phase-coherence length l_ϕ, and we neglect its self-induction. The Hamiltonian for the electrons of the rings is then simply given by

$$\mathcal{H} = \frac{1}{2m}[\vec{p} - e\vec{A}]^2 + V(\vec{r}) \tag{1}$$

where $\vec{p}$ is the momentum of the electron, e is its charge, $\vec{A}$ is the vector potential, and $V(\vec{r})$ is the periodic potential of the lattice. A simple gauge transformation $\vec{A} \Rightarrow \vec{A} + \vec{\nabla}(\int \vec{A} \cdot d\vec{l})$ leads to the Hamiltonian of free electrons $\mathcal{H}_0 = p^2/2m + V$, whereas a phase is added to the wavefunction Ψ: $\Psi(x) \Rightarrow \Psi(x)\exp(ie/\hbar \int \vec{A} \cdot d\vec{l})$. This wavefunction then obeys the new boundary conditions [39]

$$\Psi(x+L) = \Psi(x)\exp\left(i\frac{e}{\hbar}\oint \vec{A} \cdot d\vec{l}\right) = \Psi(x)\exp\left(2i\pi\frac{\Phi}{\Phi_0}\right) \tag{2}$$

where $\Phi_0 = h/e$ is the flux quantum. These boundary conditions also lead to a new quantization for the wave vector: $k = 2\pi/L(n + \Phi/\Phi_0)$.

It should be noted that, in this case, the boundary conditions can be controlled simply by varying the magnetic flux. Moreover, such boundary conditions show that wavefunctions, eigenenergies, as well as *any thermodynamic property of the system are periodic with magnetic flux [40]*, with periodicity $\Phi_0 = h/e$.

In analogy with known results on Bloch's states, one can define a velocity for each energy level [38–41]:

$$v_n = \frac{1}{\hbar}\frac{\partial \varepsilon_n}{\partial k} = \frac{L}{e}\frac{\partial \varepsilon_n}{\partial \phi} \tag{3}$$

This velocity is equivalent to a current which is given by

$$i_n = -\frac{ev_n}{L} = -\frac{\partial \varepsilon_n}{\partial \phi} \tag{4}$$

At zero temperature, the net current is then simply the sum of the currents carried by the N levels:

$$I_N = \sum_{n=0}^{N} i_n = \sum_{n=0}^{N} -\frac{\partial \varepsilon_n}{\partial \phi} = \frac{\partial E(N, \Phi)}{\partial \phi} \tag{5}$$

where E is the total energy of the N electrons of the ring. However, as can be seen in Figure 6, two consecutive levels carry two currents of the same amplitude, but of opposite sign: the net current is then simply given by the last occupied level [47], that is, the Fermi level. We thus obtain for the amplitude of the persistent current

$$I_0 = \frac{ev_F}{L} \tag{6}$$

In this expression, v_F/L is simply the time needed for an electron to perform one turn around the ring. It should be noted that this expression can be rewritten as a function of the Thouless energy hv_F/L:

$$I_0 = \frac{ev_F}{L} = \frac{hv_F}{L}\frac{e}{h} = \frac{E_c}{\phi_0} \tag{7}$$

It should be stressed that the persistent current depends strongly on the number of electrons in the ring and on its parity, both in amplitude as well as in sign: for N

Figure 6. Energy spectrum of a pure, ballistic one-dimensional ring as a function of the magnetic flux.

even, the current is paramagnetic, whereas for N odd, it is diamagnetic.[6]

This very simple approach for the pure 1D ring allows us to give a good estimate for the order of magnitude of the persistent current. Moreover, the main features, such as the dependence on the parity of the number of electrons, remain true, even in the more realistic 3D, disordered ring.

4.2. Realistic Ring

4.2.1. Introduction

In this section, we will consider the case of diffusive, 3D rings. As we have stressed above, each sample is unique due to its specific disorder configuration. To take into account this unicity, we will consider a large number of rings, which is equivalent to averaging over disorder configurations: one obtains the *average current*. As we will see, this average current is measured in many-ring experiments. Fluctuations from this average value are also of interest, as they are accessible experimentally: this is called the *typical current*. This typical current is a good approximation of the current measured in single-ring experiments.

Another important property of the 3D case is the *spectral rigidity*. In 1D, we have seen that two successive energy levels have opposite slopes. In 3D, two successive levels repel each other: this correlation between energy levels leads to a correlation in the slopes of the energy levels [43], as can be seen in Figure 7. The slopes of two successive levels are almost identical, and this correlation extends over an energy range corresponding to the Thouless (or correlation) energy E_c. In other words, it is necessary to explore an energy range E_c to find a level of opposite slope [44, 45]. An important consequence of that is that the sign of the persistent current still depends on the number of electrons, but one has to add E_c/Δ electrons, with Δ being the mean level spacing, to reverse the sign of the persistent current [46].

4.2.2. Noninteracting Electrons

Average current The calculation of the average current [47] raises an interesting problem of statistical physics. In an experiment on many rings, the number of electrons in each ring is fixed, whereas the chemical potential μ is not. We are thus dealing with the *canonical* ensemble [48, 49]. This point is very important, as it has been shown that the persistent current calculated in the grand canonical ensemble (μ fixed) is exponentially small, $I \approx \exp(-L/2l_e)$.

On the other hand, the calculation in the canonical ensemble can be related to the calculation in the grand canonical ensemble, which is much easier to perform [1]. The canonical average persistent current is given by [50]

$$\langle I_N \rangle = -\frac{\partial \langle \mathcal{F} \rangle}{\partial \Phi}\bigg|_N = -\frac{\partial \langle \Omega \rangle}{\partial \Phi}\bigg|_\mu \qquad (8)$$

where N is the number of electrons, $\mathcal{F}$ is the free energy, Ω is the grand potential, and Φ is the magnetic flux. With μ being the sample and flux-dependent chemical potential,

[6] This is the case for aromatic rings: for benzene ($N = 3$), for example, the persistent current is diamagnetic.
Figure 7. Energy spectrum of a real, three-dimensional diffusive ring as a function of the magnetic flux. Adapted with permission from [50], G. Montambaux, in "Quantum Fluctuations," 1996. © 1996, Elsevier Science.

one can then expand the expression (8) as a function of $\delta\mu(\phi) = \mu(\phi) - \langle\mu\rangle$, where $\langle\mu\rangle$ is flux independent:

$$-\frac{\partial \langle \Omega \rangle}{\partial \phi}\bigg|_\mu = -\frac{\partial \langle \Omega \rangle}{\partial \phi}\bigg|_{\langle\mu\rangle} - \delta\mu(\phi)\frac{\partial}{\partial\mu}\frac{\partial \langle \Omega \rangle}{\partial \phi}\bigg|_{\langle\mu\rangle} \qquad (9)$$

$$= -\frac{\partial \langle \Omega \rangle}{\partial \phi}\bigg|_{\langle\mu\rangle} - \delta\mu(\phi)\frac{\partial}{\partial \phi}\frac{\partial \langle \Omega \rangle}{\partial \mu}\bigg|_{\langle\mu\rangle} \qquad (10)$$

The first term is simply the grand canonical current, which is exponentially small, and will be neglected. The term $\partial\langle\Omega\rangle/\partial\mu$ corresponds to the number of electrons. Using the relation $\delta\mu = -\delta N \partial\mu/\partial N|_\phi$, we obtain

$$\langle I_N \rangle = -\frac{\partial\mu}{\partial N}\bigg|_\phi \left\langle \delta N \frac{\partial N}{\partial \phi}\bigg|_{\langle\mu\rangle} \right\rangle \qquad (11)$$

where $\partial\mu/\partial N|_\phi$ is the level spacing. Finally, one obtains [52–55]

$$\langle I_N \rangle = -\frac{\Delta}{2}\frac{\partial}{\partial\phi}\langle \delta N_\mu^2 \rangle \qquad (12)$$

The number of electrons is simply given by $N = \int_{-\varepsilon_F}^0 \rho(\varepsilon)d\varepsilon$. The fluctuation in the number of electrons is

given by

$$\langle \delta N_\mu^2 \rangle = \langle (N - \langle N \rangle)^2 \rangle$$

$$= \left\langle \int_{-\varepsilon_F}^0 (\rho(\varepsilon) - \rho_0) d\varepsilon \int_{-\varepsilon_F}^0 (\rho(\varepsilon') - \rho_0) d\varepsilon' \right\rangle$$

$$= \int_{-\varepsilon_F}^0 \int_{-\varepsilon_F}^0 (\langle \rho(\varepsilon)\rho(\varepsilon') \rangle - \rho_0^2) d\varepsilon d\varepsilon'$$

$$= \int_{-\varepsilon_F}^0 \int_{-\varepsilon_F}^0 K(\varepsilon, \varepsilon') d\varepsilon d\varepsilon'$$

where $K(\varepsilon, \varepsilon')$ is the two-point correlation function of the density of states. The average current is then given by

$$\langle I_N \rangle = -\frac{\Delta}{2} \frac{\partial}{\partial \phi} \int_{-\varepsilon_F}^0 \int_{-\varepsilon_F}^0 K(\varepsilon, \varepsilon') d\varepsilon d\varepsilon' \quad (13)$$

It has been shown [56] that the spectral form factor $\widetilde{K}(t)$ can be related to the return probability to the origin $P(t) = P(\vec{r}, \vec{r}, t)$:

$$\tilde{K}(t) = \frac{1}{4\pi^2} t P(t) \quad (14)$$

which leads to

$$\langle I_N \rangle = -\frac{\Delta}{4\pi^2} \frac{\partial}{\partial \phi} \int_0^\infty \frac{P(t)}{t} dt \quad (15)$$

This return probability contains two terms: the first one is flux independent, and will be ignored. The interference term $P_{\text{int}}(t)$ can be expressed as a function of the winding number of the different trajectories m:

$$P_{\text{int}}(t) = \sum_{m=-\infty}^{\infty} P_m(t) \cos\left(4\pi m \frac{\phi}{\phi_0}\right) \quad (16)$$

Inserting this into Eq. (15), one obtains

$$\langle I_N \rangle = \frac{2}{\pi} \frac{\Delta}{\phi_0} \sum_{m=1}^{\infty} m \sin\left(4\pi m \frac{\phi}{\phi_0}\right) \int_0^\infty \frac{P_m(t)}{t} dt \quad (17)$$

Knowing the expression for $P_m(t)$: $P_m(t) = 1/\sqrt{4\pi D t} \times \exp(-(m^2 L^2/4Dt))$, one finally obtains [57]

$$\langle I_N \rangle = \frac{2}{\pi} \frac{\Delta}{\phi_0} \sum_{m=1}^{+\infty} \sin\left(4\pi m \frac{\phi}{\phi_0}\right) \exp\left(-m \frac{L}{l_\phi}\right) \quad (18)$$

This current has a periodicity of $\Phi_0/2$, and is paramagnetic for small magnetic flux. It should be stressed, however, that the amplitude of this current is on the order of $\langle I_N \rangle \approx \Delta/\phi_0$. Taking a level spacing of 100 μK (for a metallic ring with a typical radius of 1 μm), one obtains a current in the range of the pA. Such a current would certainly not be measurable, and is by far much lower than the experimentally observed value.

Typical current The typical current I_{typ} is defined as the fluctuations around the average current [47]:

$$I_{\text{typ}}^2 = \langle I^2 \rangle - \langle I \rangle^2 \approx \sqrt{\langle I^2 \rangle} \quad (19)$$

Starting from the expression for the current

$$I = -\frac{\partial \mathscr{F}}{\partial \Phi} = \frac{\partial}{\partial \phi} \int_{-E_F}^0 \varepsilon \rho(\varepsilon, \Phi) d\varepsilon \quad (20)$$

one obtains

$$I_{\text{typ}}^2 \approx \langle I^2 \rangle = \frac{\partial}{\partial \Phi} \frac{\partial}{\partial \Phi'} \int_{-E_F}^0 \varepsilon \varepsilon' \langle \rho(\varepsilon, \Phi) \rho(\varepsilon', \Phi') \rangle d\varepsilon d\varepsilon' \quad (21)$$

$$= \frac{\partial}{\partial \Phi} \frac{\partial}{\partial \Phi'} \int_{-E_F}^0 \varepsilon \varepsilon' K(\varepsilon - \varepsilon', \Phi, \Phi') d\varepsilon d\varepsilon' \quad (22)$$

Performing a Fourier transform[7] and using again the relation (14), one obtains [50, 56]

$$I_{\text{typ}}^2 = \frac{1}{8\pi^2} \frac{1}{\phi_0^2} \int_0^\infty \frac{(t, \phi)}{t^3} dt \quad (23)$$

where P_{int}'' denotes the second derivative of P_{int} with respect to Φ. Using Eq. (16), one finally obtains

$$I_{\text{typ}}^2 = \frac{96}{(2\pi)^2} \left(\frac{E_c}{\phi_0}\right)^2 \sum_{m=1}^\infty \frac{1}{m^3} \left[1 + m\frac{L}{l_\phi} + \frac{1}{3}m^2\left(\frac{L}{l_\phi}\right)^2\right]$$

$$\times \sin^2\left(2\pi m \frac{\phi}{\phi_0}\right) \exp\left(-m\frac{L}{l_\phi}\right) \quad (24)$$

Keeping only the first harmonic, and assuming $l_\phi \ll L$, we find for the typical current [57]

$$I_{\text{typ}} \approx \frac{\sqrt{96}}{2\pi} \frac{E_c}{\phi_0} \approx 1.56 \frac{E_c}{\phi_0} \quad (25)$$

This current is Φ_0 periodic. It should be noted that the amplitude is again of order E_c/Φ_0. This result can be rewritten as $I_{\text{typ}} \propto E_c/\Phi_0 \propto e/\tau_D \propto e v_F/L \cdot l_e/L$, where τ_D is the diffusion time. As derived in Section 4.1, the typical current is hence simply given by the time needed for an electron to perform one turn around the ring.

Extensivity One important property of the typical current is the fact that its amplitude increases only as $\sqrt{N_R}$, where N_R is the number of rings, since the typical current is given by the *fluctuations* around the average value.

On the contrary, the average current, such as any average value, grows simply as N_R. This has been extensively studied in the case of conductance oscillations [51], but is also true for thermodynamics properties.

4.2.3. Interacting Electrons

Motivated by the first experimental observations, where a much larger amplitude of the persistent current has been obtained than theoretically predicted, electron–electron interaction has been recognized as an important contribution to the persistent current [58]. The calculation is made in the Hartree–Fock approximation, and one assumes a screened Coulomb interaction [3?], $U(\vec{r} - \vec{r}') = U_{2D}\delta(\vec{r} - \vec{r}')$, with $U_{2D} = 2\pi e^2/q_{TF}$, q_{TF} being the Thomas–Fermi wavevector. In the Hartree–Fock approximation, the total energy E reads [59]

$$E = E^0 - \frac{U}{4} \frac{\partial}{\partial \Phi} \int n^2(\vec{r}) d\vec{r} \quad (26)$$

---

[7] We have omitted the classical part of P which does not depend on the flux.

where E^0 is the total energy for the noninteracting electrons. Given that[8] $n(\vec{r}) = 2 \int_0^\mu \rho(\vec{r}, \omega) \, d\omega$, one finds for the interaction contribution to the average current

$$\langle I_{ee} \rangle = \left\langle \frac{\partial E}{\partial \Phi} \right\rangle = -U \frac{\partial}{\partial \Phi} \int \rho(\vec{r}, \omega_1) \rho(\vec{r}, \omega_2) \, d\vec{r} \, d\omega_1 \, d\omega_2$$

(27)

Again, this integral can be expressed as a function of $P(t)$:

$$\langle I_{ee} \rangle = -\frac{U \phi_0}{\pi} \frac{\partial}{\partial \Phi} \int_0^\infty \frac{P(t, \Phi)}{t^2} \, dt$$

(28)

Indexing by m the winding number of the trajectories, one obtains finally [60]

$$\langle I_{ee} \rangle = 16 \frac{U \rho_0}{2\pi} \lambda_0 \frac{E_c}{\phi_0} \times \sum_{m=1}^{+\infty} \frac{1}{m^2} \left[1 + m \frac{L}{l_\phi} \right]$$

$$\times \sin\left(4\pi m \frac{\phi}{\phi_0} \right) \exp\left(-m \frac{L}{l_\phi} \right)$$

(29)

with ρ_0 being the average density of states at the Fermi level and $\lambda = U \rho_0$ the interaction coupling constant. In the simple limit $l_\phi \ll L$, and considering only the first harmonic, one finds an average current of the order E_c / Φ_0, a result obtained in the simple model of Section 4.1. It should be noted that this current is much larger than the noninteracting current calculated in Section 4.2.2. Another interesting point is that the prefactor is proportional to the interaction parameter U: this implies that the sign of the average current depends on the attractive or repulsive nature of the interaction. Finally, it should be stressed that this result is independent of the statistical ensemble: coulombian interactions locally fix the electron density [53, 58], leading to this insensitivity to the statistical ensemble. Calculations including exact coulombian interactions lead to somewhat unclear results [61–65].

We should also mention that the fluctuations of the persistent current (the typical current) are much larger than its average value (even when including the interaction term): $\sqrt{\langle I^2 \rangle} \gg \langle I \rangle$. However, the typical current for N_R rings varies as $\sqrt{N_R}$, whereas the average current varies as N_R: for few (or single)-ring experiments, the Φ_0 periodic typical current dominates, whereas for a large number of rings, the signal is dominated by the $\Phi_0 / 2$ periodic average current.

Finally, it should be stressed that the calculation of the typical current is made *only* for noninteracting electrons. Attempts to include coulombian interactions [66–68] are more difficult to perform and interpret.

5. EXPERIMENTAL RESULTS

5.1. Orders of Magnitude

Due to the experimental difficulty, only a few experimental studies on persistent currents are available. In the following, we give a review of these experiments. There are two distinct sets of experiments: first, the *many-ring experiments* which have been carried out on a very large number of rings, and

second, the *single-ring experiments*. Both kind of experiments have been performed on metals and semiconductor heterojunctions. More recently, experiments have been carried out on a small number of rings.

Let us recall briefly the order of magnitude for the typical and average current. The typical current, for N_R rings, is given by

$$I_{\text{typ}} = \sqrt{\langle I^2 \rangle} = \frac{\sqrt{96}}{2\pi} \frac{e v_F}{L} \frac{l_e}{L} \sqrt{N_R} \approx 1.56 \frac{e v_F}{L} \frac{l_e}{L} \sqrt{N_R}$$

(30)

whereas the average current is given by

$$\langle I \rangle = \frac{16}{2\pi} \lambda \frac{E_c}{\phi_0} N_R$$

(31)

The coupling constant λ, when taking into account all of the orders of the interactions, is typically of the order 10^{-1}. This gives, for the average current,

$$\langle I \rangle \approx 0.25 \frac{e v_F}{L} \frac{l_e}{L} N_R$$

(32)

The average current, even when taking into account coulombian interactions, is one order of magnitude lower than the typical current.

In a metal, the Fermi velocity is on the order of $10^7 \, \text{m} \cdot \text{s}^{-1}$, whereas for semiconductors, it is typically $10^5 \, \text{m} \cdot \text{s}^{-1}$. The elastic mean-free path in a metal is typically 20 nm, and about 10 μm in a heterojunction. For N_R rings of radius 2 μm, one obtains the following.

- For metals:

$$I_{\text{typ}} \approx 0.3 \sqrt{N_R} \, [nA] \approx 430 \sqrt{N_R} \, [\mu_B]$$

(33)

$$\langle I \rangle \approx 0.05 \, N_R \, [nA] \approx 70 \, N_R \, [\mu_B]$$

(34)

$$E_c \approx 60 \, \text{mK}$$

(35)

- For semiconductor heterojunctions:

$$I_{\text{typ}} \approx 2 \sqrt{N_R} \, [nA] \approx 2700 \sqrt{N_R} \, [\mu_B]$$

(36)

$$\langle I \rangle \approx 0.5 \, N_R \, [nA] \approx 670 \, N_R \, [\mu_B]$$

(37)

$$E_c \approx 380 \, \text{mK}$$

(38)

For single- or few-ring experiments, the signal is dominated by the typical current, whereas for many-ring experiments, it is the average current which is measured. However, in all cases, the signal to be measured is rather small, and such experiments are always an experimental challenge.

In all of the experiments performed up to now, the signal detected is the magnetic flux generated by the persistent currents. Basically, two different techniques have been employed. First is the dc SQUID, either a macroscopic (standard) one [69] or an on-chip micro-SQUID [70]. The second one involves an RF resonator that allows us to detect, at the same time, both the magnetic flux generated and the "conductivity" of isolated rings.

---

[8] The factor 2 takes into account the spin.

5.2. Many-Ring Experiments

In many-ring experiments, at least when the number of rings is very large, the measured physical quantity is the average current, as it grows like the number of rings. These experiments are also easier to perform, as one deals with a "macroscopic" object, and hence the detector is simpler to design.

5.2.1. Metallic Rings

The first experimental observation of the existence of persistent currents was performed by Lévy and co-workers on a network of 10^7 copper rings [71], as shown in Figure 8. In this experiment, the rings were squares of perimeter 2.2 μm, which gives $\Phi_0 \approx 130$ G,[9] and the phase-coherence length was much larger than the perimeter of the rings.

The signal is detected using a commercial dc SQUID. It is crucial to eliminate the contribution due to magnetic impurities from the signal of the rings. For that purpose, the authors used the nonlinearity of the signal coming from the persistent currents: the magnetic field is modulated at low frequency, and the signal is detected as the second and third harmonic of the magnetic response. The procedure is repeated at several values of the magnetic field.

The experimental data are reported in Figure 9. The signal displays clear oscillations as a function of the magnetic field, with periodicity $\Phi_0/2$. The amplitude of the persistent current, deduced from the magnetic response, is 0.4 nA per ring, corresponding to $3 \cdot 10^{-3} ev_F/L$ per ring. This result, although somehow larger than predicted, is in relatively good agreement with theory, taking into account electron–electron interactions.

In this experiment, the determination of the sign of the magnetic response relies on some assumptions for the data processing. In the paper, the authors stated a *diamagnetic* response at zero field. This result is quite surprising as it would correspond to an *attractive* interaction, which is quite unlikely in a metal-like copper. On the other hand, this sign has been confirmed by a recent experiment on silver rings [72].

5.2.2. Semiconductor Rings

Another experiment has been performed on a large number of rings in a semiconductor heterojunction [73] (Fig. 10). The rings were 10^5 squares of mean perimeter 8 μm (corresponding to $\Phi_0 \approx 10$ G).[10] In such semiconductor rings, the level spacing Δ is on the order of 25 mK, much higher than in metallic rings, where it is on the order of ≈ 10 μK. In this experiment, the experimental technique to detect the persistent current is somewhat different from the technique used in the experiment by Lévy et al. Instead of measuring the dc magnetic response of the rings, the authors study the ac response of the rings to an RF excitation. Using this technique, they measure the ac complex conductance of the rings, from which they deduce the persistent currents.
Figure 8. Picture of a part of the sample used in the experiment of [71]. It consists of an array of 10^7 copper squares, of perimeter 2.2 μm. Adapted with permission from [71], L. P. Lévy et al., *Phys. Rev. Lett.* 64, 2074 (1990). © 1990, American Physical Society.

The quantity measured in this experiment is the magnetic susceptibility of the rings, $\chi(\omega) = \chi'(\omega) + \iota\chi''(\omega)$. The complex ac conductance of the rings is then deduced by $\chi(\omega) \propto \iota\omega G(\omega)$. At low frequency,[11] the imaginary part of $G(\omega)$ is just proportional to the derivative of the persistent current with respect to the flux.

The magnetic susceptibility is measured using a resonating technique. The resonator consists of a meander stripline on top of which the rings are deposited. The meander, open at both ends, is made of 20 cm of superconducting niobium. The fundamental frequency of the resonator is 380 MHz. The shift in the resonance frequency and the variations of the quality factor are proportional to the imaginary and real parts of the ac complex conductance of the rings.

The experimental conductance (see Fig. 11) shows $h/2e$ oscillations, as expected, for experiments on many rings. However, the amplitude found for the persistent current, on the order of 1.5 nA per ring, is almost an order of magnitude larger than predicted. More surprising, the measured signal implies a *diamagnetic* zero field persistent current, that is, an *attractive* interaction between the electrons. Again, such an attractive interaction is very unlikely in this two-dimensional electron gas.

It should be noted, however, that in such an experiment, the frequency is quite close to the level spacing. This may affect the response of the rings, and makes a direct comparison with the experiment by Lévy et al. somewhat difficult.

5.3. Single-Ring Experiments

Single-ring experiments are a true experimental challenge. In such experiments, it is the *typical* current which is detected, as it is roughly one order of magnitude larger than the average current for one ring. It should be stressed, however, that as the average current is an extensive quantity in contrast to the typical current that varies like $\sqrt{N_R}$, the signal to be detected in a many-ring experiment is orders of

Lett.* 64, 2074 (1990). © 1990, American Physical Society.

magnitude larger than the signal to be detected in a single-ring experiment.

5.3.1. Metallic Rings

The first single-ring experiment was performed by Chandrasekhar et al. [74] on a single gold ring. In this experiment, three different samples were measured: two were rings of diameter 2.4 and 4.0 μm, and the third one was a rectangle of dimensions[12] 1.4 μm × 2.6 μm.

The experimental setup consists of a homemade miniature dc SQUID. The SQUID itself has a sensitivity of $6 \cdot 10^{-8}\Phi_0$. The pick-up loop consists of a counterwound niobium loop in order to minimize the sensitivity to the static background field. To maximize the coupling between the pick-up coil and the sample, both were fabricated on the same chip, and the coil was deposited around the gold ring (see Fig. 12). Moreover, the field coil consists of a niobium line deposited around the ring.

In this experiment, the authors detect the modulation of the flux measured by the SQUID as a function of the magnetic field, which is swept over a few Φ_0. The magnetic field is modulated at low frequency ($\approx$4 Hz), and the signal is detected at f and $2f$. The background signal is subtracted numerically using a quadratic form, and the amplitude is extracted from the Fourier transform (power spectrum) of the data as a function of the magnetic field (see Fig. 13).

As a result, the authors found a persistent current with Φ_0 periodicity and an amplitude of 3 ± 2 nA, 30 ± 15 nA, and 6 ± 2 nA for the three samples investigated, whereas

the theoretical values are 0.09, 0.27, and 0.25 nA, respectively. Obviously, the measured signal is 30–150 times larger than expected. Different arguments have been invoked to explain this discrepancy. It should be noted, however, that the observed signal is on the order of ev_F/L, that is, the signal one should find for a ballistic ring ($l_e \approx L$). On the other hand, it is very unlikely that gold rings behave as ballistic rings, and the theoretical explanation of this experimental observation remains an open question.

The sign of the persistent current is quite difficult to determine in such a single-ring experiment. The authors claim that

the samples studied showed a paramagnetic signal. A clear statement, however, as stressed by the authors, is difficult due to the few samples measured, and due to the extreme experimental difficulty.

5.3.2. Semiconductor Rings

Another experiment was performed by Mailly and co-workers on a single, isolated ring, etched into a semiconductor heterojunction [75]. In this case, the signal is expected to be larger than in metallic rings as the elastic mean-free path is much larger compared to the latter case.

The ring was etched into a two dimensional electron gas at the interface of a GaAs–GaAlAs heterojunction. The mean

perimeter in this sample is on the order of 6 μm, which corresponds to $\Phi_0 \approx 10$ G).[13]

An important advantage of semiconductors is the possibility of using gates on the sample. This allows us to modify *in-situ* the geometry of the sample simply by applying a dc voltage to the gates. In this experiment, the authors used two different gates (see Fig. 14). The first is used to separate the ring from the reservoirs: the presence of these ohmic contacts allows us to measure at the same time the conductance and the persistent current oscillations, and hence to check the electronic temperature and the coherence of the electrons in the ring. The second gate is evaporated on top of one arm of the ring. By polarizing this gate ("open" ring), one can suppress all of the interference effects in the ring, both the Aharonov–Bohm oscillations and the persistent currents. This allows us to perform a "zero" measurement, equivalent to measuring the SQUID with no ring. The advantage is that this can be made on the same sample. Moreover, the subtraction of the signal obtained with the ring "closed" and "open" allows us to experimentally suppress the background signal of the detector.

In this experiment, a sophisticated on-chip micro-SQUID technique was employed. With such a design, no pick-up coil is needed: the SQUID itself is deposited exactly on the top of the ring. This has two major advantages. First, the absence of a pick-up coil reduces the inductance of the setup. Second, and most important, in such a geometry, the coupling between the ring and the SQUID is basically optimal, as the SQUID has exactly the same shape as the ring. The SQUID is actually designed as a gradiometer, consisting of two counterwound loops in order to compensate the externally applied static magnetic field (see Fig. 14). The two Josephson junctions are made using Dayem microbridges, evaporated at the same time as the second level of the gradiometer. For a detailed description of the miro-SQUID gradiometer technique, we refer the reader to [76].

The measurement consists of sweeping the magnetic field over several Φ_0, and recording the critical current of the SQUID. This is made successively for the "closed" and "open" rings. The signal is then obtained by taking the Fourier transform of the difference between the two measurements. The noise is evaluated at the same time by taking the Fourier transform of the difference between two "closed" or "open" ring measurements.

In the Fourier spectrum (see Fig. 15), a clear peak is observed at the Φ_0 frequency corresponding to a value of 4 ± 2 nA for the persistent current amplitude, in good agreement with the theoretical prediction ev_F/L. No measurable signal was observed at the $\Phi_0/2$ frequency, as expected when comparing the theoretical signal and the noise level of the experiment. The sign of the persistent current, on the other hand, was impossible to determine in a reliable way.

This experiment proves that, in the case of very weak disorder and a small number of channels, standard theory gives a correct description of the persistent current amplitude. Moreover, in such samples, electron–electron interactions are much enhanced due to the low electron density. This suggests that these interactions are unlikely to strongly enhance the amplitude of the persistent currents.

5.4. Few-Rings Experiments

More recently, two experiments were also performed on an ensemble of a few rings, either metallic or semiconductor. In this case, the small number of rings (typically ten rings) allows us to check the theory concerning the ensemble
Figure 15. Fourier spectrum of the magnetization of the ring of [75] in units of nanoamperes. The arrows indicate the h/e and $h/2e$ frequency. Open dot is the experimental noise. One clearly observes the signal at the h/e frequency corresponding to a persistent current of 4 ± 2 nA in the ring. Reprinted with permission from [75], D. Mailly et al., *Phys. Rev. Lett.* 70, 2020 (1993). © 1993,

averaging, and should allow us to observe both the h/e and $h/2e$ components of the persistent current. Moreover, in the experiment on semiconductor rings, the authors were able to check the effect of a connection (ohmic contacts) between the rings.

5.4.1. Metallic Rings

In this experiment, Jariwala et al. [77] used a similar experimental setup as for the experiment on the single gold ring. The sample (see Fig. 16) consists of a line of 30 isolated gold rings of radius 1.3 μm (perimeter 8 μm) corresponding to a flux period[14] of $\Phi_0 \approx 8$ G.

To extract the persistent current signal from the background signal, the magnetic field is modulated at low frequency (typically ≈ 2 Hz), and detected at the first, second, and third harmonics of the response of the SQUID.

In this experiment, both the h/e and $h/2e$ components were detected (see Fig. 17). For the h/e component, the authors found a current of $I_{\text{typ}} = 0.35$ nA $= 2.3\,E_c/\Phi_0$ per ring, in good agreement with theoretical predictions, taking into account e–e interactions. To obtain this result, the authors divided the total signal by $\sqrt{N_R}$ to account for the random sign of the persistent current. This suggests that the amplitude of the persistent current measured in the single-ring experiment [74] is somewhat overestimated.

The $h/2e$ component was found to be $\langle I_N \rangle = 0.06$ nA per ring, corresponding to $0.44\,E_c/\Phi_0$. This result is in line with the results found in the previous experiment of Lévy et al. on copper rings, and only a factor of 2 larger than the theoretical predictions when taking into account electron–electron interactions.

The sign of the persistent current, on the other hand, is much more surprising. In this experiment, the sign of the average current is *diamagnetic*. Although this has been seen in previous experiments on many rings [71, 72], in this work, the determination of the sign is unambiguous. As we have seen, such a diamagnetic response is quite unlikely as it corresponds to an *attractive* interaction between the electrons. Clearly, such a discrepancy between experiment and theory may be attributed to an unexplored physical phenomenon that modifies the ground state of the electron gas. The authors of this experiment explain their result in light of a recent theory on zero temperature dephasing in metals [84]. However, as the status of such theories is still quite controversial, we will not go further into this point.

Finally, it should be noted that, in such an experiment on 30 rings, both the average current, that grows like N_R, and the typical current, that grows like $\sqrt{N_R}$, have the same amplitude. This proves that 30 rings are not enough for ensemble averaging, and the exact variation of I_{typ} and $\langle I_N \rangle$ with the number of rings remains experimentally an open question.

5.4.2. Semiconductor Rings

Another experiment was performed on a small number of semiconductor rings by Rabaud and co-workers [78]. This experiment was performed on two arrays of 4 and 16 rings (actually squares) etched into a two-dimensional electron

[14] $l_e \approx 87$ nm, $l_\Phi \approx 16$ μm, $E_c \approx 7$ mK in this experiment.

gas at the interface of a GaAs GaAlAs heterojunction. The squares were $3\,\mu m \times 3\,\mu m$, perimeter $12\,\mu m$, corresponding to $\Phi_0 \approx 5$ G).[15] Using an original setup containing three different metallic gates (see Fig. 18), Rabaud et al. were able to measure in the same experiment (same cooling down run) both the signal of connected and isolated rings. This original setup also permits us to suppress the signal via a gate, and check the "zero" of the detector. This allows us to perform an *in-situ* subtraction of the background. Such a technique has the advantage of measuring at the same time both the signal and the noise in order to have an unambiguous determination of the magnetic signal.

In this experiment, the authors measured a clear h/e periodic signal, of amplitude 2.0 ± 0.3 nA per ring for the 4-ring sample, and 0.35 ± 0.07 nA per ring for the 16-ring sample (see Fig. 19), to be compared with the theoretical values 2.18 nA per ring for the 4-ring sample and 1.09 nA per ring for the 16-ring sample. The experimental results are in relatively good agreement with the theoretical values. The discrepancy observed for the 16-ring sample may be attributed to an overestimation of the elastic mean-free path, which is determined on wires fabricated from the same wafer of the GaAs/AlGaAs heterojunction. However, the complete lithographic process, quite complicated in this experiment, may affect l_e, mainly because of the roughness of the edges after etching.

In this work, the authors were also able to measure the persistent currents in the same array of rings, but this time with an ohmic connection between the rings. Measurements on both isolated and connected rings can be made basically at the same time, by simply applying a dc voltage on the gates on the top of the arms connecting the rings. The purpose of this experiment was to measure the persistent current in a sample much larger than l_ϕ, that is, a macroscopic sample from the quantum physic point of view. This work was stimulated by theoretical models that calculated persistent currents in arrays of rings, showing that they do not vanish, but are only reduced by some geometrical factor [79].

The lines of 4 and 16 rings used in the experiment were, respectively, ≈ 60 and $\approx 250\,\mu m$, both much larger than the phase-coherence length. In that sense, these line of rings are macroscopic objects. The authors found a current of amplitude 1.7 ± 0.3 nA per ring for the 4-ring sample, and 0.40 ± 0.08 nA per ring for the 16-ring sample, whereas the theoretical values, calculated in [79], were respectively, 1.25 nA per ring and 0.62 nA per ring. There is obviously a discrepancy between experimental and theoretical values. However, it should be noted that the theoretical model was developed for diffusive (metallic) rings, which is certainly not the case in heterojunction rings. Moreover, coulomb interactions are not taken into account for the typical current; in heterojunctions, the low electronic density strongly enhances the interactions.

The key result of this experiment is the fact that the ratio between the amplitude of the persistent currents observed in connected and isolated rings is on the order of 1 for both samples. This shows that persistent currents are basically

---

[15] $l_e \approx 10\,\mu m$; $l_\Phi \approx 25\,\mu m$; $E_c \approx 500$ mK in this experiment
Figure 18. Optical photograph of the sample used for the experiment of [78]. The three metallic gates and the aluminum microSQUID gradiometer are clearly visible. Lett.* 86, 3124 (2001). © 2001, American Physical Society.

unaffected by the connection between the rings. This suggests that, even in a macroscopic sample, there should be a reminiscence of the quantum nature of electrons.

Finally, it is interesting to compare this experiment with the experiment performed on 30 metallic rings. In the experiment on semiconductor rings, no observable signal was detected at the $h/2e$ frequency for both samples. At least for the 16-ring sample, this result is quite surprising, as the average current grows linearly with the number of rings. As
Figure 19. Power spectrum of the magnetization due to the persistent current in a line of 16 connected rings in units of nanoamperes per ring. The arrow indicates the h/e frequency window. Open symbols are the experimental noise. One clearly sees a peak in in the "signal" curve, absent from the "noise" curve. Inset shows the raw data (dashed line) after substraction of the background and after bandpassing the signal over the h/e frequency range (solid line). Adapted with permission from [78], W. Rabaud et al. *Phys. Rev. Lett.* 86, 3124 (2001). © 2001, American Physical Society.

a comparison, in the experiment on metallic rings, the signals at h/e and $h/2e$ for 30 rings were of similar amplitude. Again, this shows that the ensemble averaging, in the case of persistent currents, is still not fully understood.

6. CONCLUSION

Persistent currents are certainly one of the most spectacular manifestations of the quantum coherence of the electrons in a mesoscopic system: it manifests as a permanent, nondissipative current flowing around a normal, nonsuperconducting ring. The amplitude of this current is on the order of a nanoampere, whereas the resistance of the ring can be on the order of a kilohm, for example, for the case of semiconductor rings.

Although heavily controversial at the beginning, the existence of such currents is well established, from both a theoretical as well as an experimental point of view. However, many questions remain open, and experimental results point out the lack of a deep understanding of this phenomenon.

First, the amplitude experimentally observed seems different from the theoretical predictions. Most of the experimental results are about an order of magnitude larger than the theoretical predictions. However, it must be stressed that all of these experiments are very difficult, as they deal with the measurement of very small magnetic signals. From this point of view, and taking into account the different approximations in the theoretical models, it seems difficult in the absence of new experimental results to draw a definitive conclusion concerning the validity of the theoretical predictions on the amplitude of the persistent currents.

More surprising is the sign observed in the many-ring experiments. As we have seen, the sign of the zero-field magnetic response due to the average persistent currents are directly related to the sign of the interaction between electrons. In at least two experiments on many rings, both metallic or semiconductor, the sign was found to be diamagnetic, whereas in the first experiment on copper rings, there were indications that it was also diamagnetic. This result is quite intriguing, as it should correspond to an attractive interaction between electrons. Such an attractive interaction is very unlikely in "standard" metals like copper or gold, or even in GaAs-GaAlAs heteronjunctions. Clearly, there are many open questions in the description of the average persistent current of interacting electrons.

Another interesting point is the change of persistent currents when the sample evolves from a true mesoscopic sample to a macroscopic sample. Only one such experiment has been carried out up to now, and the result found is that persistent currents are not significantly modified when the size of the sample increases. These results suggest that persistent currents should be observable in a macroscopic objet; by extension, in the spirit of the evolution from Aharonov–Bohm oscillations to weak localization, one may think about observing the zero-field magnetic response of a standard two-dimensional metal.

Finally, there are natural extensions of this problem of equilibrium properties of mesoscopic conductors that have been largely unexplored. An interesting problem is a ballistic dot of different shape, that is, quantum billiards. In this case, the properties of the energy spectrum are no longer

given by the impurity configuration, but by the specular scattering at the boundaries of the sample [80–82]. The orbital magnetism of these systems should be controlled by the regular or chaotic nature of the billiard, and must be understood in light of the quantum chaos theory. Another point is the connection between the persistent currents and the zero temperature decoherence: it has been proposed that the anomalously high amplitude of the average current may be related to the decoherence of the electron due to the RF environment [83, 84]. It should also be interesting to study thermodynamic properties different from the persistent current. One example is the specific heat of mesoscopic samples. In an equivalent way to persistent currents, the specific heat should oscillate with the magnetic flux. However, such a measurement is certainly very difficult, as the energy involved in such a phenomenon is again on the order of the Thouless energy. Such an experiment would imply strong improvements in the sensitivity of present detectors. Finally, one subject of major interest at present is the possibility of observing the Kondo effect in artificial nanostructures [85]. Coupling this with a persistent current measurement should allow us to directly probe the reality and the extension of the Kondo cloud [86–88].

GLOSSARY

Aharonov–Bohm flux Additional dephasing of an electronic wavefunction due to the coupling between the electric charge of the electron and the vector potential.

Ballistic conductor Conductor pure enough to allow the electrons to be scattered only by the edge of the sample.

Equilibrium (thermodynamic) property Property related to the ground state of a system.

Mesoscopic (quantum) conductor Conductor whose size is between the microscopic scale (atoms and molecules) and the macroscopic scale (daily objects).

Molecular beam epitaxy Technique used to grow semiconductors with a very high purity. This technique allows the control of atomic layer growth.

Nanolithography Technique used to fabricate samples at the nanometer scale. This includes, UV lithography, e-beam lithography, X-rays lithography etc.

Quantum coherence length Length over which the associated wave of an electron maintains a well defined phase. Beyond this length scale, the electron looses its quantum, wave-like nature.

Transport property Property related to the response of a conductor to an external excitation, e.g. the current in response to a given voltage.

CONTENTS

1. INTRODUCTION

Suppose an electromagnetic wave hits the interface between two transparent media having indices of refraction n_1 and n_2. If this occurs at an angle close to normal incidence, then part of the wave is transmitted into the new medium and part is reflected back into the original medium. However, if the wave arrives from the medium with greater index of refraction $(n_1 > n_2)$ at an angle of incidence θ_i greater than the critical angle

$$\theta_c = \arcsin\left(\frac{n_2}{n_1}\right) \tag{1}$$

only a vanishing (or *evanescent*) tail of the electromagnetic field penetrates into the optically less dense medium (Fig. 1) [1]. The wave vector of this *evanescent wave* (EW) possesses a component along the interface

$$k_{\parallel} = \frac{2\pi}{\lambda} n_1 \sin \theta_i \tag{2}$$

and a component perpendicular to it

$$k_{\perp} = i\frac{2\pi}{\lambda} \sqrt{n_1^2 \sin^2 \theta_i - n_2^2} \tag{3}$$

where λ is the wavelength of light in vacuum. The imaginary component $k_{\perp}$ implies that the EW amplitude decays

exponentially with increasing the distance from the surface into the optically less dense medium. Usually a penetration depth δ is defined

$$\delta = 1/|k_{\perp}| \tag{4}$$

at which the EW amplitude decreases by a factor of *e*. Depending on the angle of incidence δ varies from an formally infinite value at the critical angle to values of the order of the wavelength for more grazing incidence. This way the EW penetration depth spans a scale of only a few hundred nanometers in the visible spectral range (i.e., the light is confined to the interface).

Hence optical methods relying on the evanescent wave should provide access to surface and interface processes. This advantage of *evanescent wave spectroscopy* (EWS) has been widely used in the past for the construction of surface-sensitive atom and molecule sensors. EWs in such sensors are implemented for example via excitation of waveguide modes in planar waveguides or in optical fibers. If the EW frequency is resonant to the optical transition frequency of molecules in the media attaching the interface, the fluorescence signal from the molecules or the dielectric losses at the resonant frequencies can be used to obtain the concentration of molecules at the interface. More detailed discussions of evanescent wave sensors can be found for example in [2, 3].

In this chapter we will focus on more recent and more sophisticated spectroscopic approaches in the evanescent wave regime of a surface. If one investigates not only peak intensities of spectroscopic lines but the *optical line shapes* at an interface between a solid and a gaseous medium much more detailed physical information can be obtained. Since the gas atoms or molecules striking the surface in general change their quantum states, polarization state, or velocity distribution the resonant optical response of a gas in the close vicinity of a surface differs from that inside a gas volume. However, departing further into the gas interior the gas particles "forget" the way they have been scattered by the surface since they undergo spontaneous relaxation or
Figure 1. Scheme for multiphoton evanescent wave particle excitation.

experience collisions with other particles. Consequently we define that gas layer bordering a surface for which the optical response differs from that in the bulk gas as the *gas boundary layer* (GBL).

Let us inspect a nonsaturated optical transition. Then the GBL can be characterized by the following *memory lengths* determining the scales at which gas particles "remember" the quantum state which they had immediately after the bounce from the surface (Fig. 2):

   (i) The population memory length within which most of the gas particles departing from the surface do not change the population of their quantum state; this length is of order $v_T/\gamma_{\parallel}$ with v_T the most probable velocity and $\gamma_{\parallel}$ the rate of the longitudinal (energy) relaxation of the quantum state [4].

  (ii) The polarization memory length within which the particles do not change their polarization; this length can be estimated as $v_T/\gamma_{\perp}$ with $\gamma_{\perp}$ the rate of the transverse (phase) relaxation of the transition [4].

 (iii) The velocity distribution memory length within which the particles do not change their velocities; this length is of the order of the mean free path.

All memory lengths decrease if the gas pressure increases. In the case of saturation of the optical transitions by the excitation light the population and the polarization memory lengths are determined not only by the corresponding relaxation rates but also by the Rabi frequencies of the transitions [4].

Particles departing from the surface within the GBL possess transient (non-steady-state) populations and/or induced dipole moments. If the latter is the case then the induced polarization of the gas is not proportional to the electric field of the wave at a given point. Hence the optical response of the GBL is *nonlocal*.

Note that the spatial scale within which the gas atoms or molecules contribute to the signal is set by the way the optical spectra are obtained. This *detection length* in the case of fluorescence spectra is determined by whatever is larger,
the EW penetration depth or the population memory length. For absorption and reflection spectra the detection length coincides with the EW penetration depth.

In general, the gas optical response depends on the relation between the detection length and the memory lengths.

When the detection length is less than or comparable to the memory length of some quantity, the EW spectra of the gas are sensitive to the behavior of that quantity during the gas-surface scattering.

Evanescent wave spectroscopy of the gas boundary layer is related to *selective reflection spectroscopy* (SRS) [5]. In selective reflection spectroscopy the frequency-dependent reflectivity of a monochromatic optical beam is monitored which illuminates under near-normal incidence the interface between a dielectric window and a resonant vapor. This technique has already been used at the beginning of last century to deduce atomic dispersion spectra [6]. Although the illuminated gas volume in SRS is proportional to the absorption length, only the gas layer of thickness of the order of a wavelength contributes to the reflection spectrum.

The first evidence of the influence of gas–surface interactions on the observed spectra was given by Cojan in 1954 [7]. He studied the wavelength dependence of the reflection coefficient of light normally incident at an interface between a glass and a mercury vapor near its resonance line. The spectrum was observed to be narrower than the Doppler width when the homogeneous linewidth, $\gamma_{\perp}$, was less than the inhomogeneous broadening, $2\pi v_T/\lambda$. Cojan [7] made the first attempt to develop a theoretical explanation of SRS taking into account wall collisions. A more appropriate theory providing good qualitative agreement with the experimental results was developed later by Schuurmans [8].

More recent SRS work allowed one to determine the strengths of the attractive [9] as well as resonant repulsive van der Waals interaction [10] between alkali atoms and dielectrics, supported by developed theoretical approaches [11–13]. In terms of the memory lengths the situation corresponds to the case where the polarization memory length is greater than the detection length in SRS, which has the value $\lambda/2\pi$.

2. EVANESCENT WAVE SPECTROSCOPY OF ATOMIC VAPORS

This section deals with applications of evanescent waves to the detailed spectroscopy of atomic vapors near dielectric surfaces.

2.1. Evanescent Wave Absorption Spectroscopy

Boissel and Kerherve reported in 1981 the absorption of the sodium D_2 line when the sodium vapor was excited by an EW at a sapphire prism surface [14]. This can be thought of as the first experiment on *linear* EWS of atomic vapors. The authors calculated—based on the theory of optical response of atoms in the vicinity of a bounding surface—the absorption of the EW in sodium vapor via the reflection coefficient of light from the prism–vapor interface. The boundary conditions for the equation describing the atomic polarization were set separately for the atoms arriving at the prism

Figure 2. Important length scales for evanescent wave spectroscopy.

surface and for the atoms departing from it. For the former ones it was assumed that their polarization equals zero at infinite times before the collision with the surface, whereas the latter ones were assumed to be diffusively scattered by the surface with a zero polarization at the moment of desorption. The number density of sodium atoms was of the order of 10^{16} cm^{-3}; therefore both Lorentz–Lorenz correction and collisional broadening effects had to be incorporated into the theory. Despite these theoretical efforts, a clear discrepancy between the calculations and the experimental results was found. The authors suggested as a possible reason the effect of attraction of sodium vapor by the sapphire surface.

2.2. Nonlinear Doppler-Free Evanescent Wave Spectroscopy

The first experiments on *nonlinear* EWS have been carried out by S. Moneau and co-authors in 1986 at the interface between sodium vapor and a glass prism surface [15] in a Doppler-free pump–probe scheme. Here, two counterpropagating beams from a single-mode continuous wave (cw) tunable dye laser irradiated the prism at an angle of incidence in the vicinity of the critical angle (cf. Fig. 1). One of the beams (pump) was amplitude-modulated, whereas the other one (probe) monitored the reflectivity when scanning across the sodium D_1 and D_2 lines. As the wave vectors of the two EWs were opposite, the recorded reflection spectra exhibited Doppler-free saturated absorption lineshapes for $\theta_i > \theta_c$. With decreasing θ_i and passing across θ_c, the absorption lineshapes suddenly turned into saturated dispersion lineshapes (Fig. 3). This transition took place within an angular interval of less than 1 milliradian.

The reflectivity change δR can be described in terms of a change of the complex refractive index $\delta n = \delta n_R + i\delta n_I$ and in terms of the angular detuning $\psi = \theta_i - \theta_c$,

$$\delta R \propto \delta n_I/\sqrt{\psi} \qquad \text{for } \psi > 0 \tag{5}$$

$$\propto \delta n_R/\sqrt{|\psi|} \qquad \text{for } \psi < 0 \tag{6}$$

provided that $|\delta n| \ll |\psi| \ll 1$. The saturated absorption lineshapes are dominated by the transit time broadening

$$\Delta\nu_T \approx (2\pi v_T/\lambda)(2\psi/\tan\theta_c)^{1/2} \tag{7}$$

which in general exceeds the natural linewidth of 10 MHz.
Figure 3. Probe reflectivity change around the sodium D_2 line. The three lines correspond to angles of incidence of $\theta_i - \theta_c = 1.4$ (1), 0.4 (2), and -0.6 mrad (3). Peaks a and b are due to the two hyperfine levels of the sodium ground state, whereas c is a crossover resonance. Reprinted with permission from [15], P. Simoneau et al., *Opt. Commun.* 59, 103 (1986). © 1986, Elsevier Science.

By using well collimated beams, the authors were able to resolve completely the hyperfine structure of the D_1 line and to observe both the main and crossover resonances.

2.3. Evanescent Wave Spectroscopy of Sublevel Resonances

EWS can be used to probe atomic sublevel coherence in the close vicinity of a surface. Such an approach has first been realized for the Zeeman sublevels of the $3\,^2S_{1/2}$ ground state of sodium atoms near a glass prism surface in 1991 [16]. A circularly polarized pump beam resonant to the D_1 line created magnetization in the atomic vapor via optical pumping, whereas the p-polarized probe beam excited an EW at the prism surface to monitor the reflectivity of the interface. A magnetic field was applied perpendicular to the plane of incidence of the probe beam and caused a precession of the magnetization of the vapor. This precession corresponds to oscillations between the ground state sublevels $m_z = \pm 1/2$ and therefore to a modulation of the index of refraction of the vapor

$$n_{2\pm} = 1 + \chi_0(1 \mp m_z)/2 \tag{8}$$

where χ_0 is the susceptibility of the unpolarized vapor and the opposite signs refer to the two eigenpolarizations. The angle of incidence of the probe beam was set near the critical angle for total internal reflection and the reflected light beam was analyzed at two different angles ($\pm 45°$) with respect to the plane of incidence. In the linear regime ($|\chi_0| \ll 1$ with the angular detuning $|\psi| \ll 1$) the difference between the two signals is given by

$$\Delta S \approx -I_0\sqrt{2}n_1(n_1^2 - 1)^{-3/4} \operatorname{Re}(\chi_0/\sqrt{\psi})m_z \tag{9}$$

with I_0 the probe beam intensity and n_1 the index of refraction of the prism (the divergence at $\psi = 0$ is induced by invoking the linear approximation). The signal is therefore directly proportional to the magnetization component along the evanescent wave vector.

In order to obtain the highest sensitivity, the pump beam should be modulated with a frequency near the Larmor frequency. Then ΔS is expected to oscillate sinusoidally at the modulation frequency which can be determined via lock-in detection with the modulation frequency as reference.

2.4. Detection of Evanescent Waves by Means of Atomic Spectroscopy

The components along and perpendicular to the interface of an evanescent wave vector determine the Doppler and transit-time broadenings, respectively. They can be deduced by means of analysis of the atomic spectral lineshapes in spectra excited by an EW. This was carried out in 1997 for the D_2 line of a cesium atomic vapor [17].

The cesium vapor cell consisted of a glass cylinder with a truncated glass prism attached to one end of the cylinder. Such a setup allows one to excite the vapor in the cell by both a laser beam propagating perpendicular to the

glass–vapor interface (i.e., a volume wave) and an EW travelling along the prism surface. The volume wave resonant to the $6\,^2S_{1/2}(F = 4) \leftarrow 6\,^2P_{3/2}(F')$ transition produced velocity-selective hyperfine pumping to the $6\,^2S_{1/2}(F = 3)$ state. The change in the population due to optical pumping was monitored by measuring the absorption of the EW at the $6\,^2S_{1/2}(F = 3) \leftarrow 6\,^2P_{3/2}(F')$ transition as a function of the pump wave frequency. The resulting absorption spectrum was analyzed in terms of the EW penetration depth [Eq. (4)]. Agreement between theoretical and experimental red wings of the absorption spectra was obtained.

In another experiment the pump laser was switched off and the intensity change of the reflected probe beam due to absorption of the EW at the $6\,^2S_{1/2}(F = 3) \leftarrow 6\,^2P_{3/2}(F')$ transition was registered. The width $\Delta\omega$ of the Doppler-broadened absorption line was measured as a function of the angle of incidence for angular values larger than the critical angle. The obtained dependence was in good agreement with the relation $\Delta\omega = k_{\parallel}v_T \propto \sin\theta_i$ which follows from Eq. (2). The quantity $k_{\parallel}$ was associated with a "pseudo momentum" $\hbar k_{\parallel}$, which is conserved during the interaction between an atom and a quantum of an EW.

Saturated absorption spectroscopy utilizing two EWs was used by the same group to demonstrate that the Doppler shift in an EW is determined by the quantity $k_{\parallel}$ [18]. For that purpose, counterpropagating EWs were generated at the prism surface. One of them (pump) was set at a fixed angle of incidence θ_{pump} slightly larger than the critical angle, whereas the other (probe) was set at various angles θ_{probe} larger than the critical angle. The laser frequency was scanned across the cesium $6\,^2S_{1/2}(F = 3) \leftarrow 6\,^2P_{3/2}(F')$ transitions. The observed saturated absorption spectra exhibited, besides Lamb dips at the transition frequencies ω_i and ω_j, also split crossover resonances around the frequency $\omega_{\mathrm{cr}} = (\omega_i + \omega_j)/2$ (Fig. 4). The splitting between the crossover resonance components is equal to

$$\Delta = |\omega_i - \omega_j| \frac{|\sin\theta_{\mathrm{pump}} - \sin\theta_{\mathrm{probe}}|}{\sin\theta_{\mathrm{pump}} + \sin\theta_{\mathrm{probe}}} \qquad (10)$$
Figure 4. Saturated absorption spectra, induced by counterpropagating evanescent waves from the same laser in a cesium cell with truncated prism. The different scans have been obtained at probe angles of 44, 50.1, 55.5, and 59.4 degrees, respectively (from top to down). "CR" denotes crossover resonances of hyperfine states $F' = 2$, 3, and 4 in the upper state. Reprinted with permission from [18], T. Matsudo et al., *Opt. Commun.* 145, 64 (1998). © 1998, Elsevier Science.

At $\theta_{\mathrm{pump}} = \theta_{\mathrm{probe}}$, the crossover resonance becomes a single peak at ω_{cr} as in the typical scheme of saturated absorption spectroscopy. The measurements carried out at different θ_{probe} thus confirm Eq. (10) and therefore the dependence of the Doppler shift on the angle of incidence.

3. EVANESCENT WAVE SPECTROSCOPY FOR SURFACE SCIENCE

In this section we consider how the strong spatial localization of an EW field near a surface can be utilized for studying the processes of adsorption, desorption, and atom–surface scattering (i.e., typical surface science problems).

3.1. One-Photon Evanescent Wave Spectroscopy

The optical response of atoms desorbing from a surface is essentially transient and their contribution to the gas spectrum differs from that of the atoms arriving at the surface. This phenomenon has a classical analogy. An atom with a transition frequency ω_0 can be represented as an oscillating dipole with an eigenfrequency ω_0. The EW with the frequency ω causes forced oscillations with two components: free oscillations with the frequency ω_0 and oscillations with the frequency of the external force, ω. The former decay exponentially and hence cannot be observed in the steady-state regime. However, in the transient regime the spectrum of the dipole radiation consists of two components, ω and ω_0.

In the case of atomic excitation by an evanescent field quantitative results for that spectrum can be obtained in the density matrix formalism [19, 20]. Decay of the atomic polarization occurs when an atom moves away from the surface. The overall fluorescence intensity is given by an integral over the gas volume, whereas the relative contribution of the free decaying term with respect to that of the forced term can be estimated as $R = (\gamma_{\perp}\tau)^{-1}$ with τ the time-of-flight across the EW. The atoms moving to the surface are in the steady-state regime and give contributions only to the component at the frequency ω. For typical atomic parameters the quantity R can greatly exceed unity. This means that the dominant contribution to the fluorescence spectrum arises from the desorbing atoms and is centered at the atomic transition frequency ω_0.

These conclusions were confirmed experimentally in fluorescence spectra of sodium atoms excited by an EW resonant to the $3S_{1/2} \leftarrow 3P_{3/2}$ transition [21]. A flux of sodium atoms was directed onto a glass prism surface situated in a vacuum apparatus. The laser exciting the EW was set at a fixed frequency. The resulting fluorescent light was spectrally analyzed with the help of a Fabry–Perot etalon. The fluorescence line of Na atoms was Doppler-broadened with the linewidth determined by the prism surface temperature and not dependent on the atomic flux. This confirmed the theoretical prediction that the fluorescence signal arises mainly from the desorbed atoms. Thus this technique enables one to enhance the spectral contribution of the atoms leaving the surface over that for the atoms impinging on the surface.

3.2. Two-Photon Evanescent Wave Spectroscopy

A rigorous comparison of experimentally determined fluorescence lineshapes with theoretical predictions asks for a good signal-to-noise ratio. This can readily be obtained by applying a two-photon excitation scheme. For example, sodium atoms could be excited by two counterpropagating EWs at a glass prism surface (Fig. 1) [22]. In the experiment, one of the exciting lasers was set in resonance with the $3P_{3/2} \leftarrow 5S_{1/2}$ transition whereas the second laser was scanned across the adjacent $3S_{1/2} \leftarrow 3P_{3/2}$ transition. The resulting fluorescence light from the $3S_{1/2} \leftarrow 4P_{1/2,3/2}$ transitions was observed as a function of detuning of the second laser (Fig. 5). Sodium atoms were directed in the plane of incidence of the laser beams toward the prism surface at an angle of about 60° with respect to the surface normal. Due to the Doppler shift, the exciting EWs were out of resonance with the atoms arriving at the surface whereas they were in resonance with the atoms desorbing from the surface. For this reason, the contribution to the fluorescence spectrum of the atoms from the source itself was negligible.

The mean free path of the sodium atoms greatly exceeded the EW penetration depth. Due to this fact the fluorescence lineshapes were described by a Maxwell distribution modified by a "flux correction" determined by the atomic velocity component normal to the surface, v_z,

$$f_K = \frac{2}{\pi v_T^4} v_z \exp\left(-\frac{v^2}{v_T^2}\right) \tag{11}$$

This correction appears in problems relevant to the statistical properties of gas atoms which strike a surface and results in the well-known cosine law of Knudsen [23].

A rigorous theory of the two-photon evanescent wave spectra [22] gave results that agreed very well with the experimental data. Note that the main difference between two-photon excitation spectra in the nonevanescent and in the evanescent wave regime is that the relaxation rates are affected by transit time broadening and that the Rabi frequency is modified in accordance with the evanescent character of the wave pumping the lower transition. A comparison between the measured and the calculated lineshapes clearly demonstrated that the velocity distribution function of the atoms leaving the surface obeys Knudsen's cosine law.

The gas spectra excited by EWs can also be influenced by the atoms *adsorbed* on the surface. Especially in the case of nonlinear optical spectra this influence is expected since the EW amplitude is determined by the boundary conditions at the surface and hence by the adsorbate properties. In particular, the atoms adsorbed at the surface are polarized by the exciting field and thus create a surface displacement current
$$\mathbf{j}(\omega) = -i\omega N_s \alpha_s(\omega) \mathbf{E}_t(\omega) \tag{12}$$

where ω is the EW frequency, N_s is the surface number density, $\alpha_s(\omega)$ is the linear polarizability of an adsorbed atom, $\mathbf{E}_t(\omega)$ is the tangential component of the electric field amplitude at the interface, and the local-field correction has been neglected. Accounting for this current in the boundary conditions for Maxwell's equations one ends up with a dependence of the EW amplitude on the parameters N_s and $\alpha_s(\omega)$. Specifically, these quantities determine the Autler–Townes splitting [24] in the fluorescence spectrum of the gas excited by two EWs resonant to adjacent transitions and thus they become measurable via this splitting (Fig. 6).

This idea was realized for adsorption of sodium atoms at a glass prism surface in the setup described in the preceding section [25, 26]. Both waves were excited near the critical angle for total internal reflection in order to decrease the time-of-flight broadening which would wash out the Autler–Townes splitting. The splitting was then measured as a function of the prism surface temperature. Assuming the Langmuir model of adsorption, it was possible to extract from this dependence the adsorption energy, the pre-exponential factor for the rate of desorption, and the linear polarizability of the adsorbed atoms. The deduced values of the parameters were then used to deduce the surface coverage as a function of the surface temperature. This method obviously can be used for highly accurate *in-situ* monitoring of the surface coverage in a gas atmosphere.

Figure 5. Sodium term scheme for two-photon evanescent wave fluorescence spectroscopy.

Figure 6. Two-photon sodium spectra in the Autler–Townes-split (ATS) domain. For comparison, the hyperfine structure splitting (HFS) is also noted.

3.3. Two-Photon Evanescent-Volume Wave Spectroscopy

An extremely small EW penetration depth into the gas allows one to excite gas atoms only within the so-called "Knudsen layer" having the thickness of the order of the mean free path [27]. This has been exploited in the previous sections.

Additional spectroscopic possibilities open up if one excites the boundary gas layer by a volume electromagnetic wave propagating normally to the surface in addition to the EW wave. Because of different Doppler shifts for the atoms moving to the surface and away from it, one can distinguish between their contributions. Therefore the combination of EW and volume waves in a two-photon excitation scheme enables one to separate spectrally the contributions of the atoms immediately before the collision with the surface from those immediately after the scattering by it [28, 29]. The Doppler-broadened two-photon fluorescence lineshape is then determined by the velocity distribution functions of the atoms approaching the surface and departing from it (i.e., contains information about the gas–surface scattering dynamics).

The experimental setup for studying sodium atoms scattering at a glass prism surface contained a truncated prism to allow normal incidence of one of the beams onto the glass–sodium vapor interface. The cw lasers excited two adjacent transitions in sodium atoms. Two excitation geometries were investigated: (i) the "normal configuration," where laser 1 resonant to the $3S_{1/2} \leftarrow 3P_{3/2}$ transition excited a volume wave and laser 2 resonant to the $3P_{3/2} \leftarrow 5S_{1/2}$ transition excited an EW (Fig. 7) and (ii) the "inverse configuration" (Fig. 8), where the character of the waves was exchanged.

In both cases laser 1 was set at a fixed frequency whereas laser 2 was scanned across the upper transition. The flux of sodium atoms reached the prism surface at an angle $\theta_0 = 55°$ with respect to the surface normal. The flux was directed in the plane of incidence of the laser beam exciting the EW along its propagation direction.

In the normal configuration and for negative detuning of laser 1, Δ_1, a narrow peak was observed besides the Doppler-broadened line, whose position changed with Δ_1. For positive Δ_1, the intensity of the narrow peak decreased. In the inverse configuration the narrow peak could also be observed, but this time at the left-wing side of the Doppler-broadened line. For negative Δ_1, the narrow peak disappeared. In this case, in contrast to the normal configuration, a clear two-peak shape of the broad fluorescence line was
Figure 7. "Normal configuration" for two-photon evanescent-volume wave spectroscopy of sodium atoms, where the pump laser provides Doppler-broadened bulk excitation, whereas the probe laser uses evanescent wave excitation.

Figure 8. Same as Figure 7, but "inverse configuration," exchanging the character of pump and probe waves.

observed. The separation between the two maxima was independent of either the intensity of laser 1 or its detuning.

The observed features can be explained by the conditions of two-photon resonance in crossed fields taking into account the Doppler shifts for both transitions. For negative detunings of laser 1 only atoms arriving at the surface give contribution to the spectrum. The narrow peak at positive detunings of laser 2 arises from the atoms approaching the surface inside a small angular interval around θ_0 (i.e., emanating directly from the sodium source). The broader line also originates from atoms arriving at the surface but which had been scattered after mutual collisions in front of the surface. Its shape is asymmetric and is determined by a nonequilibrium velocity distribution function of such atoms. For positive detunings of laser 1 only atoms departing from the surface contribute to the spectrum.

In the inverse configuration, the left wing of the spectrum arises from the atoms arriving at the surface whereas the right wing arises from the ones departing from it. The atoms flying directly from the source contribute to the left wing only when Δ_1 is positive. The dip at the line center that corresponds to $\Delta_2 = 0$ arises from the fact that, as follows from Knudsen's cosine law [see Eq. (11)], there are no atoms leaving the surface with $v_z = 0$. This dip is washed out because of the transit-time and power broadenings.

Thus combining measurements in the normal and inverse configurations one can obtain comprehensive information on the *two-dimensional* velocity distribution functions of different groups of atoms in the immediate vicinity of the surface.

The relation between the atoms arriving at the surface and the atoms departing from it is given by the gas–surface scattering kernel, a fundamental quantity in gas–surface interactions.

The scattering kernel $R(\mathbf{v} \rightarrow \mathbf{v}')$ is the probability density that an atom striking the surface with velocity between $\mathbf{v}$ and $\mathbf{v} + d\mathbf{v}$ will reemerge at practically the same point with velocity between $\mathbf{v}'$ and $\mathbf{v}' + d\mathbf{v}'$ [30]. It determines the boundary condition for the velocity distribution function $f(\mathbf{v})$ of the gas atoms

$$f^+(\mathbf{v}')v_z' = \int R(\mathbf{v} \rightarrow \mathbf{v}')f^-(\mathbf{v})|v_z| \, d\mathbf{v} \qquad (13)$$

where the superscripts $-$ and $+$ denote the atoms arriving at the surface for which $v_z < 0$ and the atoms scattered by the surface for which $v_z > 0$, respectively.

In order to comply with different scattering mechanisms the scattering kernel can be divided into two parts:

$$R(\mathbf{v} \rightarrow \mathbf{v}') = R_{\text{des}}(\mathbf{v} \rightarrow \mathbf{v}') + R_{\text{dir}}(\mathbf{v} \rightarrow \mathbf{v}') \qquad (14)$$

Here, the kernel

$$R_{\mathrm{des}}(\mathbf{v} \to \mathbf{v}') = Sf_K(\mathbf{v}') \qquad (15)$$

corresponds to desorption following trapping at the surface with S the sticking probability and f_K determined by Eq. (11). The kernel $R_{\mathrm{dir}}(\mathbf{v} \to \mathbf{v}')$ describes direct scattering. The latter quantity can be expressed in terms of the probability $N(\epsilon, \mathbf{Q})$ that the state of the substrate phonon system after scattering differs from its initial state by energy ϵ and momentum $\mathbf{Q}$ related to the velocities $\mathbf{v}$ and $\mathbf{v}'$ by the conservation laws.

The experiment was carried out in the normal configuration described previously [31]. As noted, the two-photon fluorescence spectrum obtained for positive laser 1 detuning arises from the atoms departing from the surface. At the right wing of such a spectrum the atoms which were scattered without being trapped at the surface (i.e., scattered via a direct channel) contribute to two-photon intensity.

Using an expression for the probability $N(\epsilon, \mathbf{Q})$ derived in the trajectory approximation [32] one obtains by comparing calculated and measured spectra a value of the mean energy transfer to surface phonons. Then from the fitting of the total two-photon signal the mean probability of direct scattering $\eta = 1 - S$ can also be obtained. The measurements carried out for different surface temperatures showed that this quantity decreases on lowering the temperature. This result is consistent with the fact that atoms stick better if the surface is colder.

4. PROSPECTS FOR NANOSCIENCE

Evanescent wave spectroscopy probes the dynamics of an interface region of thickness less than the wavelength of the exciting radiation. In the visible optical range typical detection lengths approach the range of 100 nm—hence this is a dynamic *nanospectroscopy* of the interface. The spectra of gaseous particles at an interface region at such a scale not only display features connected with the interface structure but can also reflect the nonlocality of its optical response. This implies that EW spectra are very sensitive to the interactions between particles of the contacting media at the boundary. A most important prospect of the possibility to distinguish spectrally between the contributions of gas particles arriving at the surface and departing from it is that it should allow us to gain deeper insight into chemical reactions on the surface [33]. Under steady-state conditions a measurement of the decrease of the flux of molecules arriving at the surface is directly related to the surface reaction rate. Such an approach does not require the study of the transient, nonequilibrium stage of the reaction and can be utilized equally well under low and high pressures of reactant gases. It could help to solve the so-called pressure gap problem in catalysis [34]: one needs to study catalytic reactions in combined experiments at low pressure and at high pressure in order to provide a more direct basis for comparison of ideal and technical catalysts. Other surface specific optical techniques such as second harmonic generation, sum-frequency generation, or reflectance anisotropy spectroscopy are based on monitoring signal intensities from adsorbed species. In such a case—in contrast to EWS—the

kinetics of a reaction can be followed only during the transient stage.

The EWS method is restricted to gas pressures at which the EW penetration depth into the gas is comparable with one of the memory lengths. For a penetration depth of 100 nm and for a gas at room temperature the upper gas pressure limit is of the order of 1 atm. If the pressure is further increased the interface specific signal disappears due to collisions between the particles. In such a regime the evanescent wave variant of second-order nonlinear optics from the gas such as second harmonic generation or sum-frequency generation could become a viable tool [35]. This is based on the broken inversion symmetry of the gas atoms or molecules in close vicinity to the surface. The distances from the surface where the lowering of the symmetry takes place are determined by the range of the surface potential and are much smaller than any other optical probe scales. Thus the relevant signals are formed very close to the surface and they reflect the details of the gas–surface interaction even at atmospheric or higher gas pressures.

We envision another development of resonant optics at a gas–solid interface that is related to evanescent wave spectroscopy. In the visible spectral range the EW depth of penetration into the gas is less than 1 μm. An atom with a mean thermal velocity passes this distance within a few nanoseconds. Hence the EW profile can be thought of as a "pulse" for an atom moving across it. At gas pressures well below 1 atm typical atomic relaxation times are larger than the "pulse duration" (i.e., the atom interacts coherently with the EW field). Due to this fact, nonstationary coherent optical effects can be observed in the EW spectra [36, 37]. For systems where elastic atom–surface scattering is predominant, such effects will be determined by a phase shift of the atomic wavefunction when the atom is moving across the atom–surface potential.

The methods described could be extended to nanostructured surfaces by means of an additional spatial localization of the fluorescence light in *lateral* directions at the surface. This could possibly be achieved by the tip of a *scanning near-field optical microscope* (SNOM) [38] for collecting the fluorescence photons. In such a modification of a SNOM, called a *photon scanning tunneling microscope* (PSTM) [39], photons from an internally reflected light beam tunnel through the region between a sample surface and a probe tip and are collected by a detection system. The presence of a sample modulates the waveform of the evanescent field, and this modulation manifests itself as a spatial variation in the field intensity at a given height above the sample surface (Fig. 9).

Instead of using evanescent wave excitation via the surface one could also imagine exciting fluorescence light within nanoscaled objects, which then are probed via near-field detection. As demonstrated in Figure 10 via measurements on light-emitting nanofibers on a mica surface, the changes in intensity picked up by the fiber probe provide topographical information about the sample surface as well as information about the optical properties of the sample. Such a scheme can be used in a spectroscopic mode by detecting the signal as a function of the wavelength of the exciting radiation.
Figure 9. Principle of photon scanning tunneling microscopy, a SNOM variant that explicitly uses evanescent waves.

One of the crucial points for the success of such a spectroscopic application is the sensitivity of the detection system to a weak signal arising from a small number of molecules below the PSTM tip. Suppose one investigates the spectra of a gas in the volume beneath the PSTM tip with the dimensions $100 \times 100 \times 100$ nm^3. At gas pressures of the order of 1 atm such a volume contains about $N = 10^4$ molecules. Suppose now that the intensity of the EW resonantly exciting the gas molecules is high enough to saturate the molecular transition. Then the number of photons emitted per second equals $\gamma_\parallel \times N/2$. With typically $\gamma_\parallel = 10^7$ s^{-1} one obtains a fluorescence intensity of 5×10^{10} photons per second. Transmissivities of fiber-optic scanning tunneling probes are of the order of 10^{-5} [38], and so we conclude that such a fluorescence signal can be detected in the PSTM scheme.

Finally, let us note that although EWS has been demonstrated to be a powerful tool for the analysis of structure and composition of various interfaces, its full potential for solving problems of surface science, heterogeneous catalysis, and rarefied gas dynamics has not yet been realized. In particular, the possibility to identify spectrally the gas fluxes to the surface and apart from it in EWS combined with the PSTM scheme could provide a tool for monitoring the formation process of nanostructures on a surface (*nanofabrication*) and for studying catalysis on nanostructured surfaces (*nanocatalysis*).
Figure 10. Photon scanning tunneling microscopy on nanoscaled optical fibers ("nanofibers") made of fluorescing organic molecules [40]. The nanofibers are excited in the far field via focused ultraviolet light from the lower side of the image and probed in the near field. Image size 50×50 μm^2. (a) Topographic image. (b) Optical image. Waveguiding along selected fibers is clearly visible.

GLOSSARY

Evanescent wave (EW) An electromagnetic wave having an amplitude decreasing in the direction perpendicular to its wave vector at a scale of the wavelength.

Evanescent wave spectroscopy (EWS) Spectroscopy using EWs for excitation of optical spectra.

Gas boundary layer (GBL) The gas layer bordering a surface for which the optical response differs from that in the bulk gas.

Photon scanning tunneling microscopy (PSTM) The kind of scanning microscopy where photons from an internally reflected light beam tunnel through the region between a sample surface and a probe tip and are collected by a detection system.

Scanning near-field optical microscope (SNOM) A microscope where a subwavelength-sized light source or detector (viz., the optical probe) is placed at subwavelength distances from the sample surface, in the region called "near field." The probe can scan over the surface thus providing its imaging.

Extreme Ultraviolet Nanolithography

Paul B. Mirkarimi

Lawrence Livermore National Laboratory, Livermore, California, USA

CONTENTS

1. INTRODUCTION

Moore's law predicts that the number of transistors or memory bits on integrated circuits (ICs) will double about every 1.5–2.0 years [1, 2]. Adherence to Moore's law is believed to be necessary to continue to decrease costs per transistor or memory bit; one important practical consequence of this is the production of much faster computers at constant or decreasing prices. For Moore's law to continue, critical features such as transistor gate lines will need to shrink to several tens of nanometers in width, bringing the process within the realm of nanotechnology. Accompanying this change will be a transition from conventional microlithography techniques to nanolithography techiques. The leading nanolithography candidate for producing feature sizes of below 45 nm in the high-volume manufacturing of integrated circuits is extreme ultraviolet lithography (EUVL) [3–5]. Because of the potential impact of the technology, it has been well covered in the popular literature [1, 6–10] as well as in scientific journals.

The highest resolution lithography used in high-volume integrated circuit manufacturing employs ultraviolet (UV) light with a wavelength of 248 nm, although the industry is in the process of implementing lithography tools/processes that employ light with a wavelength of 193 nm [2, 5]. Before the insertion of EUV lithography, it is also possible that lithography technology utilizing light with a wavelength of 157 nm will be used (likely for manufacturing 65 nm feature sizes) [2, 11]. The particular numbers of 248 nm, 193 nm, and 157 nm for the wavelength are chosen because there are lasers, which serve as the source of light for these lithographic technologies, that operate at these wavelengths. EUV lithography will use light with a wavelength of approximately 13 nm and it should be noted that there are no suitable lasers operating near this wavelength. The 13-nm wavelength was chosen based on the available source technology and on the wavelength region for optimal EUV reflectivity for the Mo/Si multilayer-coated optics, which will be discussed later. One advantage of EUV lithography is that the relatively low wavelength implies that it would enable the semiconductor industry to adhere to Moore's law for several generations of ICs.

In lithography light is shone on a partially transmitting mask with slits in the shape of the features to be transferred onto a chip. The light pattern emanating from the mask is reduced in size by a factor of 4 and projected onto an area of a silicon wafer. The silicon wafer is coated with a polymer film called a resist. The resists are designed such that a small exposure to the UV light changes the structure of the material. For negative resists, the UV light exposure may cause the polymeric chains to crosslink, making them more resistant to etching. For positive resists, the UV light exposure may break bonds, making the resist more easily etched. Etchants can then be used which are designed to preferentially etch either the exposed areas of the resist (for a negative resist) or the unexposed areas (for a positive resist). The developed resist can then act as a template for subsequent processes. For example, exposed Si could be doped with impurities by ion irradiation or etched and filled in with metals and/or insulators, to make a circuit pattern. It is also possible to have coatings between the Si wafer and resist, and the patterns can then be formed in these coatings. Real-world integrated circuits are produced with processes that have many different coating and etch steps. Leading edge lithography techniques, such as EUV lithography, will be first used for the etch steps that require the smallest features. The primary difference between EUVL and previous lithographic technologies is that EUVL uses *reflective* optics and a *reflective* mask. This is due to the fact that sufficiently thick and robust materials with sufficient transmission at EUV wavelengths do not exist. The development of suitable Mo/Si multilayer coatings with high reflectivities in the EUV wavelength range of ~13 nm have enabled this technology to move forward [12–24]. The development of this nanolithographic technique is driving other areas

further into the nanoscale regime. For example, the aspheric optic substrates require a figure (shape) and a finish of a few tenths of a nanometer be achieved simultaneously [19, 25]. Interferometry has had to be advanced to enable one to accurately measure the figure to a few tenths of a nanometer on an aspheric surface [26, 27]. The multilayer coatings require thickness control to a few tenths of a nanometer and the interfaces must be controlled with sub-nanometer accuracy to maintain a high EUV reflectivity [16, 24, 28]. In the mask, defects in the multilayer that are as small as several nanometer, in height and several tens of nanometer, in width are unacceptable, and defects on top of the multilayer that are only several tens of nanometer, in size are unacceptable [29–31].

There have been a few reviews of EUVL technology in the past several years [32–35]. In this chapter, the primary aspects of EUVL technology are covered with an emphasis on the most recent results; in particular, an emphasis is placed on the multilayer-based mask blank, which is one of the highest risk areas for the technology and where new nanoscience and nanotechnology is being developed to reduce that risk.

2. EXTREME ULTRAVIOLET LITHOGRAPHY (EUVL) SYSTEM OVERVIEW

A schematic of the components of an all-reflective EUVL system [36–38] is shown in Figure 1, and in Figure 2 is an illustration of the components of a prototype EUVL system called the Engineering Test Stand [36, 39]. The *source* sends EUV light to condenser optics which serve to collect and shape the light. Condenser mirrors which reflect light at near-grazing incidence can be made with metallic-coated substrates. Condenser mirrors needed to reflect EUV at other angles need to be multilayer-coated to achieve a sufficient reflectivity. The EUV light is then used to illuminate a mask. The mask consists of a multilayer-coated substrate that has absorbing lines deposited on it in a particular pattern. The EUV light impinging on the multilayer is reflected and the light impinging on the absorber lines is not reflected. Thus the EUV light emanating from the mask is representative of the pattern on the mask. The EUV light from the mask is then sent to the projection optics, which serve to

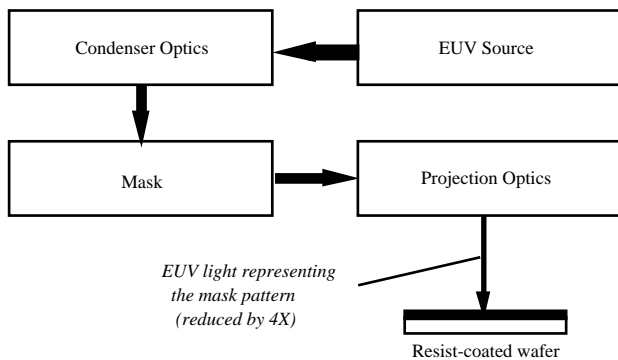

Figure 2. Schematic illustration of a prototype EUV lithography tool called the EUV Test Stand. The optics with "C" in front of them are the condenser, or illuminator optics.

reduce the pattern size by a factor of 4. This reduced pattern of EUV light impinges on a resist-coated wafer, where the resist is designed to be sensitive to EUV light. A pattern is formed on the resist-coated wafer as described in Section 1.

Wafer throughput is an important consideration in designing and building an EUV lithography tool since it has a strong impact on the cost of ownership, which essentially represents the economic viability of the lithography process. The current reported target for commercial EUV lithography tools is 80 wafers per hour [40], although that number is likely to increase [41]. The main driver for throughput is the intensity of EUV light arriving at the wafer surface and the (energy) sensitivity of the resist material. In terms of EUV light intensity, the power of the EUV source and the reflectivity of the multilayer coatings have the most dramatic effect. As is discussed in Section 3.3, while there have been improvements in the sources, significant advances are still required for the technology to be viable. The multilayer coatings have EUV reflectivities approaching 70% [23, 24] and do not represent a significant obstacle in the advancement of EUVL technology. For the resist, significant advances have been reported in synthesizing resist materials requiring as little as ~4 mJ/cm, [2, 42].

Another important consideration is wafer yield, which is impacted significantly by the quality of the mask. The pattern of the mask is copied to thousands of wafers in a high-volume production environment, and imperfections in the mask can lead to imperfections in the integrated circuits being synthesized on the wafers. Fewer acceptable integrated circuits means a lower yield and a larger cost of ownership. Like the EUV source, improvements in the mask have been made but advances are still required to make the technology commercially viable. The reflective nature of the mask makes it more susceptible to imperfections, as will be discussed in Section 3.2.

Figure 1. Schematic illustration of the components of an EUV lithography tool.

3. PRIMARY EUVL SYSTEM COMPONENTS

3.1. Optics

Unlike conventional optical microlithography techniques which employ transmissive optics, EUV lithography employs reflective optics. The first set of optics, commonly referred to as the *illuminator* or *condenser* optics, serve to collect and shape the EUV light from the source to illuminate the mask. For illuminator optics designed to reflect at grazing incidence, simple metallic films can have sufficient EUV reflectivity at those angles. For illuminator optics designed to reflect EUV light at angles closer to normal incidence, multilayer films are required. To reflect near 13.4 nm at near-normal incidence, Mo/Si multilayer films must have a bilayer period thickness (the thickness of one Mo layer plus one Si layer) of about 7 nm. Typically 40–60 bilayer periods are deposited. A schematic illustration of a reflective Mo/Si multilayer film is shown along with a cross-sectional transmission electron micrograph of a real Mo/Si multilayer in Figure 3.

Light reflected from the mask passes to the *projection* optics. Several of the projection optics have an aspherical shape, and require *simultaneous* control of the aspheric figure (shape) and surface finish (roughness) to a few tenths of a nanometer, levels not required previously. The finish requirement is driven primarily by the fact that the EUV reflectivity of the multilayer coatings, which can have a significant impact on the throughput of the EUVL system because of the number of optics, is a function of the substrate finish. The reflective coatings also cannot increase the figure error by more than a tenth of a nanometer or so, which requires that the coating thickness profile across the optic be controlled with extreme precision [22, 28, 43]. Coated optics have been successfully produced for the EUVL prototype tool called the Engineering Test Stand [28, 43] (ETS) and for other, smaller EUV tools [44]. The coatings met the specifications for commercial-grade EUVL
optics but the substrate figure/finish needs further improvement [43].

It is important that the spatial position of the projection optics not shift in the EUVL tool due to temperature fluctuations. This has led to the requirement that the substrate be made of low thermal expansion coefficient materials (LTEM). Zerodur and ULE are two of the leading LTEM candidates, with near-zero coefficients of thermal expansion (CTE). Zerodur has two phases (crystalline and amorphous), approximately twelve components, and consists mainly of SiO_2 and Al_2O_3 [45, 46]. The crystalline and amorphous phases have CTEs with opposite signs which enables the near-zero CTE to be achieved. ULE is a single-phase amorphous material consisting of SiO_2 and TiO_2 [47, 48].

The primary challenge with the optic substrates is to develop a process to manufacture sufficient numbers of optic substrates meeting the stringent figure and finish specifications with acceptable costs. For the coatings, there are several areas where work is needed. One is to develop multilayer films capable of withstanding exposure to EUV light over years in a high (but not ultrahigh) vacuum environment, where oxidation and carbon contamination could degrade the reflectivity (and hence wafer throughput) of the EUVL tool over time. Ru-capped multilayer films currently show promise for this application [24, 49]. More on environmental issues can be found in Section 4.2. Another area is to develop multilayer coatings in which the reflectance is not degraded significantly for substrates with roughness levels of a few tenths of a nanometer. EUV reflectivities approaching 70% near $\lambda = 13.4$ nm have been achieved for Mo/Si on ultrasmooth Si substrates [23, 24], and a goal is to achieve similar results on somewhat rougher LTEM for the projection optics. Conventional magnetron sputtering deposition techniques have yielded Mo/Si coatings with EUV reflectivity and thickness profile control values that meet or exceed the values from any competing deposition techniques; however, the EUV reflectivity is very sensitive to substrate roughness [50, 51] and it may be difficult to manufacture relatively large quantities of projection optic substrates that meet the ~0.1 nm desired values for the surface finish. Recent results with ion beam sputter deposition [52] show promise in this area and there is also an indication of work on this topic using ion-assisted electron beam deposition [23].

Mo/Si films typically have a stress of roughly 400–450 MPa [53, 54] and coating stress is an issue in that it has the potential to deform the precisely figured optics. One challenge is to mitigate stress effects without degrading the coating reflectivity. The use of compensating buffer layers [53], annealing [55–57], and other techniques [54, 58] have shown promise. There has been theoretical work suggesting that coating stress is not a significant issue in that most of the deformation due to stress will be spherical, and spherical deformation is expected to be compensable in the lithographic process [59, 60]. This theoretical work focused on the requirements of a prototype EUVL tool and it is possible that coating stress could become an issue for more advanced EUV lithographic tools. The arsenal of tools developed to combat stress should make this a tractable problem if it does arise.

Figure 3. Schematic illustration of a reflective multilayer film along with a cross-sectional transmission electron micrograph of a Mo/Si multilayer film.

3.2. Mask

EUV lithography employs a reflective mask. A schematic illustrating the difference between reflective and transmissive masks is shown in Figure 4. The EUVL mask blank consists of a square format LTEM substrate such as ULE or zerodur coated with a reflective Mo/Si multilayer thin film. LTEM is used so that thermal distortion of the masks will be reduced, since thermal distortion can shift and blur the light pattern coming from the mask [61]. The multilayer film is then coated with a buffer layer and an absorber layer, and processed with an electron beam lithographic tool to form a patterned EUVL mask.

A key challenge in making EUV lithography commercially viable is the ability to produce nearly defect-free mask blanks. *Critical* defects are imperfections that will cause some form of error in the pattern of light reflected from the mask, resulting in imperfections in the integrated circuit pattern formed on the wafer. Recent estimates suggest that a mask blank defect density of ~0.0025 critical defects per cm^2 will be needed [62]. This means that there can be an average of only ~1 of these defects per two 6" × 6" square mask blank, and defects as small as several tens of nanometers in diameter can be critical defects, as will be discussed later in this section.

There are two primary reasons why the defect requirements are more stringent for EUVL masks. The first reason, which is not inherent to EUV lithography, is the fact that the patterns of the mask need to be made smaller because the feature sizes to be printed are getting smaller as Moore's law is followed. This would mean that smaller defect sizes will become more of an issue for any mask technology. Note that the implementation of techniques such as phase shifting with the 248 and 193-nm lithographies is also likely to make smaller defect sizes more of an issue with transmissive masks.

The second reason for more stringent defect requirements, which is inherent to EUV lithography, is the reflective nature of the mask. This reflective mask gives rise to a new class of mask defects, referred to as multilayer phase defects. Particles as small as a few tens of nanometers in diameter on the substrate disturb the multilayer as it is deposited, resulting in the layers over the particle being shifted in height relative to adjacent regions. As illustrated in Figure 5a, EUV light reflected from the multilayer in the affected region will be out of phase with the light reflected from adjacent regions. If the size of the defective multilayer is large enough, it will result in a defect in the lithographically processed wafer. It is most likely to result in what is called a proximity defect, where a lithographically printed feature such as a line has an unacceptable variation in width.

Figure 4. Schematic illustration of a conventional transmission mask and an EUVL reflecting mask.

Figure 5. Schematic illustration of (a) a phase defect and (b) an amplitude defect in an EUVL mask blank.

This linewidth variation is often referred to as a CD (critical dimension) variation and it can affect functions such as timing in an integrated circuit. It should be noted that multilayer phase defects can result from particles arising early in the deposition process as well as from particles on the substrate.

The other type of mask blank defect is commonly referred to as an amplitude defect. This is illustrated in Figure 5b. This defect reduces the reflectivity of the multilayer in an area such that it results in an alteration of the lithographic features being formed on the wafer. Prime examples would be an absorbing particle sitting on top of the multilayer or a particle embedded in the top layers of the multilayer film. This defect is analogous to absorbing particles sitting in the transmissive area of a conventional transmissive mask.

In order to investigate the response of multilayer coatings to nanoscale substrate particles, a technique was developed to deposit monodisperse Au nanoparticles on Si substrates [63]. It was observed that the angle of incidence of the deposition flux can have a dramatic effect on the evolution of the multilayer defects [64, 65]. This is shown by the XTEM images in Figure 6. For near-normal incidence deposition, the multilayer tends to smooth over the substrate particle, mitigating its effect; however, for off-normal incidence deposition, this does not occur. It has also been suggested that the resputtering of Mo and Si during the ion beam sputter deposition process can enhance the smoothing properties of the coating [66].
Figure 6. Cross-sectional transmission electron micrographs of Mo/Si films deposited on 60-nm-diameter substrate particles with the deposition flux at (a) near-normal incidence (∼8°) and (b) off-normal incidence (∼48°) with respect to the substrate normal.

Substrate particles <50 nm in diameter are a particular concern since it is unknown if metrology will be available to reliably detect these very small particles on square format LTEM substrates. To attempt to clean the substrates of these particles, one would need a reliable metrology tool, and even then it is unknown if the particles can be removed without roughening or otherwise damaging the substrate. A strategy was suggested to enhance the smoothing properties of the Mo/Si coatings to planarize the substrates, making it as if the small particles never existed [67]. Progress has been made in this area [68], and substrate particles as large as 50 nm diameter can be smoothed to yield a surface with a defect height of ∼1 nm [69], making the defect benign according to the EUV printability theory [29]. The key process step involves etching of the Si layers in the Mo/Si multilayer [69]. This smoothing process also yields excellent film thickness/reflectance uniformity, good EUV reflectivity, and reasonable film stress, and also smooths substrate roughness [52, 69]. One outstanding issue for the smoothing technique is that it must be compatible with ultraclean deposition processes, that is, the introduction of the secondary ion source for etching cannot introduce significant amounts of particles. Another issue is that the effect of smoothing on substrate pits has not been quantified yet, although it has been reported using a different Mo/Si process that no significant difference was observed in the smoothing of substrate bumps versus divots when the substrate defects were very small (3–5 nm in height) [66].

Methods are also being developed to clean the substrates of these particles. A supersonic hydrocleaning method [70] is being developed which mixes deionized water with a carrier gas; the liquid breaks into droplets which are accelerated to a high velocity by the carrier gas and directed towards the substrate surface to remove particles. The technique shows promise and a relatively high particle removal efficiency has been reported [70]; however, the effect of this technique on the surface finish of the substrate was not discussed, which can be an important factor in evaluating potential cleaning techniques.

When there are errors in the metal patterns on a conventional transmissive mask, they can usually be repaired by removing or adding material with a focused ion beam (FIB) tool. This technique can also be used with the patterned EUVL mask to repair absorber features [71, 72]. It had been said that one of the drawbacks to EUV lithography was that it was not possible to repair the multilayer-based mask blank, since this FIB-technique would not work for multilayer defects. In response to this, several techniques have been developed to address this issue [73–75]. One technique developed to repair multilayer phase defects entails irradiating the defective area with a 10–20 kV, high current electron beam [73, 76]. This heats the multilayer in the defective region and activates silicide formation between the layers, causing them to contract. A temperature approaching 800 °C is believed to be needed to achieve the necessary contraction; such a temperature would severely degrade the multilayer structure [77–79] except for the fact that the annealing is to be done over a very short period of time (milliseconds). It was experimentally demonstrated that an electron beam could be used to controllably produce depressions in Mo/Si multilayer films with nanometer-scale depths without any significant degradation in the EUV reflectivity [73]. Due to tool limitations, this demonstration occurred over lateral sizes of hundreds of microns. To be viable, the lateral size of the beam footprint will need to be reduced to the order of 100 nm, which, considering the energy and current requirements, may require further optimization of current electron beam column design. This is an example of EUV lithography driving other technologies further into the nanoscale regime.

Another technique designed to repair amplitude defects in or on the multilayer film entails milling out a small crater in the defective area [74, 80]. According to theory, it is possible to put a crater in the multilayer which does not become a defect if (i) there is a sufficient number of unaffected multilayer bilayers under the crater to reflect the EUV light, and (ii) the slope of the sidewalls of the crater is shallow enough. Condition (ii) puts the minimum lateral size of the crater at several microns and condition (i) limits the depth to <20 bilayers if a 60-bilayer multilayer is used. It will also be necessary to put a capping layer on the surface of the crater [74] since otherwise there would be exposed Mo layers within the crater and Mo oxidation has been shown to result in a significant decrease in EUV reflectivity [81]. Craters have been produced in multilayer films with the appropriate depths of several tens of nanometers using an ion beam, but the lateral size was on the order of millimeters and needs to be reduced to <5 μm eventually. Thin Si was used to coat the crater surface and the reflectivity loss inside the crater was reduced to several percent; further improvement will be needed [74, 82].

A key challenge is to produce multilayer coatings with nearly no defects added during the coating process. Significant progress was made in the mid-1990s, taking a process yielding roughly thousands of defects/cm^2 to a process yielding ∼0.10 defects/cm^2 for particles 130 nm in diameter and larger [83, 84]. In addition to improving the cleanliness of the handling processes, one of the changes believed to be responsible for this advance was a move to ion beam sputtering from conventional magnetron sputtering [84, 85]. Most mask blank development work is now done with ion beam sputtering [86–88]. Two reasons possibly differentiating ion beam and magnetron sputter deposition processes

with respect to particles are (i) conventional magnetron sputtering can produce particle sources/traps in the immediate vicinity of the magnetron sources [89–91], and (ii) Mo/Si multilayers tend to amplify the effect of substrate particles, likely due to the off-normal flux components inherent to conventional magnetron sputtering [64]. It should be noted that by employing rotating magnets in the magnetron sources and by collimating the deposition flux, it should be possible to mitigate the above effects and make the magnetron deposition process more competitive for this application. Note that magnetron sputtering is competitive for the coating of optics because small coating defects are not currently considered to be a significant concern for the optics.

Subsequent progress in defect reduction during the coating process has been made since 1997, but at a slower rate, where the best repeatable defect levels are ~0.05 defects/cm^2 for defects 90–100 nm and larger [92, 93]. The difficulty of achieving sufficiently low defect densities during the coating process is one of the most significant challenges facing EUV lithography. Development of the repair techniques discussed above could relax the defect specification during the coating process [94].

As mentioned earlier, the multilayer-based mask blank must be processed to produce a pattern of absorbing lines and open spaces on the multilayer surface. A buffer layer is first deposited to facilitate the patterning of the absorber layer while protecting the multilayer from damage. A leading candidate for the buffer layer is SiO$_2$ and for the absorber layer it is Cr or TaN [95–97]. It should be noted that Ru is being considered not only as a capping layer for the optics, but also for the mask, where it has the potential to replace SiO$_2$ as leading candidate for the buffer layer [98]. For additional information on the topic of EUVL mask patterning, the reader is referred to papers by Hector [94] and Hector and Mangat [99].

There are two techniques to mitigate the effects of multilayer defects during and after the mask blank is patterned. The first technique, which we will call *defect obscuration*, entails putting the pattern on the mask blank in such a way as to cover multilayer defects with the absorber lines [94, 100]. While this technique has potential, it is unknown if it would be able to mitigate more than a few defects on a mask at a time; this would depend somewhat on where the mask defects are located, which will likely be a random process. The second technique, termed *defect compensation*, entails removing or adding material of an absorber line that is near a multilayer phase defect such that the effect of the multilayer defect is negated during the lithographic process [75]. An advantage that the defect obscuration and defect compensation techniques have over the multilayer repair techniques described earlier is that a smaller advancement, and hence a smaller investment, would be needed to make these techniques viable. Two disadvantages that these techniques have are that they cannot be used by the mask blank manufacturer to qualify the blanks before shipping, and some investment in terms of patterning is required before these techniques can be attempted (i.e., an unsuccessful repair attempt on a mask blank is less expensive than a failed repair attempt on a patterned mask). With the challenges posed by the EUVL stringent mask defect

specifications, there can be a strong argument that all of these techniques should be vigorously pursued.

After the mask is fabricated, protecting it from particle contamination is also an issue; this is discussed in Section 4.2.

3.3. Source

The source of EUV radiation must provide sufficient power (>47 watts) [101, 102] at EUV wavelengths and must do so for a reasonable length of time before maintenance is required. This is needed to achieve a sufficient wafer throughput to make the technology commercially viable. An additional consideration is that a minimal amount of debris be emitted from the source, since this debris could deposit on the illuminator optics, reducing the reflectivity and significantly limiting their lifetime. The technical challenges in the source area have been formidable and the source is currently one of the highest risk areas for EUVL. One positive change over the past several years is that there are now a number of source concepts being developed [101, 103–111] at companies and institutions across the globe. One of the leading EUV source candidates is a laser-based plasma source employing a Xe target, where there is a slight preference for a liquid-based Xe target at this time [104, 112]. A high-powered pulsed laser is focused onto the xenon and the laser energy is used to raise the xenon atoms to an excited state. When the xenon deexcites it give off photons with wavelengths in the EUV part of the electromagnetic spectrum. Previously, metal targets were used instead of xenon; however, xenon has lower debris [113]. One of the reasons why it is challenging to obtain sufficient EUV power is that the conversion efficiencies of the sources are typically <1%. This means that less than 1% of the power input to the Xe-based source from something like a Nd:YAG laser is converted into usable EUV power [112].

Electric capillary discharge sources are promising in that if successful, their costs should be considerably less than the laser-based plasma source, since very large, high-powered lasers should not be needed. Debris and power scale up are the two most significant challenges facing the development of the capillary discharge sources [105, 107].

Despite the greater worldwide participation and progress that has been made over the past several years, significant progress in the EUV source area is still required for EUV lithography to be commercially viable.

4. SUPPORTING TECHNOLOGIES

4.1. Resist

Standard resist materials attenuate EUV light too readily, making it necessary to develop new resist processes. A key metric for the resist is the dose needed to process the resist. A lower dose requirement means that fewer EUV photons are needed to process a given wafer, which translates into increased wafer throughput. The dose requirement must be met while satisfying other criteria, primarily maintaining a sufficiently low line edge roughness (LER) for the features formed during the lithographic printing process [42]. An impressive dose level below 4 mJ/cm^2 has been recently met; however, some improvement of the LER is needed

[42]. Recent lithographic results from the Engineering Test Stand indicate that the resist performance will need to be improved further [114].

4.2. Environment

Because EUV light is attenuated in air, it will be necessary to keep the beam path in vacuum (P > 10^{-8} torr), although it is probably not practical to maintain ultrahigh vacuum conditions (P < 10^{-9} torr) inside of the EUVL tool. Long-term exposure of the reflective coatings to EUV light, and in particular under conditions where gaseous species in the ambient may react with, or condense on, the coating, is a serious concern. One mechanism for degradation of the coating reflectance is enhanced oxidation of the Si-terminated Mo/Si surface [115]. It has been suggested that low-energy secondary electrons created by exposure of the Si-terminated Mo/Si to EUV light could interact with water molecules from the environment to enhance oxidation of the surface [24, 116]. Terminating the Mo/Si with a thin Ru film on the surface shows promise for hindering surface oxidation with a minimal impact of the EUV reflectivity from the Ru layer [24].

Another mechanism for degradation of the coating reflectance is the deposition of hydrocarbons on the surface, believed to be due to the cracking of hydrocarbons from electrons emitted from the Mo/Si during EUV exposure [115, 117–119]; carbon, like most materials, absorbs EUV light. This mechanism is not surprising considering that it has been known for many years that carbon deposition can occur on surfaces exposed to high-energy light in synchrotron beamlines [120–122]. It has been observed that optimizing the thickness of the Si layer terminating the Mo/Si multilayer can reduce the carbon buildup on the multilayer [118].

It has also been observed that ethanol can be added to the environment to significantly hinder oxidation, but it does allow carbon deposition [117, 123]. It has been suggested that the carbon could be removed via *in-situ* molecular oxygen cleaning [124]; one challenge with this approach is to remove the carbon without inducing further oxidation. Ongoing work using atomic hydrogen to clean the surface of carbon contamination shows promise [115].

Work on high-reflectance Mo/Si coatings on thin test substrates exposed to ambient conditions suggested that there is some stress relaxation that occurs in the first several weeks, but otherwise the coatings are stable over time under ambient conditions [22, 53, 125].

As noted earlier, the mask must be nearly defect-free and must remain so during the operation of the lithographic tool. Current lithographic technologies encase the transmissive mask in a *pellicle*, which essentially is a transparent cover that allows light through. If a few small particles land on the pellicle, it is not as significant as if these particles land directly on the mask surface, because the particles are offset from the mask plane by a distance equal to the pellicle thickness. For EUVL masks it is not plausible to use a pellicle during EUV exposure because suitable materials strongly attenuate EUV light. A removable pellicle can be used for the EUVL mask for all of the time except for times when it is in the lithographic tool, and this is planned [94, 102].

In order to protect the mask from particles during operation of the lithographic tool, a thermophoretic protection technique has been developed [126, 127]. The mask is maintained at a slightly elevated (<10 °C) temperature to the surroundings, providing a force opposing particle motion to the mask surface. This force arises because the gas molecules closer to the slightly warmer mask will have a higher kinetic energy and will tend to move away from the mask to the cooler region. In moving away from the mask, these molecules will collide with particles moving towards the mask, providing a net force on the particles away from the mask. Experiments to date have shown that the basic technique works [127]. One drawback to this technique is that it works better for higher pressures, and higher pressures can entail more EUV attenuation and possibly contamination. Instituting differential pumping to enable a higher pressure in the vicinity of the mask relative to the rest of the lithographic tool is a potential remedy.

4.3. Nanometrology

Defect inspection tools are currently relied on to measure defect levels on masks as well as processed wafers. The most commonly used technique scans the sample with light in the visible spectral range and detectors look at light reflected/scattered off of the surface. If the surface is relatively smooth, it is possible for defects on the surface to provide an optical signature in the scattered light that can be measured.

EUV lithography will require advances in the capability of these defect detection tools [128–132]. For wafers the extension is straightforward in that smaller defects would need to be detected as feature sizes shrink regardless of whether EUVL or some other lithographic technology is used to synthesize the features. For the mask there are EUVL-specific issues pertaining to advancing the defect detection techniques [128, 133].

Interferometry is needed to determine if the optics meet the figure (shape) specifications [26, 27] and if the masks meet the flatness specifications [134]. It is also needed to align the optics in the EUVL tool. As noted earlier, the figure specifications for the projection optics are very stringent, and a figure specification does not mean much if there is no way to measure it. The fact that some of the optics are aspheres serves to complicate the measurements even further. This has and will continue to drive the resolution capability of interferometry further into the nanoscale regime. For EUV lithography there is work employing interferometers that operate with visible [26, 27, 135, 136] and EUV light [136, 137]. The visible light interferometers currently have an absolute accuracy of ∼0.2 nm rms [27, 135] and will need to drive that to ∼0.10 nm rms for commercial-grade EUVL tools [27]; it has been suggested that one way to achieve this is to move to a lensless interferometry [27].

Miscellaneous metrology tools will be needed to characterize nanoscale features, whether it be in the development of EUVL technology or in the examination of the features of the integrated circuit patterns formed on the wafer during the lithographic process. Atomic force microscopy (AFM) is a very valuable nanoscale metrology tool for characterizing surface parameters such as high spatial frequency roughness

and defect topology; but existing AFM technology is likely to be sufficient for most applications relating to EUVL. Scanning electron microscopy (SEM) is also useful for characterizing surfaces, and advancement in the capabilities of CD-SEMs, which measure parameters such as line edge roughness in critical dimension features in integrated circuits, will be needed [138].

5. CONCLUSIONS

EUV lithography is expected to be used to manufacture integrated circuits with feature sizes below 45 nm, which will enable extremely powerful integrated circuits to be made for microprocessor and memory applications. The very low wavelength of $\lambda = 13$ nm should enable EUVL technology to be used for several generations of integrated circuit manufacturing. The two key elements differentiating EUVL from other optical lithography technologies operating at $\lambda \geq$ 157 nm are (i) the use of reflective optics and a reflective mask, and (ii) a source that is not a laser.

A prototype EUV lithography tool has been successfully constructed and work is underway to build more advanced EUV lithography tools. In addition to system integration, there has been a significant amount of work in component development. While significant progress has been made, component development issues represent the primary challenge to the successful implementation of the technology. In particular, power/stability/debris issues with the source and defect issues in the mask blank are the two greatest challenges. In order to combat mask defect issues, new nanoscience and nanotechnology has been developed. It is likely that additional advances in nanoscience and nanotechnology will occur in the development of EUVL, and if EUVL is successful it could enable widespread advances in nanotechnology by enabling nanoscale features to be formed in a well-controlled, high-volume manufacturing environment.

GLOSSARY

EUV printability theory   Theoretical models used to determine if a defect in the mask, such as in the multilayer coating in the mask, will become a printed feature (or printed variation in a feature) in the wafer when exposed in an extreme ultraviolet lithography system.

EUV resist   Material which when exposed to EUV light will become more or less resistant to etching.

Microlithography   Branch of lithography applied to integrated circuit fabrication.

Nanolithography   A more up-to-date term for "microlithography," reflecting the fact that printed features are approaching the nanometer regime in integrated circuit fabrication.

Substrate   The bulk material upon which a film or coating is deposited. Commonly used materials are silicon and quartz.

Fast Atomic Force Microscopy

Fredy R. Zypman

Yeshiva University, New York, USA

CONTENTS

1. INTRODUCTION

The atomic force microscope (AFM) was invented in the mid-1980s by Binning et al. [1]. It belongs to the family of scanning probe microscopes (SPMs), which, by different mechanisms, obtain local information of surfaces at scales down to the nanometer. It is a natural extension of its two SPM precursors, the scanning tunneling microscope (STM) and the stylus profilometer (SP), created few years before. The STM [2] consists of a metallic tip placed above a sample under study. Upon the application of a bias voltage between tip and sample, electrons move from tip to sample (or vice versa) via quantum mechanical tunneling. The flow of electrons is sensed by an external circuit as a current that, in turn, is used as the characteristic parameter of the system. This current is then processed *ex-situ* to obtain relevant information of the sample surface like topography and local electron energy level distribution. The stylus profilometer was introduced by J. B. P. Williamson. It also consists of a tip that interrogates the surface, in this case only for topographic features. Its principle of operation is extremely simple—although not necessarily its actual realization. A hard and relatively narrow tip is placed in contact with the sample under study and then moved across the surface, always remaining in contact. The vertical motion of the tip is, then, a direct measurement of surface protuberances.

The AFM is an extension of the SP and a complement to the STM. The AFM, similarly to the SP, has a tip that is scanned over a surface. However, the AFM tip (and other relevant mechanical parts) is lighter than its corresponding SP counterpart. In addition, the AFM's tip, at its apex, has a much smaller radius of curvature than that of the SP, allowing for the detection of minute morphological features of the sample's surface. The light mass of the AFM's tip allows for its quick response in time to sample variations or to variations in time due to placement of the tip at various locations. This is central to the operation of the AFM and will be discussed further. On the other hand, the STM has a spatial resolution similar to that of the AFM, but while the former is appropriate for studying conductors, the latter is also good for studying insulating materials. While the STM is suited to measure the energies of electrons in the (conducting) material, the AFM is suited to extract forces between tip and sample.

The operation of the AFM can be characterized according to its functionality. When the user seeks to obtain the shape of the surface under study, the AFM is said to operate in *topographic mode*. In this mode of operation, the tip is scanned across the sample to obtain the height of the surface at different locations. The AFM can also be used in *spectroscopic* mode, in which case we seek to measure interaction forces between tip and sample.

Figure 1 shows a schematic representation of the tip–sample system. There, the whole microscope assembly has been conceptually lumped into a support (left of figure), which comprises the link of the cantilever to the glass substrate from which it was sculpted, the link of the substrate to a larger massive holder, and, finally, the link of the holder to the external frame of the microscope. The tip, the sensing piece of the AFM is, as mentioned before, the central component. The tip is a protrusion manufactured at the end of a cantilever. The figure has not been drawn to scale so that we can show both the cantilever and the tip. In reality, typical cantilevers are about 100 μm long, while the tips are a hundred times smaller. Given that AFM measurements rely on the motion of the tip, any theory of AFM must take into consideration the cantilever, since its inertia dominates that of the tip.
Figure 1. Standard AFM setting.

2. TOPOGRAPHIC MODE

To understand the operation of the AFM in topographic mode, let us refer to Figure 1. There, the surface shows a flat region on the right and a bump on its left. Suppose that, initially, the tip dangles over the rightmost flat area of the sample and the whole assembly is at a nominal rest—in practice, perfect rest is not achieved due to the ever-present uncontrolled vibrations such as thermal vibrations of microscopic origin or simply crass street traffic. If we center our attention on the tip, it will be in static equilibrium when the total forces acting on it vanish. Thus

$$F_{\text{interaction}} = F_{\text{elastic}} \qquad (1)$$

where $F_{\text{interaction}}$ is the force that the sample exerts on the tip and F_{elastic} is the force that the flexed cantilever applies on the tip. In a simplified picture, we can view the cantilever as a spring that can be extended or contracted in accordance with $F_{\text{interaction}}$.

For data collection, a laser beam impinges on the top face of the cantilever. The beam reflected off the cantilever is directed toward a system of photodetectors, which, in turn, outputs a voltage proportional to the angle of deflection of the beam. By simple geometry, this angle can be related to the vertical position of the tip. Thus, the voltage output from the photodetectors represents a measure of the vertical position of the tip. In the static geometrical configuration just described, the reflected beam lies along a constant line, and the voltage output from the photodetectors does not change, which is a statement of the fact that the tip stays put at a constant height.

Although laser detection, almost as originally introduced, is still widely and successfully used, other techniques have been introduced lately [3].

At some instant in time, the tip is set to move toward the left, relative to the sample. Sometime later, when the tip starts touching the base of the bump, the tip–sample gap will begin to narrow. Almost simultaneously, the photodetector's voltage changes, indicating that the relative tip–sample height has changed. This happens as a result of a loss of static equilibrium: at the base of the bump, the tip–sample force changes all of a sudden as a result of the narrowing of the gap, while the elastic force remains the same. Equation (1) does not hold, the tip is not in equilibrium, and it accelerates, trying to change its position. However, the AFM, in topographic mode, is designed so that the photodetector's voltage remains fixed. To achieve this, an electromechanical transducer (a piezoelectric material) is attached to the cantilever to move it vertically when it senses a change in voltage from the photodetectors. Via a feedback loop, the piezoelectric moves the cantilever in such a way that the photodetector output regains its original voltage value. However, in order to achieve this, the piezoelectric must now have an applied voltage different from its initial value in order to keep the cantilever higher. This piezoelectric voltage permits the final image reconstruction. The idea is that as the tip visits a variety of horizontal positions on the sample surface, its height relative to the sample is kept constant at the expense of applying a bias voltage to the piezoelectric. This bias voltage defines a two-variable function $V_{\text{P}}(x, y)$, where V_{P} is the voltage applied to the piezoelectric and x and y are the Cartesian coordinates of the tip on a horizontal sample grid. In principle, a three-dimensional, graphic rendering of $V_{\text{P}}(x, y)$ corresponds to the topography of the sample's surface.

The description just given to unveil surface information with the AFM is, to a good extent, reliable, but it lacks in accuracy exactitude. We are not referring here to the experimental errors intrinsic with any measuring apparatus, but rather to the tacit limitations imposed by an algorithm of reconstruction based on the model given before. First, the model supposes that there is a one-to-one relationship between the tip–sample separation and the piezoelectric voltage. That can be seen immediately not to be true in general. As a counterexample, consider a perfectly flat surface. According to our simple model, as the tip moves horizontally above the sample, the piezoelectric voltage remains fixed since it never receives a signal to change from the photodetector system. Let us suppose that the flat surface comprises two regions of different materials A and B, separated by a horizontal line boundary on the surface. In general, as the horizontal projection of the tip's position crosses the boundary, the forces on the tip will change with a concomitant change in the reflected laser beam direction, the output voltage from the photodetectors, and, finally, the new voltage applied to the piezoelectric to bring "everything" back to where it was before. Thus, we see that a reliable algorithm needs to take into consideration not only morphology but also chemical information of the sample. Another problem with the simple algorithm is that it assumes the cantilever to be appropriately described by a spring—with its associated mass. For static measurements, that is fine. Nevertheless, how do we know when the static regime has been overcome? Many of the applications of AFM deal with samples in motion, which implies that the horizontal scanning has to be performed fast enough so that the sample does not move significantly during the time the picture is taken. Under fast

motion, the spring fails to be a good paradigm for the cantilever. It is similar to what would happen to a rubber band with a mass attached at its end: at low speeds, the rubber band acts as a spring, but, at higher speeds, other vibrations appear that cannot be taken into account by a single-degree-of-freedom system.

3. SPECTROSCOPIC MODE

In spectroscopic mode, we inquire about tip height changes while the tip–sample separation is varied. In most contemporary AFM systems, the sample is moved up or down, while we look for tip deflections via the laser–photodetector arrangement. The idea is that from the known motion (experimentally measured) of the tip we can extract—that is, reconstruct—interaction forces between tip and sample. In the pure spectroscopic mode, we are not interested in the topography of the sample but rather in the tip–sample force as a function of their separation.

In short, the aim of this mode of operation is as follows:

- Vary and monitor $z_S(t)$, the absolute vertical position of the sample's surface versus time.
- Measure directly $z_T(t)$, the absolute vertical position of the tip as a function of time.
- Reconstruct, via appropriate algorithms, $F_{interaction}(z)$, where $F_{interaction}$ has been defined previously and $z = |z_T - z_S|$ is the relative tip–sample separation for all times.

To obtain an idea of this mode of operation, we once more call on the simple—albeit somewhat incomplete—spring model to describe the mechanical response of the cantilever. Again, this picture is sufficient to describe a motion in which all parts move very slowly. A few practical applications—but by no means the majority—fall in this category.

Figure 2 depicts a representative configuration. The sample is z_S above a fixed vertical reference, which in the picture is taken to be vt, where v is the speed of the platform that holds the sample and t is the time elapsed since the beginning of the experiment. The tip is z_T above the same reference and varies in time in an unknown way a priori. The tip–sample distance is $z(t)$. The cantilever has been removed from the picture and replaced instead by a single mass–spring arrangement, with mass m and spring constant k.

Figure 3 illustrates a typical force versus separation curve. In the figure, the pale horizontal line represents the line of null force. Points below the line (negative) correspond to attractive forces, and points above the line correspond to repulsive forces. Thus, we see that the force–separation curve is negligible at large distances, corresponding to the fact that tip and sample do not interact when they are far away. Likewise, at medium-range separations (on the order of nanometers), the interaction is attractive. Finally, at very small separations, core–core atomic repulsive forces dominate, and the overall force becomes large and repulsive.

Let us use Figures 1–3 to gain insight into the kind of signal we expect to measure. In what follows, we will assume a common measuring setup in which the feedback mechanism to maintain the tip–sample separation fixed is not engaged,

Figure 2. Detailed tip–sample configuration. The tip–cantilever system is modeled as a lumped mass–spring.

in which case the output signal is the voltage from the photodetectors. The initial condition of the system has the following properties (Fig. 2):

- The tip is at its natural equilibrium point, corresponding to the balance between the spring force (upward) and the gravitational force (downward).
- The platform that holds the sample is in its lowermost position.
- Concomitantly, the tip–sample separation lies on the right-hand side of the horizontal scale in Figure 3, resulting in a nil force.

Subsequently, the platform starts moving up with a slow constant speed v (Fig. 2). During the initial period, the tip and sample are relatively far from each other, and therefore the tip stays put at its natural equilibrium point. At some

Figure 3. Typical force–separation curve.

moment, the platform moves up enough to decrease the tip–sample distance to the point at which slight interactive forces become appreciable. At that time, the tip will start to move down since the total net force now points downward, due to $F_{\text{interaction}}$. As the tip moves down, the angle that the cantilever makes with a horizontal line increases.

Consequently, the reflected beam off the cantilever will decrease its angle θ_R from the horizontal and thus induce a change (consider an increase) in the voltage of the photodetectors. As time progresses, and the tip–sample separation shrinks, the photodetector voltage, $V_{\text{PH}}(t)$, increases as a nonlinear function of time. Since $\Delta V_{\text{PH}} \propto \Delta \theta_R$ (the proportionality constant known by calibration in practical situations), and $\Delta \theta_R$ determines, from simple geometry, the position of the tip $z_T(t)$, $z(t)$ can be obtained from

$$z(t) = z_T(t) - Vt \qquad (2)$$

The force can be found by using Newton's second law:

$$m \frac{d^2 z_T}{dt^2} = F_{\text{interaction}} + k z_T(t) - mg \qquad (3)$$

where $g \cong 9.8 \text{ m/s}^2$. Equation (3) can be rewritten as

$$F_{\text{interaction}} = m \frac{d^2 z_T}{dt^2} - k z_T(t) + mg \qquad (4)$$

In Eqs. (2)–(4), the function $z_T(t)$ is completely known from the experiment described previously. Therefore, the function $d^2 z_T/dt^2$ is also completely known. In this form, Eq. (4), in combination with Eq. (2), provides a parametric form for the function $F(z)$.

Thus, we have shown in this section how to obtain $F(z)$ from $V_{\text{PH}}(t)$. Notice that the central theoretical assumption is that the cantilever can be conceptually lumped into a mass–spring system. The reconstruction algorithm (which we just described) is then simply based on using Newton's law to the model system.

4. MODULATION TECHNIQUES

Methods that are more sensitive (in the sense that they increase the signal-to-noise ratio) have been designed to extract force–separation curves. They are based on the concept of modulation—in which some input parameter is forced to oscillate at a prescribed frequency. The simplest improvement consists of forcing the tip–cantilever structure to oscillate at a constant frequency, for example, the natural frequency ω_0 of free oscillation with which it would freely vibrate when no sample is nearby. To analyze the problem and understand what information can be obtained, let us consider Figure 4. There, again, the cantilever–tip assembly is well represented by a spring (of constant k_t) and a mass (m_t). In addition, we now introduce k_i, a spring constant that characterizes the interaction between the tip and the sample. This can be understood as follows: a small-amplitude oscillatory tip in the presence of a force field (Fig. 3) will sense a small interval of forces. In this small interval, the force–separation curve can be well approximated by a straight line with slope $dF(z)/dz$. Thus, in this interval, the effect

Figure 4. As in Figure 2, but also taking into consideration the elastic properties of the sample.

of the interaction force is the same as that of a spring— "interaction spring"—with equivalent spring constant $k_i = dF(z)/dz$. In this derivation, we are assuming that the sample is very heavy and stiff, which is a very good starting point to isolate the effect of the interaction force. Later, when showing how to extract vibrational properties of the sample, we will remove these assumptions.

The equation of motion for the tip is

$$m_t \frac{d^2 z(t)}{dt^2} = \left[A_{\text{in}} e^{i\omega_{\text{in}} t} - z(t) \right] k_t - k_i z(t) - b \frac{dz(t)}{dt} \qquad (5)$$

where $z(t)$ is the position of the tip—the sample is at rest. The first term inside the parentheses corresponds to a forced vibration of the cantilever, with input amplitude A_{in} and frequency ω_{in}. The two terms with the spring constants represent the restitution forces of the springs, and the last term accounts for a friction term.

In steady state, Eq. (5) accepts a solution of the form

$$z(t) = A_{\text{out}} e^{i\omega_{\text{in}} t} \qquad (6)$$

Upon substitution of Eq. (6) into Eq. (5)

$$A_{\text{out}} = \frac{\omega_{tt}^2}{(\omega_{tt}^2 + \omega_{it}^2 - \omega_{\text{in}}^2) + i\gamma \omega_{\text{in}}} A_{\text{in}} \qquad (7)$$

where we have used the shorthand notation

$$\omega_{tt} \equiv \sqrt{\frac{k_t}{m_t}} \qquad \omega_{it} \equiv \sqrt{\frac{k_i}{m_t}} \qquad \gamma \equiv \frac{b}{m_t}$$

Next, as mentioned previously, we require that $\omega_{\text{in}} = \omega_0$, the natural frequency in the absence of interaction—the one it would have if ω_{it} were 0. Then Eq. (7) takes the form

$$A_{\text{out}} = \frac{\omega_0^2}{\omega_{it}^2 + i\gamma \omega_0} A_{\text{in}} \qquad (8)$$

Equation (8) immediately provides the physical quantities' root mean square,

$$a^{\text{rms}} \equiv \sqrt{\int_0^{2\pi/\omega_0} [\text{Re}(Ae^{i\omega_0 t})]^2 \, dt}$$

and phase Φ with respect to the input signal:

$$\frac{a_{\text{out}}^{\text{rms}}}{a_{\text{in}}^{\text{rms}}} = \frac{\omega_0}{\gamma} \frac{1}{\sqrt{1 + (\omega_{\text{it}}^2/\gamma\omega_0)^2}} \tag{9}$$

$$\Phi = -\arctan\left(\frac{\omega_0\gamma}{\omega_{\text{it}}^2}\right) \tag{10}$$

Equation (9) or Eq. (10) forms the basis for the classification of the modulation techniques in AFM, according to the quantity being detected. Thus, among many others, measurements can be made in *amplitude detection mode* or *phase detection mode*.

4.1. Amplitude Detection Mode

In this case, Eq. (9) forms the basis of the algorithm to convert experimental data into force information. Concretely, $a_{\text{in}}^{\text{rms}}$ is known since it is the input amplitude. The quantity $a_{\text{out}}^{\text{rms}}$ is also known since it corresponds to the rms output voltage from the photodetector system. Finally, γ and ω_0 are known from calibration of the cantilever–tip system. We will use Q, the quality factor instead of γ, which, for small damping—as is usually the case—are related by $\gamma = \omega_0/Q$. Therefore, Eq. (9) permits the calculation of ω_{it}. By using the definition of ω_{it} and the relationship between k_i and force, we finally arrive at the very handy relationship:

$$F(z) = \frac{m_t \omega_0^2}{Q} \int_{+\infty}^z dz \sqrt{\left[Q \frac{a_{\text{in}}^{\text{rms}}}{a_{\text{out}}^{\text{rms}}(z)}\right]^2 - 1} \tag{11}$$

where we have explicitly written the z dependence of $a_{\text{out}}^{\text{rms}}$—which varies as a result of the tip being embedded in a different force field. The constant of integration was chosen so that there is no interaction force at large distances, $F(+\infty) = 0$—recall that $a_{\text{out}}^{\text{rms}}/a_{\text{in}}^{\text{rms}} = Q$ when no interaction force is present.

4.2. Phase Detection Mode

This mode is conceptually the same as the previous one, but we use Eq. (10) instead of Eq. (9) as the reconstruction algorithm. In this case, the force is

$$F(z) = -\frac{m_t \omega_0^2}{Q} \int_{+\infty}^z \frac{dz}{\tan[\Phi(z)]} \tag{12}$$

where the limits of integration were chosen recalling that, at resonance, $\Phi(+\infty) = -\pi/2$.

Strictly speaking, the equations derived previously are valid under the hypothesis that dF/dz is smaller than the cantilever's effective spring constant. If we tried to set the tip to vibrate around the point in space for which $dF/dz = k_t$, then any small deflection of the tip closer to the sample will make the interaction force increase, pulling the tip toward the sample since the opposite elastic forces cannot balance the attractive interaction force. Once this process of approach has started, there is no natural return: the interaction force keeps increasing and the tip is pulled closer to the sample's surface. Eventually, when the tip reaches the repulsive region of $F_{\text{interaction}}$, it will stop. This process of approach of the tip to the sample is called *snap to contact*. Since this approach is fast, even for modern standard electronic instrumentation, the measurement of the force curve in this spatial range presents a challenge. Clearly, a simple solution to the problem would be the use of stiffer cantilevers, that is, cantilevers with larger k_t. The drawback of this solution is that the system becomes less sensitive to force detection, since a stiff cantilever requires larger forces to produce the same deflections as that of a soft one. Solutions to this problem using a soft cantilever exist, which involve hardware and software modifications. We will discuss here Tapping imaging and continuous modeling of the cantilever.

4.3. Tapping

Tapping mode [4] was originally invented to minimize the problems associated with shear forces when operating the microscope in contact mode. As explained before, the signal from standard AFM is obtained from a multi-photodetector system. We explained how the vertical position of the tip could be attained from the output voltage of the photodetectors, V_{PH}. It should be clear, however, that, when scanning the tip in contact across a surface, the reflected laser beam will make an angle that depends not only on the height of the tip, but also on any additional slight tilt that the top of the cantilever might have. This tilt is normally due to small-angle tip rotations produced by the torque of shear tip–sample forces. In this general situation, the reflected beam angle does not provide enough information to determine the static state of the cantilever–tip system. Tapping mode solves this problem by lightly tapping the sample with a vibrating tip while horizontally scanning. The tip moves horizontally when far from the surface, thus eliminating the shear interactions and rendering the conversion from laser angle to vertical position simple. In addition, the reduction in lateral forces is imperative when characterizing soft samples such as biological matter. In this case, simply dragging the tip across the sample would destroy the sample. However, Tapping mode is used beyond its original topographic application to obtain information about interaction forces. Given that the tip quickly traverses large intervals of the force–separation curve, it is necessary to take full account of the curve in any analysis. This makes the problem highly nonlinear and not amenable to analytical solutions. Numerical solutions to the problem have been obtained for various parameters that define the system. A particularly interesting solution has been devised by Sarid [5]. He studied numerically the dynamics of a tip, modeled as a sphere, in the presence of a planar sample, that interact via a Jones seven–one potential. He found the tip motion to be almost characterized by a single frequency. The force, on the other hand, is a train of pulses corresponding to repulsive wall–tip interactions. Viewed as a function of the stiffness of the material, the indentation of the sample is inversely proportional to the stiffness and the indentation force becomes smaller in magnitude.

5. HIGH-FREQUENCY SPECTROSCOPY

Force curves can also be reliably obtained from simple deflection measurements by considering the cantilever as an extended beam—a realistic assumption. The experimenter can just measure the deflection of the cantilever versus the separation in order to obtain force curves, even at high tip speeds, beyond the snap-to-contact point. Only minor hardware changes are needed, for example, changes in the parameters defining the light source, such as controlling the laser beam width. It turns out that one needs to take as many measurements as frequencies one believes are important in the motion of the cantilever. Let us say one decides that only two frequencies are important to describe the motion of the cantilever. Then one could obtain a deflection curve for a given laser beam width and a second one for a different laser beam width. Experimentally, it is better to take the two curves at the same time by, for example, modulating the beam width. A more mathematically elegant way to collect the data is to take a deflection–separation curve for a given laser width and then get a second curve for a small change in the width, so that one gets the signal and its derivative with respect to the beam width at constant separation. This second prescription allows for a generalization of the measurement process in terms of *moments* of the signal–width curves—one such curve for each tip–sample separation.

6. DYNAMICS OF THE CANTILEVER

Cantilever dynamics have been studied in the past [6]. Here, we describe solutions relevant to the new generation of fast AFM. In particular, we show how to solve the problem of high-frequency response and, *at the same time*, explicitly include the tip–sample interaction force.

The cantilever is modeled as a beam governed by the following equation [5]:

$$\frac{\partial^2}{\partial x^2}\left(EI\frac{\partial^2 u}{\partial x^2}\right) + \rho A\frac{\partial^2 u}{\partial t^2} = 0 \tag{13}$$

where $u(x, t)$ is the deflection of the cantilever with respect to the horizontal at position x along the cantilever and at time t, E is Young's modulus, I is the (area) moment of inertia through the middle axis perpendicular to the plane of motion, ρ is the density of the cantilever, and A is the cross-sectional area.

To fix ideas, we consider the cross-sectional area to be a constant. In this case, the parameters do not vary with x. Thus, we can define the constant

$$V^2 \equiv \frac{EI}{\rho A^2} \tag{14}$$

Now we can rewrite (13) as

$$AV^2\frac{\partial^4 u}{\partial x^4} + \frac{\partial^2 u}{\partial t^2} = 0 \tag{15}$$

To solve Eq. (15), we need to set appropriate boundary conditions (BCs). These conditions will also introduce the tip–sample interaction force that one wants to measure. At the fixed end of the cantilever, $x = 0$, we impose no deflection

$$u(x = 0, t) \equiv 0 \tag{16a}$$

Also, since the lever is not free to rotate about that point,

$$\frac{\partial u}{\partial x}(x = 0, t) \equiv 0 \tag{16b}$$

At the free end, $x = L$, the cantilever experiences no torque if we consider vertical interaction forces

$$\frac{\partial^2 u}{\partial x^2}(x = L, t) \equiv 0 \tag{16c}$$

Finally, at the free end, the internal force on that layer of the cantilever must equal the external force

$$-EI\frac{\partial^3}{\partial x^3}u(x = L, t) = F[u(x = L, t)] \tag{16d}$$

6.1. Static Solution

It is common to use the solution to the previous problem for which the interaction force F is slowly varying with time. This hypothesis typically breaks down once the tip reaches the snap-to-contact point because then the magnitude of the force changes its value very quickly. However, if one insists on a quasistatic solution, one could build the whole force–separation curve as a patch of a series of solutions for which $F = F_S$, with F_S a constant force.

In this static case, Eq. (15) reduces to

$$\frac{\partial^4 u_S(x, t)}{\partial x^4} = 0 \tag{17}$$

where we have added the subindex S to u to indicate *static solution*. This equation, in conjunction with the four BCs, provides a unique solution

$$u_S(x) = \frac{(3F_S L)x^2 - (F_S)x^3}{6EI} \tag{18}$$

If the AFM's laser beam monitors the deflection of one point of the cantilever, for example, $x = L$, then the measured deflection, z_S, would be

$$z_S(t) = \frac{F_S(t)L^3}{3EI} \tag{19}$$

As the force varies slowly with time, so does the deflection [we have explicitly written this time dependence in Eq. (19) to stress that measurements are made in time steps]. This corresponds to a one-degree-of-freedom simple harmonic oscillator (SHO) approximation of the cantilever with spring constant $3EI/L^3$. As the model makes strong approximations, it must render a solution with strong limitations. In particular, it will fail when the tip–sample interaction force does not vary slowly. Under these circumstances, the cantilever will support high-frequency vibrational modes and, consequently, a one-degree-of-freedom model will not be enough to determine the state of the system. In the quasistatic regime, on the other hand, one degree of freedom is enough because if one measures $z(t)$ by using Eqs. (18) and (19), one can get the whole shape of the cantilever.

6.2. Generalizing the SHO Solution

In order for the SFM to be of use in fast imaging, where a force–distance curve must be obtained for each pixel and as quickly as possible, as, for example, in the study of biomolecular motion, the quasistatic solution must be called into question.

With that in mind, we now generalize the previous problem by allowing for the cantilever to sense not only a constant force, but also a gradient of the force–distance curve as the tip moves away or toward the surface. This will enrich the solution for the deflection $u(x, t)$ by allowing the possibility of vibrations superimposed on the SHO solution.

Therefore, we write the force as

$$F = F_S + G[u(L, t) - u_S(L)] \qquad (20)$$

In writing Eq. (20), we assumed, as in the BC, that the force on the cantilever is applied on the tip at $x = L$. Here, F_S is the average force the tip senses at one location above the sample and G is the derivative of the force–distance curve at that same position.

We write the solution $u(x, t)$ to Eq. (15) as the sum of the static solution and a superposition of normal modes

$$u(x, t) = u_S(x) + \sum_n f_n(x)\cos(\omega_n t + \varphi_n) \qquad (21)$$

where $f_n(x)$ are the normal modes, ω_n are the angular frequencies corresponding to the $f_n(x)$, and φ_n is the phase of mode n.

Substituting expression Eq. (21) into Eq. (15) and noticing that the $f_n(x)$ are linearly independent, we obtain

$$\frac{d^4 f_n(x)}{dx^4} - \frac{\omega_n^2}{AV^2} f_n(x) = 0 \qquad (22)$$

with solutions

$$f_n(x) = f_n^1 \cos kx + f_n^2 \sin kx + f_n^3 \cosh kx + f_n^4 \sinh kx \qquad (23)$$

where f_n^1, f_n^2, f_n^3, and f_n^4 are constants and k is the wavenumber.

Next, we apply the BCs Eq. [(16a)–(16d)] and end up with BCs for each individual mode $f_n(x)$

$$f_n^1 + f_n^3 = 0 \qquad (24a)$$

$$f_n^2 + f_n^4 = 0 \qquad (24b)$$

$$-f_n^1 \cos kL - f_n^2 \sin kL + f_n^3 \cosh kL + f_n^4 \sinh kL = 0 \qquad (24c)$$

$$k^3\left(-f_n^1 \sin kL + f_n^2 \cos kL - f_n^3 \sinh kL - f_n^4 \cosh kL\right)$$
$$= \gamma\left(f_n^1 \cos kL + f_n^2 \sin kL + f_n^3 \cosh kL + f_n^4 \sinh kL\right) \qquad (24d)$$

where $\gamma = G/EI$.

In order for the system of equations (24) not to have trivially null solutions, we must require that the determinant of the system be 0. Thus

$$k^3(1 + \cos kL \cdot \cosh kL)$$
$$= \gamma(\sin kL \cdot \cosh kL - \cos kL \cdot \sinh kL) \qquad (25)$$

With the definitions $\beta = \gamma L^3$ and $\xi_n = k_n L$, one obtains a transcendental equation for the frequencies ω_n for a given G

$$\frac{1 + \cos \xi_n \cdot \cosh \xi_n}{\sin \xi_n \cdot \cosh \xi_n - \cos \xi_n \cdot \sinh \xi_n} \xi_n^3 = \beta \qquad (26)$$

We can use these frequencies to find, for each n, the normal modes f_n^i ($i = 1, 2, 3, 4$) (in fact, we will obtain three ratios between the f_n^i since the system is, by construction, indeterminate). After some tedious but easy algebra, one obtains

$$\frac{f_n^1}{f_n^4} = -\frac{\xi_n^3}{\beta} \frac{\cos \xi_n + \cosh \xi_n + \sinh \xi_n - \sin \xi_n}{\cos \xi_n - \cosh \xi_n + \sin \xi_n - \sinh \xi_n} \equiv R_n \qquad (27a)$$

$$\frac{f_n^2}{f_n^4} = -1 \qquad (27b)$$

$$\frac{f_n^3}{f_n^4} = \frac{\xi_n^3}{\beta} \frac{\cos \xi_n + \cosh \xi_n + \sinh \xi_n - \sin \xi_n}{\cos \xi_n - \cosh \xi_n + \sin \xi_n - \sinh \xi_n} = -R_n \qquad (27c)$$

Finally, using (21), one arrives at the complete solution to the problem

$$u(x, t) = u_S(x) + \sum_n f_n^4 \left[R_n \cos\left(\frac{\xi}{L}x\right) - \sin\left(\frac{\xi}{L}x\right) \right.$$
$$\left. - R_n \cosh\left(\frac{\xi}{L}x\right) + \sinh\left(\frac{\xi}{L}x\right) \right]$$
$$\times \cos(\omega_n t + \varphi_n) \qquad (28)$$

In the next section, we will derive an expression for the signal that is actually measured. That signal is a consequence of the motion $u(x, t)$ but is not it.

6.3. Detailed Study of the Laser Width and Its Use in Force Measurements

In optical detection, a light beam intensity reflected from the top of the cantilever is measured at a photodetector system. If the beam has a distribution of intensities $g(x)$ (Fig. 5), each of these intensities contributes to the total signal.

The signal originating at position x at the cantilever is proportional to the deflection $u(x, t)$ and to the light intensity at that point. If $u(x, t)$ were 0, there would not be any signal because the two photodiodes would be balanced; if the intensity were 0, then the signal would also be 0 since there would be no light to measure. Therefore, up to instrument constants, the signal at the photodiode is

$$S(t) = \int_0^L u(x, t) \cdot g(x) \, dx \qquad (29)$$

Figure 5. A laser beam of Gaussian width impinges on the cantilever.

where $g(x)$ is the light beam intensity profile. We assume it has a Gaussian shape

$$g(x) = \frac{1}{\sigma\sqrt{\pi}} \exp\left(-\left(\frac{x - x_0}{\sigma}\right)^2\right) \qquad (30)$$

By using Eqs. (27), (28), (30), and (18), the integral in Eq. (29) can be carried out explicitly. The result is

$$
\begin{aligned}
S(t) = S_{\text{static}} + \sum_n f_n^4 \Bigg[& R_n \exp\left(-\left(\frac{k\sigma}{2}\right)^2\right) \cos kx_0 \\
& - R_n \exp\left(\left(\frac{k\sigma}{2}\right)^2\right) \cosh kx_0 \\
& - \exp\left(-\left(\frac{k\sigma}{2}\right)^2\right) \sin kx_0 \\
& + \exp\left(\left(\frac{k\sigma}{2}\right)^2\right) \sinh kx_0 \Bigg] \\
& \times \cos(\omega_n t + \varphi_n) \qquad (31)
\end{aligned}
$$

where S_{static} is the following constant:

$$S_{\text{static}} = \frac{F_s}{3EI}\left[(3L - x_0)x_0^2 + \frac{3}{2}\sigma^2(L - x_0)\right] \qquad (32)$$

The constants f_n^4 are obtained from the initial conditions.

6.4. Further Generalization to the SHO Solution

Although the assumption in Eq. (20) for the force is a generalization over what is commonly used, it is natural to ask whether the problem could be solved for an arbitrary force shape. In this section, we present the theory to obtain such a solution. Regrettably, no closed-form solution can be obtained for the general case. However, by writing an algorithm following these steps, it will be easy to write computer code to obtain numerical solutions.

In Figure 6, a realistic force–separation curve is shown to be made up of the concatenation of eight linear segments. Each segment is characterized by a tip–sample separation,

Figure 6. Reconstruction of the overall force from linear pieces.

an average force, and a slope. For example, segment 2 is characterized by s_2, F_2, and G_2. For that same segment, the tip stays there during the period of time from $t = 2\Delta t$ to $t = 3\Delta t$. In general, we shall consider M intervals labeled m, that is, $m = 0, 1, 2, 3, \ldots, M - 2, M - 1$. For negative values of m (and time), we assume that the force is 0 (far-away region) and the cantilever is in its horizontal equilibrium position. Zero volts are detected at the photodetector.

Experimental measurements provide $S(t)$ at thousands or even millions of points, so it is necessary to account for situations where the number of data points is larger than M. Let us then divide each of the previously mentioned segments into P smaller segments. Each of these smaller segments will comprise a time interval δt, so that $\Delta t = P\delta t$. There will be a total number of points $D = PM$. We choose P so that D is the number of data points.

The signal $S(t)$ in Eq. (31) depends on the light beam width σ and the point x_0 at which the light beam touches the cantilever. Therefore, it is possible to collect many signals, $S_q(t)$ $(q = 1, 2, 3, \ldots, Q)$, simultaneously. Each of these signals could consist of a measurement of $S(t)$ for a given σ. In this case, σ can be written as $\sigma = \sigma_0 + [q - (Q + 1)/2]\Delta\sigma$. However, σ is not the only parameter available. The position of the light beam could also be changed. However, whatever one decides to choose, the following general derivation applies.

We choose Q to be equal to the number of frequencies the cantilever is assumed to support (it may be larger, but never smaller than that). This can be determined before the tip interacts with the surface, that is, when the tip and the surface are far away. It is true that the frequency spectrum will change as the tip approaches the sample. However, the number of frequencies involved should not change since the cantilever is driven more by inertia than by the tip–sample force. In a typical experiment, one should excite the tip with a broad array of frequencies and study the cantilever's response. If three frequencies were excited, then one would choose $Q = 3$. For safety, one may want to take $Q = 4$ and check if one gets null coefficients for modes above the third.

Equation (31) can now be rewritten to simplify the analysis

$$S_p^{qm} = S_{\text{static}}^{qm} + \sum_{n=1}^{n=Q} f_n^{4m} \psi_n^q \cos(\omega_n p\delta t + \varphi_n) \qquad (33)$$

where ψ_{nq} is shorthand for the expression in brackets in (31).

The left-hand side of Eq. (33) must be compared to the $QPM = QD$ data points. The right-hand side can then be obtained by fitting this expression to experiments. To complete the process, one needs to choose M, the number of regions into which we want to divide the whole "separation" range. It seems that $M = 10$ should be a good guess. By doing this fitting, we are solving an inverse problem, namely, that of obtaining the force–separation curve from the measured signals.

7. HISTORICAL NOTES

As mentioned previously, the details of the first AFM were published in the mid-1980s by Binning et al. Their implementation of the AFM was an actual merging between the STM and the stylus profilometer. In that original setup, they used an SP tip and monitored its vertical position with the STM. Their main claims at the time were that they could measure, in air, extremely small interaction forces (10^{-18} N), that the technique provided spatial atomic resolution, and that it was relevant for the study of nonconducting surfaces, where STM is inappropriate.

In general terms, their promises became a reality. Operating in air as opposed to high vacuum has opened many new research lines. Studies in biomolecules have been spurred by not having to operate in a vacuum. Traditional high-resolution microscopes in biology, such as the transmission electron microscope, the scanning electron microscope, and lately the scanning tunneling microscope, use dissected samples. By operating in air, the AFM can study biomolecules *in vivo*. Often, it is more desirable to use the AFM not in air, but embedded in a liquid (water, serum, buffer solution) so that biological molecules can be studied in their natural environment. In addition, by operation in liquid one avoids the creation of adhesion forces due to water meniscus formation between tip and sample in humid air. These types of forces are so large that they may mask the smaller molecular interactions between the tip and the sample. Some of the applications of AFM in biology and medicine are structural studies of DNA and RNA, ligand–receptor interactions, protein–nucleic acid systems, chromosomes, cellular membranes, peptides, molecular crystals, and polymeric biomaterials [7, 8].

Nevertheless, the impact of AFM has also made its way into the studies of materials in general [9]. The AFM is used to solve processing and materials problems in a wide range of technologies affecting the electronics, telecommunications, biomedical, chemical, automotive, aerospace, and energy industries. The materials under investigation include thin- and thick-film coatings, ceramics, composites, glasses, synthetic and biological membranes, metals, polymers, and semiconductors. The AFM is also used to study phenomena such as lubrication, plating, polishing, abrasion, adhesion, cleaning, corrosion, etching, and friction [10]. Although trying to name all of the applications would be a major task, we mention a few of the most prominent ones. Some applications in the microelectronics industry include measurements of surface roughness, depth of nanoridges in thin-film epitaxial deposition, detection of defects in growth of layers on substrates, efficiency of chemomechanical polishing, statistical classification of grain sizes in contacts with deposits,

detection and sorting of defects in photolitography masks, identification of residual photoresist, and analysis of bits in compact disc media. In basic science studies, AFM is heavily used in the characterization of the atomic structure of pure surfaces or surfaces with adsorbed atomic clusters. AFM has also provided an immense boost to the fundamental understanding of sample elastic properties and of adhesion and friction. Although friction is not yet understood from the point of view of microscopic theories, its is very clear that such an understanding will ultimately come from an exchange of ideas between atomistic computational calculations and direct observations with AFM.

Forces were initially measured by looking at force-induced changes in the amplitude or phase of oscillating cantilevers near resonance [11]. In these first attempts, there was a tradeoff between increasing the signal-to-noise ratio and increasing the available bandwidth of the system. Clearly, in principle, one would like to maximize both parameters to be able to obtain highly precise measurements in as quick a time interval as possible. To improve these tasks, the basic method was shortly refined by using frequency modulation (FM) detection [12]. Instead of measuring amplitude or phase, this approach measures (via an FM demodulator) instantaneous frequency changes in the vibrating cantilever induced by $\partial F / \partial z$. This new procedure increased the sensitivity tenfold compared with previous techniques as demonstrated by studying magnetic transitions on CoPtCr thin-film magnetic disks.

Additional progress in improving the accuracy of the AFM was restricted for a while by reconstruction algorithms based on very simplified models of the AFM system. In the beginning, to advance the technique, it was enough to use a reconstruction algorithm based on a single mass attached to a spring to model all the inertia and elastic properties of the cantilever–tip system. Soon, models that were more realistic were put forward. First, Sarid [6] extended the simple model to a rectangular cantilever and studied its modes of vibration. Other theoretical variations on the same idea dealt with more realistic modeling of the oft-used V-shaped cantilevers [13] via variational techniques.

In the mid-1990s, people realized that thermal vibrations of the tip in close proximity to the sample could be used as a technique to extract intermolecular forces in aqueous solutions [14]. The researches were able to detect forces acting in the length scale of a few nanometers, which is the relevant range for adhesion, friction, and colloidal interactions. They base their analysis on the fact that the tip deflection is (in a fluid) distributed according to the probability density

$$p(s) = C \exp\left(-\frac{V(s)}{k_{\mathrm{B}}T}\right)$$

where $V(s)$ is the tip–sample interaction energy versus separation, K_{B} is Boltzmann's constant, T is the absolute temperature, and C is a normalization constant. By measuring s with a high-speed acquisition card at many intervals (50,000 points at 100 KHz), they were able to experimentally construct $p(s)$, from which $V(s)$ can be evaluated. There exist theoretical calculations based on multimode analysis of the cantilever dynamics [15] that agree with the experimental results regarding modal frequencies. The power spectrum

curves, however, do not match exactly. The authors justify this disagreement in terms of poorly characterized manufacturers' parameters.

Further progress in the interpretation of the experimental results was put forward [16] by comparison of the frequency spectra between theoretical results from beam models and optical interferometric measurements. This work showed that, for the case of free tip–cantilever systems, experiments and theory agree, lending credence to the beam model as a data processing algorithm. However, when the tip interacts significantly with the sample, there is a disagreement between the resonant frequencies. The researchers argued that the disagreement is related to the cantilever–tip geometry and nonlinearities in the force curve. They also suggest taking into account tip deformation and material transfer between tip and sample in more realistic models as that would be more consistent with their observations.

Studies were performed comparing theoretically and experimentally the dynamics of the cantilever for the specific case of the cantilever immersed in water or gas [17]. For this purpose, the researchers solved the coupled electromechanic–hydrodynamic problem. In addition, they performed experimental tests for the cantilever in air, water, and bromoform. They found an excellent match between the two sets of resonance frequencies for any of the three embedding media.

Numerical integration techniques to study the dynamics of the cantilever in noncontact mode were known to provide poor results when the snap-to-contact mechanical instability was reached. An interesting theoretical result was found to overcome this problem [18]. The researchers found analytical solutions based on the Krilov–Bogoliubov–Mitropolsky method for the motion of a tip in noncontact but in the possible presence of instabilities. They applied this result to the case of a van der Waals interaction and found good agreement with numerical integration for distances larger than the snap-to-contact point. For closer distances, this analytical method provides a qualitatively acceptable result for the frequency shifts induced by the interaction, while the numerical integration fails even qualitatively.

Theoretical studies for cantilevers in viscous fluids presented a formidable challenge. However, successful results were obtained with the goal of extracting interaction forces from thermal vibrations [19]. The researchers were able to obtain analytical results for the motion under the hypothesis that the cantilever's length is much larger than its width, the fluid is incompressible, and the viscosity is small. For larger viscosities, they presented numerical techniques to find the kinematics of the cantilever.

AFM has been used to obtain elastic information on the sample. This capability was soon recognized after the inception of the technique. However, quantitative measurements were hindered by the irreproducibility of the vibrational power spectrum of the cantilever. This irreproducibility was largely due to the impossibility to fully characterize the shape of thin tips. This problem was partially overcome [20] by the introduction of micromachined, geometrically reproducible, tips. These studies show that the power spectrum depends on the forcing amplitude. However, for small forcing amplitudes, the power spectrum remains unchanged, only varying linearly with the tip–sample separation. This permits the problem to be inverted, in other words, to explicitly obtain elastic constants of the sample from the power spectrum of the cantilever's vibration.

Although physically different, conservative and dissipative force fields could not be separated with reconstruction algorithms until three years ago. Then, theoretical analysis [21] of shifts in frequency *and* shifts in quality factor showed that the two types of forces could be separated. As expected, frequency shifts are related to conservative forces, and quality factor shifts are related to dissipation. The researchers found that, under typical experimental conditions, phonon drag in elastic nanoindentation is negligible and thus most energy loss is due to internal viscous damping forces or intrinsic irreversibilities of the tip–sample contact. However, the calculation also shows that soft materials might lose energy through phonon drag.

Particularly important in the extraction of elastic properties from samples is the realization that common force reconstruction algorithms are incomplete since they require motion information on the sample, which is not readily available in commercial microscopes. To overcome this difficulty, a new algorithm was designed, in which the tip–sample interaction damping and Young's modulus can be derived from contact resonance frequencies [22, 23]. The beauty of this result is that it is independent of the spatial location of the driver. The only constraint is that the excitation be as frequency independent as feasible in the frequency range of interest.

Experimental work using AFM in fluids [24] has shown that water is compressed between tip and sample and contributes to dissipation. The main result of these studies is that, when using AFM dynamically in water, the resulting image is, in fact, a map of contours of constant stiffness. More sophisticated force reconstruction algorithms were developed that explicitly account for force nonlinearities, based on variational principles and studying the degree on anharmonicity of the tips orbit, when the tip is driven at high amplitudes and thus is able to probe the whole range of the interaction force [25]. These developments show that, under these conditions, the frequency shift versus tip–sample separation is a function that, in appropriate units, lies between the force and the energy curves.

AFM in dynamic mode has also been used to study the elastic properties of anisotropic crystals [26]. In this case, the cantilever was excited at frequencies higher than the fundamental one. This method is particularly relevant for the detection of different metallurgical phases in an otherwise homogeneous sample.

In the search for high information-gathering speeds, new AFM designs, with modified cantilevers, were devised [27]. Specifically, the cantilever and its attached vertical piezoelectric control were substituted by a cantilever made purely of ZnO, a piezoelectric material. In this form, the frequency bandwidth content and the quality factor are increased. In typical Tapping mode imaging, one can acquire a 1-megapixel^2 image in a few minutes. With this new technique, the same image can be obtained in seconds. Damping is reduced by an active feedback circuit, in which the position of the tip, $z(t)$, is monitored and, via a phase shifter, converted to a velocity, $\dot{z}(t)$, which is fed back into the input

circuit that controls the cantilever motion so that it reduces the speed and thus the friction.

There exist studies that compare experimental dynamical properties (frequency spectra) with theoretical results for cantilevers immersed in incompressible fluids [28]. These studies find that if only information about the lowest frequency is of interest, then a simple harmonic oscillator model appropriately describes the experimental results for quality factors $Q \geq 1$ as long as viscosity is not neglected. Neglecting viscosity renders large disagreements between theory and experiments.

The AFM has become a standard tool for biological studies. Among outstanding open problems in molecular biology is the understanding of the pathways by which biomolecules react. Due to temporal and spatial resolution limitations, typically only average values of the forces involved can be measured. The solution to this technical issue is of high priority, as it would clarify specific binding in ligand–receptor and antigen–antibody complexes, protein unfolding, and the mechanical properties of DNA [29]. To solve this problem, Heymann and Grubmüller [29] propose obtaining force profiles around molecules from force spectra obtained at various loads. This allows for augmented spatial resolution and thus for more site specificity regarding intermolecular forces. Other works have reported on the direct measurement of chemical bond formation [30]. This group worked at low temperature to avoid creep and drift and used nonlinear algorithms (as opposed to frequency shifts) to extract forces. In addition, they separated long-range forces from local chemical interactions.

During the past few years, a number of results have refined what was put forward during the 1990s. Experimentally, lateral forces have been measured in noncontact mode [31]; the collection of mechanical properties data from samples has been increased to a few megahertz by the use of stroboscopic techniques [32]; very fast acquisition rates, up to 100 MHz, have been achieved [33]; and other sensing techniques have been developed based on piezoresistive cantilevers [34]. Theoretical studies [35] have also further improved previous models in terms of speed and spatial resolution.

Hamilton's principle is used to obtain repulsive and van der Waals forces from samples by modeling and computing the acquisition via piezoelectric actuators (excited at their bases) and sensors, in contact and noncontact modes, respectively [36]. There have been attempts to extend steady-state treatments in noncontact spectroscopy by introducing transients via nonautonomous treatments [37]. The authors of this work argue that such a treatment is unavoidable since steady-state theories predict instabilities not yet observed experimentally. In addition, in the presence of flow, chaos can be generated, which cannot at all be studied within a steady-state framework.

Sometimes, the surfaces under study are so stiff that studying their elastic properties from spectral changes in the first mode of the cantilever (the softer one) is not possible. However, higher modes have been successfully used in such applications [38]. In particular, this work provides explicit results for the sensitivity of the various modes of flexural and torsional vibrations. A theoretical solution, in combination with the fast acquisition rates of the tip's position

(megahertz), exists that allows for the extraction of force–separation curves, including the snap-to-contact instability, even for nominally flimsy cantilevers [39–45]. In this work, the cantilever is modeled as a continuous beam, and an ill-posed inverse problem (from kinematics to force) is solved by regularization techniques. Results agree with observational data.

8. FUTURE PERSPECTIVES

We have presented the status of fast atomic force microscopy to the present time. In retrospect, it is now clear that AFM has played, during the last decade, an enormous role as an imaging tool in the elucidation of new structures in organic as well as inorganic materials. It is also apparent what the role of AFM will be during the next 10 years. With the boom in nanoscience and nanotechnology, it is imperative that SPMs become more quantitative to provide detailed information on the transport, elastic, and electromagnetic properties with nanometric resolution. In addition, they must be quantitative as manipulation tools, to provide accurate positioning of small elements within relatively larger, synthetic architectures.

Since the invention of the transistor, electronics has been driven by technology toward smaller dimensions, higher information densities, and higher processing speeds. To that end, many ingenious solutions have been developed, some dealing with the intrinsic properties of the materials used and some with devices. Thus, there was, in the 1960s, the inception of silicon as a better alternative to germanium in the semiconductor industry. In the 1970s, there appeared quantum wells and superlattices made of alternate nanolayers of gallium arsenide and its alloys. On one hand, electrons in gallium arsenide and its alloys have larger mobilities and coherence lengths than those in silicon, so electronics could be made to respond faster, taking advantage of quantum effects—such as discrete quantum states—for information storage. On the other hand, gallium arsenide crystals can be grown, for example, on gallium aluminum arsenide with excellent adhesion. This is because the two crystalline structures are in registry. This allows for the building of multilayer structures with up to hundreds of layers, an impossible task to achieve at that time with silicon and its derivate materials. In addition, gallium arsenide is an ideal material for optoelectronics, that is, the integration of electronics and optics in a device. Due to its direct bandgap, gallium arsenide can efficiently emit and absorb light, that is, without the need for phonon exchange.

The development toward atomic control of nanometric devices has exploded in the last decade. With the introduction of SPMs, it is not only possible to study matter at the nanoscale but also to modify it. The most notable advances in nanoscience and nanotechnology, since the beginning of the 21st century, are, arguably, the inception of nanowires and nanodots and the better understanding and use of biomolecular self-organization. Nanowires are wires of a few to a few hundred atoms long and a few atoms thick, with excellent tensile properties. They can be made into conductors or semiconductors and are thus likely to be used as contacts or active optoelectronic devices (detectors, emitters, etc). Today, the most common materials studied for

nanowires use are silicon [46], carbon [47], and metals [48]. It has been possible to fabricate and characterize these wires under laboratory conditions, but, thus far, it has not been possible to fully tame them. For example, a large number of nanotubes can be grown on substrates and viewed with an SPM or other techniques. However, their actual position cannot be perfectly controlled. Thus, it will be by about 2010 that these nanotubes will be wired industrially.

At this stage, AFM is used to structurally and electrically characterize these novel nanotubes. For electrical characterization, the AFM is used in the new surface potential imaging mode in which a bias voltage is externally applied between the tip and the sample to cancel the effect of all the other interaction forces. In this form, charge distribution along the wire can be obtained. Nanodots are atomic-size clusters of atoms. Arrays of metallic nanodots are important to guide light in optoelectronics applications below the diffraction limit [49].

Noncontact and Tapping AFM studies provide quantitative information on the charge injection and retention properties of silicon nanodots. At frequencies close to plasmon resonances, optical extinction through the nanodots is dominated by absorption, as opposed to the typical scattering mechanism. Sub-diffraction-limit wavelength light propagates coherently through the structure via near-field nearest-neighbor light-tail interactions. AFM has been used to both fabricate the array and characterize it both geometrically and electromagnetically.

The ability of biological molecules to arrange themselves into large, useful arrays will be exploited in the next generation of integrated electronics. Integrated electronics will require the ability to order nanowires (the elemental building blocks) into desired architectures. For example, DNA naturally self-assembles by molecular recognition, and it is compatible with biological technologies (polymerase chain reaction, enzymatic cutting). Peptide nucleic acids, which mimic DNA, have been attached to single-wall nanotubes [50]. Thus, nanotube connectivity to electrodes and among themselves can be controlled, with the possibility of obtaining self-assembled architectures in the nanoscale.

Metallization of nanowires can be obtained naturally or by human design. For example, silicon nanowires can be made conducting by wrapping them in Au films [51]. Carbon nanotubes are naturally conductors or semiconductors, depending on the way their surface is wrapped around the main axis. These properties have been investigated by STM and by AFM.

Nanometric micromachines that operate as voltage gate pumps and valves (membrane channels and pore proteins) have also been studied by AFM [52]. AFM will be used to obtain, with industrial quality, morphological and chemical information on self-assembled nanodevices. It will also be used to study conduction channels within nanowires as well as charge effects at the interface of nanowires used for one-dimensional quantum wells and superlattices.

Perhaps the major leap in the advance of AFM in the next decade will be the development of more robust quantitative algorithms to gain information on the tip–sample interaction. Since molecules are routinely attached to AFM tips, these developments will allow one to obtain a large database of molecule–molecule force–separation curves. A technician could then gather force information from the sample and, by comparing it with the database, he or she will be able to produce a high-quality chemical map of the sample, with the high degree of confidence with which today a technician uses nuclear magnetic resonance as an analytical chemical technique.

GLOSSARY

AFM attractive mode Operation of the AFM under the condition that the probe tip and the sample attract each other. This happens for relatively large tip–sample separation. At closer distances, atomic core–core repulsion dominates and the condition of attractiveness does not hold. This mode of operation has the advantage of being gentle on the sample, thus avoiding potential permanent damage such as scratches. One disadvantage is that the magnitude of the forces is small and thus their measurement is more delicate.

AFM reconstruction algorithm A mathematical prescription to process the experimentally available data (tip's deflection vs. nominal tip–sample separation) and convert it into useful information, namely surface topography and force–separation curves (i.e., chemical specificity).

AFM repulsive mode The tip and sample remain relatively close to each other. Under these conditions, core–core repulsion dominates the interaction. This mode of operation gives a strong signal because nominally it follows the sample's profile. However, for soft samples, as is the case in all biological applications and in many inorganic cases, the tip will likely move the sample material, thus changing the sample one wishes to study.

Atomic force microscope A modern microscope in which information is gathered via interaction forces between a probe and the sample under study.

Atomic force spectroscopy Use of an atomic force microscope to extract probe–sample forces as a function of separation.

CONTENTS

1. INTRODUCTION

Nanostructured materials, consisting of small crystallites of diameter 1–100 nm, often have novel physical and chemical properties, differing from those of the corresponding bulk materials, for example, solid solubility enhancement in nanoalloys [1]. The solubility of a solute A in a solvent B, is controlled by the chemical potential of A in B. Obviously, if the atomic structure of B is changed, the chemical potential and hence the solubility of A in B may be enhanced (or reduced). Thus, the solute solubility of nanostructured materials is expected to be different from the one of single crystals with the same chemical composition. Under thermodynamic equilibrium, the solid solubilities of iron in copper and copper in iron are negligible at low temperatures [2]. However, nanoalloying (i.e., alloying when the elemental components in a system have a size ranging 1–100 nm at least in one dimension) in the iron–copper system has been reported using nonequilibrium processing techniques (e.g., liquid quenching [3], thermal evaporation [4, 5], sputtering [6, 7], ion-beam mixing [8], and mechanical milling). The nanoalloying process has been intensively investigated in the system prepared by mechanical milling as compared to other nonequilibrium processing techniques. This chapter, therefore, focuses on recent developments of nanoalloying in the iron–copper system, as a model system for those with positive heats of mixing, by a mechanical milling process.

More than 30 years ago mechanical alloying was developed as a way to circumvent the limitations of conventional alloying [9]. In this metallurgical process, powder particles are subjected to severe mechanical deformation from collisions with balls and vial and are repeatedly deformed, cold welded, and fractured. In recent years, mechanical alloying has emerged as a versatile technique for producing materials far from equilibrium, for example, nanostructured alloys and amorphous alloys [10–12]. By comparison with other novel techniques [e.g., liquid quenching (or melt-spinning), thermal evaporation, and sputtering, etc.], it has the advantages of relatively low-temperature processing, easy control of compositions, relatively inexpensive equipments needed, and the possibility for easily scaling up to tonnage quantities of material. These advantages greatly facilitate the characterization and application of the resulting metastable alloys.

In a variety of systems it has been demonstrated that mechanical alloying of element powder blends allows metastable alloys to be synthesized. In particular, much work has concentrated on the formation of metastable phases in alloy systems which exhibit a negative heat of mixing of the alloy components and the phase formation has been studied from both the thermodynamic and the kinetic viewpoints [10–12]. The mechanism of phase formation has been explained by an interdiffusion reaction of the components

occurring during the milling process. Metastable phase formation is observed if the formation of a stable phase is suppressed under the specific milling conditions. In particular, intermetallic compounds can be energetically destabilized due to chemical disorder introduced by the deformation during milling [13]. This often results in the formation of extended solid solutions or amorphous phases. On the other hand, phase formation in alloy systems with positive heats of mixing is far from being understood, as in these systems a diffusional reaction generally results in decomposition of the alloy. Nevertheless, the formation of solid solutions prepared by mechanical alloying has been observed in several systems with positive heats of mixing, such as Cu–M (M: Ag [14], Cr [15], V [16, 17], Ta [18–21], W [22], Co [23], and Fe). Among them the Fe–Cu system has been extensively studied [24–81]. Therefore, the Fe–Cu system is selected as a model system to study phase formation during mechanical alloying of elemental powder blends with a positive heat of mixing. By using the CALPHAD (*Cal*culation of *Ph*ase *D*iagrams) method [48, 55, 68, 82], it was predicted that the positive free energy of mixing at 673 K in the Fe–Cu system would be a maximum of about 7.5 kJ/g-atom for the composition of $Fe_{50}Cu_{50}$. For the discussion of the alloying process in the Fe–Cu system, we therefore mainly concentrated on this composition.

This chapter is organized in the following way. The typical mechanical milling process is mentioned in Section 2. Then, several problems on the phase formation of the alloy system with positive heats of mixing prepared by mechanical alloying will be discussed, for example, (1) whether alloying occurs on an atomic level, (2) the solid solubility in the Fe–Cu system; (3) where the positive energy is stored in the alloy; (4) the decomposition process of the alloy, (5) the phase diagram of nanometer-sized Fe–Cu grains, and (6) the kinds of the magnetic properties the new materials have. Finally, summaries will be given in Section 9.

2. MECHANICAL MILLING

Mechanical alloying begins by blending individual powder constituents, for the Fe–Cu system, which are usually powders of iron (99.9%) and Cu (99.9%) with particle sizes smaller than 100 μm. The powder blend is mixed to a desired composition and loaded in Ar atmosphere into hardened steel vials and balls in a planetary ball mill (e.g., Fritsch Pulverisette 5) or a vibrational ball mill (e.g., SPEX 8000 mixer/mill). The vial is sealed under an Ar atmosphere to prevent oxidation of both the Fe and Cu powders. In the final stage, the morphology of the sample varies from powder to pellet depending on the composition. For example, for $Fe_{90}Cu_{10}$, the sample is powder (less than 100 μm), and for $Fe_{50}Cu_{50}$, a pellet shape of about 0.7 mm in diameter and about 0.3 mm in thickness is observed. In many laboratories a small amount of lubricant is added into the vials to prepare fine powders. But, on the other hand, it is found that the milled samples contain contamination from the lubricant as well as from the abrasion of the vials and balls [83].

3. ALLOYING PROCESS ON AN ATOMIC LEVEL

To monitor the alloying process, the samples collected after various milling times are investigated by various techniques [e.g., X-ray diffraction, neutron diffraction, Mössbauer spectroscopy, and extended X-ray absorption fine structure (EXAFS)]. Typical X-ray diffraction patterns for the $Fe_{50}Cu_{50}$ samples after different milling times are shown in Figure 1. The elemental lines of body-centered cubic (bcc)-Fe lose intensity and broaden significantly during milling. After 100 h the bcc-Fe peaks completely disappear and only face-centered cubic (fcc) peaks remain. From the X-ray diffraction patterns the lattice constants and the average grain sizes of different phases can be determined. In Figure 2 are shown the grain size and the lattice constant of the fcc phase, together with the grain size of the bcc phase, as a function of milling time. Initially, the milling process reduces the grain sizes of both elemental powders. Upon milling, the grain size of the fcc phase saturates around 15 nm. On the lattice constant of the fcc phase, a large increase was observed from 10 to 50 h milling, suggesting that alloying between Fe and Cu may take place. The increase of the lattice parameter has been attributed to the magnetovolume effects [5]. Similar results have been reported by electron and neutron diffraction measurements [43, 44]. However, the X-ray, neutron, and electron diffraction results from the Fe–Cu system cannot absolutely confirm that in the final stage the samples have been alloyed on an atomic level when the element components form coherent composites with elemental spacing <10 nm [84]. In an attempt to examine whether the alloying on an atomic level occurs, Mössbauer spectroscopy [24, 25, 32, 33, 36, 38, 44, 49, 50, 56] and EXAFS [41, 51, 54, 57, 60, 77] measurements were performed.

Mössbauer spectroscopy is sensitive to the local atomic surroundings of the iron atoms and can therefore be used to determine whether alloying occurs on an atomic level during milling. For thick samples (>100 μm) resonant lines in transmission Mössbauer measurements could become broadened. (Note that for the $Fe_{50}Cu_{50}$ composition, samples consist of small pellets with an average thickness of about 300 μm [32, 33].) Therefore, Mössbauer measurements in a backscattering geometry [i.e., conversion X-ray Mössbauer spectroscopy (CXMS) or conversion electron Mössbauer spectroscopy] are required to avoid the thickness effect. One example is given in Figure 3, where CXMS spectra and the corresponding hyperfine field distributions for the $Fe_{50}Cu_{50}$ samples after different milling times are shown. It should be emphasized that the samples used for CXMS measurements are the as-milled sample, prepared without any lubricant and without any post-treatments

(e.g., cold rolling) which could influence the structure of the metastable Fe–Cu alloys. For milling times of 0.5 and 10 h, the Mössbauer spectra are identical to those of bcc-Fe. A significant change is observed after 20 h with the appearance of two nonmagnetic spectra and one new magnetic spectrum. The two nonmagnetic spectra are attributed to Fe in fcc Cu solid solution and to a fcc Fe phase coherently attached to the fcc-Cu matrix, respectively. These results indicate that a transformation of bcc-Fe into fcc-Fe structure occurs. The new magnetic sextet with a hyperfine field of about 300 kOe observed in Figuer 3c can be attributed to bcc-Fe atoms surrounded by Cu atoms. Based on the relative area of the sextet, the Cu concentration in the bcc-Fe phase is estimated to be less than 3 at% by assuming Fe atoms surrounded by one or two Cu atoms. For a milling time of 30 h, mixing of Fe and Cu is observed. This results in an increase in the relative area of the paramagnetic doublet and the formation of a broadened magnetic sextet with an average hyperfine field of 220 kOe. However, the relative area of the component with a hyperfine field of about 300 kOe does not change much. On further increasing

the milling time (>50 h), three different components can be distinguished in the Mössbauer spectrum. The first is a broadened sextet caused by a hyperfine field distribution, which is attributed to the fcc-FeCu solid solution. The hyperfine field can be analyzed in terms of different environments for the iron atoms arising from near neighbor interactions. Since interactions influencing the hyperfine field are of a rather short-range character, it is valid to consider only the nearest neighbor interactions in the fcc structure [85]. By fitting, as shown in Figure 4, it is found that the distribution of nearest neighbor configurations in the fcc-FeCu phase follows a binomial distribution, indicating a random solid solution. This infers that many different environments of iron atoms exist in the fcc-FeCu solid solution and demonstrates that Fe and Cu are alloyed on an atomic level. The second and third components are a tiny amount of the residual bcc-Fe phase and the fcc-Fe phase, respectively. The tiny amount of the fcc-Fe phase was found in all samples for milling time longer or equal to 10 h. It should be noted that the bcc- and fcc-Fe phases are not detected by X-ray diffraction measurement. This can be explained by the very small amount (~2.6 vol%), the small crystallite sizes, and similarity of the lattice constants between fcc-FeCu and fcc-Fe phases. By comparing the Mössbauer spectra (Fig. 3e–g) with those for the small bcc-Fe particles having an average particle size of 2.4 nm [86], it is obvious that the $Fe_{50}Cu_{50}$ sample after a 100 h milling does not consist of a mixture of small Fe and Cu particles.

This conclusion is further supported by EXAFS measurements [41, 51, 54, 57, 60, 77], differential scanning calorimetry measurements [26–31, 34, 54], vacuum ultraviolet reflectance measurements [71], and magnetic measurements [37, 39] (see Section 8). For example, EXAFS studies [41, 51, 54, 57, 60, 77] on the as-milled $Fe_{50}Cu_{50}$ sample indicated that the first coordination shell around both the Fe and Cu atoms consists of a mixture of Fe and Cu atoms. In agreement with the Mössbauer spectroscopy measurements, the EXAFS measurements demonstrate that atomic level mixing has occurred around Fe and Cu sites during ball milling. The change of the copper Fermi level in the milled samples also indicated occurrence of alloying at the atomic level during milling [71].

In addition, transmission electron microscopy (TEM) and high resolution transmission electron microscopy (HRTEM) studies [38, 63, 64] of the mechanical alloying process have also been performed in Fe–Cu specimens. It is found that in the early stage of milling shear bands and grain boundary structures have been formed. Small bcc grains with sizes less than 5 nm exist in the specimens. In the intermediate stage [64] a bcc-to-fcc phase transformation occurs by simultaneous shearing process when the copper content reaches 20 at% in bcc-Fe_{rich}Cu grains with a grain size of about 20 nm, as shown in Figure 5. The interface is clearly illustrated

Figure 4. Mössbauer spectrum for an as-milled fcc-$Fe_{50}Cu_{50}$ sample fitted as a superposition of nine subspectra. Reprinted with permission from [38], J. Z. Jiang and F. T. Chen, *J. Phys. Condens. Matter* 6, L343 (1994). © 1994, Institute of Physics.

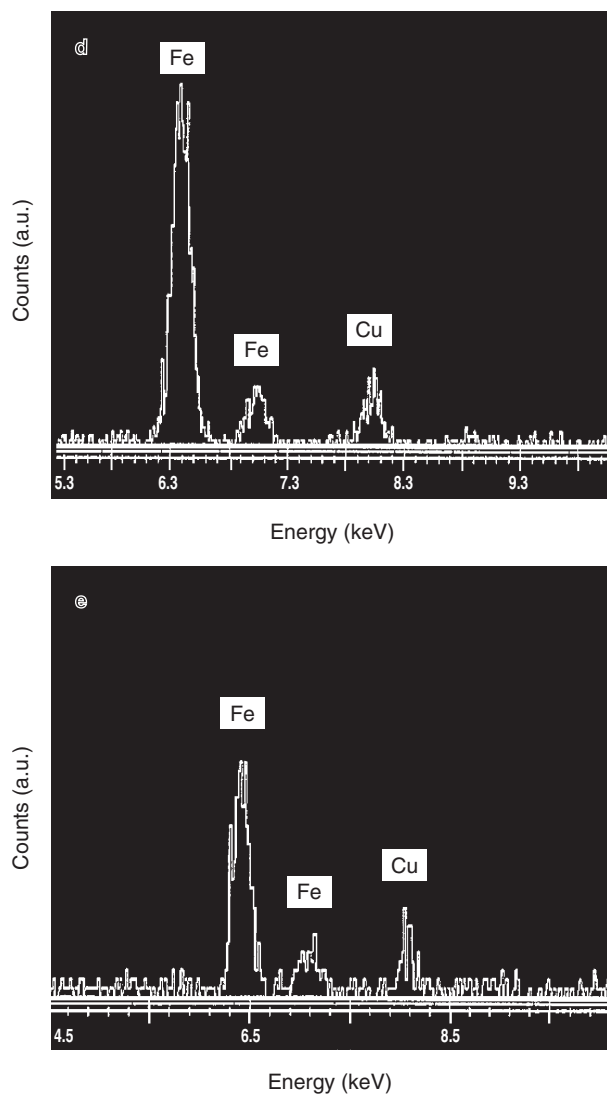

Figure 5. Continued.

in Figure 5a together with the electron diffraction patterns (EDP) from both the upper grain (Fig. 5b) and the lower grain (Fig. 5c). Both the lattice image and the EDP of the lower grain can be identified as $[001]_{bcc}$, while those of the upper grain can be identified as $[011]_{fcc}$. Nanoscale composition analyses (Fig. 5d and e) revealed that both grains have a similar composition to $Fe_{80}Cu_{20}$. The upper grain was unambiguously identified as fcc-$Fe_{80}Cu_{20}$. The Nishiyama–Wasserman (NW) orientation relationships, $[001]_{\alpha}//[011]_{\gamma}$ and $(110)_{\alpha}//(111)_{\gamma}$, were found, which are typical orientation relationships held in a Martensitic transformation. After prolong milling, the structure is fine and homogeneous with a distribution of grain size in a range of a few nm to a few tens of nm. Deformation twins are often observed in the mechanically alloyed specimen. The formation of deformation twins could result from the high strain rates induced by mechanical milling. A nanoscale composition analysis [63] (with an electron beam size around 1 nm) of the $Fe_{16}Cu_{84}$ specimen after the longest milling time shows that the average iron content in both the

interior of grains and interfaces between grains are close to the designed composition. Their results support the earlier conclusion that supersaturated Fe–Cu solid solutions are formed.

According to the experimental results reported, it can be concluded that true alloying occurs in the Fe–Cu system during milling. Initially, the milling process reduces the crystallite sizes of both elemental powder blends and additional interfaces between Cu and Fe regions are formed. Further, refinement of the microstructure increases the density of interfaces making interdiffusion of Cu and Fe energetically possible. Finally a random fcc-FeCu solid solution is formed, in which Fe and Cu are alloyed on an atomic level.

4. SOLID SOLUBILITY IN THE Fe–Cu SYSTEM

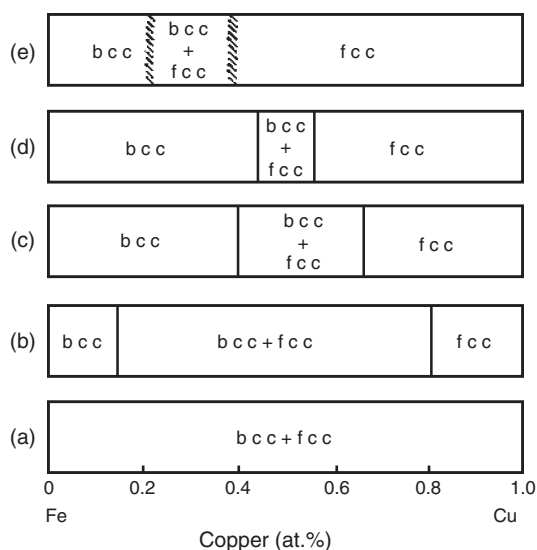
From X-ray diffraction measurements of $Fe_{100-x}Cu_x$ samples in the final stage [19, 21–23, 26, 39] it is found that for $x \geq 40$ the bcc peaks disappear completely and only fcc peaks remain. When $x \leq 20$, only bcc peaks remain and the solutions have the bcc structure. For $20 < x < 40$, both fcc and bcc diffraction lines coexist even after extended milling. These findings have been confirmed by TEM investigations [25]. The obtained values of lattice constant for the Fe–Cu alloys agree well with data reported in these alloys prepared by evaporation techniques [87, 88]. A schematic illustration of the solid solutions prepared by various techniques in the Fe–Cu system is shown in Figure 6. It is clear that the single fcc phase field is extended significantly by mechanical alloying. The observed fcc–bcc transition can be predicted by the calculated free energy curves determined by the CALPHAD method [48, 55, 68]. When $x > 40$, the free energy of mixing for the fcc structure is smaller than that for


Figure 6. Schematic diagram of the equilibrium phase boundary at room temperature (a), and the phase boundaries obtained by liquid quenching (b), thermal evaporation (c), sputtering (d), and mechanical alloying (e) [65].

the bcc structure, for $x < 20$ the bcc structure is more stable, and in between, differences of the free energy between both structures are small, resulting in the existence of both structures in the samples as observed. However, from the calculated free energy curves only one crossover ($\Delta G = 0$) point exists; one expects the fcc (or bcc) phase does not immediately transform into the bcc (or fcc) phase once the solute content is beyond the crossover concentration. This question has been further investigated. Hong and Fultz [68], based on the results obtained from Mössbauer spectroscopy measurements and modifying CALPHAD-type free energy calculations to consider defect enthalpies induced by mechanical milling, about 1.5 kJ/mol for the bcc phase and 0.5 kJ/mol for the fcc phase, suggested the two-phase coexistence links in part to spatial heterogeneity in the defect distribution induced by milling. Once crossover in the free energy curves is reached in a region, the bcc-to-fcc (or fcc-to-bcc) transformation will immediately proceed to completion. The heterogeneity of stored defect energy results in different crossover points in different local regions, and this leads to the two-phase region observed. On the other hand, Schilling et al. [70], based on the results obtained from X-ray absorption near-edge structure spectroscopy measurements, found that the compositions of the two phases in coexistence are nearly the same (i.e., they are practically polymorphs with the same composition as the overall mixture). This rules out the possibilities of any two-phase stable or metastable equilibrium under a common-tangent construction that would dictate two fixed end compositions with varying phase fractions across the two-phase region. Furthermore, they [70] proposed that the transformation of one phase to another is not only governed by free energy, but only when there is a sufficient driving force (ΔG) to overcome a transformation barrier. This is contrast to the model suggested by Hong and Fultz [68], in which no such barrier is present. A single fcc (or bcc) phase becomes unstable as the composition passes the free energy crossover. Phase transformation (e.g., via Martensitic transformation observed in [64]) occurs, which requires a driving force ($\Delta G \neq 0$) to overcome the transformation barrier arising most likely from the strain energy associated with nucleation and growth. At compositions outside the two-phase region, sufficient driving force is available to accomplish the transformation.

Hong and Fultz [68] further studied the milling intensity effect on the composition range for the two-phase coexistence. They found that with higher milling intensity, there was a narrowing of the range of compositions for fcc and bcc coexistence, and a shift toward Fe-rich compositions. However, Schilling et al. [70] found that low-temperature milling at around 77 K gives a similar two-phase coexistence composition as compared to that using room temperature milling, although it was thought that low-temperature milling would influence the two-phase coexistence composition range because low-temperature milling effectively reduced the powder agglomeration and cold welding. The formation of a fcc-$Fe_{50}Cu_{50}$ solid solution by mechanical alloying requires the free energy to be raised by about 7.5 kJ/mol. However, there is a basic question (i.e., where

the energy is stored in the as-milled solid solutions). The following section will deal with this problem.

5. DRIVING FORCE FOR THE ALLOYING

The mechanism by which a solid solution is formed by mechanical alloying in systems exhibiting positive free energies of mixing has been extensively studied in the last few years. First, Veltl et al. [21] suggested that the energy stored in the grain boundaries serves as a driving force for the formation of a solid solution. Their assumption is based on the observation that alloying occurs when the grain sizes of elemental components decrease down to the nanometer range and that a substantial amount of enthalpy can be stored in nanocrystalline metals due to the large grain boundary area [89]. In the Fe–Cu system, mechanical alloying leads to the formation of single-phase solid solutions of up to 60 at% Fe in Cu and 20 at% Cu in Fe. X-ray diffraction investigations reveal that the average grain size of the elemental components prior to alloying is not smaller than 5 nm. (Note that X-ray line broadening is determined by the volume-weighted average grain size). An increase of the grain size from 5 to 15 nm during alloying corresponds to a maximum decrease in the grain boundary enthalpy of the alloy of $3\sigma_{gb}V_m(1/d_1 - 1/d_2) \approx 1.4$ kJ/g-atom, where V_m is the average molar volume and $\sigma_{gb} = 0.5$ J/m^2 is the grain-boundary enthalpy of Cu as measured on nanocrystalline samples [90]. Compared to the free energy of mixing this value may not be sufficient to explain the alloying behavior in the Fe–Cu system.

Second, Yavari and Desré [91] suspected that alloying of immiscible elements in the systems with high solubilities for oxygen originates from a high oxygen content thus resulting in a negative heat of mixing of the multicomponent mixture. This suggestion becomes less possible in Fe–Cu samples due to low oxygen contents (e.g., less than 0.5 wt% in a fcc-$Fe_{50}Cu_{50}$ solid solution milled for a 100 h) [32]. Eckert et al. [27–31] suggested another mechanism, which explains alloy formation by an enhanced solubility due to the high dislocation density during the milling of nanocrystalline powders. The effect of point defects formed during plastic deformation on the alloying process has also been stressed [52]. However, Ma et al. [34, 48] estimated the magnitude of the contribution of the strain relief in the Fe–Cu solid solutions. They found that for a root-mean-square (rms) strain of 0.3%, usually observed in the Fe–Cu system, only an enthalpy of less than 0.5 kJ/g-atom is associated, which indicated the strain energy induced by mechanical deformation is insignificant in the Fe–Cu system for the alloying process. (Note that strain energy will be on the order of 1 kJ/g-atom in other systems in which a rms strain of a few percent is observed.)

Later, Yavari et al. [26, 40, 47] proposed alternative alloying mechanisms, based on the assumption that upon deformation of the composite, elemental fragments with small tip radii are formed and a small fraction of materials is expected to be in crystallite diameters of 2 nm or less, corresponding to the tail of the particle size distribution. In these cases the

capillary pressure forces the atoms at the tips of the fragments to dissolve. This process will continue to full dissolution, due to generation of such small particles by necking at tips of larger ones with continued milling. They further estimated the chemical energy of the Fe–Cu interface as a function of grain size. They found that for grain sizes less than 2 nm, the formation of solid solutions can be energetically possible. A similar mechanism was also suggested earlier by Gente et al. [23] in a study of the immiscible Co–Cu system. They suggested that the chemical enthalpy associated with the interface between the elemental components can enhance the free energy of a composite above that of the related solid solution thus providing a driving force for alloying in systems with a positive free energy of mixing. Gente et al. [23] and Yavari et al. [40, 47] both claimed that the dimensions of the element components before alloying may be significantly smaller than the average grain size, which has indeed been observed in recent high-resolution TEM studies of Fe–Cu [43, 63, 64]. The chemical energy stored in the Fe/Cu interfaces is very high, for example, up to 6.3 kJ/g-atom for elemental domains of 1 nm size and a chemical interfacial energy of 0.3 J/m² [23]. This value is comparable to the free energy of mixing for a $Fe_{50}Cu_{50}$ alloy. Hence, the driving force for the formation of the single-phase solid solution could originate mainly from the chemical enthalpy of the Fe/Cu interfaces formed during ball milling. The main difference between the models proposed by Yavari et al. [26, 40, 47] and Gente et al. [23] is that Yavari et al. assume incoherent interfaces between the elemental components, whereas Gente et al. suggest the formation of composites with coherent elemental domains before alloying occurs. So far, microstructural information obtained might not be sufficient to decide between the two models and further investigation is needed.

The kinetic process of the nanoalloying in the Fe–Cu system has been investigated by means of Monte Carlo simulation [46] and HRTEM measurements [64]. Both investigations suggested that mechanical deformation-induced diffusion is an important factor in controlling the alloying process. Monte Carlo simulation [46] showed that with an increasing shearing frequency, the interfaces become increasingly rough, leading to refinement of the microstructure and eventually to homogeneous alloying of the system. The HRTEM study [64] of a sample milled in the intermediate stage revealed that a bcc-to-fcc phase transformation occurs by a simultaneous shearing process when the copper content reaches 20 at% in bcc-Fe_{rich}Cu grains with the grain size of about 20 nm. Thus, the kinetic process of the nanoalloying was suggested as follows: Initially, the milling process reduces the crystallite sizes of both elemental Fe and Cu powder blends to a few tens of nanometers due to the mobility of dislocations. Many defects, (e.g., lattice distortion, dislocation, and low- and high-angle grain boundaries) are formed in these nanostructured materials. The solubilities of Fe in Cu and Cu in Fe are then enhanced according to the Gibbs–Thomson equation [92]. This promotes the defect-induced interdiffusion processes in the system, which has indeed been experimentally confirmed by Mössbauer measurements [32] and the nanoscale composition analyses. Note that a diffusional reaction in the systems

with a positive heat of mixing generally results in decomposition of the alloy under equilibrium conditions. However, by decreasing the grain size, the solubility, especially iron in fcc Cu matrix, can be large even under equilibrium condition (details given in Section 7). The bcc-Fe_{rich}Cu grains which have the Martensitic transformation temperature lower than the local temperature at collisions with balls and vial become unstable and then the bcc → fcc phase transformation occurs by simultaneous shearing of the whole grain. On further increasing the milling time, although the average crystallite size of the fcc phases remains unchanged, interdiffusion between fcc-Fe_{rich}Cu and fcc-$FeCu_{rich}$ is favored because of the similarity of the lattice structures. The last stage of milling is a homogenization process until a complete fcc-FeCu solid solution is formed. It is concluded that the alloying process in the Fe–Cu system during milling is kinetically governed by the atomic shear effect and the defect-induced interdiffusion process.

6. THERMAL STABILITY OF THE ALLOYS

Using a high energy ball milling technique, many new materials have been produced, which may have potential industrial applications. Structural stability of the new materials prepared should be studied.

The thermal stability of the Fe–Cu solid solutions has been investigated extensively [24–31, 33, 34, 36, 41, 42, 44, 47, 56, 69]. In bcc Fe-rich solid solutions, segregation of Cu to the grain boundaries was observed [56]. Figure 7 shows typical X-ray diffraction patterns for the $Fe_{50}Cu_{50}$ samples after milling and for those subsequently annealed at different temperatures for one hour in vacuum. With annealing at 473 K, the (110) peak of the bcc-Fe phase appears. However, within the accuracy of the measurements, the grain size of the fcc phase does not change with respect to the as-milled sample. The lattice constant of the fcc phase decreases, corresponding to a reduction of the iron content in the fcc phase due to Fe precipitation [33]. By increasing the annealing temperature from 473 to 873 K the amount of the bcc-Fe phase increases at the expense of that of the fcc-FeCu phase. Thereby the lattice constant of the fcc-FeCu phase is further reduced and the grain sizes of the fcc and bcc phases increase up to about 50 nm. However, due to the similarity of the lattice constants between fcc-Fe, fcc-Fe_{rich}Cu, and fcc-Cu_{rich}Fe phases, it is impossible to detect the early coherent stage of the decomposition by diffraction techniques [84]. On the basis of a simulation of the saturation magnetization of the fcc-$Fe_{50}Cu_{50}$ solid solution as a function of annealing time at a given temperature, Drbohlav and Yavari [47] suggested that fcc-Fe_{rich}Cu and fcc-Cu_{rich}Fe zones are formed in the early stage by the spinodal decomposition process. Furthermore, in the Mössbauer measurements [33], it is found that at the beginning, fcc iron precipitates coherently in the fcc-FeCu matrix. Upon further annealing, the Fe particles grow and transform into the stable bcc-Fe phase. The average hyperfine field of the fcc-FeCu component decreases gradually as the annealing temperature increases, which indicates a continuous reduction of the Fe content in the fcc-FeCu phase. The decomposition process of the fcc-$Fe_{50}Cu_{50}$ solid solution prepared
Figure 7. Typical X-ray diffraction patterns for various $Fe_{50}Cu_{50}$ samples in the as-milled state (a) and annealed at 473 (b), 573 (c), 673 (d), and 873 K (e) [33]. Reprinted with permission from [33], J. Z. Jiang et al., *Appl. Phys. Lett.* 63, 1056 (1993). © 1993, American Institute of Physics.

by mechanical alloying can be summarized as follows: Initially, composition fluctuations within grains occurs (i.e., formation of coherent fcc-Fe_{rich}Cu and fcc-Cu_{rich}Fe domains). Upon further annealing decomposition proceeds while the fcc-Fe particles grow and transform into the stable bcc-Fe phase. Finally, separated bcc-Fe and fcc-Cu phases are formed.

Xu et al. [69] further studied the low-temperature ball milling effect at elevated temperatures (373–523 K) on the decomposition of the unstable fcc-$Fe_{50}Cu_{50}$ solid solution prepared by high-energy ball milling. They found that despite the reduced driving force due to the homogenizing effect of the deformation, milling-induced deformation significantly enhanced the initial decomposition rate as compared to the isothermal annealing at the same temperatures used. At 423 K, the initial milling (10 h) led to the formation of bcc phase. Increasing the milling time, the relative amount of the bcc phase reached a maximum at about 20 h and then decreased. After 80 h, the bcc phase disappeared. By further milling, only the fcc phase was detected. A similar reversal fcc-to-bcc-to-fcc phase transformation process during milling was observed in samples milled at 473 K ≥ T ≥ 373 K. On the other hand, at 523 K,

after 2 h, bcc phase appeared, and its fraction increased with milling time up to about 30 h. Further milling did not change the relative fraction ratio of fcc to bcc phase. The observed results were explained by an effect-temperature model, which was originally proposed by Martin [93]. Under competition between externally driven mixing and thermal back-diffusion toward equilibrium, the model revealed that the configuration of a regular binary solution would be the same as that in thermal equilibrium at the effect temperature, T_{eff}. Based on this model, Xu et al. [69] constructed a dynamic Fe–Cu phase diagram in T_{eff}. T_{eff} decreased with increasing milling temperature. At 423 K, T_{eff} still favors a single fcc phase while at 523 K, T_{eff} drops from the fcc single-phase region (e.g., at T_{eff}^1) to lower values (e.g., T_{eff}^2) corresponding to the two-phase region, where coexistence of fcc and bcc phases is expected. It should be noted that T_{eff}, estimated from the model for the Fe–Cu system, was significantly higher than their melting points.

7. Fe–Cu BINARY PHASE DIAGRAM WITH NANOMETER-SIZED PARTICLES

It is mentioned in Section 4 that the solid solubilities of Fe in the fcc phase and Cu in the bcc phase are enhanced by mechanical alloying, as shown in Figure 6. The enhancement of solid solubility could be linked with small grain sizes induced by milling. Although some attempts [21, 26–31, 91] tried to explain the extension of the solid solubility during the mechanical milling process, the subject is still not well understood. Recently, a method to calculate phase diagram with nanometer-sized grains was proposed [94], which is given as follows.

Using the CALPHAD method [95, 96], the Gibbs energy of the solid solution phase in the bulk state is described by the regular solution model. For instance, the Gibbs energy of the fcc and bcc phases in the Fe–Cu binary system is expressed as

$$G^\phi = {}^0G_{Cu}^\phi x_{Cu}^\phi + {}^0G_{Fe}^\phi x_{Fe}^\phi + RT(x_{Cu}^\phi \ln x_{Cu}^\phi + x_{Fe}^\phi \ln x_{Fe}^\phi)$$
$$+ L_{FeCu}^\phi x_{Cu}^\phi x_{Fe}^\phi + G^{mag} \quad (\phi = bcc \text{ and } fcc \text{ phases}) \quad (1)$$

where $^0G_{Cu}^\phi$ and $^0G_{Fe}^\phi$ are the Gibbs energy of pure components Cu and Fe in the respective reference state, x_{Cu}^ϕ and x_{Fe}^ϕ is the mole fraction of components Cu and Fe, respectively, and L_{CuFe}^ϕ is the temperature and composition dependent interaction energy in binary system.

The Gibbs energy of pure components Cu and Fe in its different phase states is taken from the SGTE database [97]. The thermodynamic assessment of the Fe–Cu phase diagram has been carried out by several groups [98–103]. The latest version was performed by Chen and Jin [103], whose parameters are used in the present work. G^{mag} is the magnetic contribution, which is described by the Hillert and Jarl model [104]. The magnetic term to the Gibbs energy is given by

$$G^{mag} = RT \ln(B + 1)g(\tau) \quad (2)$$

where $\tau = T/Tc$, T_c is the Curie temperature, and B is the average magnetic moment per atom. $g(\tau)$ is given by

$$g(\tau) = 1 - \left[\frac{79\tau^{-1}}{140} + \frac{474}{497}\left(\frac{1}{p} - 1\right)\right. \\ \left.\left(\frac{\tau^3}{6} + \frac{\tau^9}{135} + \frac{\tau^{15}}{600}\right)\right]\Big/ D \qquad \tau < 1$$

$$g(\tau) = -\left[\frac{\tau^{-5}}{10} + \frac{\tau^{-15}}{315} + \frac{\tau^{-25}}{1500}\right]\Big/ D \qquad \tau > 1$$

where

$$D = \frac{518}{1125} + \frac{11692}{15975}\left(\frac{1}{p} - 1\right)$$

The value of p, which is the fraction of the magnetic enthalpy absorbed above the critical temperature, depends on the structure; for the bcc phase $p = 0.40$ and for the fcc phase $p = 0.28$.

In the system with nanometer-sized grains, the pressure and volume contributions should be considered. x_0 is the concentration of Fe in the bulk state at certain T_0 and P_0. Thus, the chemical potential corresponding to the system with nanometer-sized grains can be written as the following series:

$$\mu(T, x, P) = \mu(T_0, x_0, P_0) + \frac{\partial \mu}{\partial x}\bigg|_{x=x_0}(x - x_0)$$
$$+ \frac{\partial \mu}{\partial P}\bigg|_{P=P_0} \times (P - P_0) + \frac{\partial^2 \mu}{\partial x^2}\bigg|_{x=x_0}(x - x_0)^2$$
$$+ \frac{\partial^2 \mu}{\partial P^2}\bigg|_{P=P_0} \times (P - P_0)^2 + \frac{\partial^2 \mu}{\partial x \, \partial P}\bigg|_{\substack{x=x_0 \\ P=P_0}}$$
$$\times (x - x_0)(P - P_0) + \cdots \qquad (3)$$

In this treatment, we will restrict our considerations to second-order terms. The Gibbs–Duhem relationship is given by the expression

$$-V \, dP + S \, dT + x_{\text{Cu}} \, d\mu_{\text{Cu}} + x_{\text{Fe}} \, d\mu_{\text{Fe}} = 0 \qquad (4)$$

Using the Gibbs–Duhem relationship, we may obtain the equations

$$\frac{\partial \mu_{\text{Cu}}}{\partial P} = -\frac{V}{x_{\text{Cu}}} \qquad \frac{\partial \mu_{\text{Fe}}}{\partial P} = -\frac{V}{x_{\text{Fe}}}$$
$$\frac{\partial^2 \mu_{\text{Cu}}}{\partial P^2} = \frac{\kappa V}{x_{\text{Cu}}} \qquad \frac{\partial^2 \mu_{\text{Fe}}}{\partial P^2} = \frac{\kappa V}{x_{\text{Fe}}}$$
$$\frac{\partial^2 \mu_{\text{Cu}}}{\partial P \, \partial x} = -\frac{V_{\text{Fe}}}{x_{\text{Cu}}^2} \qquad \frac{\partial^2 \mu_{\text{Fe}}}{\partial P \, \partial x} = -\frac{V_{\text{Cu}}}{x_{\text{Fe}}^2}$$

where V_i and V are the molar volumes of an i element and alloy, respectively, and κ is the isothermal compressibility coefficient. $\partial \mu/\partial x$ and $\partial^2 \mu/\partial x^2$ can be calculated from Eq. (1).

If we consider the phase equilibrium of the bcc and fcc phases in the Cu–Fe binary system, the equilibrium equation $\mu_{\text{Cu}}^{\text{bcc}}(T_0, x^{\text{bcc}}, P^{\text{bcc}}) = \mu_{\text{Cu}}^{\text{fcc}}(T_0, x^{\text{fcc}}, P^{\text{fcc}})$, $\mu_{\text{Fe}}^{\text{bcc}}(T_0, x^{\text{bcc}}, P^{\text{bcc}}) = \mu_{\text{Fe}}^{\text{fcc}}(T_0, x^{\text{fcc}}, P^{\text{fcc}})$ should hold, and the equation may be written as

$$\mu_i^{\text{bcc}}(T_0, x_0^{\text{bcc}}, P_0^{\text{bcc}}) - \mu_i^{\text{fcc}}(T_0, x_0^{\text{fcc}}, P_0^{\text{fcc}}) + \frac{\partial \mu_i^{\text{bcc}}}{\partial x}(x_{\text{Fe}}^{\text{bcc}} - x_0^{\text{bcc}})$$
$$- \frac{\partial \mu_i^{\text{fcc}}}{\partial x}(x_{\text{Fe}}^{\text{fcc}} - x_0^{\text{fcc}}) - \frac{V^{\text{bcc}}}{x_i^{\text{bcc}}}(P^{\text{bcc}} - P_0^{\text{bcc}})$$
$$+ \frac{V^{\text{fcc}}}{x_i^{\text{fcc}}}(P^{\text{fcc}} - P_0^{\text{fcc}}) + \frac{\partial^2 \mu_i^{\text{bcc}}}{\partial x^2}(x_{\text{Fe}}^{\text{bcc}} - x_0^{\text{bcc}})^2$$
$$- \frac{\partial^2 \mu_i^{\text{fcc}}}{\partial x^2}(x_{\text{Fe}}^{\text{fcc}} - x_0^{\text{fcc}})^2 + \frac{\kappa^{\text{bcc}} V^{\text{bcc}}}{x_i^{\text{bcc}}}(P^{\text{bcc}} - P_0^{\text{bcc}})^2$$
$$- \frac{\kappa^{\text{fcc}} V^{\text{fcc}}}{x_i^{\text{fcc}}}(P^{\text{fcc}} - P_0^{\text{fcc}})^2 + \frac{V_j^{\text{bcc}}}{x_i^2}(x_{\text{Fe}}^{\text{bcc}} - x_0^{\text{bcc}})$$
$$\times (P^{\text{bcc}} - P_0^{\text{bcc}}) - \frac{V_j^{\text{fcc}}}{x_i^2}(x_{\text{Fe}}^{\text{fcc}} - x_0^{\text{fcc}})(P^{\text{fcc}} - P_0^{\text{fcc}}) = 0 \quad (5)$$

$i, j = $ Cu and Fe, respectively.

The molar volume and the isothermal compressibility coefficient of alloy are described as $V^\phi = (1 - x_0^\phi)V_{\text{Cu}}^\phi + x_0^\phi V_{\text{Fe}}^\phi$ and $\kappa^\phi = (1 - x_0^\phi)\kappa_{\text{Cu}}^\phi + x_0^\phi \kappa_{\text{Fe}}^\phi$, respectively. Both X_0 and P_0 can be chosen to be the concentration and pressure associated with the bulk phases. Therefore, in the bulk state, there are the equilibrium equations as follows:

$$\mu_{\text{Cu}}^{\text{bcc}}(T_0, x_0^{\text{bcc}}, P_0^{\text{bcc}}) = \mu_{\text{Cu}}^{\text{fcc}}(T_0, x_0^{\text{fcc}}, P_0^{\text{fcc}}) \qquad \text{and}$$
$$\mu_{\text{Fe}}^{\text{bcc}}(T_0, x_0^{\text{bcc}}, P_0^{\text{bcc}}) = \mu_{\text{Fe}}^{\text{fcc}}(T_0, x_0^{\text{fcc}}, P_0^{\text{fcc}})$$

The pressure P^ϕ in the ϕ phase is given by the Laplace law,

$$P^\phi = P_0^\phi + \frac{2\sigma^\phi}{r^\phi} \qquad (6)$$

where r is the radius of the particle, P_0^ϕ is the pressure in the gaseous phase, and σ^ϕ is the surface tension in the ϕ phase.

Experimental data for surface tension of solids are limited, and the existing theoretical attempts did not give the dependence of structure on surface tension. For example, the different structures such as the bcc-Fe and fcc-Fe phases are not distinguished in the literature [105–107]. A method to predict the surface tension of solids for pure metals and binary alloys in various structures was suggested [108]. The calculated surface tension results for the bcc and fcc phases in the Cu–Fe system at 400 K are given in Figure 8, which correspond to the metastable bcc and fcc phases because the miscibility gap of the fcc phase exists at 400 K. It is seen that the surface tensions of both bcc- and fcc-Fe phases, 2894 and 2807 mN/m, respectively, sharply decrease due to a small addition of copper. There exist minima at about 4 at% copper. Then, they increase with increasing copper content. For pure bcc- and fcc-Cu, the surface tensions are 1622 and 1730 mN/m, respectively.

Two equations can be obtained from Eq. (5) with respect to Cu and Fe, respectively, and $x_{\text{Fe}}^{\text{fcc}}$ and $x_{\text{Fe}}^{\text{bcc}}$ can be calculated by simultaneously solving these two equations, which correspond to the concentrations of Fe with the particle radius (r). On the basis of this consideration, in principle phase equilibria in binary systems with nanometer-sized
Figure 8. Calculated surface tensions of metastable fcc and bcc phases at 400 K [94].

grains can be calculated. The fcc/bcc phase equilibria in the Fe–Cu system with various grain sizes are shown in Figure 9. Two main characteristics for the phase diagram with decreasing grain size can be deduced: (1) the solubilities of Fe in the fcc phase and Cu in the bcc phase are enhanced by decreasing grain size, and (2) a negative temperature dependence of solid solubility is found in both fcc and bcc phases. The calculated results indicate that the solid solubility of Fe in the fcc phase is larger than that of Cu in the bcc phase for the same grain size at low temperatures, in agreement with the experimental ones reported previously
Figure 9. Calculated fcc/bcc phase equilibria with various nanometer-sized particles [108].

in Figure 6. Some quantitative difference of solubility may originate from other factors such as high dislocation density and internal strains, etc., which were not considered in the present calculation.

8. MAGNETIC PROPERTIES OF THE ALLOYS

Like the studies of the thermal stability of the Fe–Cu solid solutions, the magnetic properties of these alloys have been also studied by several groups [25, 34–37, 39, 42, 47, 49, 75, 81]. The saturation magnetization ($M(T)$) of the as-milled fcc-$Fe_{50}Cu_{50}$ alloy as a function of temperature [39], measured in a 1 T field, is shown in Figure 10. The magnetization decreases with increasing temperature up to about 510 K. With a further increase in temperature, the magnetization increases. By extrapolation of the curve below this minimum to zero magnetization, the Curie temperature for the metastable fcc-$Fe_{50}Cu_{50}$ solid solution is estimated to be $T_c = 505 \pm 5$ K. The temperature dependence of saturation magnetization in the temperature range above 500 K can be explained by the decomposition of the fcc-$Fe_{50}Cu_{50}$ alloy. When the annealing temperature reaches 473 K, the fcc-$Fe_{50}Cu_{50}$ phase decomposes into fcc-Fe, fcc-Fe_{rich}Cu, fcc-Cu_{rich}Fe, and bcc-Fe phases. With higher annealing temperatures the amount of the bcc-Fe phase rapidly increases at the expense of the Fe content in the fcc-FeCu and fcc-Fe phases. Although the saturation magnetization for the fcc-FeCu solid solution is zero when the temperature is above 500 K, the bcc-Fe phase can still maintain high saturation magnetization values (e.g., about 208 emu/g at 500 K and about 185 emu/g at 750 K) [109]. This accounts for the increase
Figure 10. The saturation magnetization of an as-milled fcc-$Fe_{50}Cu_{50}$ sample as a function of temperature in 1 T field. Reprinted with permission from [39], J. Z. Jiang et al., *J. Phys. Condens. Matter* 6, L227 (1994). © 1994, Institute of Physics.

Table 1. Summary of the saturation magnetic moment, M_s, values per atom versus the Cu concentration or number of electrons per atom at 4 K of the metastable alloys in the Fe–Cu system [81].

Cu content (%)	10	20	25	30	35	40	45	50	60	65	70	80
Electrons per atom	26.3	26.6	26.75	26.9	27.05	27.2	27.35	27.5	27.8	27.95	28.1	28.4
M_s (μ_B)	2.26	1.89	1.69	1.47	1.30	1.30	1.21	1.09	0.83	0.73	0.62	0.25

of the saturation magnetization in the sample with temperatures above 510 K. The saturation magnetization [37, 39] for the as-milled fcc-$Fe_{50}Cu_{50}$ alloy at temperatures lower than 200 K ($0.4T_c$) follows Bloch's law, $M(T)/M(0) = 1 - BT^{3/2}$, or $(1 - M(T)/M(0)) = B_{3/2}(T/T_c)^{3/2}$, with $M(0) = 108.7$ emu/g and $B = 0.00457$ (emu/g) K$^{-3/2}$. The values of the parameters B and $B_{3/2}$ for the as-milled fcc-$Fe_{50}Cu_{50}$ alloy are many times larger than those for crystalline Fe and Ni but are similar to those for the amorphous alloys [39]. It is known that the disordered structure in amorphous alloys leads to the high values of B and $B_{3/2}$ [110]. Consequently, the larger values of B and $B_{3/2}$ in the fcc-$Fe_{50}Cu_{50}$ solid solution imply that the atomic structures are very disordered. This is in good agreement with results obtained in Section 3.

The microscopic arrangement of the magnetic moment in the fcc-$Fe_{100-x}Cu_x$ alloys has been investigated [25, 39, 49, 75]. The bulk magnetic moments data at 5 K were reported [75]. The system is nonmagnetic for concentration below about 5 at% Fe. Above this concentration the magnetic moment increases at a rate of about 2.85 μ_B/Fe atom with a pronounced tendency to level off at higher Fe concentration, similar to what is observed in the case of Fe–Ni [111]. The onset and linear dependence of the bulk magnetization on the Fe concentration for less than 30% can be interpreted by means of a simple model: charge transfer from Cu to Fe bands. Many theoretical investigations on the fcc phase of Fe reveal a high-spin state, stable at high atomic volume and favoring strong ferromagnetism (i.e. an almost full spin-up band). When Cu concentration in the system increases, a transfer of electrons takes place from the delocalized ($s + p$)-like bands to the spin-down $3d$-like band of Fe, which is weak ferromagnetism. Consequently, a decrease of magnetic moment is expected as observed in [75]. The nonlinear trend of the bulk magnetization as the concentration of Fe is increased over 30% needs a mechanism different from the simple charge transfer model, which might be explained by the two-magnetic-state model of Fe suggested by band theory of ferromagnetism for fcc Fe alloys [112–115]. It has been suggested that an Fe atom with a larger atomic volume in the high-spin state has a larger magnetic moment. The second state, a low-spin state, with a low atomic volume is associated with a lower magnetic moment, and it favors the antiferromagnetic coupling. The existence of both states may result in the nonlinear trend of the bulk magnetization as the concentration of copper. Further investigation is required to clarify the two-magnetic-state mechanism. Low-temperature magnetization measurements of $Fe_{100-x}Cu_x$ ($100 > x > 0$) alloys prepared by mechanically milling were performed by Mashimo et al. [81]. The saturation magnetization moment per atom versus the number of electrons per atom at 4 K of the metastable alloys in the Fe–Cu system was

obtained together with other binary systems. The values are summarized in Table 1. They found that the saturation magnetization moment reaches a local maximum at about 26.2 electrons per atom, which is similar to the cases in the Fe–Co and Fe–Ni systems. It decreases with increasing Cu concentration and approaches zero at about 28.6 electrons per atom. Their results were consistent with other binary systems in the Slater–Pauling curve.

The coercive field of the fcc-$Fe_{50}Cu_{50}$ at 300 K is only a few tens of Oe [35, 37, 42, 47, 49], which means a negligible structural anisotropy. The result reflects the disordered atomic configurations in the alloy. The temperature dependencies of the coercive field of some Fe–Cu solid solutions have been studied by Crespo et al. [49]. They found that for the $Fe_{20}Cu_{80}$ sample, an anomalous temperature dependence of the coercive field is observed, which has also been observed during the decomposition of some alloys (i.e., a high coercive field of about 150 Oe at 300 K, a minimum value at 50 K, and a further increase to 260 Oe at 10 K). This behavior could be explained by the existence of a distribution in composition, that is, different Curie temperatures, which would give rise to isolated ferromagnetic grains as the temperature continuously increases above the Curie temperatures of such distributed phases. However, for temperatures below 50 K, the coercive field increases with decreasing temperature. At the moment, no plausible explanation for this experimental result has been found. The room-temperature Mössbauer spectrum [32, 69] of the as-milled $Fe_{50}Cu_{50}$ sample (see Fig. 3g) shows that the intensity ratio of the second (or fifth) line to the first (or sixth) line is about 0.4. This means that the spins in the inside of a pellet prefer the normal direction of the pellet, which could be caused, via the magnetoelastic effect, by strain stress induced by the ball milling in the sample. Low-energy ball milling at 423 K for 240 h of the unstable fcc-$Fe_{50}Cu_{50}$ solid solution led to a random orientation of the spins [69].

9. SUMMARY

The studies of mechanical alloying on the Fe–Cu system, as a model system for those with positive heats of mixing, are reviewed. Several problems involved in the mechanical alloying process are discussed. The results demonstrate that alloying, on the atomic level, in systems with positive heats of mixing occurs by the high-energy ball milling. The driving force for the formation of the alloy is mainly derived from the chemical enthalpy associated with Fe/Cu interfaces formed during the ball milling. The alloying process in the Fe–Cu system during milling is kinetically governed by the atomic shear effect and the defect-induced interdiffusion process. The solubilities in the Fe–Cu system were largely

extended, especially for the single fcc structure, which is linked with grain-size enhanced solid solubilities. The magnetic parameters of the fcc $Fe_{50}Cu_{50}$ alloy were investigated in detail (e.g., the Curie temperature, coercive field, orientation of spins, and the saturation magnetization). Furthermore, the thermal stability of the alloy was investigated and shows that iron particles already precipitate at temperatures around 473 K.

GLOSSARY

Driving force   The difference in Gibbs free energy between parent phase and daughter phase.

Equilibrium system   The system has the lowest Gibbs free energy for all possible configurations.

Grain boundary   The boundary between at least two grains.

Immiscible system   System with a positive heat of mixing.

Interface energy   The free energy of an interface with a unit of J/m^2.

Mechanical alloying   Alloying occurs by means of mechanical treatment.

Metastable alloys   Alloys have configurations, which lie at a local minimum in Gibbs free energy.

Nanoalloying   At least two components, having a nanometer size (1–100 nm) at least in one direction, mix on an atomic level.

Nanostructured material   Material consists of components which have a nanometer size (1–100 nm) at least in one direction.

Solid solubility   The concentration limit of one component in a solid solution.

Solid solution   Solid material with at least two elements which mix on an atomic level.

Unstable alloys   Alloys have configurations, which do not lie at a minimum in Gibbs free energy.

CONTENTS

1. INTRODUCTION

During the last two decades, semiconducting properties of many multicomponent and transition metal oxide (TMO) and other metal oxide glasses have been studied because of their probable technological applications [1–4] in optical and electrical memory switches, oxygen sensors, etc. The high temperature ($T > \theta_D/2$, θ_D being the Debye temperature) conductivity data in many of these glasses, for example, V_2O_5–TeO_2 [5], V_2O_5–Bi_2O_3 [6], V_2O_5–P_2O_5 [7], V_2O_5–MnO–TeO_2 [8], V_2O_5–SnO–TeO_2 [9], V_2O_5–P_2O_5–TiO_2 [10], V_2O_5–CoO–TeO_2 [11], etc., were explained by using the "small polaron" hopping (SPH) model [12–15] based on strong electron–phonon interaction. On the other hand, in the low temperature phase ($T < \theta_D/2$), a variable-range hopping (VRH) conduction mechanism [15, 16] with $T^{-1/4}$ dependence was used to explain the conductivity data. The dielectric constants of these glasses are, in general, very low and follow Debye-type dielectric relaxation behavior. Another class of semiconducting glasses like CdS nanoparticles dispersed in sol–gel derived polymers [17], NiO–SiO_2 nanocomposites [18], ZnS nanocrystals stabilized in silica [19], etc. have been studied. Recently Itoigawa et al. [20] also observed the formation of nanosize silver and bismuth particles, respectively, in the Na_2O–B_2O_3–Ag_2O and Na_2O–B_2O_3–BiO_3 glasses. Lately Sakuri and Yamaki [2] reported the presence of such nanocrystalline phases in the V_2O_5–CoO–TeO_2 glass following multiphonon tunneling conduction mechanism. In the high temperature range (above $\theta_D/2$), these glasses also followed the SPH conduction mechanism but the VRH mechanism was found to be

not strictly followed [2] as these glasses showed extremely large values of the density of states (DOS) at the Fermi level $N(E_F)$, which is not possible. Similarly, Ag_2O doped Bi–Sr–Ca–Cu–O glasses, precursors for high T_c superconductors, also dispersed with nanocrystalline silver particles showed a high value [21] of $N(E_F)$ estimated from the VRH model. But none of these nanocrystal-dispersed glasses are ferroelectric (FE) or they do not show high dielectric permittivity. However, some of the TMO glasses containing $BaTiO_3$, $PbTiO_3$, TeO_2, etc. are found to show FE behavior due to the presence of nanocrystalline phases.

The aforementioned ferroelectric behavior in nanocrystals of pure FE material like $PbTiO_3$ is, however, not new [22]. Glass ceramics containing ferroelectric phases have been studied for long time to obtain useful dielectric and electro-optic properties [23–26]. Nanophase materials and nanocomposites, characterized by an ultrafine grain size (<50 nm), have created high interest in recent years by virtue of their unusual mechanical, electrical, optical, and magnetic properties. Pure nanocrystalline ferroelectric $PbTiO_3$ studied earlier showed a critical size of the nanocrystals [27] (different for different systems) at which the dielectric constant showed a maximum value. There is, however, a large difference in the ferroelectric behavior (Curie temperature, dielectric constant, polarization, etc.) of the bulk and its nanocrystalline counterpart [27]. But still today, ferroelectricity in pure glass has not been discovered. Ferroelectricity in liquid crystalline phase has, however, been observed [28].

Our major interest in this chapter is to report the synthesis, characterization, and study of transport and other properties of such FE glass–nanocomposite (hereafter referred to as FGNC) materials. It has also been shown how different theoretical models are used to explain the electrical transport and dielectric relaxation behavior of these FGNCs. This chapter will focus on this new class of materials for further theoretical and experimental studies and also find new applications of the glass–nanocrystal composites showing giant dielectric permittivity.

2. FERROELECTRIC NANOCRYSTAL DISPERSED OXIDE GLASSES

Recently it has been observed that some multicomponent oxide glasses [29–39] dispersed with ferroelectric nanocrystalline phases are formed for suitable choice of the glass compositions with TiO_2, $BaTiO_3$, $PbTiO_3$, $SrTiO_3$, $PbZrO_3$, $KTiOPO_4$, $Bi_2VO_{5.5}$, $Li_2Ge_7O_{15}$, PbS, etc. Some of these nanocrystal-dispersed glasses (referred to as FGNC) are found to show ferroelectric or relaxor type ferroelectric behavior [29–30, 40–43]. Figure 1 schematically represents the nanocrystals dispersed in the glassy matrix. Some important parameters of studied FGNC materials (both opaque and transparent) are shown in Table 1 for comparison.

Many low melting TMO glasses like vanadium phosphate glasses (V_2O_5–P_2O_5, for example), containing different concentrations of TiO_2, $BaTiO_3$, $PbTiO_3$ etc., have been prepared in recent years, which contain nanocrystalline ferroelectric phases embedded in the glass matrix [29, 30]. All these FGNCs are, however, opaque. The alkali metal doped
Figure 1. Schematic diagram of a ferroelectric nanocomposite glass. The dispersed nanocrystals are shown by dark black spots in the glass matrix.

Bi–Sr–Ca–Cu–A–O (A = Li, K, Na) glasses are also found to be ferroelectric for typical concentrations [42, 44]. As mentioned, the dielectric constants of these opaque TMO glasses are found to be extremely large (more than $BaTiO_3$) [30, 44]. Such a giant dielectric constant has also been obtained very recently in crystalline $CaCu_3Ti_4O_{12}$ oxide [45, 46] and La containing $PbTiO_3$ [47]. These materials of high dielectric constant are very important for their applications in devices. However, the origin of such a high dielectric constant is not yet clearly elucidated. In the nanoparticle dispersed glassy systems, the presence of nanocrystalline TiO_2, $BaTiO_3$, $PbTiO_3$, $SrTiO_3$, $PbZrO_3$, $KTiOPO_4$, $Bi_2VO_{5.5}$, $Li_2Ge_7O_{15}$, PbS, etc. phases are considered to be responsible for giant dielectric constant. As stated, this is a new class of material of immense technological as well as fundamental importance. By varying the glass compositions or the quenching rate, the size as well as the concentration of the FE nanoparticles/clusters can be varied.

The amorphous characters in the aforementioned oxide glasses and FGNCs are, in general, examined by an X-ray powder diffraction (XRD) technique. Nevertheless, depending on the smaller size and concentrations of the embedded nanocrystals, XRD is not sufficient to detect the presence of the nanocrystals in these glasses and FGNCs. XRD simply indicates amorphous character of these systems. Transmission electron microscopic (TEM) study can clearly reveal the presence of nanocrystalline phases in these FGNC materials. Some physical properties (like high dielectric constant) also indicate the presence of such nanocrystalline phase in some typical TMO glasses. It is also noticed from the TEM studies that many of the semiconducting TMO glasses, earlier reported to be pure homogeneous glasses, are found to contain nanocrystalline particles or clusters of different sizes (5–100 nm) and concentrations embedded in the corresponding glass matrices. Using the TEM technique, very little microstructural study of the semiconducting glassy system was, however, accomplished earlier [6, 11]. It is found that the size and concentration of the nanocrystals affect the transport, optical, and other properties of these ferroelectric nanocrystal-dispersed glasses. This behavior is similar to that observed in ferroelectric materials, for example, $PbTiO_3$ where dielectric permittivity and other properties strongly depend on the grain sizes [22].

Table 1. Some important physical parameters of different ferroelectric glass nanocrystal composites.

Glass matrix/FE nanoparticle	Cluster size (nm)	T_g (K)	T_c (K)	ε' at 1 kHz and 300 K	Ref.
$70(80V_2O_5–20PbO)/30BaTiO_3$	70–90	300	393	3.5×10^4	[30]
$50SrB_4O_7/50Bi_2VO_{5.5}$	15	730	763	3.2×10^3	[31, 32]
$50.5PbO–25.5ZrO_2 24TiO_2/PbS$	15.3	—	—	3.5×10^3	[34]
$80SiO_2/20KTiOPO_4(KTP)$	10–50	600	—	—	[35]
$(12Li_2O–88GeO_2)/Li_2Ge_7O_{15}$	10	—	283	—	[36–38]
$10(90V_2O_5–10P_2O_5)/90BaTiO_3$	~100	250	290	—	[50]

Note: T_g, T_c, and ε' represent, respectively, the glass transition temperature, Curie temperatures, and dielectric constants.

It was reported earlier [48] that the TMO glasses prepared with $BaTiO_3$, etc. contain nanocrystalline clusters and these FGNC samples, for example, $V_2O_5–Bi_2O_3 + xBaTiO_3$, showed giant dielectric constants because of the presence of nanocrystal/clusters of $BaTiO_3$ embedded in the glass matrix. The transport and dielectric properties of the pure host glasses, viz. $80V_2O_5–20P_2O_5$, $80V_2O_5–10Bi_2O_3$, $80V_2O_5–20PbO$, etc., where FE nanocrystals are precipitated (hereafter referred to as VP glass) by adding TiO_2, $BaTiO_3$ etc., have been well studied and reported in the literature [6, 7, 49]. Dielectric constants of these VP type base glasses are, on the other hand, very small and none of them exhibited ferroelectric behavior as mentioned earlier. The TiO_2, $PbTiO_3$, $BaTiO_3$, etc. with high melting oxide content in the VP glasses or similar other mostly binary TMO glasses, in spite of this, show extremely high dielectric constant [48] (compared to the pure base glass, VP, or similar other TMO glasses). Very little increase of conductivity observed in these systems is assigned to the appearance of nanocrystalline phases. Interestingly, the general behavior of all the ferroelectric FGNC composites, studied so far, is found to be similar.

Another class of nanocrystal-dispersed glasses [35, 39], for example, $KTiOPO_4$ dispersed oxide glasses, is found to be transparent. The transparent ferroelectric glass nanocomposites (TFGNCs) are suitable for second harmonic generation. More about these glass nanocomposites will be discussed separately in Section 8. Some of the important parameters of these TFGNCs are shown in Table 1 for comparison.

3. SYNTHESIS

3.1. Melt Quenching Technique

The melt quenching technique is widely used to prepare glasses and glass–ceramics. It needs higher temperature compared to that required for the sol–gel technique, but it takes less time. The TiO_2, $BaTiO_3$, $SrTiO_3$, $PbTiO_3$, etc. doped vanadate glasses (or the VP glasses) or other low melting TMO glasses (VP type base glasses), in general, can be prepared by a fast quenching method [48, 50]. For example, VP glass can be used to prepare a typical $(80V_2O_5–20P_2O_5) + xTiO_2$ type FGNC with different concentrations of TiO_2 ($x = 0.5, 5, 10, 20$, and 30 wt% TiO_2). Here $80V_2O_5–20P_2O_5$ (or VP glass) acts as the base glass. In brief, V_2O_5, $NH_4H_2PO_4$, and TiO_2 (or $BaTiO_3$, $SrTiO_3$, $PbTiO_3$, etc. can be used), each of purity 99.99% or better,

were well mixed in appropriate proportions and preheated in air at about 500 °C for five hours with occasional grinding [48, 50]. The preheated mixed oxide samples were melted in air taking in a platinum crucible at about 1100 to 1250 °C (depending on the TiO_2, $BaTiO_3$, $SrTiO_3$, etc. concentrations) for about 30 minutes. The homogeneous melt was then quickly quenched between two cooled copper or steel blocks resulting in thin (0.6–0.7 mm thickness) pellets of the glassy FGNC samples. Ferroelectric glass nanocomposites in the pseudobinary systems like $(100 − x)SrB_4O_7–xBi_2VO_{5.5}$ ($0 \le x \le 70$) were prepared by the splat quenching technique [31, 32]. Strontium borate and bismuth vanadate were melted in a platinum crucible at 1100 °C. The melt was then quenched between two flat stainless steel blocks placed at a temperature around 100 °C to prevent cracking at the time of glass formation. The prepared glasses were then annealed well below the glass transition temperature (T_g). The Cr^{3+} doped lithium germanate glasses were also obtained [36–38] by similar fast quenching of the $12\%Li_2O–88\%GeO_2:0.5\%Cr_2O_3$ melt from 1350 °C. Subsequent annealing of the glass at different (480–520 °C) temperatures resulted in the precipitation of ferroelectric $Li_2Ge_7O_{15}$ nanocrystals in the glass matrix [36–38]. More details about the preparation of some other nanocrystal–glass composite samples by the melt quenching technique are available in the literature [51–53].

3.2. Sol–Gel Technique

The sol–gel technique is one of the most important methods to prepare glasses and ceramics of uniform grain sizes. The advantage of this technique is the mixing of the raw materials in the atomic scale during preparation. The disadvantage of this technique is that it is time consuming and the glass/ceramic may get through unnecessary water molecules. Glass–ceramics containing micrometer sized lead zirconate titanate (PZT) was synthesized by the sol–gel method and subsequently nanometer-size lead sulfide (PbS) phase was grown by treatment in hydrogen sulphide gas [33, 34]. A typical sol–gel method is as follows. One first needs to synthesize a gel of the target composition, viz. $50.5PbO–25.5ZrO_2–24TiO_2$. Here a solution of ethyl alcohol and acetic acid in the volume ratio of 75:25 was used. An appropriate amount of tetra-isopropyl orthotitanate ($C_{12}H_{28}O_4Ti$) was added to the solution and stirred for one hour. Subsequently, a suitable amount of lead acetate–acetic acid solution was added and stirred for more than one hour. An adequate amount of $Zr[O(CH_2)_3CH_3]_4$ was then added and

stirred for two hours. The sol was dried at 70 °C for 72 hours. Then it was subjected to several heat treatments [33, 34] to get the crystalline PZT phase in the glass matrix. This glass–ceramic was cold pressed and sintered at 900 °C for 2 hours in PbO atmosphere. The sintered pellet was polished with alumina powder and reduced in H_2S at different temperatures. Nanometer size particles of PbS were precipitated in the glass ceramic matrix. The detailed preparation procedure of transparent glass–nanocomposites, like $xKTiOPO_4(KTP)–(1-x)SiO_2$, by the sol–gel method has been described elsewhere [35, 39]. Multicomponent $K_2O–TiO_2–P_2O_5–SiO_2$ glass was prepared by the sol–gel method first [35, 39]. When this glass was heated above 650 °C, it was transformed into a dense nanocomposite of glass and KTP nanocrystals [35, 39]. Preparation of nanocomposites in some other techniques are also found in the literature [54–58].

4. DENSITY

The density of the FGNCs is generally measured by using the Archimedies method. Concentration dependent density of the FGNCs showed nonlinear variation [42]. This is an important property of nanocrystal-dispersed glasses. Since both size and concentrations of the nanocrystals depend on the compositions and there is also a critical size of the nanocrystals above which physical properties change [42] abruptly; the density of the FGNC system showed nonlinear variation with concentration. Both density and the glass transition temperature (T_g) showed little increase with increasing TiO_2 or $BaTiO_3$ concentration in these glass–nanocrystal composites [59]. But the corresponding increase of the average intersite separation (R) between two TMO (vanadium, for example) ions (V–O–V) with large increase of TiO_2 content (5–30 wt%) was relatively small (about 5%). R was calculated from the relation $(R = 1/N)^{1/3}$, where N is the vanadium ion concentrations. A similar small variation of R was also observed for the $BaTiO_3$ containing $V_2O_5–Bi_2O_3–xSrTiO_3$ glass–nanocrystal composites [29, 41] that followed the nonadiabatic hopping conduction mechanism.

The relationship between the density and the composition of nanocrystal-dispersed glasses is frequently expressed by the effective volume occupied by 1 g. wt of oxygen (V_o^*). The values of V_o^* can be determined from the theoretical formula given by Drake et al. [60]. Both density and V_o^* change in a similar manner with composition indicating that the topology of the glass–nanocrystal composites do not change appreciably for higher concentration of $SrTiO_3$ (or $BaTiO_3$). Variation of density (ρ) of the $(1-x)(90V_2O_5–10P_2O_5) + xBaTiO_3$ glass–nanocomposites [50] with concentrations (x) of $BaTiO_3$ is shown in Figure 2. Initially, the density decreases with x and then shows a maximum for the highest concentration of $BaTiO_3$ (Fig. 2). The particle diameters of a typical composite also show a nonlinear variation with the change of concentration of composite components [34]. Density of the $20KTP–80SiO_2$ type FGNC system increased with the increase of heat treatment (annealing) time and temperature (being 2.34 g/cm³ at 850 °C with 0.2% porosity) [35]. The density and V_o^* values of a typical TiO_2 containing FGNC for different TiO_2 concentrations (along
Figure 2. Variation of density of a typical glassy ferroelectric nanocomposite, viz. $(1-x)(90V_2O_5–10P_2O_5) + xBaTiO_3$ with concentrations (x) of $BaTiO_3$ Reprinted with permission from [50], M. Sadhukhan et al., *J. Chem. Phys.* 105, 11326 (1996). © 1996, American Institute of Physics.

with average size of the precipitated nanoparticles/clusters) are shown in Table 2.

5. DIFFERENTIAL THERMAL ANALYSIS STUDY

The glass transition temperature (T_g) is being measured from the differential thermal analysis (DTA) curve with heating rate 10 °C per minute (say). Figure 3 shows the DTA traces for typical as-quenched and heat-treated $50SrB_4O_7–50Bi_2VO_{5.5}$ ferroelectric glass nanocomposites [31]. In Figure 3a, the first exotherm was attributed to the crystallization of $Bi_2VO_{5.5}$. The second exothermic peak was associated with the crystallization of $Bi_{12}V_2O_{23}$ and $BiVO_4$ impurity phases. The third peak was attributed to the reformation of $Bi_2VO_{5.5}$ due to reaction of $Bi_{12}V_2O_{23}$ and $BiVO_4$ impurity phases. The fourth peak was due to the crystallization of the host glass matrix SrB_4O_7. All these findings were consistent with the XRD study of the sample [31]. The heat-treated samples did not show the first exotherm peak as shown in Figure 3b and c. Elaborate DTA study of $50SrB_4O_7–50Bi_2VO_{5.5}$ glass-nanocomposites has also been made [32]. The DTA curve of the $(80V_2O_5–20PbO) + x$ wt% $BaTiO_3$ type glass-nanocomposites showed [30] an increase of T_g with the corresponding increase of $BaTiO_3$ concentration (x). DTA traces of several glasses [60–63] indicated a clear correlation of T_g with the change of coordination number of the network former and the formation of nonbridging oxygen (NBO) atoms which means a destruction or depolymerization of the network structure. The increase of T_g, in general, indicates the increase of coordination number of the network former. In contradiction to this, formation of NBO causes a decrease of T_g as observed in lead vanadate glasses [15]. Thus the continuous increase of T_g with

Table 2. Certain significant physical structures of a typical ferroelectric glass nanocrystal composite system, viz. $(80V_2O_5-20P_2O_5)$ glass embedded with x wt% TiO_2 nanocrystalline particles/clusters [64].

Values of x (wt%)	Grain/cluster size (nm)[a]	ρ[b] (gm/c.c.)	γ_p	V_o^* (c.c.)	Q (μV K^{-1})	η	T_g (°C)

x indicated strengthening of the bond [30]. The difference between T_g and crystallization temperature (T_{cr}) was less than 30 °C and it increased with the increase of x. Accordingly, the stability of the glasses increased with the increase of $BaTiO_3$. The values of T_g for TiO_2 containing FGNCs are given in Table 2.

6. SPECTROSCOPIC CHARACTERIZATION

6.1. X-Ray Diffraction

The amorphous character of all the $(80V_2O_5-20PbO)$ + x wt% T (where T = $BaTiO_3$) type nanocrystal dispersed glassy system is demonstrated from the study of XRD

Figure 3. Differential thermal analysis traces for (a) as-quenched, (b) 447 °C, and (c) 547 °C heat-treated $50SrB_4O_7–50Bi_2VO_{5.5}$ glass nanocomposites. T_g and T_{cr} stand, respectively, for glass-transition and crystallization temperatures. Reprinted with permission from [31], N. S. Prasad and K. B. R. Varma, *J. Mater. patterns (with Cu K_α radiation) as shown in Figure 4a and b [30]. No crystalline peak was seen from the XRD patterns of this system. The corresponding annealed samples, however, showed the presence of $BaTiO_3$ as demonstrated in Figure 4c and d. The nanocrystals precipitated in these glasses (referred to as VPTI glasses) during glass formation are mostly $BaTiO_3$ or TiO_2 as indicated from the XRD patterns of the corresponding glass–ceramic samples obtained by annealing the as-quenched glass samples at 300 °C for a few hours in air (Fig. 4c and d). The very large dielectric permittivity of these multicomponent glasses compared to that of the base glasses V_2O_5–PbO or many other TMO glasses [12, 43, 48] also confirmed the presence of nanocrystalline $BaTiO_3$ or TiO_2 in the glass matrix. This result supported the earlier observation [48] that the dielectric constant of nanocrystalline TiO_2 or $BaTiO_3$ was much higher than that of bulk TiO_2 or $BaTiO_3$. The infrared (IR) spectra of all the glass samples exhibited almost identical

Figure 4. X-ray diffraction pattern of the as-quenched $(80V_2O_5–20PbO)$ + x wt% $BaTiO_3$ glassy nanocomposite for (a) $x = 15$ and (b) $x = 30$ wt%. XRD of the corresponding annealed samples (annealed at 300 °C for 9 h) for (c) $x = 15$ and (d) $x = 30$ wt% with some of the identified crystalline peaks: PbV_2O_6(●), $PbTiO_3$ (○), PbV_2O_7 (◆), $BaTiO_3$ (△), and TiO_2(▲). features [30, 43] as will be discussed. The observed fine $Bi_2VO_{5.5}$ crystallites present in the SrB_4O_7 glass matrix were also confirmed by XRD studies [31, 32]. Systematic XRD studies corroborated the crystallization of $Bi_2VO_{5.5}$ phase along with minor impurity phases like $Bi_{12}V_2O_{23}$ and $BiVO_4$, depending on the temperature range of heating of the as-quenched samples [31, 32]. The XRD spectra well confirmed the presence of PZT crystals embedded in the glass matrix and the diffraction lines corresponding to PbS phase were broadened due to the small size of these crystallites [34].

6.2. Scanning Electron Microscopy

The scanning electron microscopic (SEM) study of the nano-crystal dispersed glassy composite gives clear evidence of the presence of crystallites in the glass matrix. The glassy character of the as-quenched FGNC samples was confirmed by SEM study as shown in Figure 5a and b for the two samples $(80V_2O_5–20PbO) + x$ wt% A (where A = $BaTiO_3$, etc.) with $x = 15$ and 30 wt% respectively [30]. The SEM micrographs of a typical sample (with $x = 30$ wt%) annealed at two different temperatures (290 and 300 °C) are shown, respectively, in Figure 5c and d. It is concluded from the SEM photographs (Fig. 5) that no crystallite was present before annealing the glasses. The presence of nanocrystals was, however, observed in the corresponding annealed samples consistent with the XRD pattern (Fig. 4). The SEM micrographs of ferroelectric PZT in glass–nanocrystal composite samples also showed identical results [34].

6.3. Transmission Electron Microscopy

Transmission electron microscopy is very important for the microstructural study of nanocomposites. The TEM studies of fine glass powder are made on carbon grids [21], which clearly reports the presence of nanocrystalline
particles/clusters present in all the annealed glasses [48, 50]. The nanocrystals of TiO_2 or $BaTiO_3$ are formed in the glass matrices because of the large difference between the melting point of TiO_2 or $BaTiO_3$ than those of the base glasses (VP glasses). TEM indicated the presence of nanocrystalline $BaTiO_3$ or TiO_2 particles/clusters in these glasses (with maximum grain/cluster sizes varying from 5 to 80 nm with change of $BaTiO_3$, TiO_2, etc. content from 5 to 30 wt%). For lower concentration ($x = 5–10$ wt%), the size as well as concentration of the nanoparticles was very low. The TEM micrographs of $(80V_2O_5–20PbO) + 30$ wt% $BaTiO_3$ glass and the corresponding glass ceramic (annealed at 300 °C for 9 h) samples are shown, respectively, in Figure 6a and b. The selective area electron diffraction (SAED) pattern of the same glass and glass ceramics sample are shown correspondingly in Figure 6c and d. The TEM as well as the SAED patterns of the glass showed their amorphous nature (Fig. 6a and c) and those of the glass ceramic sample (Fig. 6b and d) indicated the distributed nanocrystalline particles/clusters in the glass matrix. These findings were in agreement with the XRD and SEM patterns of these samples [30]. Similar nanocrystalline particles were also observed in the $V_2O_5–CoO–TeO_2$ glasses [11] and also in the $(Bi_3Pb_1)Sr_3Ca_{4−m}(M_m)O_x$ glasses [44, 64] with M = Li, K, Cr, Mn, Zn, Ti, Ag. Prasad and Varma [31] found the presence of $Bi_2VO_{5.5}$ crystallites in SrB_4O_7 glass matrix by TEM and SAED study. Li et al. [35] also located the presence of KTP nanocrystals in SiO_2 transparent glass matrix.

6.4. Infrared Characterization

The IR spectra of the ferroelectric nanocrystals dispersed oxide glasses are generally studied in KBr matrix. Figure 7 shows the IR spectra of the $(80V_2O_5–20PbO) + x$ wt%

$BaTiO_3$ ($x = 10, 15, 20,$ and 30) glass–nanocomposites along with the pure $BaTiO_3$. The characteristic features of the IR spectra of all the glasses were found to be identical. The vibrational frequencies corresponding to the $Pb_2V_2O_7$ and $Pb_3V_2O_8$ structural units as reported for the lead vanadate glasses [65, 66] are not clearly observed from the IR spectra of these $(80V_2O_5–20PbO) + x$ wt% $BaTiO_3$ glasses [30]. Sadhukhan et al. [30] found a water band around 3400 cm^{-1} and an –OH stretching peak at 2920 cm^{-1} in all the glasses and crystalline $BaTiO_3$ due to the hygroscopic nature of the powder sample [67, 68]. In all the glass composites, signatures of the bonds and peaks of $BaTiO_3$ were not well visualized. However, instead of a band around 1500 cm^{-1} present in crystalline $BaTiO_3$, a new band around 1600 cm^{-1} was present in all the glasses. This might be due to the glassy environment of $BaTiO_3$ nanoparticles. The characteristic phonon frequency (ν_{ph}) estimated from the IR spectra was of the order of 10^{13} Hz corresponding to an IR band around 1000 and 1600 cm^{-1} for different glasses. This value of the phonon frequency agreed with that obtained from the conductivity data [30] of the sample.

7. PROPERTIES

7.1. Thermal Properties and Thermoelectric Power

The study of thermal property of glassy materials is difficult due to the higher thermal resistivity of the materials. However, that of glass–ceramics becomes much easier due

to the crystalline nature of the glass–ceramics. The Seebeck coefficient (Q) of the FGNC sample is higher than that of the pure base glass as it contains crystalline nanoparticles of relatively higher conductivity [29, 41]. The Q values of FGNCs are determined by measuring the thermoelectric power (TEP) of the samples with a temperature difference around ∼8 K between the two electrodes [29, 41]. For TEP measurements, samples of higher thickness (∼1 mm or more) were generally used. All the FGNC systems showed negative values of thermoelectric power between 300 and 450 K. Table 2 shows the Q values of a typical TiO_2 containing FGNC system indicating it as an *n*-type semiconductor. Like many ternary vanadate glasses [49, 69–73], no appreciable temperature dependence of the TEP was observed between 300 and 400 K for the FGNCs. However, the magnitude of Q decreased with an increase in TiO_2 or $BaTiO_3$, etc. concentrations in the FGNCs (that is, with increase of grain size and their concentrations). The Q values were fitted with Heike's formula [73], viz.

$$Q = k_B/e[\ln\{C/(1 - C)\} + \eta] \qquad (1)$$

where e is the electronic charge and η is a constant of proportionality between the heat transfer and the kinetic energy of carrier. Values of $\eta < 1$ indicated a small polaron hopping transport mechanism [5, 29, 72–77] while for $\eta > 2$, the conduction was due to large polaron hopping [15, 60]. Equation (1) implies no temperature dependence of Q. Though it was reported earlier that the values of Seebeck coefficients of the glasses followed [5, 72–74] Heike's law, this model was also found to be applicable to FGNCs and the estimated values of η were almost constant and less than one (Table 2) indicating the validity of the small polaron hopping conduction mechanism in these FGNCs. Similar values of η (=0.44–0.98 depending on the concentrations) were also reported in other multicomponent vanadate glasses [49, 70] dispersed with nanocrystals. Interestingly, the values of η for these FGNCs were also positive and <1. For many TMO glasses η values are large and negative [42, 44].

7.2. Electrical Conductivity

7.2.1. dc Conductivity

For the temperature dependent dc conductivity (σ_{dc}) measurement, the thin pellets of the composites (diameters ∼8 mm and thickness 0.3–0.4 mm) are generally used. The two polished faces of the pellets are gold plated by sputtering. Interestingly, like density, concentration dependent conductivity of the FGNC also showed an anomaly (change of slope) around the same concentration where density illustrated an anomaly between 5 and 10 wt% TiO_2 as shown in Figure 8 for typical $80V_2O_5–20P_2O_5 + xTiO_2$ glass-nanocomposites [64]. The dielectric constant of the same sample (discussed in a separate section) also decreased for TiO_2 content higher than 5 wt% as shown in Figure 8 for 0.1 kHz. This indicates that the dielectric constant is smaller (or larger) for the FGNC with grain/cluster size greater (or smaller) than a critical size (between 5 and 10 nm) [64]. This new result also supported the outcome of Zhang and co-workers [78]. It was shown by Wang et al. [22] that there was a critical grain size (∼10 nm) around which the
Figure 8. TiO$_2$ concentration (x) dependent logarithmic dc conductivity (log σ_{dc}) of the (80V$_2$O$_5$–20P$_2$O$_5$) + xTiO$_2$ glass–nanocrystal composites at a fixed temperature (300 K). The dielectric constant (ε') at two different frequencies (0.1 and 1 kHz) and at a fixed temperature (300 K) of the same glass-nanocomposite. Reprinted with permission from [64], D. K. Modak et al., *Sol. State Phys.* 43, 368 (2000).

dielectric constant of nanocrystalline ferroelectric PbTiO$_3$ was maximum. Most of the FGNC systems also behave in a similar way.

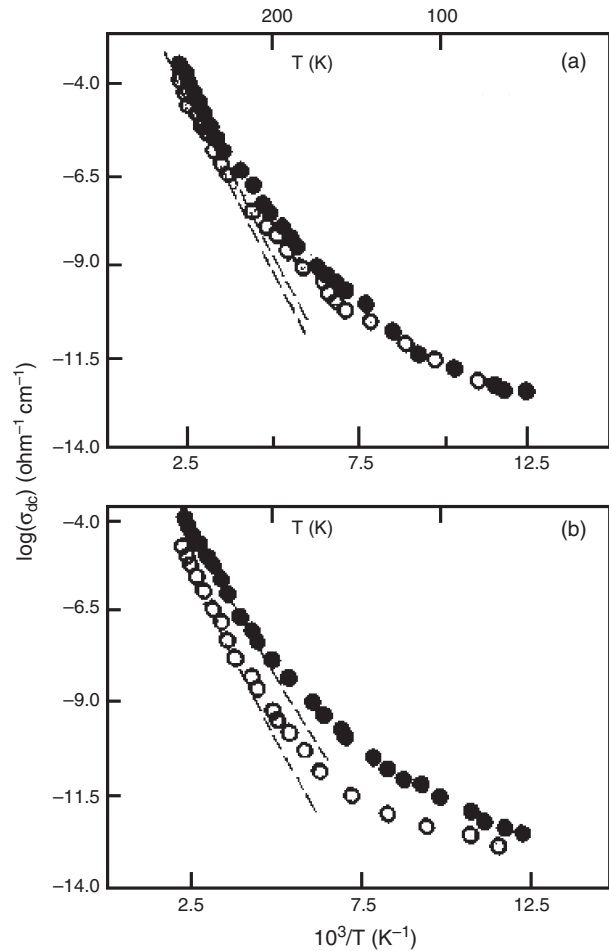
Thermal variations of the dc electrical conductivity (σ_{dc}) of the ferroelectric nanoparticle dispersed glassy system have been shown by different groups [29, 30, 50]. The logarithm of the dc conductivity (log σ_{dc}) vs 10^3/T curve (Fig. 9) for a typical FGNC (80V$_2$O$_5$–20PbO + x wt% BaTiO$_3$ with $x = 10$–30) indicated a change of slope around $\theta_D/2$ (Debye temperature θ_D being different for different samples) [30]. All the other FGNCs also showed an analogous nature of variation of conductivity with change of temperature. As mentioned, density increased with increasing TiO$_2$ or BaTiO$_3$ concentration (x) exhibiting a break around $x = 5$ wt% (Fig. 2) which was also reflected in the dc conductivity vs TiO$_2$ concentration (x) curves shown earlier (Fig. 8). For lower concentrations ($x < 10$ wt%), σ_{dc} at a fixed temperature (300 K) increased slowly with increase of TiO$_2$ content in the FGNC (Fig. 8). This behavior was in sharp contrast to those of other pure vanadate glasses (base glasses), for example, V$_2$O$_5$–MnO$_2$–TeO$_2$ [8] and V$_2$O$_5$–CoO–TeO$_2$ [11], where a decrease in conductivity with increase of the second transition metal ion, viz. Mn or Co ions, was observed. The increase of σ_{dc} in these VPTI type FGNCs with increasing TiO$_2$ content (say) was comparatively very small [6] (the values of log σ_{dc} at room temperature are -5.90, -5.5, -5.35, and -5.20 ohm^{-1} cm^{-1}, respectively, for 5, 10, 20, and 30 wt% TiO$_2$). The corresponding increase of R (from 0.498 to 0.526 nm for $x = 5$–30 wt% TiO$_2$) was also little. As the V ion concentration in all the glasses was fixed (since the glass composition 80V$_2$O$_5$–20P$_2$O$_5$ or 80V$_2$O$_5$–20PbO was fixed for all the VPTI type FGNCs), this small increase of conductivity was not supposed to be due to an increase of V ion concentration. Again, little increase in the estimated values of average intersite separation R (separation between the transition metal ions) with increasing TiO$_2$ concentration in the VPTI type FGNC samples


Figure 9. The logarithmic dc conductivity (log σ_{dc}) as a function of inverse temperature (10^3/T) of the (80V$_2$O$_5$–20PbO) + x wt% BaTiO$_3$ glass-nanocomposites with (a) $x = 10$ (●), 20 (○), (b) 15 (●), and 30 wt% (○). should rather cause a decrease of conductivity. The corresponding decrease of activation energy (W) and hence the observed small increase of conductivity with increase of TiO$_2$ (for example) content was, therefore, considered to be due to the presence of precipitated nanocrystalline particles/clusters uniformly dispersed in the glass–nanocrystal composites. This conclusion was also supported from the results of earlier observation [73] that the conductivity in nanocrystalline phase increased in glasses and in ceramic semiconductors while it decreased in the metallic systems. This is an interesting property of the nanocrystalline grains. No theoretical model has yet been developed explaining this increase of conductivity in the glassy system with the appearance of nanocrystalline phase. Therefore, dc conductivity of the FGNCs is not solely due to the hopping between the TMO ions. In fact, the precipitated nanoclusters also contribute to the total conductivity. The magnitude of this contribution also depends on the size and concentration of the nanoclusters as in other FGNCs. With increase of TiO$_2$ content (from $x = 5$ to 30 wt%) in the FGNC system, like 80V$_2$O$_5$–20P$_2$O$_5$ + xTiO$_2$ FGNCs, the rise of conductivity

was quite sharp between 5 and 10 wt% TiO$_2$ (where nano-particle size varying between 5 and 20 nm) and for the values of x between 10 to 30 wt% (maximum grain/cluster size varying from 20 to 80 nm), the corresponding rise in conductivity with concentration was slow (Fig. 8). These two regions of conductivity are separated by an anomaly (change of slope) occurring between $x = 5$ and 10 wt% TiO$_2$ (Fig. 8). Similar types of concentration (x) dependent anomalies in the conductivity and other properties, above a particular (or critical) size and concentration of the nanoparticles, were also present in many other nontransition metal semiconducting oxide glasses. The importance of the contribution of such nanoclusters in the transport and other properties of glasses is, in general, overlooked as the overall behavior of the nanocrystal dispersed glasses and pure nanocrystal free glasses appears identical.

The relation between $\log \sigma_{dc}$ and inverse temperature (T^{-1}) is almost linear (Fig. 9) indicating the temperature dependent activation energy (W). This behavior of dc conductivity was described by the relation $\sigma_{dc} = (\sigma_o/T) \exp(-W/k_B T)$, where σ_o is the pre-exponential factor. The values of W were obtained from the plot of $\log \sigma_{dc}$ vs $1000/T$ (Fig. 9). At temperatures lower than $\theta_D/2$, the linearity in the $\log \sigma_{dc}$ vs T^{-1} curve deviated as seen from Figure 9. Similar thermal variation of dc conductivity (σ_{dc}) was also exhibited in V$_2$O$_5$–P$_2$O$_5$ [79] and many other TMO glasses [4, 69, 70] and followed a polaron hopping conduction mechanism. The high temperature ($T > \theta_D/2$) conductivity data of the VPTI type FGNCs thick pellets were interpreted in terms of the phonon-assisted hopping model given by [15]

$$\sigma_{dc} = (\sigma_o/T) \exp(-W/k_B T) \qquad (2)$$

where $W = W_H + W_D/2$ (for $T > \theta_D/2$), $W = W_H + W_D/4$ (for $T < \theta_D/4$), and

$$\sigma_o = \nu_{ph} N e^2 R^2 C(1-C) \exp(-2\alpha R)/k_B \qquad (3)$$

ν_{ph} is the optical phonon frequency ($\sim 10^{13}$ Hz), α is the decay constant of the localized wave function, W_H is the polaron hopping energy, W_D is the disorder energy, and other parameters have usual meanings as mentioned earlier. The importance of the tunneling term $\exp(-2\alpha R)$ in Eq. (3) for the FGNCs could be understood [79] by plotting $\log \sigma_{dc}$ against W at a chosen temperature for all the VPTI type FGNCs. The temperature T_e (say), estimated from the

slope of such a plot, would be close to the experimental temperature when the hopping is considered in the adiabatic regime [5, 79]. On the other hand, T_e would be very different from the experimental temperature when the hopping is considered in the nonadiabatic regime. The FGNC system was found to follow a nonadiabatic hopping conduction mechanism [64]. It is interesting to mention that Sayer and Mansingh [79] reported an adiabatic hopping conduction mechanism for the TiO$_2$ free base glass 80V$_2$O$_5$–20P$_2$O$_5$. Therefore, a change of conduction mechanism occurred in the TiO$_2$ containing VPTI air quenched FGNCs. It is, however, rather difficult to uniquely identify the type of small polaron hopping conduction mechanism, adiabatic or nonadiabatic, only if the temperature dependence of conductivity is used, because a hopping process of nonadiabatic small polarons requires several restrictions on the electron transfer integral between neighboring hopping sites. So we have also attempted to confirm the nature of hopping conduction using other theoretical methods discussed later.

Dc conductivity data of FGNCs were well fitted with Eq. (2) above $\theta/2$. The estimated phonon frequencies agreed well with those estimated from the infrared spectra as mentioned (shown in Table 3). The polaron radius r_p was estimated from the formula [75], viz.

$$r_p = (1/2)(\pi/6N)^{1/3} \qquad (4)$$

The estimated values of r_p (~ 0.2 Å) suggested strong localization in these FGNCs. The polaron hopping energy W_H was calculated from the relation [10]

$$W_H = e^2/4\varepsilon_p(1/r_p - 1/R) \qquad (5)$$

where $1/\varepsilon_p$ ($= 1/\varepsilon_\alpha - 1/\varepsilon_s$, ε_s and ε_α are the static and high frequency dielectric constants of the FGNCs, respectively). W_H can be calculated from Eqs. (4) and (5) under the approximation $\varepsilon_p = \varepsilon_\alpha = n^2$, where n is the refractive index of the FGNC. The values of W_H were obtained from fitting of the conductivity data with Schnakenberg's model [76] [Eq. (6)] and were found to be of the order of ~ 0.53, 0.42, 0.35, and 0.26 eV, respectively, for TiO$_2 =$ 5, 10, 20, and 30 wt% in VPTI glass-nanocomposites [72]. These values of W_H were then used to estimate ε_p ($= 2.047$, 2.486, 2.847, 3.932, respectively, for 5, 10, 20, and 30 wt% TiO$_2$ in VPTI glass-nanocomposites) [72]. The polaron binding energy (W_p) can be obtained from the formula [24] $W_p = e^2/\varepsilon_p r_p$. The calculated values of W_p are shown in Table 3. Using the values of ε_p, the calculated values of

[b] W, W_H, W_p, and W_D stand, respectively, for activation energy, polaron hopping energy, polaron binding energy, and disorder energy.

refractive index (n) agree quite well with those determined from the Berwster angles [64]. The values of polaron binding energy W_p (Table 3) were found to decrease a little with increase of TiO$_2$ concentration (or with increase of nanocrystalline grain/cluster size) in the FGNCs. The disorder energy W_D can be estimated independently from the generalized polaron hopping model of Schnakenberg [72]. In this model, optical multiphonon and acoustical single-phonon processes determine the conductivity in the high temperature region. According to this model, the expression for the dc conductivity can be written as

$$\sigma_{dc}T \approx \sin h(h\nu_{ph}\beta)^{1/2} \exp[4W_H/h\nu_{ph}\tan h(h\nu_{ph}\beta/4)]$$
$$\times \exp(-W_D\beta) \qquad (6)$$

where $\beta = 1/k_BT$. Equation (6) is fitted to the experimental high temperature dc conductivity data by a least squares method. The values of the parameters W_H and W_D obtained from fitting the dc conductivity data with Eq. (6) are shown in Table 3. These values of W_H and W_D appeared to be a little higher than those of many other vanadate glasses referred in this chapter. This is considered to be due to the presence of dispersed nanocrystalline phases in the FGNCs. Precipitation of this phase caused some modifications of the glass network structure and hence some changes in the values of W_H and W_D (compared to those of the base glass without TiO$_2$) were observed. According to Eq. (2), the difference existing between W and W_H (Table 3) arose from the disordering energy term ($W_D/2$). This discrepancy had been explained as the effect of the partial charge of the cations of the glass forming oxides on activation energy for hopping conduction in transition metal oxides [4].

It has already been mentioned that Eq. (2) can only fit the high temperature (above $\theta_D/2$) dc conductivity data. For the low temperature regime ($T < \theta_D/2$) where the polaron binding energy is smaller [15, 16], σ_{dc} was explained, as usual, by the VRH models of Mott and Davis [15]. The expression for the conductivity in the three-dimensional VRH model is given by

$$\sigma_{dc} = A \exp[-(B/T)^{1/4}] \qquad (7)$$

where A and B are constants, $B = 19.4\alpha^3/k_BN(E_F)$ with the $N(E_F)$ as the density of states at the Fermi level. Figure 10 shows the plot of $\log \sigma_{dc}$ against $T^{-1/4}$ for $(1-x)(90V_2O_5-10P_2O_5) + xBaTiO_3$ FGNCs. These curves indicate straight-line behavior with slightly different slopes. The values of

$N(E_F)$ were estimated from the best fitting of Eq. (7). The estimated values of $N(E_F)$ are shown in Table 4 for a typical FGNC ($80V_2O_5-20P_2O_5 + xTiO_2$) [64]. Knowing $N(E_F)$ and other parameters, the nature of hopping conduction (adiabatic or nonadiabatic) can also be decided from the theory of Emin and Hilstein [74]. According to this theory, the hopping conduction mechanism is adiabatic for $J > \varphi$ and nonadiabatic for $J < \varphi$ where

$$\varphi = (2k_BTW_H/\pi)^{1/4}(h\nu_{ph}/\pi)^{1/2} \qquad (8)$$

J is the polaron bandwidth related to the electron wave function overlap on the adjacent sites. For the present VPTI type glassy–nanocomposite system, the limiting values of φ estimated from the right hand side of Eq. (8) are 4.12×10^{-2}, 3.78×10^{-2}, 3.49×10^{-2}, and 3.54×10^{-2} eV, respectively, with 5, 10, 20, and 30 wt% TiO$_2$. The values of J were also estimated independently from the relation [15] $J = e^3[N(E_F)/\varepsilon_p^3]^{1/2}$. Using the values of $N(E_F)$ and ε_p one finds $J = 1.89 \times 10^{-3}$, 4.24×10^{-3}, 3.66×10^{-3}, and 2.99×10^{-3} eV for the VPTI type FGNCs with $x = 5$, 10, 20, and 30 wt% TiO$_2$, respectively. Comparing the estimated values of J and φ, it is observed that J is about one order of magnitude less than that of φ for all the glass compositions. This indicates nonadiabatic hopping conduction in all the VPTI type FGNCs, which is in agreement with the results obtained earlier from the plot of $\log \sigma_{dc}$ vs activation energy (W) curves [64]. So the TiO$_2$ containing VPTI

Table 4. Various model parameters obtained from the best fitting of the ac and dc conductivity data of the nanoparticle dispersed $(80V_2O_5-20P_2O_5) + xTiO_2$ (FGNC) [64] sample with different TiO$_2$ concentrations (x).

[a] W_{HO} stands for polaron hopping energy between two sites at an infinite distance.
[b] Values of $N(E_F)$ were obtained from the fitting of the dc conductivity data with the VRH model [Eq. (7)]. The corresponding values within the brackets are obtained from the ac conductivity data of these FGNCs.

type FGNCs followed the nonadiabatic hopping conduction mechanism. A similar nonadiabatic hopping conduction mechanism was also reported for the BaTiO$_3$ doped V$_2$O$_5$–Bi$_2$O$_2$ FGNCs [29, 41, 50]

Attempts were made to fit the conductivity data of these nanoparticle dispersed glasses (FGNCs) with the percolation theoretical model of Triberis and Friedman [77] who applied percolation theory to the small polaron hopping regime. Considering correlation due to energy of a common site in a percolation cluster, they [77] obtained $\sigma_{dc} = \sigma'_o \exp[-(T'_o/T)^{1/4}]$, where σ'_o and $T'_o(= C'\alpha^3/k_B N_o)$ are constant. N_o is the constant DOS in the mobility gap, and the constant C' has two values, 12.5 and 17.8, in the high and low temperature regimes, respectively. It may further be noted that this equation is similar to that of Mott's VRH model [Eq. (7)] with slightly different values of the constant T'_o. In Figure 10, two different slopes (high and low temperatures) are not clearly observed in the log σ_{dc} vs $T^{-1/4}$ plot for the FGNC system. The difference between the low and high temperature slopes might, however, be larger at higher temperatures beyond the range of measurements. So it was concluded that the percolation theory of Triberis and Friedman [77] was not suitable for application to these FGNCs in the measured temperature range.

An estimation of the small polaron coupling constant (γ_p), which is a measure of the electron–phonon interaction in the VPTI type nanocrystal dispersed glasses, was made from the relation [12] $\gamma_p = W_H/h\nu_{ph}$. Using the value of W_H from Table 3, the authors [64] calculated γ_p which varied from 25.25 to 12.44 for different VPTI type FGNCs. These values of γ_p were much larger compared to those of BaTiO$_3$-free V$_2$O$_5$–Bi$_2$O$_3$ glasses [60] or other TMO glasses where γ_p varied from 4 to 9. Such high values of γ_p were also obtained by Sega et al. [9] for the multicomponent V$_2$O$_5$–NiO–TeO$_2$ ($\gamma_p = 19$–23) and V$_2$O$_5$–MnO–TeO$_2$ ($\gamma_p = 21$–25) FGNCs of different concentrations. All these FGNCs, in addition, followed the nonadiabatic small polaron hopping conduction mechanism. According to Austin and Mott [12], higher values of γ_p (>4) indicate a strong electron–lattice (phonon) coupling. So it was found that the electron–lattice interaction decreased with the increase of TiO$_2$ content in the VPTI type FGNCs. The decrease of γ_p with decreasing TiO$_2$ concentrations indicated a decrease of electron–phonon interaction with an increase of concentration and size of the nanoclusters. Considering the diffusion of electrons in small polaron hopping, the hopping carrier mobility [75, 77] was estimated from the relation $\mu = 2\pi e R^2 \beta/h(\pi\beta/4W_H)^{1/2} J^2 \exp(-W\beta)$ (for nonadiabatic hopping). Using the aforementioned values of R and W_H, the values of μ estimated at 300 K are 4.24 × 10^{-8}, 5.17 × 10^{-7}, 5.33 × 10^{-6}, and 2.26 × 10^{-5} cm^{-2} V^{-1} s^{-1}, respectively, for $x = 5$, 10, 20, and 30 wt% TiO$_2$ FGNCs. These values of μ were comparable to those of other multicomponent vanadate glasses, viz. V$_2$O$_5$–Bi$_2$O$_3$–SrTiO$_3$ [29], V$_2$O$_5$–Sb$_2$O$_3$–TeO$_3$ [70], etc. The observed increase in mobility with concentration (x) was again attributed to the change of nanocrystalline grain sizes with increase of TiO$_2$ content in the VPTI type FGNCs. The localization condition for hopping electrons, viz. $\mu \ll 0.01$ cm^{-2} V^{-1} s^{-1} [80], was satisfied for the VPTI type FGNCs. This result indicates that electrons in these FGNCs are localized mainly

at the V ion site which is similar to that observed in the V$_2$O$_5$–Sb$_2$O$_3$–TeO$_2$ type of FGNCs [70]. Therefore, conduction in these glassy systems was primarily due to a polaron-hopping mechanism between the vanadium ions of different valence states though the authors [64] considered there to be little increase of conductivity due to the precipitation on nanocrystalline particles. The carrier concentrations N_c calculated from the relation [49, 70] $\sigma_{dc} = eN_c\mu$ were 5.56 × 10^{21}, 1.14 × 10^{22}, 1.57 × 10^{21}, and 5.24 × 10^{19} eV^{-1} for the VPBT type FGNCs, respectively, with TiO$_2$ concentration of 5, 10, 20, and 30 wt%. Concentration (x) dependent N_c showed little discontinuity (increase and then decrease with increasing x) around $x = 10$ wt% which might also be due to the phase separation in the FGNCs.

7.2.2. Ac Conductivity

For the frequency and temperature dependent dielectric constants (ε) and ac conductivity [($\sigma_{ac}(\omega)$)] measurements, the two polished faces of each of the samples (thickness 0.25–0.30 mm) were gold plated by sputtering and then annealed at about 150 °C for half an hour before conductivity measurement. This was done for better electrical contact with the sample surface. Conductivity measurements were made in the ohmic region as determined from the study of current–voltage (I–V) method.

It is well known that the frequency dependent ac conductivity data of amorphous or powdered semiconductors follow the relation [13, 14]

$$\sigma_{ac}(\omega) = A\omega^s \tag{9a}$$

where A is a constant weakly dependent on temperature and s is the frequency exponent, generally less than unity. The ac conductivity was calculated from the total conductivity $\sigma_t(\omega)$ measured at frequency ω and at a fixed temperature. Both dc conductivity (σ_{dc}) and total conductivity, $\sigma_t(\omega)$, are measured independently and then ac conductivity [$\sigma_{ac}(\omega)$] is estimated from the relation [13–14]

$$\sigma_t(\omega) = \sigma_{dc} + \sigma_{ac}(\omega) \tag{9b}$$

In the glassy FGNC system, the ac and dc conductivities arise due to completely different processes [81]. In other words, ac conductivity represents the dc conductivity in the limit [81] $\omega \to 0$. Analyses of the ac conductivity [$\sigma_{ac}(\omega) = \sigma_t(\omega) - \sigma_{dc}$] data of the semiconducting TMO glasses are generally made in the framework of quantum mechanical tunneling (QMT) [82], correlated barrier hopping (CBH) [12], and overlapping large polaron tunneling (OLPT) [83] models. In the following section, the temperature dependent ac conductivity data and the frequency exponent (s) of the nanoparticle dispersed glasses have been analyzed in terms of the OLPT model which is found to be the most appropriate for these nanocrystal–glass composite systems. Long [82] proposed the polaron tunneling model where the potential wells of two sites overlap thereby reducing the value of polaron hopping energy [84, 85] due to the long-range nature of the dominant Coulomb interaction. The polaron hopping energy has the form [81] $W_H = W_{HO}(1 - r_p/R)$ where W_{HO} is the polaron hopping between

two sites at infinite distance. The ac conductivity for the OLPT model [83] is given by

$$\sigma_{ac}(\omega) = (\pi^4/12)e^2(k_BT)^2[N(E_F)]^2$$
$$\times[\omega R_\omega^4/(2\alpha k_BT + W_{HO}r_p/R_\omega^2)] \qquad (10)$$

where $R_\omega = (1/2\alpha)[\ln(1/\ln(\omega\tau))]$ is the optimum hopping length at a frequency ω calculated by the quadratic equation $R_\omega'^2 + [\beta W_{HO} + \ln(\omega\tau_o)]R_\omega' - \beta W_{HO}r_p' = 0$ (where $R_\omega' = 2\alpha R_\omega$, $r_p' = 2\alpha r_p$, and $\beta = 1/k_BT$). The frequency exponent (s) of $\sigma_{ac}(\omega)$ in this model is calculated from the relation

$$s = 1 - (4 + 6\beta W_{HO}r_p'/R_\omega')/(1 + \beta W_{HO}r_p'/R_\omega')^2/R_\omega' \quad (11)$$

Thus, the OLPT model [Eq. (11)] predicts that the exponent(s) [in Eq. (9a)] should be both temperature and frequency dependent.

At high temperatures (above $\theta_D/2$), the temperature dependence of both σ_{dc} and $\sigma_t(\omega)$ were strong and consequently the measured $\sigma_{ac}(\omega)$, at all frequencies, coincided with σ_{dc} in the high temperature region. Figure 11 represents the plots of $\log\sigma_{ac}$ of a typical glass nanocomposite [50] as a function of inverse temperature and frequency, viz. $\log\omega$. The solid lines are obtained by a least-square fitting procedure. It is evident that $\sigma_{ac}(\omega)$ obeys the universal relation $\sigma_{ac}(\omega) = A\omega^S$, suggesting that the loss mechanism should have a distribution of relaxation times. The plots of exponents s (calculated from the slopes of the curves) as a function of temperature are shown in Figure 12 (for two typical FGNC samples with $x = 10$ and 20 wt%) which indicated that the exponent (s) decreased with increasing temperature and then exhibited a minimum at a temperature around 300 K and subsequently increased. This typical behavior of s suggested that the OLPT model [Eq. (11)] was appropriate for these FGNC systems. In the intermediate temperature range (i.e., below 300 K), the values of s resided around the theoretical curves (solid lines in Fig. 12) for various values of the normalized polaron radius r_p' (shown in Table 4). In the high-temperature regime (above 300 K), an increase in s with increasing temperature was observed which was consistent with the behavior of the OLPT model. The best fit to the experimental points has been observed for the values of W_{HO} and r_p' as shown in Table 4. Both W_{HO} and s decrease with increasing TiO$_2$ content in the VPTI type FGNCs (i.e., with increase of nanocrystal size and concentration).

Ac conductivity of the FGNC system increased linearly with increasing temperature [i.e., $\sigma_{ac}(\omega)\alpha T^n$ with $n = 1$] over a limited range of temperature below 175 K as predicted by the QMT model [82]. Hence the experimental values of σ_{ac} could also be fitted with the QMT model that predicted a linear temperature dependence of $\sigma_{ac}(\omega)$ due to weak ac conductivity and the corresponding expression for the $\sigma_{ac}(\omega)$ can be written as

$$\sigma_{ac}(\omega) = \{\kappa K e^2 k_BT[N(E_F)]^2\omega R_\omega^4\}/\alpha \qquad (12)$$

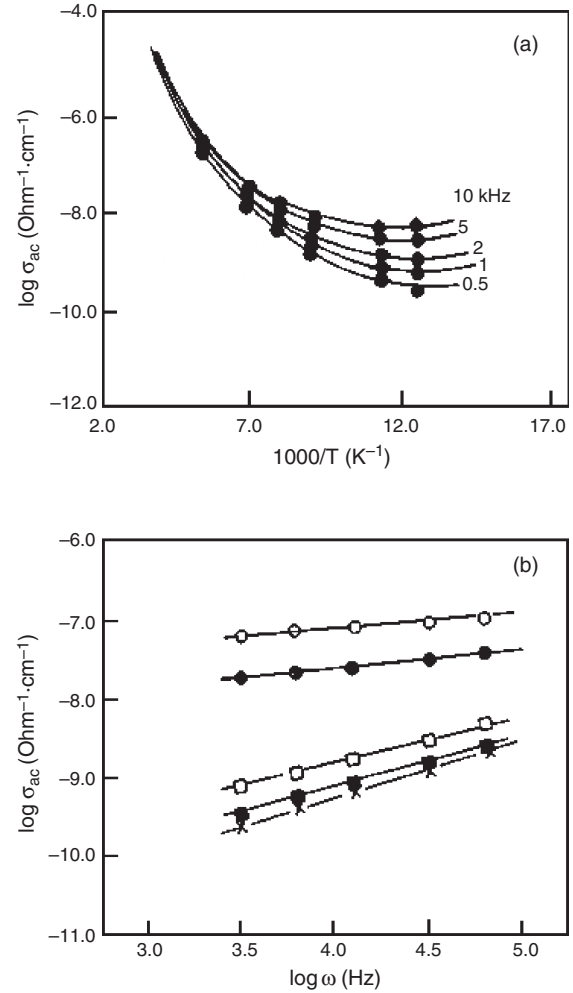
where κ is a constant factor and varies slightly between different treatments, and R_ω $[=(1/2\alpha)\ln(1/\omega\tau_o)]$ is the characteristic tunneling distance and the corresponding frequency exponent has the form $s = 1 + 4/\ln(\omega\tau_o)$. Therefore, according to the QMT model, the exponent s was


Figure 11. (a) Inverse temperature dependent logarithmic ac conductivity ($\log\sigma_{ac}$) of a typical $(1 - x)(90V_2O_5–10P_2O_5) + x$BaTiO$_3$ glass-nanocomposite with $x = 0.3$ at different frequencies (0.5–10 kHz). (b) Frequency dependent ac conductivity of the same glass-nanocomposite sample with $x = 0.1$ at different temperatures [182 ($\circ$), 176 ($\bullet$), 120 ($\square$), 96 ($\blacklozenge$), 88 K (x)]. From the slope of these curves, the values of s (frequency exponent) were estimated. Similar curves were obtained for other glass concentrations. (Solid lines are guides for the eyes.) independent of temperature that appeared to be valid for the FGNCs only in the low temperature region. The values of the DOS at the Fermi level, $N(E_F)$, were obtained by least-square fitting of the linear region in the low temperature phase for the same composition. The values of $N(E_F)$ presented in Table 4 seem to be reasonable and comparable to those obtained from the dc conductivity data (Table 4) of the same nanoparticle dispersed glasses. However, although the QMT mechanism appears to be consistent with the thermal variation in $\sigma_{ac}(\omega)$ of these VPTI nanocomposites in the low temperature regime, it completely failed to interpret the observed temperature dependence of the exponent s. The QMT model as discussed predicted a value of $s = 0.81$ (assuming $\tau_o = 10^{-13}$ sec and $\omega/2\pi = 10^4$ sec^{-1}), independent of temperature. It has already been
Figure 12. Thermal variation of frequency exponent (S) for $(1-x)\cdot$ $(90V_2O_5-10P_2O_5) + xBaTiO_3$ $(x = 0.1, 0.3, 0.5,$ and $0.9)$ glass-nanocomposites fitted with the OLPT model [Eq. (10)]. The continuous lines are the best-fit curves. Reprinted with permission from [50], M. Sadhukhan et al., *J. Chem. Phys.* 105, 11326 (1996). © 1996, American Institute of Physics.

shown in Figure 12 that s decreases with increasing temperature and then it increases after reaching a certain minimum value, which is also in complete contradiction to the prediction of the simple QMT model. However, at higher temperatures, the ac conductivity starts to deviate from linearity and the temperature (around $\theta_D/2$) at which deviation from linearity starts increases with increasing frequency. Thus the QMT model can explain only the experimental ac conductivity data at low temperature of these VPTI type FGNCs.

It is to be mentioned here that the OLPT model [Eq. (10)] is also applicable in the low temperature range if it is approximated to low temperature condition. One can show that at low temperature this equation reduces to the form

$$\sigma_{ac}(\omega) = (\pi^4/12)e^2(k_BT)^2[N(E_F)]^2[\omega R_\omega^4/2\alpha k_BT]$$
$$= (\pi^4/24)e^2(k_BT)[N(E_F)]^2\omega R_\omega^4/\alpha \qquad (13)$$

Equation (13) can explain the data of Figure 11 and the estimated $N(E_F)$ values fairly agree (within $\pm2\%$) with the corresponding values estimated from the QMT model. The OLPT model is, therefore, applicable for a wide

range of temperature (both low and high) for these glass-nanocomposites. And the failure in temperature dependence of the exponent s as shown by the QMT model can also be avoided.

It was also observed that the CBH model [12] which correlates the barrier height W with the intersite separation R for single-electron hopping [84] was not applicable for the ac conductivity in these VPTI type nanoparticle dispersed glasses, even though this model was found to hold good for the base glass [69] $V_2O_5-P_2O_5$ (with 80–90 mol% V_2O_5) in the temperature range 80–400 K. A similar feature was observed as well for the $SrTiO_3$ doped $V_2O_5-Bi_2O_3$ FGNC system [41, 48]. The presence of TiO_2 in the $V_2O_5-P_2O_5$ glass, therefore, not only favors the formation of nanocrystals but also modifies the network structure, which in turn was responsible for the change of physical behavior of the nanocrystal dispersed glass. The nonlinear behavior of the TiO_2 doped VPTI type FGNCs, as discussed, was in addition a special property of these FGNCs which might be responsible for the observed differences in the conductivity mechanism in the TiO_2 doped FGNCs from that of the pure base glass, viz. vanadium phosphate (VP) glasses. The thermal variation of dielectric constant (both real and imaginary) of these glasses to be discussed is also interesting, indicating nonlinear behavior of these glasses with $x > 5$ wt% TiO_2 [64].

7.3. Dielectric Properties

Dielectric constants of the FGNC composites are, in general, measured by a GR-1615A Bridge and also by a HP 4291 impedance analyzer [48, 50]. Figures 13 and 14 show, respectively, the thermal variations of the real part (ε') of the dielectric constants of $80V_2O_5-20PbO + 30$ wt% $BaTiO_3$ and $80V_2O_5-20P_2O_5 + 10$ wt% TiO_2 nanoparticle dispersed FGNCs for different frequencies (0.1–100 kHz) [30, 64]. Interestingly, the values of dielectric constants of these FGNCs were several orders (three to four) of magnitude higher than those of the undoped $80V_2O_5-20P_2O_5$ glasses [5]. It was also observed from the T vs ε' curve (Fig. 13) that this relaxation peak above 360 K was shifted to a higher temperature region with the increase of frequency. For higher concentrations ($x > 5$ wt% TiO_2, or $BaTiO_3$) at a fixed frequency [30, 64], where grain size became larger, or at higher frequencies (for a fixed concentration), the dielectric constant decreased (Figs. 13 and 14). A maximum dielectric constant for the VPTI type FGNC was observed with x around 5 wt% (having smallest grain/cluster size ∼10 nm) at 100 kHz [64]. This behavior was also observed in the $V_2O_5-P_2O_5-KTiO_3$ glasses [86].

The Debye type relaxation behavior [87] can be characterized by a complex dielectric constant of the form $\varepsilon^* = \varepsilon_\alpha + (\varepsilon_s - \varepsilon_\alpha)/(1 + j\omega\tau)$ where ε_s and ε_α are the static and high frequency dielectric constants, respectively. ω is the angular frequency and τ is the dielectric relaxation time. Using the relation $\varepsilon^* = \varepsilon' + i\varepsilon''$, we get both real ($\varepsilon'$) and imaginary ($\varepsilon''$) parts of dielectric constants expressed as $\varepsilon' = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)/(1 + \omega^2\tau^2)$ and $\varepsilon'' = (\varepsilon_s - \varepsilon_\infty)\omega\tau/(1 + \omega^2\tau^2)$. Debye type dielectric relaxation
Figure 13. The thermal distinction real part of dielectric constant (ε') of the glass-nanocomposite sample $(80V_2O_5–20PbO) + 30$ wt% $BaTiO_3$ (annealed at 300 °C for 9 h in air) showing one broad peak around 390 K at four different frequencies, 100 Hz ($\square$), 1 kHz ($\bullet$), 10 kHz ($\triangle$), and 100 kHz ($\circ$), corresponding to ferroelectric transition of $BaTiO_3$ at 393 K. Reprinted with permission from [30], M. Sadhukhan et al., *J. Appl. Phys.* 85, 3477 (1999). © 1999, American Institute of Physics.

behavior is also characterized by relaxation frequency $f_c = 1/2\pi\tau = \nu_{ph}\exp(-W/k_BT)$, where ν_{ph} is the characteristic phonon frequency. This relaxation process can be more clearly resolved [88] from the calculation of dielectric modulus $M^* (=M' + iM'') = \varepsilon^{*-1} = \omega\varepsilon_0 Z^*$, where ε_0 is the vacuum permittivity and Z^* is the complex impedance. The real (M') and imaginary (M'') parts of the complex dielectric modulus M^* are related to the dielectric constants as

$$M' = \varepsilon'/(\varepsilon'^2 + \varepsilon''^2) \quad \text{and} \quad M'' = \varepsilon''/(\varepsilon'^2 + \varepsilon''^2) \quad (14)$$
Figure 14. Real part of dielectric constant (ε') of $(80V_2O_5–20P_2O_5)+ xTiO_2$ glass–nanocrystal composites for a fixed ($x = 10$ wt%) TiO_2 content at different frequencies (0.1 to 100 kHz) as a function of temperature. Reprinted with permission from [64], D. K. Modak et al., *Sol. State Phys.* 43, 368 (2000).

Again according to Cole and Cole [89], the complex dielectric constant can be expressed as

$$\varepsilon^* = \varepsilon_\infty + (\varepsilon_s - \varepsilon_\infty)/(1 + i\omega\tau_m)^{1-\phi} \quad (15)$$

where τ_m is the mean relaxation time and ϕ is an empirical parameter lying between 0 and 1. The slope of the Cole–Cole plot [89] at $\varepsilon'' = 0$ gives the value of $(1 - \phi)\pi/2$. A value of $\phi = 0$ leads to a single relaxation time and $\phi = 1$ gives an infinite distribution of relaxation time which is very common in the glassy system.

The thermal variations of loss tangent $\tan\delta$ ($=\varepsilon''/\varepsilon'$) for TiO_2 doped nanoparticle dispersed FGNCs were large (since $\varepsilon'' > \varepsilon'$) indicating a very high loss factor in these FGNCs [64, 78]. The high loss of these glasses might be due to the more conducting nature of the precipitated nanocrystals embedded in the glass matrix, or the effects of space-charge polarization [90] of nanocrystalline TiO_2. In the high temperature region, a sharp increase of the loss tangent was observed with increasing frequency. Interestingly, at lower concentrations ($x \leq 10$ wt% which was almost below the critical concentration x above which "phase transition" occurred), loss tangent of the VPTI type glass–nanocrystal composites showed peaks, which shifted to a higher temperature region for higher concentration for a constant frequency of 10 kHz. The $\tan\delta$ vs temperature curves of higher concentrations did not show any peak. It should be mentioned that Kundu et al. [34] did not observe any peak in temperature variation of $\tan\delta$ curves and the loss was also very low. Because of the absence of a well defined loss peak and the uncertainties involved in the subtraction of the dc conductivity from the total conductivity, it was difficult to use conventional methods of estimating the relaxation frequency f_c and the nature of the dispersion (i.e., whether it is characterized by a single relaxation time or by a distribution of relaxation times). However, the following two approaches may be used [79] for the analysis of the data. The first involves the dielectric modulus, defined by Macedo et al. [88], and the second approach is to extract information about the dielectric relaxation time from the temperature or frequency variation of the dielectric constant alone assuming a symmetric distribution of relaxation times. Although no peak was observed in the temperature dependent ε'' curves of $80V_2O_5–20P_2O_5 + 5$ wt% TiO_2 nanoparticle dispersed FGNC (Fig. 15) for a fixed frequency up to the highest temperature limit measured (460 K), it exhibited Debye type dielectric relaxation behavior characterized by relaxation frequency f_c ($=1/2\pi\tau$) [64]. It is interesting to note that Prasad et al. [31, 32], however, found peak in temperature variation of dielectric loss (ε'') data of $50SrB_4O_7–50Bi_2VO_{5.5}$ type FGNCs. The relaxation process in these FGNCs can be more clearly resolved by using Eq. (14). It was seen from the thermal variation of M' for a fixed (20 wt%) TiO_2 doped VPTI type FGNC (Fig. 16) that M' varies slowly with temperature for fixed measured frequency (10 kHz) above 260 K [64]. This type of temperature dependence of M' indicates that the dielectric constants of the samples are thermally activated. Similarly M'' vs T curves for a sample with 30 wt% TiO_2 (Fig. 17) at different fixed frequencies (1–100 kHz) showed peaks within the measured temperature limit around 110 K. The peak position of M''
Figure 15. Imaginary part of dielectric constant (ε'') as a function of temperature for $(80V_2O_5–20P_2O_5) + xTiO_2$ glass–nanocrystal composites (with $x = 5$ wt% TiO_2) at frequencies 0.1 and 1.0 kHz (a) and 10 and 100 kHz (b). Reprinted with permission from [64], D. K. Modak et al., *Sol. State Phys.* 43, 368 (2000).

gave the temperature at which the measuring frequency was given by $f_c = \nu_{ph} \exp(-W/k_B T)$. Attempts were also made to find the nature of the dielectric relaxation behavior of these FGNCs from the Cole–Cole plot [89] of Eq. (15) at different fixed temperatures with different frequencies [64]. The semicircular nature of the curves as predicted from the Cole–Cole plot [89] for the TiO_2 or $BaTiO_3$ nanocrystal doped VPTI type FGNCs was not prominent [30, 50, 64]. From the Cole–Cole plot [89], it was also evident that ϕ resided between 0 and 1, which suggested that all these glass–nanocrystal composite samples had a distribution of relaxation times.

Grain size effects on ferro- and antiferroelectric oxides have been well investigated theoretically and experimentally [90, 91]. For ferroelectric $PbTiO_3$, the estimated critical size of the nanoparticle clusters [40] was between 8 and 12 nm. The high dielectric constant of these nanoparticle dispersed glasses might be related to the space charge polarization or ionic relaxation polarization occurring at the
Figure 16. Thermal variation of the real part of dielectric modulus (M') for $(80V_2O_5–20P_2O_5) + xTiO_2$ glass–nanocrystal composites for a fixed TiO_2 concentration ($x = 20$ wt%) at 10 kHz. Reprinted with permission from [64], D. K. Modak et al., *Sol. State Phys.* 43, 368 (2000).

interface as suggested by Zhong et al. [90, 91]. The dielectric loss of the VPTI type nanoparticle dispersed FGNC was also very high which might be related to the more conducting character of the precipitated nanoclusters.

7.4. Ferroelectric Properties

For a typical FGNC system, viz. $Bi_{2-x}Pb_xSr_2Ca_2Cu_{3-y}K_y$ ($x = 0.1–0.3$, $y = 0.2–0.3$), the ferroelectric property is discussed. The T_g values of this system were found to be (340, 350, 360, and 400 K) depending on the values of x and y [44]. For a typical FGNC, viz. ($x = 0.2$, $y = 0.2$), its
Figure 17. Thermal variation of imaginary part of dielectric modulus (M'') of $(80V_2O_5–20P_2O_5) + xTiO_2$ glass–nanocrystal composites for a fixed TiO_2 concentration ($x = 30$ wt%) at 1 (x), 10 (◆), and 100 (○) kHz. Reprinted with permission from [64], D. K. Modak et al., *Sol. State Phys.* 43, 368 (2000).

TEM micrograph clearly indicated the presence of micro-crystals/clusters (10–50 nm size). The concentration of the nanoparticles slightly increased with the increase of Pb concentration. As mentioned earlier, these nanoparticles are considered to be responsible for the ferroelectric behavior of K containing FGNCs since nanoparticle free glasses are not ferroelectric. Interestingly, the K free glasses are reported to become also superconductors [59] by annealing around 840 °C. Hereafter these K free glasses are referred to as SG glasses. But due to the presence of alkali metal (partial substitution of Cu by K) in these glasses, they show FE behavior and do not become superconductors by annealing [44] around 840 °C. The K doped ferroelectric glasses are termed FG glasses.

The structure of Bi–Sr–Ca–Cu–O glasses depends to a great extent on the Cu content and its valence state [21]. So the addition of alkali metal (K, say) in the Cu site distorted the average structure of the K free SG type glass to a great extent [44]. Though both Bi_2O_3 and CuO are not glass-forming oxides, it is well established that both Bi_2O_3 and CuO are necessary to form a glassy state in the Bi–Sr–Ca–Cu–O system as reported by several authors [78, 79]. Bi_2O_3 enhances the glass-forming ability in the Bi-based FGNC systems; Bi_2O_3 acts as "glass former" in the presence of CuO. It has been reported [92] that Bi^{3+} ions are six coordinated (distorted BiO_6 octahedra) in the Bi-based glasses. The oxygen coordination number of Cu^+ in Cu_2O is 2 and that of Cu^{2+} in CuO is 4. The density of CuO is more than Cu_2O, concluding that CuO structure is more compact than that of Cu_2O. Recently Sato et al. [93] proposed a glass network structure unit of $Bi_4Sr_3Ca_3Cu_4O_x$ glasses as shown in Figure 18. In this model, BiO_6 octahedra are connected to other octahedra through two-coordinated Cu^+ ions and particularly in the K free SG type glasses Cu^+ ions take part mainly in the formation of networks. The other cations of Cu^{2+}, Ca^{2+}, and Sr^{2+} may be distributed randomly in the surrounding network. Partial replacement of Cu sites by K changed some ionic states of Cu and distorted the glass network structure in favor of dipolar ordering and hence appearance of ferroelectricity as observed from the dielectric properties discussed. The difference between the glass structures of superconducting precursor glass (SG type glass) can be compared in terms of the oxygen molar volume [94, 95] V_o^*. The value of V_o^* of the present FGNC was calculated using the
Figure 18. Network structure model of $Bi_4Sr_3Ca_3Cu_4O_x$ glasses. In K doped glasses, Cu ions are partially replaced by K ions. Reprinted with permission from [93], R. Sato et al., *J. Non-Cryst. Solids* 160, 180 (1993). © 1993, Elsevier Science.

equation

$$V_o^* = \frac{(M_{CuO} - 16C)X_{CuO} + M_K X_K + M_{Ca} X_{Ca} + M_{Sr} X_{Sr} + M_{Pb} X_{Pb} + M_{Bi} X_{Bi}}{d[(5-C)X_{Cuo} + 3X_K + 3X_{Ca} + 3X_{Sr} + 1X_{Pb} + 3X_{Bi}]}$$

(16)

where M_{CuO}, M_K, M_{Ca}, M_{Sr}, M_{Pb}, and M_{Bi} are the molecular weights of CuO, K_2CO_3, $CaCO_3$, $SrCO_3$ PbO, and Bi_2O_3, respectively. X_{CuO}, X_K, X_{Ca}, X_{Sr}, X_{Pb}, and X_{Bi} are the mole fractions of CuO, K_2CO_3, $CaCO_3$, $SrCO_3$, PbO, and Bi_2O_3, respectively. The parameters d and C are the density of the glass and fraction of reduced Cu ions, respectively. Both T_g (400 °C) and V_o^* (14.52) of the K containing FGNCs were a little higher than those of the K free SG glasses ($T_g = 340$ °C, $V_o^* = 11.23$) [44]. This indicated that K doped glasses had a more stable glass network structure than that of the K free SG glasses. However, the network structure also depended on the K and Pb concentrations.

The dielectric constant of the Bi-based glassy precursor ($Bi_4Sr_3Ca_3Cu_4O_x$) for high T_c superconductors (SG glasses) did not show any ferroelectric behavior [96–100]. Figure 19a shows the variation of the dielectric constant (ε') of a typical K-doped FGNC, viz. (with $x = 0.2$, $y = 0.2$) as a function of temperature for different frequencies 0.1, 0.12, 1.0, 10, 100 kHz. The appearance of small broad peak in the (ε'–T) curve (Fig. 19a) around 600 K along with the large peak for every frequency indicated the presence of the relaxation mode in the glass. The ε' values of the FGNCs are of the same order as those of the Bi-based multicomponent SG glasses (Fig. 19b) [96–100]. It has already been shown [78] that the dielectric constant of nanocrystalline TiO_2 is much larger than that of the corresponding bulk sample. As mentioned earlier [30–32, 34, 50, 64], the $Bi_2VO_{5.5}$, PbS, $BaTiO_3$, and TiO_2 ferroelectric nanocrystals containing FGNCs also showed high dielectric constants as shown in Table 1.

The dielectric constant data of the K doped FGNC followed the Curie–Weiss relation $\varepsilon' = C/(T - T_0)$, where C is the Curie constant. T_0 is the extrapolated intersection of the high temperature part of the plot with the temperature axis as shown in Figure 20a [44]. The order of transition was identified by finding the ratio of the slopes $\frac{\partial (1/\varepsilon)}{\partial T}$ below and above T_{cf} [44]. The value of this ratio ($=-2.63$) indicated that the transition was of first order type. Prasad et al. [31, 32], also analyzed the dielectric constant data of the SrB_4O_7–$Bi_2VO_{5.5}$ type FGNCs in the same way. In case of second order phase transition, T_0 is practically the same as the transition temperature or the Curie point T_{cf}, while in case of a first order transition T_0 is lower than the Curie temperature T_{cf}. T_{cf} of this FGNC was found to vary from 500 to 530 K depending on K concentrations. It is more interesting to mention here that for any of the K-free superconducting precursor glasses (SG glasses), becoming superconductors by annealing, the plot of $1/\varepsilon'$ vs T (Fig. 20b) did not at all match with that of K doped FGNC showing ferroelectric behavior (Fig. 20a). Detailed analysis of the dielectric properties of other SG glasses without showing ferroelectric behavior can be found in the text [96–100].

Here we like to mention that frequency dependent conductivity $\sigma_{ac}(\omega) \propto \omega^s$ (where $s < 1$ is frequency exponent [13, 14]) of these FGNCs also supported the small polaron hopping conduction mechanism [86]. Murawski

and Barczynski [101] showed that a fractal structure was responsible for relaxation currents and the total conductivity $\sigma_t(\omega) = \sigma_{dc} + \sigma_{ac}(\omega)$ can be expressed as $\sigma_t = \sigma_{dc}[1 + K(d)(\omega/\omega_c)^r]$, where $r = 1 + d - d_f > 1$, d is the dimensionality of the space containing relevant clusters, and d_f is the fractal dimensionality of such clusters. For frequency $\omega < \omega_c = 2\pi f_c$, where f_c is the peak frequency at which dielectric constant data showed peaks and $K(d)$ is a dimensionally dependent constant related to the statistics of the contributing clusters ($K = 0.001$–0.0025) for many TMO glasses [90]. For a typical glass sample with $x = 30$ wt% of TiO_2, Mukherjee et al. [44] estimated d_f from the knowledge of ac conductivity and dielectric constant data of this sample. The estimated value of d_f was ~2.71 meaning that in the clusters the percolation paths also have three-dimensional character in the nanocrystal dispersed FGNCs.

Prasad et al. [31] observed that $50SrB_4O_7$–$50Bi_2VO_{5.5}$ glass nanocomposites heat-treated at 820 K/h did not show

a polarization (P) versus electric field (E) hysteresis loop at room temperature (300 K) indicating that the coercive field required to switch on the polarization at this temperature was much higher. However, the sample exhibited a hysteresis loop in the vicinity of the ferroelectric to paraelectric transition temperature (720 K) associated with a remnant polarization (P_r) of 5.63×10^{-9} C cm^{-2} and coercive field (E_c) of 1250 V/cm (Fig. 21a). However, the values of P_r and E_c were, respectively [102], 2.25×10^{-8} C cm^{-2} and 650 V/cm for micrometer size crystallites containing $Bi_2VO_{5.5}$ ceramic. The loops disappeared and the plots became linear (Fig. 21b) at 780 K, which was beyond the phase transition temperature of this glass-nanocomposite. On cooling, the loops reappeared around 730 K, which was similar to that of the ferroelectric behavior of $Bi_2VO_{5.5}$ ceramics. Similar behavior was also exhibited by the K doped Bi–Sr–Ca–Cu–O FGNCs as discussed.

7.5. Piezoelectric Properties

Though transport and other properties of the ferroelectric nanocrystal dispersed oxide glasses have been studied widely, the piezoelectric nanocrystal–glass composites have not been so extensively investigated. However, composites having perovskite dispersed polymer and glasses have been studied as electronic–ceramics [103–110].

$P_r = 5.63 \times 10^{-9}$ C cm^{-2}

$E_c = 1250$ V cm^{-1}

The piezoelectric particulate reinforced nanocomposite ceramics have been broadly reported [111–119]. Various piezoelectric–nanocomposite systems like PZT/Ag, PZT/Al$_2$O$_3$, MgO/PZT, BaTiO$_3$/Ni, BaTiO$_3$/SiC, etc. have been explored by several groups [111–119]. The PbZr$_{0.5}$Ti$_{0.5}$O$_3$ type system can be used to prepare piezoelectric–glass nanocomposites [120]. The relative permittivity (ε') of these piezoelectric–nanocomposite systems is in the range of 1000–3000 at a temperature of 300 K and frequency of 1 kHz [119]. The dielectric constant and dielectric loss of the piezoelectric–nanocomposite system generally have an abrupt increase above the critical field as shown in Figure 22. This effect has been confirmed by different research groups [121]. Hagemann [122] proposed that this change is due to hysteretic domain wall motion and the resultant reorientation by spontaneous polarization. Similar to piezoelectric nanoparticle–glass composites,
Figure 22. General trend of dielectric loss with applied electric field of piezoelectric glass-nanocomposites. Hysteretic domain wall motion above a critical field (indicated by arrow) leads to an increased dielectric loss. Reprinted with permission from [119a], S. R. Panteny et al., preprint (2002).

the pyroelectric nanoparticle–glass composites are not widely studied. Some composite films of lead titanate, PZT, lanthanum–lead titanate, and calcium–lanthanum–lead titanate into copolymer matrices for pyroelectric sensor application are already available in the literature [123–128].

7.6. Mechanical Properties

The mechanical behavior of a material is determined by its type of bonding and defect structure. Nanophase materials show increasing hardness with decreasing grain size. When the grain size of the material is reduced to the nanoscale, its mechanical property becomes strongly influenced due to the fact that a large fraction of the atoms in the material lie in the grain boundaries. So the material becomes superhard possessing hardness rivaling diamond [129, 130]. Glasses are generally very brittle. Dispersing nanocrystals inside the glass matrix can decrease its brittleness. Toughening is an extremely important property of glass for their practical use. A piezoelectric secondary phase (e.g., PZT particles) can increase the toughening when incorporated into the glass matrix. The works on PZT-containing ceramic matrix composites suggest that energy dissipation due to the piezoelectric effect as well as the motion of the domain wall should contribute to toughening. The sintering process of the mixtures containing different concentrations of PZT particles should be optimized in order to obtain a pore-free material. Transparent glass fiber reinforced silicate glass matrix composites with improved mechanical and optical properties are important for technical applications. The studies of mechanical properties of these products, viz. fracture strength, toughness, and thermal shock resistance, and the optical properties, viz. composite effective refractive index and light transmittance, are also very important for future investigation and analysis. Hot pressing is generally used to obtain dense glass-nanocomposite materials. The hardness of ferroelectric glass-nanocomposites are generally done by heat treatment of the material to produce a fine dispersion of particles within the microstructure which increases the resistance to domain wall motion [131].

8. TRANSPARENT FERROELECTRIC GLASS NANOCOMPOSITES

Some of the glass-nanocomposites are transparent since these have a big bandgap for light absorption for electrons, and so light absorption is very low and thus transmitted light fraction is very high. The nanoparticles in the glassy matrix are so small that light is unable to interact with them (i.e., the object is smaller than light wavelength) and thus the transparency of the glass-nanocomposite is not hampered by the inclusion of nanoparticles in the glass matrix. On the other hand, if the refractive index of the dispersed nanoparticles is the same as that of the base glass, it will also not affect the transparency of the glass. These materials have several advantages like easy formability, optical transparency, and low cost. Examples of some TFGNCs are $LiNbO_3$ nanocrystal embedded $Li_2O–SiO_2–Al_2O_3$ glass matrix and $KTiOPO_4$ (KTP) nanocrystals dispersed in SiO_2 glass matrix [35, 39].

In $KTiOPO_4$ (KTP)/SiO_2 TFGNC, the ferroelectric KTP nanocrystals were directly precipitated from $K_2O–TiO_2–P_2O_5–SiO_2$ parent glasses by heat treatment [35, 39]. The SAED, SEM, and TEM of these TFGNCs showed the distribution of the nanoparticles in the glass matrix beautifully before and after heat treatment. Particle sizes were measured from TEM photographs [35, 39]. The ultraviolet (UV) absorption band in these TFGNCs originated from the Ti–O band. There was also a strong absorption near 2800 nm, which corresponded to the well-known IR absorption band of the OH-band stretching mode. The transparency of these TFGNCs decreased with the increase of heat-treating temperature as shown in Figure 23. With the increase of heat-treatment temperature, the particle size increased and hence became able to interact with the light and as a result the transmittance decreased. However, these TFGNCs had a transmittance cutoff edge in the UV range at ~350 nm [35, 39].

The second order nonlinear susceptibility is generally induced only in a noncentrosymmetric crystal structure or anisotropic materials. In other words, second harmonic
generation (SHG) in glasses should be forbidden as glasses have macroscopic inversion symmetry. Therefore, SHG and other electro-optical effects are usually unexpected in glassy systems. In fact, no SHG signal was observed in different SiO_2-based glasses [35] like $20P_2O_5–80SiO_2$, $10K_2O–10TiO_2–80SiO_2$, $10TiO_2–10P_2O_5–80SiO_2$, and $20TiO_2–80SiO_2$. But the SHG signal has been reported in some poled glasses [132] and photoinduced glasses [133–135] though the origin of the SHG signal was completely unclear. SHG was also observed in GeO_2-, CeO_2-, and Eu_2O_3-containing SiO_2 glass fibers which was due to the defects and additives and may be the origin of the SHG centers in the glasses [135–138]. The multicomponent $K_2O–TiO_2–P_2O_5–SiO_2$ parent glasses, when annealed at 550 °C, did not contain resolvable crystallites [39] as analyzed by XRD and hence did not exhibit any SHG signal (Fig. 24a). Nevertheless, when annealed at 750 °C, it contained KTP nanocrystals dispersed in SiO_2 glass matrix and exhibited the SHG signal with a narrow bandwidth at 532 nm signifying a true SHG process (Fig. 24b). These results suggested that the SHG in KTP/SiO_2 TFGNC originated from KTP nanocrystals embedded in SiO_2 matrix [35]. It is to be noted here that a third order nonlinear optical susceptibility or third harmonic generation in silver nanocrystal dispersed $BaO–B_2O_3–P_2O_5$ glass was observed around the surface plasmon resonance band [51].

9. APPLICATIONS

Nanophase engineering with organic and inorganic materials is expanding enormously to manipulate optical and electronic functions. Semiconducting nanoparticles have been the subject of increasing interest since the demonstration in 1975 of the enhancement of their third order nonlinear optical properties [139]. Very small semiconductor (<10 nm) or metal particles in glass composites and semiconductor/polymer composites show interesting quantum effects and nonlinear electrical and optical properties. Nanocomposite materials consisting of small metal or oxide particles dispersed in glass matrices are attracting much

attention because of their potential use in a variety of fields, such as optics, magnetism, and electronics [140–146]. Semi-conducting nanoparticles are particularly interesting due to their possible applications in diverse areas like photocatalysis, solar cells, display panels, and new devices, viz. single electron transistors and so on [147–149]. A high third order optical nonlinearity of semiconducting nanocrystal composites allow a wide range of useful function, such as high speed all-optical switching and other signal processing operations. Ferroelectric nanoparticles can be treated as built in electrical dipoles, which can produce electro-optic effects, photorefraction, and harmonic generation. The FGNC systems are both semiconducting and ferroelectric with a giant dielectric constant. The FGNCs with high permitivitty may be attractive for applications in microelectronics. Because of the ferroelectric behavior of glass-nanocomposites, they have additional applications as sensor materials [150]. When an ordinary glass is doped with quantized semiconductor colloids, it becomes a high-performance optical medium with potential applications in optical computing. Very small particles have special atomic structures with discrete electronic states that give rise to an extraordinary property like superparamagnetism. Magnetic nanocomposites have been used for mechanical force transfer (ferrofluids), high-density information storage, and magnetic refrigeration. Piezoelectric nanocrystal–glass composites are more sensitive materials for high frequency hydrophones.

Transparent FGNCs having nonlinear optical properties are used in transducers, sensors, and actuators in the fields of communication, energy, and health. These new totally inorganic materials will be attractive for various optical applications (switching and memory devices) where currently standard monolithic glasses cannot be used due to poor mechanical properties. More conventional applications of wide commercial interest such as architectural and building materials are also possible including applications where high fire and thermal shock resistance are required and where standard laminated glasses are not suitable due to their organic components. The superhardness of the glass-nanocomposites can be used as a material requiring friction and wear resistance. The superhard nanostructured films promise revolutionary improvements for wear protection for applications in high speed machining as well as in the emerging field of miniaturized moving parts in microelectromechanical systems [129, 130].

10. CONCLUSIONS

The ferroelectric glass-nanocomposites (FGNCs) are formed by uniformly dispersing nanocrystalline particles/clusters of TiO_2, $BaTiO_3$, $PbTiO_3$, $SrTiO_3$, $PbZrO_3$, $KTiOPO_4$, $Bi_2VO_{5.5}$, $Li_2Ge_7O_{15}$, PbS, etc. in the glass matrices. These FGNCs show giant dielectric constant, ferroelectric, and piezoelectric behavior depending on their composition. The electrical and the dielectric properties of these FGNCs are found to depend on the size and concentration of the dispersed nanoclusters in the glass matrices. For lower concentrations of FE nanocrystals (≤ 5 wt% with average grain or cluster size <10 nm), the increase of conductivity was found to be small. A sharp rise of conductivity occurred for the FGNCs with 5 and

10 wt% TiO_2 embedded in $80V_2O_5$–$20P_2O_5$ glass. For higher concentrations (>10 wt% with average grain or cluster size >20 nm), the conductivity increased slowly with increase of concentration. The increase of electrical conductivity compared to the base glass was considered to be due to the precipitation of nanocrystalline phase in the base glass matrix. A phase separation appeared in the FGNC between 5 and 10 wt% TiO_2 showing nonlinearity in the concentration dependent conductivity and dielectric permittivity. The dielectric constant also showed the maximum value for the FGNC between 5 and 10 wt %. The high dielectric constant of these FGNCs might be related to the space charge polarization or ionic relaxation polarization occurring at the interface as suggested by Zhang et al. [78]. Very strong polaronic couplings (γ varies from 12 to 25, generally for TMO glasses; $\gamma > 4$ indicates very strong electron–phonon interaction constant) observed for these FGNCs play an important role for their high dielectric constant. It appears that there is an average critical grain/cluster size (~10 nm) above which dielectric constant of these FGNCs tends to decrease. In the literature, grain size effects on ferro- and antiferroelectric oxide materials have been well established both theoretically and experimentally [29, 77]. For ferroelectric $PbTiO_3$, the estimated critical size resides between 8.2 and 13.8 nm [29]. Recently the high dielectric constant in $CaCu_3Ti_4O_{12}$ [45, 46] was also explained by considering semiconducting grains with insulating grain boundaries. Further study of dielectric and conductivity relaxation behavior in these FGNCs would be interesting. Problems related to the uniform size and distribution of the nanoparticles and preparation of the samples in the form of wire, tapes, thin films, etc. from these nanoparticle-dispersed glasses are yet to be explored. More elaborate theoretical analysis is necessary to understand the origin of the giant dielectric constant in these systems. Moreover, our understanding of higher harmonic generations in nanocrystal dispersed glassy materials is no way complete. Thorough experimental and theoretical investigations on such materials are highly encouraging. SHG signal in TFGNCs was found to originate from the KTP nanocrystals embedded in SiO_2 glassy matrix [35, 39].

The ferroelectric nanocrystal dispersed oxide glasses will most probably gain rapidly increasing importance in the near future. In general, properties, production, and characterization methods and their interrelations are, however, not yet satisfactorily understood. Hence, efforts need to be made to enable the directed tailoring of nanophase, nanoscopic, and nanocomposite materials for future technological and industrial applications. The main disadvantage of ferroelectric crystals grown within a glass medium is the difficulty in poling them because of the low dielectric permittivity of the glass matrix. However, the precipitating of nanocrystalline FE metallic phase in glass matrix is easy and it enhances the dielectric constant of the glass enormously [33].

GLOSSARY

AC conductivity Frequency dependent conductivity. The conductivity of the material changes both with temperature and frequency. From the study of electric conductivity of solid materials (composites etc.), mechanism of electron or

ion transport, responsible for the electrical conductivity, can be explained.

Correlated barrier hopping (CBH) Mechanism of electrical conductivity. The charge carrier is assumed to hop between site pairs over the potential barrier (W) separating them. For the neighboring sites at a distance R the effective potential barrier will be reduced to a value Wo due to overlap of Coulomb potential of the two sites. Thus the barrier height is correlated with the site separation R (for references see text).

Curie temperature The ferroelectric property of a crystal disappears above a critical temperature TC. This temperature is called Curie temperature. Above the Curie temperature, the ferroelectric phase become paraelectric, like ferromagnetic to paramagnetic transition.

Ferroelectricity It is a special property of some crystalline materials showing spontaneous polarization. A necessary, but not sufficient, condition for a solid to be ferroelectric is the absence of a canter of symmetry. In total there are 21 classes of crystals, which lack a center of symmetry. The classes are based on the rotational symmetry of crystals.

Ferroelectric glass nanocrystal composite (FGNC) When some transition metal oxides are mixed with ferroelectric oxides PZT etc. nanocrystal of the ferroelectric oxides are precipitated in the glass matrix. These nanocrystals embedded glassy phase is called the glass-nanocrystal composite. Depending on the grain size and concentration of these nanoparticles, the properties of the FGNC change.

Melt-quenching This technique is widely used for preparing disordered glassy and amorphous materials. The materials (metallic oxides, in particular) are melted to the liquid phase and quickly quenched to room temperature.

Overlapping large polaron tunneling (OLPT) If there is appreciable overlap of the lattice distortion in the electron wave function, this model is used to explain ac conductivity of semiconductors in disordered materials. The electronic wave function in this case extends over many atomic sites, hence the polaron is termed as large polaron. (See text for details).

Phonon The vibrations of the atoms or molecules are considered to be quantized and phonon is the quantized lattice vibration.

Piezoelectric Of the 21 classes of feroelectric crystals, 20 are piezoelectric, i.e. these crystals become polarized under the influence of external stress.

Polaron Localized charged carriers (formed due to strong interaction between the phonon and the carriers) which strongly interacts with the lattice. If the electron wave function extends over many atomic sites, the polarons are called large polarons, otherwise polarons are called small polarons.

Pyroelectric Ten out of the 20 piezoelectric classes exhibit pyroelectric effects. These pyroelectric crystals are spontaneously polarized.

Quantum mechanical tunneling (QMT) In this process variable range phonon assisted quantum mechanical tunneling between sites close to Fermi level is considered for explaining electrical conductivity in disordered materials like composites, glass etc.

Scanning electron microscope (SEM) This is a technique for studying the surface structure of the materials.

Transition metal oxide (TMO) glasses The transition metal (Fe, Co, Ni, Cu, Mn etc) oxides when melted at higher temperature and quickly quenched to room temperature, forms oxide glasses. These glasses are semiconductors because of the the hopping of electrons/holes from higher valence to lower valence states of the transition metal ions. Strong electron-phonon interaction is responsible for the polaron formation in these glasses.

Transmission electron microscope (TEM) This is a technique for studying the surface structure of the materials.

CONTENTS

1. INTRODUCTION

Ferroelectrics are a class of polar dielectrics characterized by a reversible spontaneous polarization [1]. Ferroelectrics possess a unique set of physical properties, that makes them attractive for application in a variety of electronic devices, such as nonvolatile memories and microelectromechanical systems. Their piezoelectric, electrooptic, and nonlinear optical properties are largely determined by arrangement of ferroelectric domains. Domains form during phase transition to relieve mechanical stress associated with transformation strains and to minimize the depolarization energy associated with the spontaneous polarization. The presence of the domain structure is one of the fundamental properties of ferroelectrics. Domain arrangements reflect the effects of sample conductivity, mechanical strains, and imperfections such as dislocations, vacancies, and impurities. Polarization reversal under an external electric field proceeds via domain nucleation and motion of domain walls. Direct observation of ferroelectric domains provides a wealth of information on static and dynamic properties of ferroelectrics. A number of techniques, such as polarized optical microscopy, electron microscopy, surface decoration, pyroelectric emission, and etching, have been employed for visualization of domain structures [1]. The main limitations of these methods have been either low spatial resolution or the destructive nature of the visualization techniques.

Rapid development of electronic devices based on ferroelectric thin films [2] generated a strong need for studies of ferroelectric properties at the nanoscale. Fortunately, this need appeared at the same time as new techniques for nanoscale characterization of materials became available. Specifically, scanning force microscopy (SFM) has emerged as a powerful tool for high-resolution characterization of virtually all types of materials, such as metals, semiconductors, dielectrics, polymers, and biomolecules [3–5]. In the field of ferroelectricity, the application of the SFM technique resulted in a real breakthrough providing an opportunity for nondestructive nanoscale visualization of domain structures in ferroelectric thin films. The employment of SFM makes possible nanoscale mapping of the surface potential, evaluation of local electromechanical properties, and dielectric constant measurements. In other words, characterization by means of SFM provides crucial information on the dielectric properties of ferroelectrics with unprecedented spatial resolution. Another promising development related to SFM is modification of the ferroelectric properties at the nanoscale via local polarization reversal induced by a conductive SFM tip.

Figure 1 illustrates the pace with which publications on SFM studies of ferroelectrics have been evolving over the last 10 years. An increasing number of papers indicates the growing importance of SFM in the field of ferroelectricity. Research groups in the United States, Europe, and Asia are actively using SFM for high-resolution characterization of ferroelectric materials in both bulk and thin-layer forms.

The purpose of this chapter is to review the application of SFM to nanoscale studies of ferroelectric domains. The wide variety of physical properties of ferroelectric materials allows the use of various SFM modes for domain imaging, depending on which physical mechanism provides the higher domain contrast. In this paper, experimental results related to different mechanisms of domain contrast are presented along with consideration of limitations and advantages of each SFM-based approach. Particular emphasis is given to one specific imaging method, namely, piezoresponse force microscopy (PFM), which proved to be the most effective approach for nanoscale studies of ferroelectric domains in bulk crystals and thin films. Future directions in nanoscale studies of ferroelectric materials are discussed.

2. FERROELECTRIC DOMAIN IMAGING IN SCANNING FORCE MICROSCOPY (SFM)

Scanning force microscopy can be considered as a combination of a surface force apparatus and a surface profilometer, as it is based on local monitoring of the interaction forces between a probing tip and a sample [4]. The forces acting on the tip after it has approached the sample surface cause a deflection of the cantilever according to Hooke's law. This deflection can be detected optically or electrically with sub-angstrom accuracy and is controlled by a feedback device, which regulates the vertical position of the tip over the surface. By keeping the deflection constant while scanning the sample, a three-dimensional map of the surface topography can be obtained. Besides this constant force mode, many other modes have been developed. The response of the cantilever to the externally modulated force (for example, due to an applied ac bias) can be used to map such physical properties as mechanical stiffness, friction, electric fields, density of electronic states, and so forth.

Depending on the type of tip-sample force interaction (attracting or repelling), the SFM can operate in two different regimes: noncontact or contact, respectively. In the noncontact regime, the tip is scanned over the surface at a distance of 10–100 nm, which is controlled, for example, by monitoring the resonant frequency of the cantilever [6]. The tip-sample interaction in this regime is dominated by the long-range polarization and electrostatic forces. Because of this feature, noncontact SFM can be used for ferroelectric domain imaging by detecting the electrostatic field of the surface polarization charges. This mode of SFM is called electrostatic force microscopy (EFM) [7]. Quantitative information on local surface potential related to spontaneous polarization can be obtained by means of scanning surface potential microscopy (SSPM), or Kelvin probe force microscopy (KPFM) [8, 9], a technique complementary to EFM. Scanning capacitance microscopy (SCM) can be used to generate an image of trapped charges by measuring local

tip-sample capacitance [8, 10]. SCM is not necessarily a noncontact mode of operation, as the probing tip can be placed in direct contact with the sample surface to measure the sample capacitance. General disadvantages of noncontact methods include susceptibility to screening effects, sensitivity to sample surface conditions, and low resolution in ambient air.

In the contact regime, the probing tip is in mechanical contact with the sample surface and senses repulsive short-range forces. The difference in mechanical, structural, electrochemical, dielectric, and piezoelectric properties of opposite ferroelectric domains can provide domain contrast in the SFM contact regime. Contact SFM methods of domain imaging include a topographic mode of atomic force microscopy (AFM), lateral (friction) force microscopy (LFM), piezoresponse force microscopy (PFM), and scanning nonlinear dielectric microscopy (SNDM). SFM-based methods of ferroelectric domain imaging are summarized in Table 1 and are discussed in the following sections.

3. NONCONTACT DOMAIN IMAGING

3.1. Electrostatic Force Microscopy

Imaging of ferroelectric domains in the noncontact mode is based on the detection of the modulated electrostatic interaction force between the probing tip and polarization charges. There are two modulation methods in the noncontact imaging.

In the conventional approach, the cantilever is made to oscillate near its resonant frequency by use of a piezoelectric bimorph. When the tip is brought close to the surface, the attractive force gradient acting on the tip alters the force constant k_0 of the cantilever as $k' = k_0 - \partial F/\partial z$. This in turn leads to a change in the resonant frequency and in the vibration amplitude. A feedback loop adjusts the tip-sample distance to keep the amplitude of oscillation constant [6]. Obviously, in the case of the ferroelectric sample, there is an electrostatic contribution to the attractive force due to the Coulomb interaction between a surface polarization charge and an image charge Q_t in the probing tip. As the tip crosses the wall, it experiences a change in the force gradient, and the feedback loop alters the tip-sample distance to keep the gradient and the vibration amplitude constant. This produces a variation of contrast in the feedback signal image, which can be interpreted as an image of the domain wall (Fig. 2) [11]. Since the Coulomb force is

Figure 2. (a) Sketch illustrating a mechanism of domain wall image formation in EFM. (b) Topographic and (c) EFM images of the etched lead titanate crystal. The domain structure consists of antiparallel *c*-domains, which appear with the same contrast in the EFM image, and domain walls appear as bright lines due to the surface charge gradient at the 180° domain walls. Topographic contrast is due to the differently etched surfaces of positive and negative domains Reprinted with permission from [11], P. Lehnen et al., *J. Phys. D: Appl. Phys.* 33, 1932 (2000). © 2000, Institute of Physics.

proportional to the product of the polarization and image charges, the force gradient signal provides information only on the polarization magnitude and not the sign. This implies that the contrast of opposite 180° domains will be the same and that only domain walls will be visible because of the spatial variation of the charge density in the vicinity of a 180° domain boundary.

Using this approach, the pioneering work on SFM domain imaging has been performed by Saurenbach and Terris in a single crystal of gadolinium molybdate [12]. A rather wide image of the domain wall (about 10 μm, while the actual wall thickness is on the order of several lattice constants) had been attributed to the tip-sample separation and the finite size of the tip, which broadened any sharp changes in the force gradients. Later works of Luthi et al. [13–16] and Eng et al. [17–19] demonstrated that lateral resolution in EFM can be significantly improved: in single crystals with cleaved polar surfaces, such as GASH and TGS, the width of the walls measured in EFM was in the range of 8 to 80 nm.

However, this method of domain imaging may suffer from the cross-talk with other sources of the force gradient, such as van der Waals forces. As a result, the force gradient image is usually a superposition of domain and surface topographic features. In the case of domains of irregular shape and complex surface topography, the interpretation of the EFM images could be quite difficult. One of the ways to alleviate this problem is to use a liftmode technique, which combines the contact and noncontact modes. In this approach, the tip scans each line twice: first, recording the topography in the contact regime, and second, retracing the topographic line at the predetermined height while detecting the variations in the vibration amplitude. In this case, since the tip-sample

distance is kept constant during the second scan, the force gradient is related to the surface charge.

Another method of circumventing the cross-talk effect is by using a dual-modulation scheme, developed for the detection of static surface charges by two IBM groups [6, 7, 20, 21]. In this approach, also used by Saurenbach and Terris, the cantilever is additionally modulated by an ac voltage $V_t = V_{ac} \cos \omega t$ applied between the probing tip and the bottom electrode. The frequency of the electrostatic modulation is chosen so that it is well below the frequency of mechanical modulation to avoid any resonance effect. In this case, an additional capacitance component will be introduced to the force acting on the tip, which can be written as

$$F = F_{cap} + F_{coul} = \frac{1}{2}\frac{\partial C}{\partial z}V_t^2 + \frac{Q_s Q_t}{4\pi\varepsilon_0 z^2} \quad (1)$$

where C is the tip-surface capacitance and z is the tip-surface separation. The total charge induced in the tip will be $Q_t = -(Q_s + Q_e) = -(Q_s + CV_t)$. The force gradient can be expressed as

$$\frac{\partial F}{\partial z} = \left[\frac{V_{ac}^2}{4}\frac{\partial^2 C}{\partial z^2} + \frac{Q_s}{2\pi\varepsilon_0 z^2}\right] + \frac{Q_s V_{ac} \cos \omega t}{2\pi\varepsilon_0 z^2}\left[\frac{C}{z} - \frac{1}{2}\frac{\partial C}{\partial z}\right]$$
$$+ \frac{V_{ac}^2}{4}\frac{\partial^2 C}{\partial z^2}\cos 2\,\omega t \quad (2)$$

Three terms in Eq. (2) represent a dc component and first and second harmonics of the force gradient. In the absence of net polarization ($Q_s = 0$), the only oscillating signal that can be measured is the signal oscillating at 2ω. For electrically polarized samples ($Q_s \neq 0$), the first harmonic is nonzero and can be used to obtain information on the surface charge distribution. This method of domain imaging, which has been used by a number of groups [22–31], is sensitive to the charge only and allows determination of its sign by monitoring the phase of the first harmonic signal with a lock-in.

Figure 3 illustrates an application of this technique to domain imaging in a tetragonal Pb(Zr,Ti)O$_3$(PZT) film. Prior to the imaging, a small part of the film was polarized by scanning with a positively biased tip, and two lines were written across this area with a tip under a negative bias. The positively and negatively polarized domains appear as bright and dark areas in Figure 3, respectively, because of uncompensated polarization charges of newly switched domains. At the same time, this image illustrates one of the limitations of the EFM method, namely, an unwritten area shows only slight variation of the contrast, although it contains as-grown domains with polarization normal to the film surface, which was confirmed by another SFM method. Furthermore, the contrast of the written structure gradually fades and almost disappears within several hours. This behavior is due to the accumulation of surface charge on the film surface, which neutralizes polarization charges and causes a uniform contrast over the surface due to zero net charge. Therefore, although the EFM charge detection mode has the advantage of distinguishing between topographic features and the electrostatic signal, the domain contrast in this mode can easily be obscured. In addition, a surface contamination layer
Figure 3. EFM charge image of a PZT film. Bright and dark areas correspond to positively and negatively poled regions, respectively. The scanning area is $10 \times 10\ \mu m^2$. Image courtesy of H. Yokoyama, National Institute of Advanced Industrial Science and Technology, Japan.

always present on the sample surface under ambient conditions can change or even conceal the image of real domain structure. Conducting experiments in a vacuum or in an inert atmosphere can eliminate these detrimental effects and make possible detailed investigation of the spatial distribution of polarization charges and stray electric fields at ferroelectric surfaces. Another problem is that quantification of the EFM signal is problematic since the tip-sample capacitance is difficult to measure accurately.

3.2. Scanning Surface Potential Microscopy

A method closely related to EFM is the SSPM method of domain imaging based on detection of a surface potential associated with spontaneous polarization. In the presence of a surface potential, the electrostatic force acting on the tip depends on the tip-sample potential difference V_s:

$$F = \frac{1}{2}(V_t - V_s)^2 \frac{\partial C}{\partial z} + \frac{Q_s Q_t}{4\pi \varepsilon_0 z^2} \qquad (3)$$

The absolute value of the surface potential can be measured with the so-called nulling method [28]. In this approach, the probing tip is additionally biased by a dc voltage, so that $V_t = V_{dc} + V_{ac} \cos \omega t$. In the case of complete screening of polarization charges by adsorbed surface charges ($Q_s = 0$), the three components of the electrostatic force can be written as

$$F_{dc} = \frac{1}{2}\left((V_{dc} - V_s)^2 + \frac{1}{2}V_{ac}^2\right)\frac{\partial C}{\partial z} \qquad (4)$$

$$F_{1\omega} = (V_{dc} - V_s)V_{ac}\frac{\partial C}{\partial z} \cos \omega t \qquad (5)$$

$$F_{2\omega} = \frac{1}{4}V_{ac}^2\frac{\partial C}{\partial z} \cos 2\omega t \qquad (6)$$

The first harmonic of the electrostatic force is then nullified by adjusting the constant bias on the tip so that

$V_{dc} = V_s$. By detecting the nullifying V_{dc} value during scanning, a surface potential image can be obtained. This approach has been extensively used by Kalinin and Bonnell to study polarization screening processes in ferroelectrics [32–34]. Figure 4 shows schematic diagrams of domain structure, surface topography, and surface potential in a single crystal of barium titanate. Corrugated surface topography is an indication of a- and c-domain regions (with in-plane and out-of-plane spontaneous polarization, respectively). An SSPM image provides additional information on the domain structure: inverted potential contrast within the c-domain region indicates the presence of antiparallel c-domains. The low value of the surface potential change across the 180° domain boundaries (on the order of 150 mV) is due to almost complete screening of polarization by surface charges. The SSPM approach has also been used for nanometer detection of two-dimensional potential profiles at the semiconductor interfaces [35].

3.3. Scanning Capacitance Microscopy

Additional information on local electronic properties of ferroelectrics can be obtained by monitoring the second harmonic component of the electrostatic force signal. Since it is proportional to the capacitance gradient (Eq. (6)), this method is often referred to as scanning capacitance microscopy (SCM). This technique has been used to map carrier distribution in gate oxides and dopant profiles in nonuniformly doped semiconductors [36, 37]. In an original SCM setup, where the tip is held at some distance from the surface [8, 38], the constant capacitance contour contains information on the thickness of the sample, its dielectric constant, and charge carrier concentration underneath the tip. Alternatively, surface topography and capacitive force imaging can be obtained sequentially, that is, the capacitive force image can be obtained with the tip scanned at a predetermined distance from the surface following the previously measured topography profile. In this case, the measured capacitance signal includes information only on the dielectric constant and charge concentration.

In a more widely used SCM configuration, the probing tip is placed in direct contact with the sample surface, which allows independent recording of the surface topography. The tip-sample capacitance is measured by a capacitance sensor electrically connected to the cantilever. This approach has a very strong potential for charge storage and detection of trapped charge in semiconductor heterostructures [10, 39, 40]. Application of a variable dc bias to the probing tip results in the shift of the free carriers in a semiconductor and formation of the depletion or accumulation layer underneath the tip, which is equivalent to the capacitance change. A modulation ac voltage is used to detect the capacitance derivative $\partial C/\partial V$ as a function of the tip dc bias.

With respect to ferroelectrics, the SCM method can be considered as a complementary approach to SSPM in the sense that it allows estimation of the carrier concentration in the subsurface regions of ferroelectric samples and evaluation of effect of the free carriers on polarization screening. Figure 5 shows the SCM image of the SrBi$_2$Ta$_2$O$_9$ film acquired at a dc bias of -1 V. Prior to the imaging, a central part of the film was polarized by a positive voltage applied
to the tip. The observed contrast is due to the different effect of the imaging dc bias on a screening charge layer in oppositely poled regions. A higher concentration of the electrons in the positively poled area yields a smaller layer thickness and, therefore, larger capacitance, which leads to higher SCM contrast. Measurements of the $\partial C/\partial V$–V curves yield a voltage shift between oppositely poled regions:

$$\Delta V = P_{\mathrm{s}} \frac{\varepsilon_{\mathrm{i}} W + \varepsilon_{\mathrm{f}} d_{\mathrm{i}}}{\varepsilon_0 \varepsilon_{\mathrm{i}} \varepsilon_{\mathrm{f}}} \qquad (7)$$

where ε_{i} and ε_{f} are the dielectric constants of a surface dielectric layer and a ferroelectric sample, respectively, and d_{i} and W are the thicknesses of the dielectric layer and a depletion (accumulation) layer, respectively.

Still, quantitative interpretation of the SCM data is difficult since it requires an accurate account of the parameters of the dielectric layer and nonlocal cantilever contribution to the capacitance signal. One attractive possibility would be to use SCM and SSPM on cross-sectional samples of ferroelectric capacitors, which would allow characterization of the depletion layers in the vicinity of the film/electrode interfaces [37]. A likely problem of relatively low spatial resolution of SCM can be overcome by using a wedge-like sample, which was recently suggested by Lu et al. [41]. In this case, the depth profiling of the carrier concentration can be performed by changing the lateral position of the probing tip at the slope of the wedge sample.

4. CONTACT DOMAIN IMAGING

Contact domain imaging can be divided into static and dynamic, or voltage-modulated, methods (Table 2). Static imaging methods, such as a topographic mode of AFM and lateral force microscopy, make use of the surface domain-dependent properties of ferroelectrics, such as surface corrugations associated with the presence of different domains, difference in structure of polar faces of opposite domains, variations in friction forces, and so on. Dynamic methods, which include PFM and SNDM, are based on voltage modulation and detection of the electrical and mechanical responses of opposite ferroelectric domains to the applied ac voltage. The contact SFM imaging methods provide significant advantages, such as high lateral resolution (well below 10 nm), a possibility of the three-dimensional reconstruction of domain structure, and effective control of nanodomains. However, interpretation of the domain images

Figure 5. SCM image of the SrBi$_2$Ta$_2$O$_9$ film acquired at a dc bias of $+1$ V. Prior to the imaging a central part of the film was polarized by a positive voltage. The higher concentration of the electrons in the positively poled area yields a smaller depletion layer thickness and, therefore, a larger capacitive force. Image courtesy of Y. could be complicated by cross-talk between different mechanisms involved in the domain contrast formation.

4.1. Domain Imaging via Polarization-Dependent Friction

The first imaging of antiparallel domains via polarization-dependent friction was performed by Luthi et al. [13, 14]. With this approach, domain structure has been revealed on freshly cleaved surfaces of single crystals of GASH and TGS [17, 19, 42–44]. In most of the papers, the imaging mechanism is attributed to the permanent charging of the probing tip by a ferroelectric surface. Electrostatic tip-sample interaction causes an additional contribution to the lateral force acting on the tip and results in different torsion of the cantilever when the tip is scanning surfaces of opposite 180° domains. The lateral resolution has been reported to be less than 8 nm. The image contrast depends on the scanning direction and can be reversed by switching from forward to backward scan, which is an indication of the tribological effect rather than of the surface morphology (Fig. 6). A complementary mechanism of the domain contrast in LFM can be the difference in surface structure of opposite domains, which gives rise to different friction coefficients of the regions occupied by these domains [45, 46]. One of the greatest limitations of this method is that it is extremely sensitive to the surface conditions affecting sample tribological properties: adhesion layers, interfacial wetting, contamination, and roughness. As a result, its application is mainly limited to crystals with atomically flat surfaces of cleavage planes, such as GASH and TGS. On atomically flat terraces of the freshly cleaved surfaces, even small variations in the friction forces can easily be detected. However, even in these crystals, friction images exhibit a wide diversity and should be interpreted with caution. For example, because of the different orientation of molecules on the chemically homogeneous terraces making up the surface of individual domains, frictional contrast can occur not only between opposite domains, but also inside individual domains [46]. Long exposure to the ambient environment could lead to deterioration of surface quality and to degradation of the domain contrast.
Figure 6. Friction force micrograph of a GASH cleavage surface. An imbedded domain exhibits opposite contrast compared with the surroundings because of the difference in tip-surface friction forces. Scan direction: (a) left to right; (b) right to left.

4.2. Domain Imaging via Surface Topography

The conventional topography mode of SFM has been used for domain studies via investigation of the domain-related surface morphology of ferroelectrics. There are several mechanisms that can provide morphological contrast of ferroelectric domains: (1) topographic steps at domain boundaries due to the structural difference between positive and negative ends of domains [47]; (2) inclination of the *cleaved* surfaces according to the polarity of domains and the direction of cleavage propagation [47–49]; (3) surface corrugation at the junction of *a*- and *c*-domains in perovskite ferroelectrics [11, 17, 50–58].

Topographic steps several angstroms in height have been observed at the 180° domain boundaries on the cleaved surface of TGS crystals by Bluhm et al. [45] and Eng et al. [25, 59]. This effect was explained by the relative shift of atom positions in opposite domains. An additional factor, which can affect the surface topography and reveal domain structure, is the different etching behaviors of positive and negative domains. Selective etching with subsequent topographic imaging has been used to reveal nanoscale domains in $LiNbO_3$ crystals [29, 60]. For hydrophilic materials such as TGS and GASH, exposing a sample to a humid atmosphere can reveal domains due to selective surface etching by water vapor. Topographic imaging of the etched surface can be used for identification of domain polarity [15, 43, 45]. At the same time, this feature of TGS could be a complicating factor: fine morphological structures of ferroelectric domains on opposite cleavage faces of TGS vary strongly, even for domains of equal polarity. Etching of positive domains can result in both etch hole formation and recrystallization of islands from the saturated solution at the surface, depending on which molecular layer is exposed to ambient air after the cleavage. Etch patterns can easily be confused with domain structure.

Another mechanism, which can lead to domain topographic contrast, is surface corrugation at the 90° domain walls separating domains with in-plane polarization (*a*-domains) and out-of-plane polarization (*c*-domains). With this approach, *a-c*-domain structure has been observed in $BaTiO_3$ and $PbTiO_3$ crystals and PZT thin films [11, 51–58]. A difference between *a* and *c* lattice constants of the tetragonal cell produces a lattice distortion at the junction of *a*- and *c*-domains and surface inclination with a characteristic angle determined as $\theta = \pi/2 - 2\arctan(a/c)$ (Fig. 7). Domain structures consisting of alternating *a*- and *c*-domains arise to reduce elastic energy in mechanically strained ferroelectric samples, such as epitaxial thin films [61–65]. SFM can provide a simple and nondestructive method for studying domain patterns in epitaxial ferroelectric films by topographic imaging of their surfaces. Figure 7 shows a topographic image of a $Pb(Zr_{0.20},Ti_{0.80})O_3$ film deposited by laser ablation on a $LaAlO_3$ substrate. The *a-c*-domain arrangement appears as a rectangular structure with height variations in the range of 1.5–3.5 nm, occurring as a result of twinning between *a*- and *c*-domains. A value of surface tilting of approximately 2° was measured at the 90° domain boundaries, which is consistent with the *c/a* ratio of the unit cell of the film at room temperature. Considering
Figure 7. (a) Topographic image of a PZT film on a LaAlO$_3$ substrate showing a rectangular structure of a- and c-domains. (b) Lattice matching at the 90° domain wall through the formation of a strained unit cell. Twinning occurs on the (101) plane. Arrows indicate the polarization vectors [86]. Reprinted with permission from [86], A. Gruverman et al., *Integrated Ferroelectrics* 19, 49 (1998). © 1998, Gordon and Breach Science.

that the tetragonality of a PZT film with a Zr/Ti ratio of 20/80 is about 4%, the 90° domain wall should stand at an angle of 43° 44′ to the polar direction. The relative tilt between the surfaces of two adjacent a- and c-domains, therefore, will be 2° 32′, which fits fairly well with the value obtained from the SFM measurements.

There are obvious limitations to the applicability of the SFM topographic mode for domain imaging. Any treatment of the surface during sample preparation inevitably eliminates the fine structure of morphological steps associated with domain patterns. Therefore, only crystals with cleavage planes, like TGS and GASH, are suitable for SFM topographic studies. Also, since formation of 180° domain walls does not influence the surface topography, this method is not applicable for imaging of domain structure consisting of antiparallel c-domains, which is of direct interest for investigation of the polarization reversal processes in ferroelectrics. In some limited cases, the topographic mode can be used for visualization of opposite 180° domains via detection of the static piezoelectric sample deformation induced by an external dc bias [66], as will be discussed in one of the following sections.

4.3. Domain Imaging via Nonlinear Dielectric Response

Recently, Cho et al. have developed a pure electrical dynamic method of domain delineation [67–70]. This method, termed scanning nonlinear dielectric microscopy
Figure 8. (a) Probe configuration in SNDM, (b) a sketch, and (c) two-dimensional image of the 90° a-c-domain structure in a BaTiO$_3$ single crystal. Reprinted with permission from [68], Y. Cho et al., *Appl. Phys. Lett.* 75, 2833 (1999). © 1999, American Institute of Physics.

(SNDM), is based on the detection of the capacitance variation with an alternating electric field. To measure the capacitance variation, Cho et al. developed a special lumped constant resonator probe by using an electrolytically polished tungsten needle and a LC resonance circuit operating in the microwave frequency range. Application of the modulation voltage E (in the range of 100 Hz to 1000 Hz) across the sample leads to an oscillating change ΔC_s in the capacitance between the needle and the bottom electrode due to the nonlinear dielectric response of the sample with the first harmonic component proportional to the nonlinear dielectric constant ε_{333}:

$$\frac{\Delta C_s}{C_s} = \frac{\varepsilon_{333}}{\varepsilon_{33}} E \cos \omega t \qquad (8)$$

where C_s and ε_{33} are a static capacitance and a linear dielectric constant, respectively. The change in the capacitance is measured by detecting the modulated high-frequency signal (around 1.3 GHz) of the oscillator with a demodulator and a lock-in amplifier. The sign of an even rank tensor, such as the linear dielectric constant, does not depend on the polarization direction. On the other hand, the lowest order of the nonlinear dielectric constant ε_{333} is a third-rank tensor, similar to the piezoelectric constant, so the sign of ε_{333} changes with inversion of the spontaneous polarization. Therefore, a polarization map can be obtained by point-to-point detection of the field-induced changes in the nonlinear dielectric constant. This method, as it is designed, allows nanoscale detection of antiparallel 180° domains in the surface layer with a thickness much smaller than the probe size (<10 nm). According to [71], subnanometer lateral resolution can be obtained by detecting the higher order nonlinear dielectric constants. However, in this case the imaged region will become even shallower. Figure 8 shows a two-dimensional SNDM image of a-c-domain structure in single-crystal barium titanate. The sign of ε_{333} in the +c domain is negative, whereas it is positive in the −c domain. Furthermore, the magnitude of ε_{111} is zero in the a-domain. It is possible to measure ferroelectric polarization parallel to the sample surface by detecting ε_{311} constant with the use of different configuration of electrodes [70]. Therefore, three-dimensional domain structure can be determined by SNDM.

Since in SNDM the probing tip is in contact with the sample surface, nanoscale domain dots can be switched by applying a relatively low dc bias to the probe, which in combination with high spatial resolution can be used for ultrahigh-density data storage [69].

Closely related near-field scanning microwave techniques have been used for domain imaging and dielectric constant measurements in single crystals of LiNbO$_3$, BaTiO$_3$, and deuterated triglycine sulfate and thin films of Ba$_{0.6}$Sr$_{0.4}$TiO$_3$ [72–75]. However, the lateral resolution has been just below 1 μm because of the size of the inner probe of the resonator.

4.4. Domain Imaging via Static Piezoresponse

The next domain imaging method makes use of the piezoelectric properties of ferroelectrics and therefore is often referred to as piezoresponse. It is based on the detection of

local piezoelectric deformation of the ferroelectric sample induced by an external electric field. Since all ferroelectrics exhibit piezoelectric properties, application of an external voltage results in the deformation of a ferroelectric sample. Depending on the relative orientations of the applied field and the polarization vector, sample deformation can be in the form of elongation, contraction, or shear. For the converse piezoelectric effect, the field-induced strain S_j can be expressed as [76]

$$S_j = d_{ij}E_i \qquad (9)$$

where d_{ij} is the piezoelectric coefficient and E_i is the applied field.

On the other hand, with the thermodynamic approach it can be shown that the piezoelectric coefficient relates to the spontaneous polarization P_s via the following expression [77, 78]:

$$d_{ij} = \varepsilon_{im}Q_{jmk}P_{sk} \qquad (10)$$

where ε_{im} is the dielectric constant and Q_{jmk} is the electrostriction coefficient. For a single domain ferroelectric of tetragonal symmetry, the relation between the piezoelectric coefficients and the polarization in the reduced matrix notation can be written as

$$d_{33} = 2\varepsilon_{33}Q_{33}P_{s3} \qquad (11)$$

The longitudinal piezoelectric coefficient, d_{33}, represents an expansion or contraction of the sample along the polar direction when the applied field is parallel to it. The transverse piezoelectric coefficient, d_{31}, represents an expansion or contraction of the sample in the direction perpendicular to the applied field. The d_{15} coefficient describes shear deformation of the ferroelectric sample.

The linear coupling between the piezoelectric and ferroelectric constants implies that the domain polarity can be determined from the sign of the field-induced strain. This is illustrated in Figure 9, which shows a simple case of a ferroelectric sample consisting of two antiparallel c-domains. In the absence of the external field and under zero stress within the sample, the two domains have equal size in polar direction since spontaneous strain is proportional to the square of the polarization and under ideal conditions should be the same in antiparallel domains [50]. Application of the electric field along the polar direction results in the elongation of the domain with polarization parallel to the applied field and in the contraction of the domain with opposite polarization. The field-induced strain in this case can be
Figure 9. Deformation of c-domains as a result of the converse piezoelectric effect.

written as

$$S = \frac{\Delta L}{L} = \pm d_{33}E \qquad (12)$$

where ΔL is the sample deformation and L is the sample thickness. Equation (4) can be rewritten as

$$\Delta L = \pm d_{33}V \qquad (13)$$

where V is an applied voltage. The $\pm$ sign reflects the opposite piezoelectric coefficients for antiparallel domains. Therefore, opposite domains can be visualized by monitoring their voltage-induced surface displacement.

Because of its extremely high vertical sensitivity, nanoscale topography variations can be routinely measured in SFM. However, domain imaging based on detecting the static piezoelectric deformation is difficult to implement unless a sample has a very smooth surface. In a sample with an average surface roughness of several nanometers per square micrometer, the static cantilever deflection due to the piezoelectric deformation (typically on the order of several angstroms) will be superimposed on the much larger deflection signal due to the surface roughness, which will make domain imaging very problematical.

A seemingly obvious conclusion from Eq. (13) is that the contrast between opposite c-domains can be infinitely enhanced by increasing the imaging voltage. However, there is a strict limitation imposed on this parameter: to perform *nondestructive* visualization of domain structure, the imaging voltage should be kept below the coercive voltage of the ferroelectric sample. In addition, a high imaging voltage will lead to an increased contribution of the electrostatic signal to the tip-sample interaction, which in some cases can obscure the domain image. Given that a typical value of the coercive field in a 200-nm-thick $Pb(Zr,Ti)O_3$ ferroelectric film is approximately 50 kV/cm, the imaging voltage should not exceed 1 V, otherwise the imaging process will change the domain structure by inducing the polarization reversal. In a PZT film with the d_{33} constant of about 200 pm/V the surface displacement induced by an external voltage of 1 V will be only 0.2 nm. Obviously, such a displacement could not be reliably detected in ferroelectric films, where topographic features can be on the order of several nanometers. The static approach can be applied in some limited cases, for example, to ferroelectric samples with relatively high values of piezoelectric constants and coercive fields. Wang et al. [66] used this approach to delineate domains in a doped crystal of $Sr_{0.61}Ba_{0.39}Nb_2O_6$ (SBN), known for a high concentration of pinning centers, which gives rise to an increase in local coercive fields. Because of this feature of the SBN sample, even under an applied voltage of 200 V, there exist nonswitched c-domains antiparallel to the external field. At the same time, this voltage is high enough to produce a surface indentation of about 2 nm due to contraction and elongation of opposite domains (Fig. 10), which makes them discernible in the topographic mode. Another interesting observation reported in [66] includes the photostimulated nanoscale topographic changes due to the piezoelectric effect by an internal electric field.
Figure 10. Topographic images of a SBN crystal under normal external electric fields of (a) $E = 0$, and (b) $E = 200$ V/mm. Reprinted from [66], Y. G. Wang et al., *Phys. Rev. B* 61, 3333 (2000). © 2000, American Physical Society.

4.5. Domain Imaging via Dynamic Piezoresponse: Piezoresponse Force Microscopy

A problem of low sensitivity of a static piezoresponse mode can be circumvented by employing a dynamic piezoresponse imaging method based on the voltage-modulation approach, which increases sensitivity by three orders of magnitude. In this approach, known as piezoresponse force microscopy (PFM), an ac modulation (imaging) voltage $V = V_0 \cos \omega t$ is applied to the ferroelectric sample, and surface displacement is measured by a standard lock-in technique by detecting the vertical vibration of the cantilever, which follows sample surface oscillation. A domain map can be obtained by scanning the surface while detecting the first harmonic component of the normal surface vibration (vertical piezoresponse):

$$\Delta L = \Delta L_0 \cos(\omega t + \varphi) \tag{14}$$

where $\Delta L_0 = d_{33}V_0$ is a vibration amplitude and φ is a phase difference between the imaging voltage and piezoresponse, which provides information on the polarization direction. With the modulation voltage applied to the probing tip, positive domains (polarization vector oriented downward) will vibrate in phase with the applied voltage so that $\varphi(+) = 0°$, whereas vibration of negative domains (polarization vector oriented upward) will occur in counter-phase: $\varphi(-) = 180°$.

The SFM piezoresponse mode, after being developed for detection of polarized regions in ferroelectric copolymer films of vinylidene fluoride and trifluoroethylene [79], had been successfully applied for visualization of domain structure in PZT thin films and quickly became one of the most widely used methods for nanoscale characterization of ferroelectrics [80–82].

One of the significant advantages of the PFM method is that it also allows delineation of domains with polarization parallel to the sample surface (*a*-domains) [57, 83, 84]. In the lateral PFM approach, developed by Eng [83], *a*-domains are visualized by detecting the torsional vibration of the cantilever. Application of the modulation voltage across the sample generates sample vibration in the direction parallel to its surface due to the piezoelectric shear deformation (Fig. 11). This surface vibration, translated via
Figure 11. Deformation of *a*-domains as a result of the converse piezoelectric effect.

the friction forces to the torsional movement of the cantilever, can be detected in the same way as the normal cantilever oscillation in vertical PFM. The amplitude of the in-plane oscillation (lateral piezoresponse) is given by

$$\Delta X_0 = d_{15}V_0 \tag{15}$$

whereas the polarization direction can be determined from the phase signal since oscillation phases of opposite *a*-domains differ by 180°. It should be noted that Eq. (15) could be used only when the in-plane polarization vector is perpendicular to the physical axis of the cantilever. However, in the general case the in-plane polarization vector can be oriented arbitrarily with respect to the cantilever. Therefore, to obtain a complete picture of the in-plane distribution of polarization, X and Y components of the lateral piezoresponse image should be recorded by physically rotating the sample by 90°. Although quantitative analysis of the lateral piezoresponse signal is rather difficult because of the complexity of the friction mechanism involved, it can readily provide valuable information on in-plane distribution of polarization facilitating the three-dimensional reconstruction of the nanoscale domain arrangement [83].

Figure 12 presents experimental results on simultaneous acquisition of vertical and lateral piezoresponse images of a $SrBi_2Ta_2O_9$ film. A grain in the upper part of the image shows a strong vertical piezoresponse signal (dark contrast in Fig. 12b), whereas its contribution to the lateral piezoresponse signal is rather weak (gray contrast in Fig. 12c), suggesting predominantly out-of-plane orientation of the polarization vector. On the other hand, grains in the lower part of the image exhibit gray contrast in Figure 12b and black-white contrast in Figure 12c, which is an indication of the in-plane polarization.

The PFM experimental setup is shown in Figure 13. During PFM imaging the modulation frequency is usually kept far above the cutoff frequency of the SFM feedback to avoid
Figure 12. Topographic (a), normal piezoresponse (b), and lateral piezoresponse (c) images of the SBT film. A large grain in the upper part of the images has black contrast in (b) and gray contrast in (c), suggesting out-of-plane polarization. Grains in the lower part of the images exhibit gray contrast in (b) and black-white contrast in (c), which is an indication of the in-plane polarization. The scanning area is $1 \times 1 \ \mu m^2$. Figure 13. Experimental setup of piezoresponse force microscopy.

cross-talk between the static cantilever deflection due to the surface topographic features and modulated deflection due to the piezoelectric effect. With this setup it is possible to perform simultaneous acquisition of the piezoresponse and topographic images.

In terms of exciting the piezoelectric vibration of the sample, there are two main approaches in PFM. In one approach, the vibration is generated locally by applying a modulation voltage between the bottom electrode and the conductive SFM tip, which scans the bare surface of the film without a deposited top electrode. A great advantage of this approach is the possibility of establishing a correlation between domain configurations and film microstructure. In addition, this method can be used for nanoscale domain writing and direct investigation of domain wall interaction with microstructural features, such as defects and grain boundaries, for local spectroscopy measurements and investigation of electrical and mechanical coupling between adjacent grains. Furthermore, this approach offers extremely high resolution, potentially allowing investigation of the microscopic mechanism of the domain wall motion.

However, the electric field generated by the SFM tip in this configuration is highly inhomogeneous, which makes quantitative analysis of the field-dependent parameters difficult. This problem is exacerbated by the likely presence of a contamination layer at the film surface, which increases the resistance of the tip-sample electric contact. As a result, an increased time constant of the electric circuitry makes it difficult to extend the experiments on switching behavior to the micro- and nanosecond range, which is of direct application interest. In an alternative PFM approach, domain structure can be visualized through the top electrode of a ferroelectric capacitor. In this case the piezoelectric vibration is generated in a film region underneath the deposited top electrode, which is much larger than the tip-sample contact area. The modulation voltage can be applied either by using an external wire attached to the top electrode or, in the case of a micrometer-size electrode, directly through the conductive SFM tip. In both cases the piezoelectric displacement is probed locally by the SFM tip. In such a configuration, a homogeneous electric field is generated throughout the ferroelectric film, which allows quantitative treatment of domain wall dynamics and investigation of the polarization reversal mechanism in ferroelectric capacitors. Because of

the reduced time constant, fast pulse switching and transient current measurements can be accomplished in submicrometer capacitors, thus making PFM suitable for memory device testing. Combined PFM studies of the ferroelectric films and capacitors bring about complementary information and provide direct assessment of the effect of the electrical and mechanical boundary conditions on domain stability and polarization reversal.

5. APPLICABILITY OF SFM TO DOMAIN IMAGING

Versatility of SFM can provide critical information on the dielectric properties of ferroelectrics at the nanoscale. Each of the SFM-based methods of domain imaging has its own advantages and limitations. Noncontact methods (EFM, KPFM) are the most universal methods, which can be applied to all ferroelectrics; however, they are susceptible to screening effects and have low spatial resolution in air. Static imaging methods (AFM, LFM) have limited applicability because of the specific domain contrast mechanisms. The SNDM approach is characterized by high imaging resolution and universality but is technically challenging and, like most of the SFM methods, provides information on the surface properties of ferroelectrics. The PFM method is the only method based on analysis of bulk properties. Therefore, combined study of ferroelectric samples by various SFM methods seems to be the best way to obtain a complete picture of nanoscale properties of ferroelectrics. A summary of different SFM methods of domain imaging is presented in Table 3.

It is generally accepted that the PFM method is the most suitable technique for investigation of the domain structure in ferroelectric materials, particularly in thin films [85]. This view is based on several key features of PFM:

- **High lateral resolution in domain imaging.** In the PFM approach, the electromechanical response of the sample is detected locally by the probing tip, which is in contact with the sample surface. In this case, the lateral resolution is determined by the size of the tip-sample contact area, which is a function of the tip radius, the contact force, and the relative hardness of the tip and sample materials [86, 87]. It has been demonstrated that in typical PFM experimental conditions the 180° domains can be imaged with a resolution better than 10 nm [88, 89].
- **Easy implementation** of the PFM imaging method stems from the fact that it can yield data by analyzing samples in the ambient environment and without special sample preparation. In addition, PFM detects the modulated surface displacement due to the converse piezoelectric effect, which minimizes cross-talk between the piezoresponse and topographic signals. As a result, topographic features have a negligible effect on domain image.
- **Three-dimensional reconstruction of domain structure.** The PFM approach can be used to determine the orientation of out-of-plane and in-plane components of local polarization, which opens the possibility for three-dimensional reconstruction of the nanoscale domain structures [57, 83, 84, 90, 91].

Table 3.

Method	Imaging mechanism	Features	Materials studied
EFM, KPFM	Electrostatic tip-sample interaction	• Measures surface potential and charge distribution • Low resolution in air • Susceptible to screening effects	Films: PZT, SBT, Crystals: $PbTiO_3$, $BaTiO_3$, $LiNbO_3$, GASH, TGS
AFM	Static surface deformation	• High lateral resolution • Limited applicability	Films: PZT Crystals: $PbTiO_3$, $BaTiO_3$, GASH, TGS
LFM	Polarization dependent surface friction	• High lateral resolution • Sensitive to surface conditions • Limited applicability	Crystals: GASH, TGS
SNDM	Nonlinear dielectric response	• High resolution • Measures in-plane and out-of-plane polarization	Films: PZT Crystals: $BaTiO_3$, $LiTaO_3$, $LiNbO_3$
PFM	Piezoelectric effect	• High resolution • Measures in-plane and out-of-plane polarization and piezocoefficients • Detects domains through top electrodes	Films: PZT, SBT, $PbTiO_3$ Crystals: $PbTiO_3$, $BaTiO_3$, $LiTaO_3$, $LiNbO_3$, TGS, $Sr_{0.61}$ $Ba_{0.39}Nb_2O_6$

- **Effective manipulation and control of nanosize domains**. In PFM, a probing tip can be used not only for domain imaging but also for modification of the original domain structure by inducing local polarization reversal. Application of a voltage pulse to the probing tip generates a strong and sufficiently localized electric field, which makes possible writing of ferroelectric domains of nanoscale dimensions and their subsequent readout [80–82, 85, 92–95].
- **Nanoscale hysteresis loop measurements** can be accomplished by monitoring a piezoresponse signal as a function of a poling dc voltage. These measurements are closely related to investigation of the switching behavior and provide information on coercive voltage, switching time, and local polarization at the nanoscale level [81, 85, 96–102].
- **Insensitivity to charge screening effects.** Since PFM is based on detecting the bulk properties of the ferroelectrics, it is less susceptible to the effect of the surface charges. As such, PFM allows reproducible imaging of a true polarization distribution.
- **Possibility of domain imaging in capacitor structures.** PFM allows detection of the piezoelectric displacement of a ferroelectric layer through the top electrode, which is one of the most significant advantages of this method [103–109]. This allows one to circumvent the problems of inhomogeneous tip-generated field distribution and possible contribution of Maxwell stress to the piezoresponse signal [87, 110], which are the major drawbacks of the PFM approach when applied to the samples with a bare surface. Applicability of PFM to nanoscale characterization of capacitor structures is of direct application relevance since it can be used for testing of ferroelectric memory devices.

In spite of the apparent simplicity of the PFM method, quantification of the PFM data, particularly in the case of thin films, is nontrivial because of the complexity of the tip-sample interaction. Experimental conditions, such as driving voltage, frequency, loading force, cantilever force constant, tip apex radius, and ambient environment, as well as physical properties of the samples (thickness, dielectric constants, orientation, defect structure, crystallinity, electrode material), should be taken into account to avoid misinterpretation of the PFM results [87]. Despite this difficulty, PFM has become one of the main tools for high-resolution characterization of ferroelectric crystals and thin films. PFM can provide crucial information on the correlation between domain configurations and microstructural features, basic mechanisms of polarization reversal, the scaling effect, and the intrinsic variability of properties at the nanoscale. One of the examples of the recent breakthrough results made possible because of PFM is characterization of the switching behavior of 0.04 μm^2 ferroelectric capacitors [111].

6. SFM OF FERROELECTRICS

Application of SFM to ferroelectric materials opened new possibilities for their characterization, control of ferroelectric properties at the nanoscale, and fabrication of regular nanodomain patterns for use in functional devices.

6.1. Characterization

Ferroelectric thin films are currently attracting significant interest because of the recent achievements in their integration into nonvolatile random access memory devices characterized by high-speed access, low power consumption, almost unlimited endurance, and extreme radiation hardness [112]. However, for ferroelectric memories to become high-volume, mainstream devices competitive with other types of nonvolatile memories, two major requirements must be fulfilled. The first is the ability to manufacture at high device density in the gigabit range, where the constituent ferroelectric capacitors are reduced to submicrometer dimensions. The second is the necessity to ensure that ferroelectric memory devices of these dimensions can achieve the necessary performance, reliability, and lifetime requirements. These two requirements demand intensive studies of ferroelectric films to achieve a major breakthrough in understanding their nanoscale properties. For high-density memories, the

ferroelectric capacitor must be scaled to area and thickness dimensions, which may approach the stability limits for the ferroelectric phase. In addition, the intrinsic capacitor-to-capacitor variability becomes an issue as the number of grains per capacitor becomes small. Despite significant progress in the development of ferroelectric films and devices over the last several years, there remains a great deal that is not known regarding the domain structure of thin films and its role in determining device switching speed and lifetime. The major limitation in acquiring this crucial information has been the lack of experimental methods to characterize ferroelectric switching behavior at the microscopic level. Most of such experiments have been performed by destructive methods, such as transmission electron microscopy.

In this respect, SFM has a significant advantage over other high-resolution techniques, as it provides the possibility of direct nondestructive high-resolution characterization of ferroelectric materials at the nanoscale level. Over the last 10 years SFM has proved to be an indispensable tool capable of dielectric, surface potentiometric, and electromechanical characterization of ferroelectrics at the micro- and nanoscale levels. Application of SFM has rendered direct information on local surface potential and charge distribution, nanoscale domain arrangement, and domain kinetics during phase transition [17, 23, 32, 34, 43, 54, 113]. SFM has been successfully applied to high-resolution studies of static and dynamic properties of domains in ferroelectric thin films and capacitors [80–111]. Recent achievements facilitated by the SFM approach include manipulation of domains as small as 20 nm in diameter [69, 85], direct study of domain nucleation and growth during polarization reversal [104], investigation of the mechanisms of polarization decay and ferroelectric fatigue at the subgrain level [82, 88, 94, 97], evaluation of the switching behavior of individual nanocapacitors via hysteresis loop measurements [105–110], and investigation of the dielectric breakdown mechanism [114]. Figure 14 illustrates several examples of SFM capabilities in the nanoscale characterization of ferroelectrics. These results demonstrate that SFM is well positioned to become a major characterization and testing tool for ferroelectric devices. Nanoscale SFM characterization in combination with phenomenological theory for ferroelectric films will lead to better understanding of their basic properties and significant improvement in the performance of nanoscale ferroelectric devices.

6.2. Control

SFM provides a unique opportunity for controlling ferroelectric properties at the nanoscale and direct studies of the domain structure evolution under an external electric field, which cannot be matched by previously available techniques. A conductive probing tip can be used not only for domain visualization but also for modification of the initial domain structure. Application of a small dc voltage between the tip and bottom electrode generates an electric field of several hundred kilovolts per centimeter, which is higher than the coercive voltage of most ferroelectrics, thus inducing local polarization reversal.

(3) Measurement of local (within 20-nm size region) coercive voltage and piezoelectric coefficient. Reprinted with permission from [85]. (4) Measurement of current-voltage characteristics of a micrometer-size ferroelectric capacitor. Reprinted with permission from [114].

When an electric field is applied opposite to the polarization direction of a single-domain ferroelectric, the switching mechanism involves several steps [115]. First, new domains with the reverse polarization direction nucleate, mainly at the surface, and then grow through the sample thickness (forward growth). Second, the grown domains expand sideways as new domains continue to form. Finally, the growing domains coalesce to complete the polarization reversal of a ferroelectric. The contribution of the forward and sideways growth mechanisms is a function of the applied field and the electrodes and to a large extent determines the switching time. Until recently, observation of domain dynamics during switching in thin films has not been performed because of the absence of an appropriate experimental technique. It has become possible with the help of the PFM method. This approach allows direct studies of the mechanism of polarization reversal and measurements of the key parameters of domain dynamics, such as nucleation rate, domain wall velocity, spatial distribution of nucleation sites, etc.

However, a poor time resolution, which is determined by the time required for image acquisition (at a scan rate of 2 Hz and an image resolution of 256×256 pixels, it takes about 2 min to acquire an image), makes the *in-situ* measurements of domain dynamics during fast switching processes difficult. Although SFM can readily be used to investigate slow polarization relaxation processes with characteristic times on the order of minutes and above, it is a challenge to deduce the mechanism of domain transformation when polarization reversal occurs in a matter of microseconds and faster.

This problem is usually circumvented by studying of domain structure dynamics in a quasi-static regime using *step-by-step switching*. This method has previously been used at the macroscopic level in classical switching experiments on correlating domain structure evolution and transient current in ferroelectric crystals [115] and later was applied to thin films [116, 117]. In this approach, partial reversal of polarization is generated by applying a voltage pulse shorter than the total switching time with subsequent piezoresponse imaging of the resulting domain pattern. By applying a sequence of voltage pulses of successively increasing duration and acquiring piezoresponse images after each pulse, a consistent picture of time-dependent behavior of domain structure can be obtained, providing information on the domain wall velocity, its spatial anisotropy, and its field dependence. To avoid data misinterpretation due to spontaneous backswitching between the pulses, stability of the produced intermediate patterns should be checked by acquiring domain images at different time intervals after single pulse application.

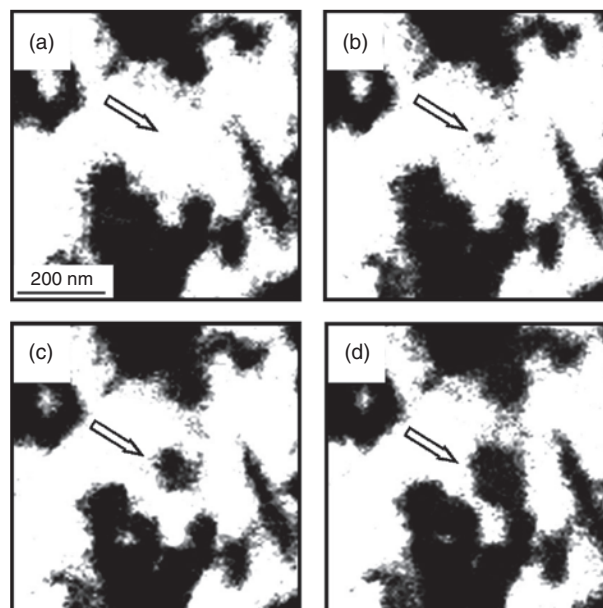
An example of this approach is illustrated in Figure 15, which shows a sequence of piezoresponse images of a growing domain in the PZT film. Based on the contrast of the domain, it is assumed that it fully extended through the film thickness after the first pulse and further growth occurs via the sideways expansion only. The diameter of the smallest stable domain produced by the first voltage pulse of 5 V varied from 20 nm to 40 nm. Since the electric field generated by a probing tip quickly decreases with distance, the rate of domain growth, after fast initial expansion, declines until the domain stops growing. To describe the sideways expansion


Figure 15. Sequence of PFM images of PZT film showing a sideways growth of a domain in the center of the image. The growth is induced by application of 5-V voltage pulses of increasing duration to the same spot by a fixed probing tip. (a) Original domain structure. (b–d) Domain images after application of voltage pulses. Pulse duration: (b) 0.25 s, (c) 0.5 s, (d) 1 s.

of the domain it is necessary to take into account the field dependence of the domain wall velocity and the spatial distribution of the electric field generated by the probing tip [118].

6.3. Fabrication

SFM capability of domain control creates a possibility of developing ferroelectrics with specifically designed nanoscale domain patterns, which can find application in novel electronic devices. For example, Hidaka et al. [81] and Cho et al. [69] proposed to use SFM as a basis for high-density data storage with a ferroelectric layer as a recording medium and nanoscale domains as data bits. Recently, a pioneering work by Kalinin et al. [119] has demonstrated the feasibility of practical application of ordered domain structures for the fabrication of nanostructures. Manipulation of polarization of ferroelectric substrates in SFM opens a new way to assemble nanostructures consisting of oxide substrates, metal nanoparticles, and organic/biological molecules. The idea of using ferroelectric templates for nanofabrication is based on utilizing the local surface electronic properties and surface chemical reactivity, which can be controlled by switching the direction of spontaneous polarization. On the surface of a ferroelectric, an abrupt change in the normal component of the spontaneous polarization results in bound polarization charges and in the appearance of a depolarizing field [120]. Energy consideration requires that this field must vanish outside the ferroelectric, that is, it must be compensated for. In a ferroelectric capacitor, this field can be completely compensated (screened) by the charges on the electrodes.
Figure 16. SFM-generated nanoscale domain patterns in (a) $BaTiO_3$, (b) $Sr_{0.61}Ba_{0.39}Nb_2O_6$ (Reprinted with permission from [122], K. Terabe et al., *Appl. Phys. Lett.* 81, 2044 (2002). © 2002, American Institute of Physics), and (c) $RbTiOAsO_4$ single crystal. (Reprinted with permission from [121], G. Rosenman et al., *Appl. Phys. Lett.* 82, 103 (2003). © 2003, American Institute of Physics.

In addition, screening by charge absorption at the surface can be accompanied by accumulation of the free carriers in the ferroelectric sample just near its surface. Surface potential, determined by the relative contribution of the external (surface charges) and internal (nonequilibrium carriers) screening mechanisms, is a crucial parameter for assembling molecular structures. Therefore, investigation of the interface properties and the deconvolution of the external and internal screening in ferroelectrics is critical for developing new nanofabrication methods using domain patterned ferroelectric templates.

Several groups reported generation of regular domain patterns with nanoscale periodicity by SFM [42, 69, 81, 117, 121, 122]. Nanodomain patterns can be successfully fabricated not only in thin films but also in bulk crystals, in spite of the fact that the tip-generated electric field quickly decreases with distance to the bulk of the sample [58, 121]. Examples of SFM-fabricated nanodomain patterns in $BaTiO_3$, $Sr_{0.61}Ba_{0.39}Nb_2O_6$, and $RbTiOAsO_4$ single crystals are shown in Figure 16.

For successful application of this domain-based approach to fabrication of novel electronic devices, several key issues related to the scale of domain engineering should be addressed.

First, reproducibility of high-resolution domain writing is necessary for the fabrication of reliable, large-scale ferroelectric templates. This requirement critically depends on the uniformity of the properties of the ferroelectrics at the nanoscale. This problem can be addressed based on statistical analysis of the PFM data of written domains in thin films [98, 123]. With this approach the effect of grain size and orientation on spatial homogeneity and reproducibility of the domain writing in thin films has been determined. The same approach can be used for bulk crystals and thin films to investigate the statistical variations in domain sizes as a function of the microstructure of the samples, their dielectric properties, and domain writing conditions.

Second to be considered is the AFM domain writing resolution, that is, the ability to scale the size of the written

domains below 50 nm. There are a number of factors affecting a process of polarization reversal in SFM: microstructure, interface electrical and mechanical conditions, spatial distribution of an SFM-generated electric field, etc. The role of these factors can be different for different types of materials and samples. For example, the domain writing conditions in single crystals and thin films will be quite different.

Third, long-term stability of the written domain patterns is a key requirement necessary for the fabrication of large-scale nanodomain patterns. This problem is closely related to the problem of thermodynamic stability of the ferroelectric phase at the nanoscale. One of the most important factors affecting domain stability is the screening of spontaneous polarization. EFM and SSPM studies can provide an insight into the process of polarization screening at the nanoscale and will open a way for local stabilization (and destabilization when necessary) of the domain patterns. This combined approach allows quantitative examination of screening processes as a function of time, type of interface, template microstructure, and ambient environment. Preliminary studies showed that domains as small as 20 nm in diameter could be written and detected by SFM [69]. In addition, it has been found recently that ferroelectric films as thin as 1.6 nm (two unit cells) still exhibit ferroelectric behavior [124]. SFM studies of domains of these dimensions can contribute to better understanding of the size effects and stability issues in ferroelectrics.

Fourth, and probably the most serious problem for the use of SFM in nanodomain fabrication, is throughput [125], which is limited by the tip scanning rate: whereas the write speed in ferroelectrics can be in the nanosecond range, the typical scanning speed of most scanning probe microscopes is in the range of tens of micrometers per second. The likely solution of this problem lies in the use of massive parallelism, as has recently been demonstrated by the IBM Millipede concept [126]. High data rates have been achieved through the use of large (32×32) two-dimensional arrays of SFM probes, which operate simultaneously.

7. CONCLUSIONS

Rapid development of ferroelectric-based devices generated a strong need for extensive investigation of the nanoscale properties of ferroelectric materials. Application of SFM to ferroelectrics opened new possibilities not only for their high-resolution characterization, but also for control of ferroelectric properties at the nanoscale and for fabrication of nanodomain patterns for use in functional devices. This paper presented a review of the recent advances in nanoscale investigation of ferroelectrics by means of SFM. Applicability of different SFM modes to domain imaging and mechanisms of domain contrast has been discussed. Comparative analysis of SFM-based imaging methods and problems that can be addressed by SFM has been presented. SFM has made a decisive contribution to solving such problems as investigation of the basic mechanism of polarization reversal in ferroelectric thin films, three-dimensional reconstruction of domain structure in ferroelectric films at the subgrain level, establishing a correlation between domain configurations and film microstructure, and mechanisms of

degradation effects. Future trends in the characterization of ferroelectrics and in the fabrication of ferroelectric-based functional nanostructures have been discussed.

GLOSSARY

Ferroelectric Crystalline dielectric possessing spontaneous polarization the direction of which can be reversed by application of an electric field.

Ferroelectric domains Regions of uniform polarization in a ferroelectric.

Piezoelectricity Property of a crystal to exhibit electric polarity when subject to mechanical stress (direct piezoelectric effect) or mechanical deformation upon application of an electrical field (converse piezoelectric effect).

CONTENTS

1. INTRODUCTION

1.1. Basic Concepts

1.1.1. Ferroelectrics

A ferroelectric is a solid that exhibits a *spontaneous* dielectric polarization, P_S (when $T < T_C$, the Curie temperature), that can be *reversed* by the external application of an electric field, E. The spontaneous (remanent) polarization at $E = 0$ can have one of two values, $\pm|P_R|$, depending on the sign of E just before it was switched off. We define these quantities with respect to the dielectric hysteresis curve (Fig. 1). The spontaneous polarization is defined as the dipole moment per unit volume and its axis is usually a high symmetry direction of the crystal structure. Of the 20 noncentrosymmetric, piezoelectric crystal classes, only 10 (those with C_n, C_{nv}, and C_{1h} point symmetries) have a unique, "polar" axis because their primitive cell has a nonzero dipole moment. These are the 10 pyroelectric crystal classes. A crystal belonging to any of these classes *may* show ferroelectricity provided the polarization is reversible. The usual signatures of a ferroelectric system are: (a) a peak in the temperature dependence of the low frequency dielectric response function (ε) at $T \approx T_C$, and (b) a hysteresis in the P–E curve for $T < T_C$. In most ferroelectrics, the temperature dependence of ε_0 above the Curie point (i.e., in the paraelectric phase) can be described fairly accurately by the Curie–Weiss law,

$$\varepsilon = \varepsilon_0 + C/(T - T_0) \qquad \text{for } T > T_0 \qquad (1)$$

where C is the Curie–Weiss constant and T_0 is the Curie–Weiss temperature. In general, a spatially coherent alignment of electric dipoles occurs only in limited regions ("domains") of the crystal, such that a ferroelectric crystal normally has a polydomain structure reminiscent of a ferromagnet. However, such domains may be switched in the same direction ("poled") by the application of a suitable external field. In an antiferroelectric, on the other hand, the ground state consists of an antiparallelly ordered array of local dipoles, which results in the net polarization being zero.

The paraelectric to ferroelectric phase transition may be of the second order ($P_S \to 0$ continuously as $T \to T_C$, although $\mathrm{d}P_S/\mathrm{d}T$ is discontinuous) or of the first order, in which case P_S has a discontinuity at T_C. Similar continuous or discontinuous behaviors are also exhibited by ε in the two cases. Conventionally, a ferroelectric is termed "displacive" when the elementary dipoles strictly vanish in the paraelectric phase, and "order–disorder" when these dipoles are nonvanishing but thermally average out to zero in the paraelectric phase. In a displacive transition, the displacements of the atoms in the low-temperature ferroelectric phase from their corresponding positions in the high-temperature paraelectric phase are small compared to the internuclear distances. Just below T_C such displacements can indeed be infinitesimally small in the case of a second order displacive phase transition. However, in an order–disorder transition, the displacements across T_C are comparable to the internuclear distances. Though it is often possible to rigorously distinguish between the two types of systems on the basis of the dynamics of their phase transition and the nature of the soft mode involved (whether propagating or diffusive), it is difficult to classify certain ferroelectrics and antiferroelectrics strictly as "displacive" or "order–disorder." The basic physics and phenomenological aspects of ferroelectricity are covered by a number of excellent textbooks [1–4]. Some of the more common ferroelectrics and antiferroelectrics (out of more than a thousand known ones) are listed in Table 1.
Figure 1. The dielectric hysteresis curve (polarization vs applied electric field) for a typical ferroelectric.

1.1.2. Size Effects in Ferroelectrics

The study of finite size effects in ferroelectric nanoparticles and thin films is an important contemporary problem. Though ferroelectric materials (which are also, by definition, piezoelectric) have been widely used as bulk capacitors and transducers, there are a number of interesting current and futuristic applications that involve these materials in microscopic form. These include sensors of various types and nanorobotic and microelectromechanical devices. In addition, interest in ferroelectrics is growing rapidly because its high dielectric constant can be utilized in dynamic random access memories (D-RAM), while its capacity for being polarized in opposite directions makes it an attractive candidate for nonvolatile random access memories (NV-RAM) and electrically erasable programmable read-only memories

Table 1. List of some common ferroelectrics (F) and antiferroelectrics (A).

Chemical formula	Structural family	F/A	T_C (°C)
$BaTiO_3$	perovskite	F	120, 5, −90
$PbTiO_3$	perovskite	F	490

(EEPROM). An important motivation for the study of size effects in ferroelectrics is to determine the ultimate level to which a device based on such systems can be miniaturized, since certain properties may get degraded while others are enhanced with a decrease in the characteristic size of the ferroelectric element. From the point of view of basic physics, it is no less interesting to investigate model ferroelectric systems in which the particle size is smaller than the correlation length corresponding to the long range dipolar ordering. For example, the existence of the superparaelectric state (analogous to superparamagnetism in magnetic fine particles) in nanocrystalline ferroelectrics is yet to be established unambiguously.

1.1.3. Experimental Aspects

It is pertinent to make a few brief comments about the experimental techniques involved in these studies. Other than direct observations using electron microscopes and atomic force microscopes, the most popular method for characterizing the particle size is based on X-ray diffraction (XRD) line broadening. Assuming that the small crystallite size is the only cause of line broadening, the coherently diffracting domain size (d_{XRD}) can be related to the full width at half maximum (FWHM) of a particular diffraction peak by the Scherrer equation: $d_{XRD} = K\lambda/\beta(\theta)\cos\theta$, where λ is the X-ray wavelength, $\beta(\theta)$ is the instrument-corrected FWHM of the diffraction line, θ is the diffraction angle, and $K \approx 1$ for equiaxed particles. Different aspects of ferroelectric phenomena are governed by different length scales, such as particle size, grain size, ferroelectric domain size, film thickness, and the lateral dimensions of the relevant devices. The important "intrinsic" length scales are the ferroelectric correlation length and the electron mean free path.

The important characteristics of a ferroelectric material are manifested mainly through its dielectric, piezoelectric, pyroelectric, acoustic, optical, electro-optic, and nonlinear optic properties, and a reduction in the crystallite size may affect many of these. Clearly, the ferroelectric T_C of a system may be measured by studying the temperature dependence of any one of a number of properties, such as the dielectric response, tetragonal distortion, mode softening, etc., though there are subtle differences in the information obtained from these distinct properties. It is, therefore, possible for the nature of the "size effect" to actually depend on the method used to observe it. Thus, structural measurements may show that a ferroelectric system has become pseudo-cubic at a particular critical size, while vibrational spectra may still show evidence for a low symmetry structure.

1.2. Ferroelectricity in Perovskites

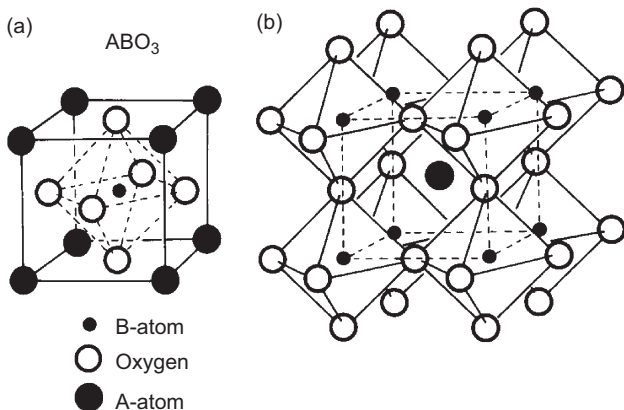
Most of the technologically important ferroelectrics and antiferroelectrics are oxides that possess the well-known perovskite structure. These include $BaTiO_3$, $PbTiO_3$, $PbZrO_3$, $KNbO_3$, and mixed oxides such as $Pb(Zr_{1-x}Ti_x)O_3$ and $(Pb_{1-y}La_y)(Zr_{1-x}Ti_x)O_3$. Since much of the work on finite sized ferroelectrics also relates to this class of compounds, we briefly recapitulate the mechanism of ferroelectric ordering in them. Most perovskites are oxide ceramics with the

general formula ABO_3. In their cubic unit cell, the cube corners are occupied by the "A" cations, which may be monovalent (e.g., K^+, Na^+, Ag^+) or bivalent (e.g., Ba^{2+}, Sr^{2+}, Pb^{2+}, Ca^{2+}, Cd^{2+}), while the body center is occupied by the smaller B cations, which are pentavalent (e.g., Nb^{5+} or Ta^{5+}) or tetravalent (e.g., Ti^{4+} or Zr^{4+}). The O^{2-} ions are situated at the face centers (Figure 2a). The perovskite lattice is basically a three-dimensional network of BO_6 octahedra, as shown in Figure 2b. The phenomenon of ferroelectricity is controlled by a delicate interplay between the long-range Coulomb forces that favor the ferroelectrically ordered state and short-range repulsive forces that favor the paraelectric state.

The cubic perovskite structure shown in Figure 2a actually represents the high-temperature ($T > T_C$), high-symmetry (cubic) paraelectric phase. It is the off-centering of the B cation in the oxygen octahedron that leads—through a lowering of the symmetry—to the creation of a local dipole moment, and ultimately to ferroelectric or antiferroelectric ordering. The structural distortion from the high-symmetry (paraelectric) phase is therefore of fundamental importance to the stabilization of ferroelectric order in this class of systems. This concept is central to the understanding of finite size effects in displacive ferroelectrics.

In the case of second order transitions of the displacive type, or of relatively "gentle" first order transitions, the static displacements involved in the transition from the high symmetry to the low symmetry structure are similar to the lattice vibrational amplitudes. The link between lattice dynamics and ferroelectricity is the Lyddane–Sachs–Teller equation:

$$\frac{\varepsilon(0)}{\varepsilon(\infty)} = \prod_i \frac{[\omega_{LO}(\vec{k}=0)]_i^2}{[\omega_{TO}(\vec{k}=0)]_i^2} \tag{2}$$

Here $\varepsilon(0)$ and $\varepsilon(\infty)$ are the static and optical dielectric constants, respectively, while ω_{LO} and ω_{TO} are the longitudinal and transverse optical modes, the product being over all optic branches. If any one of the TO modes (the "soft mode") exhibits an anomalous temperature dependence of the type $\omega_{TO}^2 = K(T - T_0)$, a behavior that is experimentally verified, then $\varepsilon(0)$ would diverge as $T \to T_0$, as expected across the ferroelectric transition.


The nature of the soft mode can be visualized rather simply in the case of a typical perovskite (ABO_3) compound. The allowed normal modes of vibration (optical modes) are shown in Figure 3. The first three modes are infrared active (i.e., they involve an oscillating dipole moment) while the fourth is "silent" (i.e., neither infrared nor Raman active). Generally, the lowest frequency TO mode is the soft mode (Fig. 3a). As $T \to T_0$, the frequency of only this mode decreases continuously and at T_0, the restoring force for this mode vanishes due to a cancellation of the long-range (dipole) attractive forces and the short-range repulsive forces. The structure of the low-symmetry phase ($T < T_0$) is determined by the frozen-in soft mode displacements. Referring to Figure 3a, it is clear (since the mode-softening takes place at $k \approx 0$) that a dipole moment would be produced along the z-direction in all the unit cells. Further, the lattice would undergo a *tetragonal distortion*, getting slightly elongated in the direction of the dipole moment and contracted perpendicular to it.

1.3. Size Effects in Ferroelectrics: A Historical Perspective

Though nanoparticle physics, in general, picked up momentum only in the 1980s, research on finite size effects in ferroelectric materials started surprisingly early (in the early 1950s) by Jaccard and co-workers. The first systematic study [5] involved potassium dihydrogen phosphate, KH_2PO_4 (KDP), which is a rather complicated system in that it has characteristics of both displacive and order–disorder mechanisms. In this study of KDP fine particles embedded in an insulating medium with a low dielectric constant, it was found that the spontaneous polarization (which can be considered as the order parameter in ferroelectric

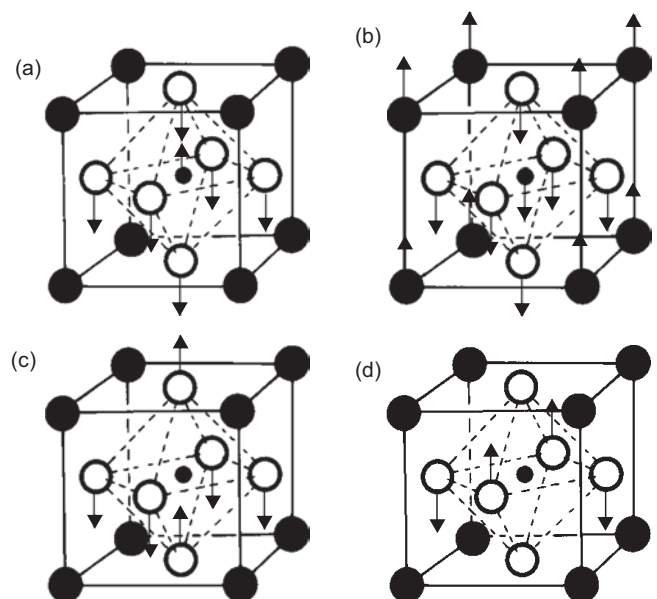
Figure 2. (a) A unit cell of the cubic perovskite (ABO_3) structure, (b) The cubic perovskite lattice consisting of a three-dimensional network of BO_6 octahedra.


Figure 3. The atomic displacements in the perovskite unit cell (see Fig. 2) for the four normal optical modes of vibration. Though only the vibrations along the z-direction are shown, each of these modes is actually triply degenerate.

systems) was hindered when the particle size was less than 150 nm. Below a critical particle size that depends upon the embedding medium, the depolarization field was thought to prevent polar, ferroelectric structures. Bulk ferroelectric behavior was exhibited only when the particle size was above 0.5 μm.

A contrasting result was obtained in $BaTiO_3$, in which the paraelectric phase (with a cubic perovskite structure) undergoes a tetragonal distortion of about 1% below $T_C \approx 125$ °C to a polar phase. Ball milled fine particles of $BaTiO_3$ in the size range of 0.03–2.3 μm showed a small *increase* in the T_C and a smearing of the transition with decreasing particle size [6, 7]. No critical size (for the destabilization of ferroelectricity) was observed in this size range. The authors concluded from their electron diffraction studies that the deviation from normal ferroelectric behavior was due to the existence of a 10–15 nm thick surface layer that was under a higher tetragonal strain than the bulk and had a *higher* T_C. This layer appeared to remain ferroelectric up to a few hundred degrees higher than the bulk T_C. They suggested that the misfit between the surface layer and the interior caused the broadening of the transition region and the lattice distortions.

The inconsistencies in the early results can be ascribed to the fact that some of the samples were prepared by mechanical grinding, in which case the observations often did not reflect intrinsic size effects but were influenced by residual surface stresses, inhomogeneities, and imperfect crystallization. In spite of such problems, Jaccard et al. were able to make the key observation that the spontaneous tetragonal strain (c/a) in the ferroelectric phase decreases with decreasing particle size.

During the 1960s and 1970s there was considerable progress in the study of grain size effects in ferroelectric *ceramics* or sintered compacts. Such systems, and the results pertaining to them, differ in certain essential aspects from the quasi-free nanoparticles—which would appear to be more suitable for the study of "intrinsic" size effects. However, since ferroelectric ceramics are technologically important, one cannot ignore the possibility of enhancing some of their properties by controlling the size of the polycrystalline grains. The salient observations on ceramic samples of $(Pb_{1-y}La_y)(Zr_{1-x}Ti_x)O_3$ or PLZT [8], $Pb(Zr_{1-x}Ti_x)O_3$ or PZT [9], and other systems can be summarized as follows. With a decrease in the grain size—generally in the 1–5 μm range—(i) there is a decrease in the peak dielectric constant ε_{max}, (ii) the peak of the dielectric response near T_C becomes broader, and (iii) the ferroelectric T_C goes up. According to Martrena and Burfoot [9], these observations can be explained in terms of an intergranular effect (involving the size dependence of the domain wall mobility) and an intragranular effect, where each grain is assumed to be a monodomain and one considers the effect of different-sized grains having different values of T_C. The dielectric response of the system was simulated using a distribution model [10], which assumes that the T_C for different grains obeys a Gaussian distribution. Below each individual T_C, the grains are assumed to have a constant dielectric constant, while the Curie–Weiss law is obeyed above T_C.

Martrena and Burfoot also made use of the concept of a diffuse phase transition (DPT). They considered the crystal or ceramic to consist of many noninteracting microregions that can independently switch from a ferroelectric to a paraelectric state. Several physical situations that could result in a DPT were proposed. In the case of solid solutions such as PZT and PLZT, microscopic variations in the local chemical composition could give rise to a T_C distribution and hence a DPT. The DPT effectively leads to a Curie *region* rather than the conventional Curie *peak*. We will later introduce a physical situation that can lead to a DPT even in *pure* compounds where there is no compositional variation.

2. SIZE EFFECTS IN PEROVSKITE FERROELECTRICS

During the period described, the study of ferroelectric fine particles was mainly an academic exercise, except in the technologically important case of piezoelectric ceramics. After a period of relative inactivity (1975–1987), there was a rather sudden renewal of interest in ferroelectric nanomaterials due to a revival of the idea of a ferroelectric memory device. The possible applications of ferroelectrics and piezoelectrics as microelectromechanical devices, sensors, etc. also provided a strong motivation for a spurt in both theoretical as well as experimental activities in this area. By this time a lot of progress had been made in the development and improvement of synthesis techniques for nanomaterials. These included wet chemical techniques such as sol–gel, co-precipitation, spray-pyrolysis, and microemulsion-mediated reactions (Section 8), and physical vapor deposition techniques such as sputtering, evaporation–condensation, and laser ablation (Section 9). This made it possible to study different compounds in the form of phase-pure, ultrafine particles with a relatively narrow size distribution, as also high-quality ultrathin films on desired substrates.

2.1. $BaTiO_3$

Barium titanate has a cubic perovskite structure in its high-symmetry, paraelectric phase (above $T_C \approx 125$ °C). With a decrease in the temperature, it transforms successively to three structurally distinct ferroelectric phases: a tetragonal phase ($T_C < T < 5$ °C), an orthorhombic phase (5 °C $< T < -90$ °C), and a rhombohedral phase ($T < -90$ °C). All three transitions are of the first order.

Early measurements involved sintered samples with grain size in the submicrometer to few micrometer range and relatively broad size distributions. In samples with grain size in the 1–50 μm range, the dielectric function (ε) was found to depend strongly on size in the ferroelectric phase but not so in the paraelectric phase [11]. The strong dependence of ε on the grain size was explained from the observation that the width of the 90° domains is proportional to the square root of the grain diameter and assuming that the value of ε is determined mainly by the 90° domain walls [12]. In the absence of ferroelectric domains above T_C, the value of ε in the high temperature phase is almost size-independent. For sintered (but not hot-pressed) samples with 20 μm $< d < 0.2$ μm, the tetragonal to orthorhombic transition is relatively insensitive to the particle size, d [13]. There is, however, an increase in the thermal hysteresis with a decrease in d, indicating that the latent heat of

transition is strongly size-dependent. Uchino et al. [14] studied the variation of the tetragonal distortion (c/a) in $BaTiO_3$ fine particles (0.1–1.0 μm) prepared by co-precipitation and hydrothermal routes. Identifying T_C as the temperature at which $c/a \to 1$, they determined the critical size for the existence of ferroelectricity (d_{crit}) in $BaTiO_3$ to be 120 nm. This implies that the $T_C < T_R$ (room temperature) when $d < d_{crit}$.

Detailed X-ray diffraction (XRD) measurements on smaller-sized (0.01–1.0 μm) $BaTiO_3$ nanocrystals indicate [15] that the structural phase change associated with the ferroelectric transition does not occur when $d < 50$ nm. This was supported by second harmonic generation (SHG) measurements and differential scanning calorimetry (DSC). Interestingly, *no change* was observed in the Raman spectra of the tetragonal structure, with a decrease in the particle size. Note that while XRD and SHG probe the average crystal structure over several unit cells, Raman spectral response is determined by the symmetry of individual unit cells. These results appear to imply that the polar distortion of the TiO_6 octahedra continues to be maintained irrespective of the particle size, though the *average* structure over many unit cells does become cubic. The authors suggest that such local distortions (in apparently "cubic" nanoparticles) exist only at the time scales of light scattering ($\approx 10^{-13}$ s). These results are supported by EXAFS and XANES measurements of the local structure around Ti atoms [16], which show that the magnitude of the Ti atom off-center displacement *does not* depend on the particle size. A careful study of size effects in well-characterized sol–gel derived nanocrystalline $BaTiO_3$ showed that with decreasing size, the cubic–tetragonal transformation temperature shifts downward *only slightly* before getting substantially suppressed, while the tetragonal–orthorhombic transformation temperature shifts slightly upward before getting suppressed [17]. These authors also point out that though hydroxyl defects are clearly observed by infrared (IR) spectroscopy in nanocrystalline samples synthesized at low temperature, the Raman activity observed in XRD-cubic material cannot be ascribed to their presence only.

A more precise understanding of the locally acentric structure in $BaTiO_3$ nanoparticles (15–155 nm) has been recently obtained from electron paramagnetic resonance measurements on Mn^{2+}-doped samples [18]. Comparatively larger crystallites consist of a regular ferroelectric core with a tetragonality gradient toward the outer surface, surrounded by a peripheral layer with strongly distorted symmetry. In particles smaller than ≈ 40 nm the regular core no longer exists at room temperature. Thus, the regular core undergoes a size-driven transition into the paraelectric phase, but the distorted surface layer does not participate in this transition. The size-driven transition is considerably smeared out by the grain-size distribution. The application of Landau theory to individual $BaTiO_3$ particles suggests a critical size of ≈ 50 nm at room temperature whereas in the size-distributed nanopowder a considerably lower mean size (≈ 25 nm) represents the effective threshold for the size-driven transition into the paraelectric phase.

The value of d_{crit} obtained in these experiments (≈ 50 nm) contradicts an earlier study of a surfactant-stabilized *suspension* of $BaTiO_3$ particles [19]. Probing the spontaneous polarization through the electro-optic Kerr effect, the authors claim to have detected a permanent dipole moment even in 10 nm particles. However, such a claim may be contested because: (a) the nanoparticles were prepared by a relatively crude ball-milling technique and some relatively large particles may have remained, (b) such a mechanical attrition process may create surface damage and induce defects that show a "polar" response, and (c) the size determination process with arbitrary correction factors appears questionable. Studies on $BaTiO_3$-based glass ceramic composites also show that the T_C, ε_{max}, and dielectric peak broadening all scale systematically with the mean $BaTiO_3$ crystallite size, but the value of d_{crit} was found to be only 17 nm [20].

2.2. PbTiO₃

Lead titanate is a typical displacive ferroelectric with very good dielectric, pyroelectric, and piezoelectric properties. It has a cubic perovskite structure above $T_C = 490$ °C and transforms to a tetragonal ferroelectric phase below it. The room temperature tetragonal distortion, $(c-a)/a$, is as large as 6%, as compared to only 1% for $BaTiO_3$. Due to its obvious application potential, detailed size effect studies have been carried out in this system during the past decade.

Ishikawa et al. [21] prepared $PbTiO_3$ fine particles ($22 < d_{XRD} < 52$ nm) by an alkoxide route and made a Raman study of samples with different average size as a function of temperature. They measured T_C indirectly using the principle that in displacive ferroelectrics, the frequency (ω_s) of the ferroelectric soft mode (which is usually the lowest TO mode) tends to vanish as $T \to T_C$ [22]. For each sample, ω_s was plotted as a function of T and the T_C was identified as the temperature at which ω_s extrapolates to zero. They found that T_C decreases monotonically when the average particle size, $d < 50$ nm, and its deviation from the bulk value, $T_C(\infty)$, can be fitted to the equation

$$T_C(d) = T_C(\infty) - C/(d - d_{crit}) \qquad (3)$$

with $d_{crit} = 12.6$ nm and $C = 588.5$ °C. Note that d_{crit} is the size at which $T_C \to 0$ K. Zhong et al. [23] also made Raman-scattering measurements (at room temperature) on sol–gel-derived $PbTiO_3$ nanoparticles (20–200 nm) and found that the ω_s decreases with decreasing particle size, implying a lowering of T_C with size. Even when T_C is identified as the peak of the heat flow curve in DSC, it is found to vary with particle size following Eq. (3) but with $d_{crit} = 9.1$ nm. However, results obtained from such indirect measurements can be influenced by surface depolarization fields that may affect the TO mode frequency.

The nanostructure of ultrafine ferroelectric $PbTiO_3$ particles (20–2000 nm) has been imaged by high-resolution transmission electron microscopy (HR-TEM) [24]. High-resolution images and selected area diffraction patterns showed that all the particles had tetragonal structure, and that the c/a ratio and domain size both decreased with decreasing particle size. The particles became monodomain when $d < 20$ nm. A domain wall width of 1.4 nm was deduced from strain contrast shown by 90° domain walls, but there was no evidence of amorphous surface layers.

Because it has a large spontaneous polarization, a high T_C, only one structural transition (at T_C), and there is

a satisfactory conceptual understanding of its transition mechanism, $PbTiO_3$ is certainly the candidate of choice for studying finite size effects in ferroelectric systems. However, the studies reported suffer from certain drawbacks: (i) the transition temperature is measured either indirectly, or using only a single method, (ii) there are no proper studies of the size dependence of the dielectric response, which is the single most important property of ferroelectrics, and (iii) no clear correlation is made between the dielectric properties and the structural parameters (particularly the ferroelectric distortion). The following study [25] fills up some of these lacunae and provides data that could lead to a clearer conceptual understanding.

Ultrafine $PbTiO_3$ particles ($20 < d_{XRD} < 200$ nm) were synthesized by co-precipitation. Though the average particle size was obtained from X-ray line broadening (d_{XRD}), specific surface area measurements (gas adsorption), and scanning electron micrographs (see Fig. 4), the X-ray domain size (d_{XRD}) is expected to be more relevant to the problem since ferroelectric phenomena in displacive systems are controlled by lattice vibrational mechanisms. The T_C was obtained from three complementary measurements: (i) dielectric response vs temperature, (ii) temperature dependence of the tetragonal distortion (c/a), which scales with the spontaneous polarization, and (iii) differential scanning
calorimetry. XRD measurements were also made down to 15 K to confirm that the large deviation observed in c/a at room temperature is an inherent particle size effect.

Figure 5 shows the variation of the ferroelectric distortion (c/a) with particle size at room temperature. The unit cell dimensions do not change down to ≈ 100 nm, below which c decreases and a increases with decreasing size. The resulting reduction in c/a is especially rapid below ≈ 50 nm. To estimate the critical size at which $PbTiO_3$ transforms to the cubic (paraelectric) phase *at room temperature*, the c/a vs d_{XRD} data were fitted to an equation of the form

$$y = y_\infty - C \exp[C(d_{crit} - x)] \qquad (4)$$

with $x \equiv d_{XRD}$, $y \equiv c/a$, $y_\infty \equiv 1.065$, and $C \equiv y_\infty - 1$. Using the critical size (d_{crit}) as a fitting parameter, one finds—by extrapolation—that $c/a \to 1$ when $d_{crit} \to 7.0$ nm (ferroelectric order cannot be sustained below this size). The dielectric, thermal, and structural (variable temperature XRD) data also indicated that the T_C decreases monotonically with decreasing particle size.

A study of the temperature dependence of the low frequency dielectric response function, ε (Fig. 6, top), shows that with a decrease in the particle size, T_C decreases (Fig. 7, inset), ε_{max} decreases, and the peaks become increasingly broader. Samples with $d_{XRD} \leq 26$ nm exhibited no peaks in the ε vs T curves. In larger particles of $PbTiO_3$ ($d_{XRD} \geq 60$ nm), a decrease in frequency leads to an increase in ε_{max}, but the ferroelectric T_C remains constant at $\cong 500$ °C. In smaller particles of $PbTiO_3$ (e.g., with $d_{XRD} = 31$ nm), however, the T_C moves up with an increase in frequency from 476 °C at 500 kHz to 488 °C at 1 MHz. Also, for a particular frequency, the temperature interval between the maxima in $\tan \delta$ (dielectric loss tangent) and ε is larger in

Figure 4. Scanning electron micrographs ($\times 50,000$) of chemically synthesized samples of nanocrystalline $PbTiO_3$ with an average size of about 80 nm (top) and 40 nm (bottom).
Figure 5. Variation of the ferroelectric distortion (measured at room temperature) with the particle size (d_{XRD}) in nanocrystalline $PbTiO_3$. The dashed line represents a fit to Eq. (4). The inset shows ($c/a - 1$) as a function of the reduced particle size, where $L \equiv d_{XRD}$, and a is the lattice constant. The solid line represents a fit to the model described in Section 4.3.

Figure 7. Particle size dependence of the diffuseness coefficient (γ) in PbTiO$_3$ (solid circles) and PbZrO$_3$ (open circles). The variation in the "dielectric" T_C with particle size for the same two systems is shown in the inset.

where C is a constant and the critical exponent $\gamma = 1$ for a perfect Curie–Weiss ferroelectric. According to the prediction of the local compositional fluctuation model, $\gamma = 2$ for a system with a completely diffuse transition. For systems exhibiting intermediate degrees of diffuseness we expect γ to have values between 1 and 2. Figure 7 shows that the ferroelectric phase transition becomes increasingly diffuse with a reduction in the particle size (see Section 4.4 for a discussion).

2.3. PbZrO$_3$

Though size effects have been studied for over 35 years in ferroelectrics, there were no systematic studies in nano-crystalline antiferroelectrics prior to the study of PbZrO$_3$ by Chattopadhyay et al. [26] in 1997. At 300 K, PbZrO$_3$ has an orthorhombic structure with eight formula units per crystallographic unit cell. This structure is derived from a cubic perovskite prototype (the high-temperature paraelectric phase) by *antiparallel* displacements of the Pb ions along one of the original [110] directions—which becomes the *a*-axis of the orthorhombic phase. Ignoring the displacements of the Pb ions (so as to compare the paraelectric and ferroelectric unit cells), the ordered phase has a pseudo-tetragonal unit cell whose lattice constants (a_T, c_T) are related to the real orthorhombic unit cell (a, b, c) through $a_T = a/\sqrt{2}$ and $c_T = c/2$. At $T_C \approx 500$ K, PbZrO$_3$ shows a strong dielectric anomaly.

Figure 8 shows the dependence of the pseudo-tetragonal distortion (c_T/a_T) on the particle size in sol–gel-derived ultrafine particles of PbZrO$_3$ ($d_{\text{XRD}} \geq 30$ nm). The crystallographic unit cell remains relatively undistorted (from the bulk) down to ≈ 100 nm but thereafter shows an increasing tendency to become cubic. From a downward extrapolation of these data, one may conclude that the crystal structure would become perfectly cubic below a size of 23 nm. With

Figure 6. Top: Temperature dependence of the dielectric response function (ε) for PbTiO$_3$ samples with different average particle size (d_{XRD}) measured at 1 MHz. Bottom: Differential scanning calorimetric study of the effect of particle size on the thermal transition at T_C in nanocrystalline PbTiO$_3$, scanned at 5 °C/min.

finer particles. These properties are typical of materials with a diffused phase transition and will be discussed later (Section 4.4). With a reduction in the particle size, the nature of the changes in the "dielectric" and the "thermal" transitions (observed by DSC) were found to be qualitatively similar. Thus, the peak in the heat flow shifted toward lower temperatures and became broader and flatter with decreasing size in PbTiO$_3$ (Fig. 6, bottom).

A quantitative estimate of the "diffuseness" of the ferroelectric phase transition in nanoparticles can be obtained by fitting the ε–T data ($T > T_{\text{max}}$, where T_{max} is corresponds to the peak in ε) to the equation

$$\frac{1}{\varepsilon} - \frac{1}{\varepsilon_{\text{max}}} = \frac{1}{C}\left(T - T_{\text{max}}\right)^{\gamma} \tag{5}$$

Figure 8. The particle size dependence of the pseudo-tetragonal distortion of the $PbZrO_3$ unit cell, measured at room temperature. The solid line represents a least-squares fit to an empirical function of the form $(1 - e^{-x})$. The inset shows the variation in the "thermal" T_C (obtained from DSC) and the heat of transition with particle size.

decreasing particle size, there is a monotonic reduction in the T_C as observed by both dielectric (Fig. 7, inset) and thermal (Fig. 8, inset) measurements. The ferroelectric phase transition also becomes increasingly diffuse with a reduction in the particle size (Fig. 7). The broadening of the transition is also reflected by the fact that the heat of transition (measured by DSC) decreases with decreasing size (Fig. 8, inset). In general, the nature of size effects in antiferroelectric $PbZrO_3$ is qualitatively similar to those in the ferroelectrics $PbTiO_3$ and $BaTiO_3$.

2.4. Pb(Zr,Ti)O₃

Binder has shown that when only intrinsic effects are considered (i.e., contributions from domain walls, defects, and impurities are disregarded) a decrease in particle size should, in general, cause a reduction in the T_C, a reduction in ε_{max}, and a broadening of the dielectric response peak [27]. However, in solid solutions, a broadening in the dielectric response (and other critical parameters) may also take place because of the disordering of the two ions occupying equivalent crystallographic positions. A number of ferroelectric mixed oxides or solid solutions such as PZT, barium strontium titanate (BST), and strontium bismuth tantalate (SBT) are technologically important and studies of particle size effects have been carried out in a few of these compounds. Since it has a number of important applications, it is not surprising that the majority of such studies involve PZT.

PZT or $Pb(Zr_{1-x}Ti_x)O_3$ is obtained by a random replacement of the Ti^{4+} ions in $PbTiO_3$ by Zr^{4+} ions. The ferroelectric T_C increases monotonically from 235 °C ($x = 0$) to

490 °C ($x = 1$). With decreasing x, the structure transforms from tetragonal (as in $PbTiO_3$) to rhombohedral at $x \approx 0.5$ to orthorhombic (as in $PbZrO_3$) at $x \approx 0.05$. The tetragonal to rhombohedral phase boundary is almost temperature-independent (morphotropic), though its exact position and width depends crucially on the purity and local homogeneity of the sample. The piezoelectric properties of PZT are particularly good in the neighborhood of the morphotropic phase boundary and may be further improved by suitable doping. Both the cubic–rhombohedral as well as the cubic–tetragonal transitions get progressively suppressed below ≈ 0.6 μm. Though the ε–T curves get flattened with decreasing size there no discernible change in T_{max} in the rather narrow size range (0.5–0.8 μm) investigated by the authors [28]. They also point out that the values of ε_{max} are higher in samples sintered at higher temperature (and have higher density) even though the X-ray domain size does not differ much between them. This is ascribed to the higher porosity and the discontinuity of electric flux between grains in low-density samples.

Long ago, Kittel [29] had obtained a relation between the grain size (t) and the ferroelectric domain size (d) from a simple model involving the competing effects of the depolarization energy and the domain wall energy:

$$d = \left[\left(\frac{\sigma}{\varepsilon^* P_0^2} \right) t \right]^{1/2} \qquad (6)$$

In PZT ceramics, Cao and Randall [30] found that though this relation was valid in the grain size range of 3–10 μm, there was a deviation at lower grain sizes, probably due to the clamping of domain walls at the grain boundaries. Randall et al. [31] have attempted to separate out the role of extrinsic (i.e., due to domain wall, lattice defects, and impurities) and intrinsic contributions to particle size effects in Nb-doped PZT. They suggest that extrinsic contributions to the dielectric and piezoelectric properties get drastically suppressed when the grain size falls below about 2 μm while intrinsic properties get affected below ≈ 0.8 μm, mainly through a progressive reduction in the spontaneous strain.

The dielectric property of *amorphous* nanoparticulate PZT (synthesized by the sol–gel process) was studied by Srinivasan et al. [32]. The results were explained using a model that assumes that the glassy phase contains frozen-in dipoles with random magnitudes and orientations formed by a distortion of the dielectrically soft prototype units (the BO_6 octahedra), which are expected to retain their identity even in the glassy phase.

2.5. Other Solid Solutions

Size effects have also been investigated in a number of other mixed ferroelectric or antiferroelectric oxides. The effect of grain size reduction on the piezoelectric properties in *sintered* ceramics of $(Pb_{1-y}La_y)(Zr_{1-x}Ti_x)O_3$ or PLZT was studied by Okazaki et al. [33]. The authors measured the piezoelectric coefficients (d_{31} and g_{31}) and the planar coupling factor (k_p) in hot-pressed, low-porosity, electrically polarized PLZT samples ($y = 0.2$, $x = 0.35$), with grain sizes (G) in the 1–14 μm range. The size dependence of each property (X) could be expressed by a general equation of

the form $X = A + B/G^{0.5}$. They also observed an increase in the coercive field with decreasing size. This paper provided an early guide to the optimization of piezoelectric properties of fine-grained ceramics.

Zhang et al. [34] have carried out a detailed study of size effects for different values of x in BST. Deviations from "bulk" properties in solid solutions typically occur at much larger particle sizes than in pure compounds. Thus, in the case of BST, $d_{crit} = 317$ nm (for $x = 0.3$), 246 nm (for $x = 0.5$), and 176 nm (for $x = 0.7$). The diffuseness coefficient (γ) again increases with decreasing size. However (unlike in PbTiO$_3$ or PbZrO$_3$) the transition becomes *completely* diffuse ($\gamma = 2$) below 300 nm (for $x = 0.3$). We emphasize that in solid solutions such as BST it is difficult to obtain a homogeneous cation distribution, which may be the main reason for the extremely diffuse transition and reduced values of ε_{max}.

In $(Pb_{1-x}La_x)TiO_3$, Raman studies of the soft mode indicate that both the phase transition temperature *and* pressure get reduced with a reduction in particle size [35]. A detailed study [36] of size effects in $Pb(Sc_{0.5}Ta_{0.5})O_3$ in the 10–160 nm range revealed that c/a reduces to unity (at 0 °C) when $d_{XRD} \leq 53$ nm. The T_C decreases gradually and the phase transition becomes more diffuse with decreasing size. Representative studies on size effects in ferroelectric solid solutions (mostly based on the perovskite structure) are summarized in Table 2.

3. SIZE EFFECTS IN OTHER TYPES OF FERROELECTRICS

The preceding part of this chapter shows that nanoparticles of *displacive* systems such as BaTiO$_3$, PbTiO$_3$, and PbZrO$_3$ exhibit certain basic similarities such as (i) a monotonic decrease in the T_C with particle size below ≈ 100 nm, (ii) existence of a critical particle size below which ferroelectricity cannot be observed, (iii) a broadening of the ferroelectric transition peak and behavior reminiscent of a diffuse phase transition at low sizes, and (iv) an interrelation between the T_C, the ferroelectric distortion, and the particle size.

The behavior of a typical *order–disorder* system such as NaNO$_2$, however, is somewhat different. Bulk NaNO$_2$ undergoes a first order ferroelectric–paraelectric transition at 165 °C, which is associated with a relatively large latent heat. Marquardt and Gleiter [46] prepared nanocrystalline NaNO$_2$ (down to 5 nm) by three different methods and studied the ferroelectric phase transition by differential thermal analysis. Very little change in T_C was observed down to 5 nm, whereas displacive systems start showing deviations in the T_C at sizes as large as 100 nm. This clearly emphasizes the importance of the size-induced *structural distortions* in nanoparticles of displacive systems. The other obvious difference in the two types of system is that thermal as well as dielectric phase transitions are usually not observed at all in nanoparticles of displacive systems that are smaller than ≈ 25 nm, while even 5 nm NaNO$_2$ nanoparticles show a clear transition peak. Size effects, therefore, appear to be much weaker in order–disorder ferroelectrics.

Again, no change in T_C (≈ 440 K) was found in a study of 40–50 nm NaNO$_2$ particles impregnated in the free spaces between the 200 nm SiO$_2$ spheres that form the three-dimensional (3D) lattice in synthetic opal [47]. However, the authors reported a giant enhancement in the dielectric constant of the NaNO$_2$-impregnated opal (at 100 Hz) above 550 K by about 10^7 times! They ascribed this to the melting of the dispersed NaNO$_2$ in the host lattice and the formation of electrolytic drops. This is similar to the large dielectric constants observed in electrolyte-saturated porous ceramics. More recently, the temperature evolution of the structure of nanodispersed NaNO$_2$ confined within a porous glass with an average pore size of ≈ 7 nm has been studied across T_C with the help of neutron diffraction [48]. This study suggests that there is a lattice softening above T_C, manifested by

Table 2. Studies of size effects in ferroelectric solid solutions (other than PZT) based on the perovskite structure.

System	Sample specs	Nature of study	Ref.
(Pb, La)(Zr, Ti)O$_3$	(1) sintered ceramics	piezoelectric properties	[33]
or PLZT	(2) sintered ceramics	$\varepsilon - T$, T_C	[37]
	(3) sintered ceramics	electro-optic properties	[38]
$(Pb_{1-x}La_x)TiO_3$	(1) 0.6–11 μm, sinter	$\varepsilon - T$, T_C	[39]
or PLT	(2) $0 \leq x \leq 0.2$, sol–gel	Raman at high press. & temp.	[35]
	(3) sol–gel	Raman, soft mode	[40]
$(Pb_{1-x} Sr_x)TiO_3$	sintered ceramic	S/TEM, AFM, DPT	[41]
$Pb(Sc_{1/2}Ta_{1/2})O_3$	10–160 nm	$\varepsilon - T$, T_C, DPT, XRD-T, DSC, $d_{crit} = 10$–20 nm	[36]
$Pb(Zn_{1/3}Nb_{2/3})O_3$– BaTiO$_3$/PbTiO$_3$	model	compositional fluctuation at nanoscale	[42]
$Pb(Mg_{1/3}Nb_{2/3})O_3$– PbTiO$_3$	granular thin film	(1) local piezoelectric properties using SFM	[150]
(Pb, Ba)TiO$_3$	$0 \leq x \leq 1$, sol–gel	micro-Raman, soft mode	[43]
$(Ba_{1-x}Sr_x)TiO_3$	$x = 0.3, 0.5, 0.7$, sol–gel	(1) $\varepsilon - T$, T_C, DPT	[34]
or BST		(2) barrier height, relaxation frequency	[44]
$(Sr_xBa_{1-x})Nb_2O_6$ or SBN	sol–gel	$\varepsilon - T$, T_C, DSC, Raman	[45]

a pronounced growth in the thermal vibration parameters. The appearance of an ionic current due to oxygen diffusion in the lattice above T_C is presumed to lead to the giant increase in the dielectric response.

KNO_3 is also believed to be an order–disorder ferroelectric. On heating it transforms from an orthorhombic ferroelectric phase (II) to a trigonal paraelectric phase (I) at 130 °C. On cooling, phase I transforms to a metastable trigonal phase (III) at 125 °C, which goes to phase II at 115 °C. Westphal [49] has studied the effect of particle size on the II–I, I–III, and III–II phase transitions and found that the III–II transition shifted to lower temperature, while the II–I transition temperature increased with decreasing size. However, these measurements were made on powdered single crystals, in which surface stress effects and deformations could play a major role. It is also essential to extend these results to the submicrometer size range and use samples with a narrower size distribution to in order to obtain more reliable results.

4. CONCEPTUAL APPROACHES

4.1. Size Induced Structural Phase Transition

All the perovskite-type oxide ferroelectrics appear to exhibit a decrease in the tetragonal (ferroelectric) distortion with a reduction in particle size. It is important to note that this effect is a manifestation of a much more general phenomenon and is *not* restricted to ferroelectrics. Detailed studies show that in a large number of partially covalent oxides, the crystal lattice tends to transform into structures of higher symmetry when the particle size is reduced [50]. In systems such as Fe_2O_3 and Al_2O_3, the size-induced lattice distortion is large enough to actually produce a crystallographic transition to a high-symmetry structure [51]. In most other cases, there is a gradual reduction in an asymmetry parameter—such as $(c/a - 1)$—with decreasing size.

A decrease in the particle size may cause a change in the bulk lattice parameters via surface stresses [52, 53]. The *anisotropic* nature of the lattice expansion in the nanoparticles of most oxides can be understood in terms of a tendency of such systems to become increasingly *ionic* with decreasing size [54]. As a result, the interatomic bonds lose their directional character and the crystal tends to assume a structure with a comparatively higher symmetry. Interestingly, the size dependence of many important physical properties (such as superconductivity and magnetism, in addition to ferroelectricity) is often directly or indirectly connected to the anisotropic lattice distortion that accompanies a reduction in the particle size [50].

4.2. Overview of Theoretical Models

Experiments on perovskite-type ferroelectrics and antiferroelectrics indicate that a reduction in the average particle size leads to a decrease in the Curie temperature, the ferroelectric distortion (c/a), the heat of transition, and the soft mode frequency. Various attempts have been made to obtain a conceptual understanding of these observations. It is beyond the scope of this chapter to provide a complete review of the theoretical studies of size effects in ferroelectric

nanoparticles. We will merely attempt to present a flavor of the area and briefly discuss some simple, general models. Attempts to explain the basic experimental features using the Landau–Devonshire phenomenological theory have been reasonably successful. For a finite-sized, inhomogeneous ferroelectric with a second order phase transition, Zhong et al. [55] write the total free energy in the form

$$\int \left[\frac{1}{2} A(T - T_{C\infty})P^2 + \frac{1}{4}BP^4 + \frac{1}{2}D(\nabla P)^2 \right] dv + \int \frac{1}{2}D\delta^{-1}P^2 \, dS \tag{7}$$

where P is the polarization, and $T_{C\infty}$ refers to the "bulk" value of T_C. D is connected to the correlation length (ξ): $D = \xi^2 |A(T - T_{C\infty})|$. The volume and surface integrals represent, respectively, the free energies of the interior and the surface. Compared to the analogous expression for an infinite, homogeneous ferroelectric, Eq. (7) contains additional contributions due to the gradient term and the surface term. The "extrapolation length," δ, turns out be particle size dependent. The authors carry out numerical calculations to obtain the size dependence of the polarization as well as the T_C and show that both decrease with decreasing size and vanish as $d \to d_{\text{crit}}$. A few years later, Rychetský and Hudák analytically solved the phenomenological model for the second order phase transition in spherical ferroelectric particles and obtained the temperature and size dependence of both the static and dynamical dielectric susceptibilities [56].

In these treatments, the surface charge is assumed to be fully compensated, such that the depolarization fields can be ignored. Shih et al. [57] have considered the effect of the depolarization field and a space charge layer—which tend to break up the particles into domains of different polarization. For simplicity, they assume cubic particles with alternating domains separated by 180° domain walls and incorporate the depolarization energy as well as the domain wall energy into the Landau free energy density. Since the multidomain ferroelectric state disappears in small enough particles, the presence of a depolarization field is found to substantially lower the ferroelectric T_C.

More recently, Jiang and Bursill [58] have extended the macroscopic phenomenological approach by calculating the size dependence of the Landau–Ginzburg–Devonshire coefficients [A, B, and D in Eq. (7)] themselves. Other than predicting the size driven phase transition to a paraelectric state for $d < d_{\text{crit}}$, the model can explain the changes in the other physical parameters and appears to give a relatively better description of the changes in the latent heat than previous models. It also yields a simpler free energy expression, which allows some of the physical properties to be discussed analytically. Other than the macroscopic Landau theories, there have also been reasonably successful attempts to investigate size effects with the help of a microscopic pseudo-spin theory based on the Ising model in a transverse field [59, 60].

4.3. Microscopic Model for Nanoferroelectrics

The nature of size-induced changes in displacive ferroelectrics such as $PbTiO_3$ can be understood with the help of the simple model [61, 62] that we now describe. Interestingly,

the model also allows one to make certain predictions about order–disorder ferroelectrics which appear to be consistent with the available data. The model is based on two simplifying assumptions: (a) the finite sized ferroelectric system is quasi-free (i.e., it consists of loosely aggregated, unclamped nanoparticles) and (b) the ferroelectric nanoparticles are not electrically isolated. Under these conditions, we can ignore the effects of external strain and depolarization.

Experiments show that a reduction in the size of ABO_3-type displacive ferroelectrics and antiferroelectrics is accompanied by a monotonic decrease in the ferroelectric T_C, which is the temperature at which the high symmetry paraelectric structure transforms to a low symmetry phase in which the B ions no longer occupy the centrosymmetric positions in the BO_6 octahedra. When the particle size is made sufficiently small ($d < d_{crit}$), the ferroelectric system reverts to the paraelectric phase, *however low the temperature*. In other words, the ferroelectric to paraelectric transition may be made to occur as a function of increasing temperature as well as decreasing size. The following microscopic model naturally leads to a size-induced structural phase transition of the first order.

The displacement of the centrosymmetric B-ion to an off-centric position at the ferroelectric T_C is accompanied by a distortion in the cubic (paraelectric) unit cell to one of lower symmetry (e.g., in PbTiO₃, a tetragonal one with sides $a \times a \times c$. The tetragonal distortion ($c/a - 1$) is experimentally found to scale with the order parameter. The displacement (d) of each such ion clearly requires some energy, and the system would undergo a ferrodistortive transition only when it gains a *larger* amount of energy from the interaction of the resulting dipoles, which are aligned in some particular fashion.

The dipolar interaction energy of the stable ordered phase, ($\sim Jzd^2$), should be comparable to kT, where z is the coordination number. Thus, dipolar alignment may take place provided $d \geq \sqrt{kT}/Jz$. Note that this argument itself implies the possibility of driving the transition by varying either the temperature or the system size (which controls the average value of z). So the model describes the temperature-driven transition in the bulk material, as well as the size-driven transition in finite systems.

Phenomenologically, we can describe the interaction energy between the nearest neighbor dipoles by $Jd_id_j\alpha_i\alpha_j$, where $\alpha = \pm 1$ is an Ising variable, which accounts for the fact that the central ion can be displaced in two opposite directions. J is positive for ferroelectrics and negative for antiferroelectrics. The effective Hamiltonian for the problem is thus the sum of an elastic part and an Ising part. From symmetry considerations, we obtain

$$H = \sum_i (\frac{1}{2}\lambda_2 d_i^2 + \frac{1}{4}\lambda_4 d_i^4) - J\sum_{i,j} d_id_j\alpha_i\alpha_j \qquad (8)$$

This Hamiltonian is solved by treating the Ising variable via an inhomogeneous mean-field theory and the displacement variable within a saddle point approximation. The free energy density is obtained in the form $F(d) = E(d) + I(d)$, where the elastic part, $E(d)$, is given by

$$E(d) = \frac{1}{2}\lambda_2 d^2 + \frac{1}{4}\lambda_4 d^4 \qquad (9)$$

and the Ising part, $I(d)$, is given by

$$I(d) = \frac{1}{2}Jzm^2 d^2 - T\ln 2\cosh\left(\frac{Jzmd^2}{kT}\right) \qquad (10)$$

where $m \equiv \langle\alpha\rangle = \tanh(Jzmd^2/T)$. With increasing d, $E(d)$ increases monotonically and rapidly, while $I(d)$ decreases more slowly. The saddle point values of d, obtained by minimizing $F(d)$, are $d = 0$ and $d = d_0 = \sqrt{(Jzm^2 - \lambda_2)/\lambda_4}$. Clearly, it is this two-minima structure of the free energy that is responsible for the first order ferroelectric ($d = d_0$) to paraelectric ($d = 0$) transition.

Taking the model parameters (λ_2, λ_4, and J) for PbTiO₃ from experimental data [25], it is possible to plot the phase diagram in the temperature–particle size plane (Fig. 9). The phase boundary for displacive systems ($\lambda_2 > 0$, solid line) represents first order transitions for all $T > 0$. Thus, the theory predicts a depression in T_C with reducing size. In systems with $\lambda_2 < 0$ (which usually describes order–disorder ferroelectrics), size effects are greatly suppressed, as shown by the dotted curve in Figure 9. One would need to study very small particles at temperatures very close to T_C to observe such effects. This is also in qualitative agreement with experimental observations [46]. Thus, in general and to the first order, particle size effects in ferroelectrics appear to arise mainly from a lower average coordination number for the atoms close to the surface of a nanoparticle.

This model has the important advantage of simplicity—having only three fitting parameters—while the phenomenological Landau theories [55, 57] have about twice as many. Also, by making J negative, the model can be easily extended to describe displacive-type *anti*ferroelectrics.
Figure 9. The phase diagram of nanocrystalline ferroelectrics (reduced temperature against reduced particle size) obtained from the model described in Section 4.3. The solid line separates the ferroelectric phase from the paraelectric phase in typical displacive systems, while the dotted line does the same for typical order–disorder systems ($L \equiv d_{XRD}$, a = lattice constant).

4.4. Diffused Phase Transition

We now discuss another important experimentally observed feature in ferroelectric and antiferroelectric nanoparticles. The dielectric behavior (ε vs T) of nanoparticles of ferroelectric $PbTiO_3$ [25] and antiferroelectric $PbZrO_3$ [26] can be summarized as follows. With a decrease in the particle size: (i) the peaks in the ε–T curve become broader, (ii) there is an increase in the separation between the peaks in the $\tan\delta$ (dielectric loss) vs T and ε vs T curves, (iii) there is an increasing deviation from the Curie–Weiss law (increase in γ), (iv) both the ε vs T and $\tan\delta$ vs T curves show marked frequency dispersion, (v) the decrease in the tetragonal distortion (c/a) as $T \rightarrow T_C$ becomes more gradual in samples with smaller particle size, (vi) values of T_C obtained from different measurements (dielectric, thermal, and structural) do not necessarily coincide, and (vii) with a decrease in frequency, T_C decreases while $\varepsilon_{\max}$ increases.

The broadening of the dielectric and thermal peaks at the ferroelectric transition and most of the other observed features are known characteristics of the so-called "relaxor" ferroelectrics which exhibit a diffuse phase transition (DPT) [63–66]. A quantitative measure of the degree of diffuseness can be obtained by fitting the dielectric data to Eq. (5). The fitted value of the critical exponent (γ) lies between 1 (for an ideal Curie–Weiss ferroelectric) and 2 (for a ferroelectric with a totally diffused transition). Other than nanocrystalline ferroelectrics, a DPT is also exhibited by many complex perovskite ferroelectrics, random dipole ferroelectrics, and ferroelectrics with a graded composition. The near-T_C dielectric response of such relaxor ferroelectrics is often substantially higher than what might be expected from the LST relation [Eq. (2)], making them technologically important. The feature common to all relaxor ferroelectrics is that they possess structural inhomogeneities or compositional variations at the submicrometer scale.

Applying the Landau–Ginzburg free energy formulation to an inhomogeneous medium, Li et al. [67] have provided a thermodynamic approach to DPT in mesoscopically inhomogeneous ferroelectrics. They find that a coherent coupling can take place across the interface between two chemically different dipole-ordered regions. They assume each localized cluster to have a mean-field character, such that the DPT can be understood as an inhomogeneous condensation of localized soft modes.

DPTs were discovered in perovskite solid solutions of the type $A(B_{1-x}C_x)O_3$, in which, generally, there is no long range crystallographic ordering of the B and C cations. Local compositional fluctuations are therefore present throughout the crystal, so that it could consist of microscopic domains of ABO_3 and ACO_3 as well as intermediate compositions (Fig. 10, top). Since ABO_3 and ACO_3 would—in general—have different values of T_C, this would lead to a microlevel T_C distribution about a central value corresponding to the T_C for $A(B_{1-x}C_x)O_3$. There could also be an intermixture of ferroelectric and paraelectric regions if only one of the constituents of the solid solution is ordered at the observation temperature. The scale of heterogeneity is believed to be ~10–20 nm [65].

One can now understand the conceptual similarity between a solid solution and a nanocrystalline system in

Figure 10. A schematic equivalence of the phenomenon of diffuse phase transition in a typical ferroelectric solid solution (top) with a variation in the local stoichiometry and a nanocrystalline ferroelectric system (bottom) with a particle size distribution. In both situations, different shades represent local regions with different values of T_C.

a simple manner [25]. A nanocrystalline ferroelectric with an average size in the range of 10–50 nm would consist of a collection of crystallites with varying sizes (due to the inherent size distribution) centered around the mean size (Fig. 10, bottom). Recall that in the size range being discussed, particles of different sizes also have different values of T_C. Since the variation of T_C with size is more conspicuous in smaller particles, the latter should exhibit a more diffused phase transition. Many workers have invoked the T_C-distribution model [9] to explain the dielectric behavior of sintered ceramics, in which a complicated stress distribution occurs due to the high compaction. In the comparatively loosely aggregated nanocrystalline material studied by us, the observed strain and the T_C appear to depend directly on the particle size. However, in this case, the strain dependence is *inherently* a size effect and is not an artifact of sintering or pressure compaction.

5. FERROELECTRIC THIN FILMS

5.1. Size Effects in Thin Films

During the past decade, a very large amount of developmental work has been carried out on the synthesis and characterization of ferroelectric thin films—as evidenced by the publication of nine large volumes of the Materials Research Society (MRS) Symposium Proceedings titled *Ferroelectric Thin Films*. This has been fueled mainly by the intense interest in the development of ferroelectric memory devices. A detailed discussion of the technological aspects

and the related synthesis problems are not within the scope of this chapter. Readers interested in applications aspects of ferroelectric thin films may refer to the recent and excellent reviews by Scott [68] and Shaw et al. [69], in addition to the aforementioned MRS Symposium Proceedings. Here, we attempt to cover some of the important aspects of inherent size effects in ferroelectric thin films. We will also present an interesting effect in antiferroelectric thin films which appear to show ferroelectric behavior below a critical thickness.

The important length scales in thin films are the film thickness, the grain size (in granular films), and the lateral device size (in thin film devices), and it is interesting to observe the consequences of any of these quantities approaching the ferroelectric critical size (d_{crit}). We also point out that in thin films, it is often difficult to distinguish genuine size effects from extraneous effects related to crystalline quality, microstructural heterogeneities, and mechanical stresses induced by the substrate.

5.2. Intrinsic Effects

A large body of experimental data indicates that size/thickness effects in ferroelectric thin films are manifested mainly in the following five ways [70, 71]. A decrease in the thickness (t) usually leads to (i) a larger coercive field, (ii) a lower T_C, (iii) a smaller remanent polarization, (iv) a lower dielectric constant, and (v) a broadening of the dielectric peak at the ferroelectric transition.

In bulk ferroelectrics, the measured value of the coercive field E_C (the external field required to reverse the macroscopic polarization, see Fig. 1) is almost always much smaller than the theoretical or intrinsic value predicted by the Landau–Ginzburg mean field theory. This is due to domain nucleation and domain wall motion. The energy required to switch the polarization of such small nucleation volumes is much smaller than that required for the collective polarization reversal of the entire crystal. Thus, the obvious way to increase E_C would be to use particles that are so small or films that are so thin that domain nucleation is inhibited. Recently, Ducharme et al. [72] have been able achieve the intrinsic value of E_C in Langmuir–Blodgett films of a polyvinylidene fluoride (PVDF)-based polymeric ferroelectric with $t \approx 1$ nm. The measured E_C is in good agreement with theoretical predictions and is *independent* of t in the range 1–15 nm.

Considering only intrinsic effects, the shift in the T_C and the jump in the spontaneous polarization (P_S) at the T_C as a function of the film thickness (t) are given, respectively, by

$$\Delta T_C = At^{-1} \quad \text{and} \quad \Delta P_S(T_C) = Bt^n \quad (11)$$

where A and B are constants independent of temperature and thickness, while the exponent n is of the order unity. In addition, the film thickness may affect other types of phase transitions. For example, the morphotropic phase boundary (see Section 2.4) that separates the tetragonal phase from the rhombohedral phase in $Pb(Zr_{1-x}Ti_x)O_3$ (PZT) shifts from ≈ 0.5 in the bulk to about 0.2 in thin films [73]. There have been numerous attempts to calculate the intrinsic, thickness dependent electric susceptibility, χ_f. Starting from the continuum, phenomenological free energy, Qu et al. [74] obtain the expression:

$$\chi_f = \chi_b \left[1 + \frac{C_0}{(L - L_0)} \right] \quad (12)$$

where C_0 is independent of L, the film thickness.

The study of ultrathin ferroelectric films also gives us an opportunity to investigate the possible existence of the superparaelectric (SPE) state. This is analogous to the phenomenon of superparamagnetism observed in ultrafine magnetic particles. The latter occurs when the particle size is small enough and the temperature is low enough such that the magnetic anisotropy energy of individual particles is smaller than the thermal energy. Under this condition the magnetization vector of individual particles continues to flip spontaneously by a coherent reorientation of atomic spins. Similarly, the SPE state would occur when the energy required to coherently flip the polarization vector of individual ferroelectric particles is smaller than kT. A simple calculation based on the *intrinsic* coercive field and remanent polarization of typical ferroelectrics, tells us that for the switching energy to approach kT, one requires a particle having a volume ≈ 1 nm^3 [69].

5.3. Extrinsic Effects

Changes in ferroelectric properties usually occur when the film thickness is below ~ 200 nm, but the actual value of this "critical thickness" often depends sensitively on the nature of the microstructure (and hence on the synthesis conditions), interfacial stresses, crystallographic orientation, and epitaxy. As mentioned earlier, it may be difficult to distinguish between particle size effects and thickness effects since the microstructure often changes continuously with t—thinner films being usually composed of smaller particles. Ren et al. [75] provide an example of this in their study of free standing polycrystalline $PbTiO_3$ films. They find that the domain structure and dynamic response change drastically when the thickness is reduced below 200 nm, because the thinner films are composed of nanosized, single-domain grains. From a study of the effect of granularity on the dielectric response of apparently dense radio-frequency (rf)-sputtered thin films of $BaTiO_3$, Dudkevich et al. [76] found that ε decreases considerably and the ferroelectric state becomes unstable when the coherently scattering X-ray domain size (d_{XRD}) ≤ 30 nm. Since the thinner films are also usually composed of smaller particles, this phenomenon is apt to be misinterpreted as a "thickness" effect.

The issue of thickness induced phase transitions in ferroelectrics is interesting and important. Batra et al. [77] had suggested long ago that a ferroelectric exhibiting a second order transition in the bulk should exhibit a new type of first order transition. This was ascribed to the presence of thickness-dependent depolarization fields in a ferroelectric thin film deposited on a semiconductor surface.

Another type of thickness-dependent phase transition has recently been reported [78]. The study involves the two antiferroelectric compounds $BiNbO_4$ (which is antiferroelectric up to 360 °C, ferroelectric between 360 and 570 °C, and paraelectric above 570 °C) and $PbZrO_3$ (which has a

$T_C \approx 230°C$. In high-purity $PbZrO_3$ samples, it is possible to stabilize a rhombohedral *ferroelectric* phase in a temperature range of 220–230 °C. Polycrystalline $BiNbO_4$ and c-axis oriented $PbZrO_3$ films (100 nm $\leq t \leq$ 900 nm) were pulsed laser deposited on Si (100) wafers. Atomic force micrographs showed that the thinner films were (expectedly) composed of smaller grains in both systems. Dielectric hysteresis (P vs E) measurements showed that in both $PbZrO_3$ and $BiNbO_4$ thin films, the thicker films are antiferroelectric, while—below a characteristic thickness—they show ferroelectric behavior. Note that the critical thickness (t_C) below which ferroelectricity is found to be stabilized is quite large—about 500 nm. The observed stabilization of ferroelectricity in thin films of normally antiferroelectric materials may be ascribed to the effect of the electric field produced at the semiconductor–dielectric interface. For a typical semiconductor–insulator interface, the interfacial field $E_{\mathrm{if}} \approx 100$ kV cm^{-1}, which is high enough to induce ferroelectricity in many antiferroelectric crystals. The nucleation of $PbZrO_3$ and $BiNbO_4$ grains on the substrate takes place at 700 °C (which is above their respective T_C's) in the presence of a strong electric field (E_{if}) that tends to orient the local dipoles along the field, leading to ferroelectric ordering. In thicker films ($t > t_C$), the grains are larger and have multiple domains, which stops this sequential polarization process and the system shows its original antiferroelectric property.

In general, the piezoelectric coefficients of thin films are appreciably lower than those of the corresponding bulk crystals or ceramics. This can be mainly ascribed to (a) the clamping of the film by the substrate, which retards field-induced motion and (b) a reduction in the extrinsic contribution to the piezoelectric response—such as a reduction in the mobility of certain types of domain walls [69].

6. DEVICE APPLICATIONS

The high level of interest in the synthesis, structure, and properties of nanoferroelectrics is obviously related to their current and potential use in devices of various types. Applications are envisaged in memory devices [79] such as D-RAM, NV-RAM, and EEPROM. Important nonmemory applications are in nanorobotic and microelectromechanical (MEMS) devices [80], and in sensors and detectors of various types.

Size effects have a direct bearing on applications. One of the main problems involving ferroelectric thin film capacitors of finite area has been pointed out by Scott [68]. This arises from a reduction in the total quantity of switched charge due to the effect of fringing fields. Thus, in a circular disc of diameter 2 μm and thickness 200 nm (aspect ratio = 10:1) the fringe fields produce a 7% reduction in the switched charge. But this effect increases nonlinearly with decreasing aspect ratio and is about 23% for an aspect ratio of 5:1.

The ferroelectric NV-RAM works on the principle that at zero applied field, a ferroelectric system has two thermodynamically stable states described by $\pm P_R$ (see Fig. 1), each direction of polarization encoding either "0" or "1." Since no external field is required to maintain these states, the memory device is nonvolatile. The polarization can be switched

between the two states by the application of an external electric field, $E > \pm E_C$. The criteria for an ideal NV-RAM are fast read/write speed, high recording density, high endurance and retention, radiation hardness, compatibility with current integrated circuit (IC) technology, nondestructive readout capability, low power operation, and commercial viability. Property for property, ferroelectric-based memories are expected to beat most competing technologies. The recent discovery of a series of titanate-based layered perovskite compounds with very high values of spontaneous polarization might turn out to be very useful for NV-RAM applications. For example, a c-axis oriented $Bi_{4-x}Nd_xTi_3O_{12}$-based capacitor was found to have a switchable remanent polarization ($2P_r$) of over 100 μC/cm^2 and fatigue-free behavior [81].

Each memory cell consists of a ferroelectric capacitor sandwiched between metal electrodes and integrated with an access transistor. Thus the chip layout is composed of a matrix of capacitors and transistors. In order to achieve 1 Gbit NV memories, one needs to fabricate ferroelectric capacitors with lateral dimensions of 100 nm or less. The fundamental question to be answered is: what is the smallest size of the capacitor that will still behave like a ferroelectric? One is particularly concerned with the possibilities of depolarizing fields that might become large enough to inhibit switching. According to a recent review [82], the smallest switchable ferroelectric memory cells up to now have been fabricated by Mitsubishi–Symetrix (1 μm × 1 μm) [83], NEC (0.7 μm × 0.7 μm) [84], U. Maryland (100 nm × 100 nm) [85], and MPI Halle (75 nm × 75 nm) [86]. The fabrication process involved is either e-beam lithography, focused ion-beam milling, or self-assembly. Materials and process parameters for ferroelectric D-RAM applications have been reviewed by Scott [87]. As an example, Figure 11 shows a sample of PZT nanodots patterned by e-beam lithography on a $SrTiO_3$ substrate by the group at MPI. See also Table 3.
Figure 11. Scanning electron micrograph of large-scale-ordering of PZT (30/70) nanoparticles on $SrTiO_3$ (111) substrate, patterned by electron beam lithography and crystallized at 650 °C. Inset shows magnified view of single dot. Courtesy of Dr. M. Alexe, Max Planck Institute of Microstructure Physics, Halle.

Table 3. Approximate size of smallest switching single ferroelectric cells obtained by various research groups.

Research	Element dimension	Material used	Process	Ref.
Mitsubishi–Symetrix	1000 nm × 1000 nm	$(Ba, Sr)TiO_3$	e-beam lithography	[83]
NEC	700 nm × 700 nm	$SrBi_2Ta_2O_9$	e-beam lithography	[84]
University of Maryland	100 nm × 100 nm	$Pb(Nb,Zr,Ti)O_3$	focused ion beam milling	[85]
MPI, Halle	100 nm × 100 nm	$SrBi_2Ta_2O_9$	e-beam lithography	[86]
	75 nm × 75 nm	$Pb(Zr,Ti)O_3$		

To be useful as a memory element, a ferroelectric should ideally have a low dielectric constant, moderate spontaneous polarization, T_C higher than the operating temperature range, switching speed in the nanosecond range, high chemical and environmental stability, and low fatigue properties. The need for low voltage operation (<5 V) demands that film thickness be in the submicrometer range and the coercive field be low. Two classes of materials, the perovskites (mostly PZT, doped PZT, and BST) and the layered perovskites SBT and $SrBi_2Nb_2O_9$ (SBN) have turned out to be particularly useful for this purpose. For many integrated ferroelectric thin film applications, SBT has now become the material of choice because: (a) it exhibits very little fatigue, (b) it has low leakage currents, and most importantly, (c) bulk properties are retained even in extremely thin films. In recent years, some success has also been achieved in depositing $PbTiO_3$ films on Si [88].

The simpler form of the ferroelectric memory is the destructive readout (DRO) consisting basically of a transistor and a capacitor. Each read operation consists of switching the capacitor, comparing with the linear response of an unswitched reference capacitor, and finally resetting the capacitor. The signal is measured and the state of the bit identified by means of a sense amplifier at the end of each bit line. The reset operation of the DRO device obviously enhances the fatigue. A more sophisticated version is the nondestructive readout (NDRO) where the information can be read over and over again, without the need to switch until the next write operation. The NDRO involves a field effect transistor (FET) with a ferroelectric thin film replacing the metal gate in a conventional FET. Here the polarization of the ferroelectric element (0 or 1) can be sensed without reversal by measuring the source–drain current. The magnitude of the current would depend on whether the gate is biased positively or negatively. Though such a device has many attractive features and some progress has been made in its development [89], a true ferroelectric memory FET has not yet been realized. The main problem is short memory retention and this is ascribed to the depolarizing field and the gate leakage current [90].

Ferroelectric thin films and nanoscale systems are also very useful in several nonmemory applications. These include IR detectors, gas sensors, surface acoustic wave devices, electro-optic switches and modulators, optical FETs, and waveguides. A lot of interest has been generated due to the futuristic applications of MEMS (which include transducers, actuators, accelerometers, etc.) that incorporate piezoelectric thin films such as PZT. Recent developments in this field are now covered by a new journal (*Journal of MEMS*). Other applications of ferroelectric thin films include multilayer capacitors, boundary layer capacitors, varistors, etc.

7. COMPOSITE STRUCTURES

The formation of micro- or nanodispersed ferroelectric phases in ceramics, polymers or glasses with different well-defined geometric structures has opened up a new dimension in the engineering and optimization of desired physical properties. This affords, for example, the interesting possibility of combining the flexibility of a polymer with the piezoelectric or pyroelectric property of an oxide. In addition to the specific properties of its two phases, a biphasic composite is characterized by the scale of the dispersion and the nature of connectivity. In the Newnham convention, the connectivity of a biphasic composite is specified by n–m $(0 \leq n, m \leq 3)$ since each phase may be self-connected in zero, one, two, or three dimensions in an orthogonal coordinate system. Thus, a "1–2" connectivity pattern implies that the first phase is self-connected in the form of 1D chains or fibers, while the second phase is self-connected in the form of 2D layers. The convention does not specify whether the fibers of the first phase are parallel or perpendicular to the layers of the second. By convention, the first index (n) usually denotes the ferroelectric phase while the second (m) denotes the matrix (polymer, glass, other ceramic, etc.). Three of the more common and practically realizable connectivity patterns relevant to ferroelectric-polymer systems are 0–3, 1–3 and 3–3 (see Fig. 12). A 0–3 composite consists of dispersed ferroelectric particles in a matrix, a 1–3 composite represents isolated ferroelectric fibers in a matrix, while a 3–3 composite consists of two interpenetrating networks. Similarly, a 3–1 composite may consist of a ferroelectric matrix with parallel cavities filled with a polymer. Some of the earlier work involving ferroelectric composites has been reviewed by Mendiola and Jimenez [91].

7.1. Piezoelectric Properties

Early activity in this area mostly involved piezoelectric–polymer composites [92] and, in view of the strong application potential of such materials, this trend has persisted. PZT, the most studied piezoelectric, has a high piezoelectric strain coefficient (d_{33}) but low voltage coefficient (g_{ij}),[1] which is a drawback in many transducer applications. On the other hand, piezoelectric polymers such as PVDF have comparatively low d values, but their g values are high due to a low dielectric constant. Thus, one expects a PZT/PVDF

---

[1] The third rank tensors d (piezoelectric strain coefficient) and g (piezoelectric voltage coefficient) are conventionally defined as $d_{ij} = dP_i/d\sigma_j$ and $g_{ij} = dE_i/d\sigma_j$ ($i = 1, 2, 3$ and $j = 1, 2, 3, 4, 5, 6$) where P_i is the polarization, E_i is the electric field, and σ is the stress tensor (of rank 2). The two coefficients are related by $g_{ij} = d_{ij}/\varepsilon_0 \varepsilon$ where ε is the dielectric constant and ε_0 is the permittivity of free space.
Figure 12. Four of the ten possible connectivity patterns in a biphasic composite system. The pink cells represent the piezoelectric phase, while the yellow cells represent the polymer.
